## 343/W/Poster Board #1

**Increasing IKAP/ELP1 using transgenes improves splicing and extends development in Ikbkap null mice.** *Y. Chen[1], J. Mull[1], R. Shetty[1], L. Liu[1], M. Leyne[1], J. Pickel[2], S. Slaugenhaupt[1].* 1) Ctr Human Gen Res, HMS and Massachusetts General Hosp, Boston, MA; 2) National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

Familial dysautonomia (FD) is one of the best known autosomal recessive sensory neuropathies. It is known that all FD patients carry at least one intronic mutation (IVS20+6T>C) in the IKBKAP gene that disrupts mRNA splicing and leads to tissue specific reduction of the IKBKAP/hELP1 protein, IKAP/hELP1. In FD patients, abnormalities in the nervous system suggest the importance of IKBKAP for neural development and function. To better understand the role of IKBKAP in vivo, and determine the underlying mechanism of FD, an Ikbkap knockout mouse line and several mouse lines that carry human wild-type or mutant IKBKAP transgene were created. We have recently reported that ablating mouse Ikbkap disrupts both neurulation and vascular development, and leads to embryonic lethality during gastrulation. To test whether the abnormalities caused by ablation of mouse Ikbkap could be rescued or ameliorated by the human wild-type or mutant IKBKAP gene, the transgenic lines that carry the human wild-type (TgWT) or different copy numbers of the mutant IKBKAP (TgFD) transgene were crossed with the Ikbkap knockout mouse lines. Results from our study show that embryonic lethality was rescued by TgWT and TgFD25, the line with the highest copy number of mutant IKBKAP transgene. These findings suggest not only the functional conservation of IKAP between human and mouse during development; more importantly, the rescue by TgFD25 indirectly demonstrates that FD results from abnormal reduction of IKAP and not from the presence of a truncated IKAP, as speculated by some researchers. Intriguingly, lower copy numbers of mutant IKBKAP transgene (TgFD1; TgFD3; TgFD4; TgFD9) could not overcome the lethality; however, they do prolong the survival of Ikbkap null embryos from 12.5 to 14.5 dpc. Further analyses indicated that increased expression of IKAP could transiently and differentially improve the embryonic development via a dosage-dependent manner. Treating pregnant mice with kinetin, a cytokinin that is capable of increasing the exon 20 inclusion in IKBKAP mRNA, could further improve the development of Ikbkap null embryos bearing mutant IKBKAP transgene, as revealed by the establishment of primitive cardiovascular and neural structures at 12.5 dpc. Results from current study demonstrate for the first time the existence of a stage-specific threshold for IKAP during development, and present a putative in vivo platform for testing drugs that might benefit FD patients in the future.

## 344/W/Poster Board #2

**A Defect in the N-Linked Glycosylation Pathway Causes Nonsyndromic Hearing Impairment in Mice.** *F. Probst[1], D. del Gaudio[1], A. Salinger[1], S. Gao[2], J. Oghalai[3], M. Justice[1].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Bioengineering, Rice University, Houston, TX; 3) Otolaryngology, Baylor College of Medicine, Houston, TX.

The study of mouse deafness mutants has lead to the identification of a number of human hearing impairment genes. The novel ENU-induced mouse deafness mutation *nse5* is a therefore a potential model of human hearing impairment. Homozygous *nse5* mutants have abnormal auditory brainstem responses (ABRs) and distortion product otoacoustic emissions (DPOAEs) to sounds up to 80 decibels (dB) at frequencies ranging from 4 to 90 kiloHertz (kHz), demonstrating a severe-to-profound hearing impairment. While most mouse deafness mutants show circling and head-tossing behaviors in addition to hearing impairment, *nse5* homozygotes behave normally and have no noticeable vestibular defects at up to 6 months of age. The gross appearance of the external and middle ears of mutant animals is normal, and only minor anomalies of the cochlea can be seen on light microscopy. Genetic analysis of several hundred backcross and intercross progeny has localized the mutant locus to a 715 kilobase (kb) interval on mouse chromosome 15. A missense mutation at a highly-conserved amino acid was found in the mouse homologue of the yeast asparagine-linked glycosylation-10 gene (*Alg10b*), which is within the critical interval for the *nse5* mutation. A 20 kb transgene containing a wildtype copy of the *Alg10b* gene rescues the phenotype *nse5*/*nse5* homozygous animals. Additional mutations in *Alg10b* will be isolated from the Harwell sperm bank to more clearly establish the biological function of this gene. This study provides the clearest example to date of the critical link between.

## 345/W/Poster Board #3

**Characterizing the Effect of Increased Expression of Glucosylceramide-Synthesizing Enzyme in Mouse Models of Gaucher Disease.** *S. Barnes, Y-H. Xu, Y. Sun, G.A. Grabowski.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center and Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH.

Gaucher disease (GD) is a lysosomal storage disease caused by deficient acid β-glucosidase [GCase] enzyme activity. This deficiency leads to accumulation of toxic substrates mainly glucosylceramide (GC) in cells of monocytic origin, mainly macrophages. Several viable models of GD have been generated by introducing point mutations into the mouse GCase (gba) locus, including N370S, V394L, D409H, or D409V. These mouse models share only some characteristics of the human phenotypes. To create more severe variants, transgenic mice were developed to overexpress the glucosylceramide-synthesizing enzyme, UDP-glucose:ceramide glucosyltransferase (GCS). The transgene was driven by the ROSA promoter and crossbred into our D409V/null line. RT-PCR, Northern and western analyses (with GCS specific antibody) showed high level expression of GCStg in brain, liver, lung, and spleen. Immunofluorescence with GCS specific antibodies indicated GCStg has a similar pattern of localization as endogenous GCS in liver. In vitro assays using NBD-ceramide as a substrate showed high levels of GCS activity in liver compared to controls. LC/MS revealed accumulation of both GC and GS in lung tissues in 9 wk old D409V/null (9V/null) mice expressing the GCStg which is at least 11 weeks earlier than expected for 9V/null mice indicating the increased substrate load for GC and GS in these mice. Increased CD68 immunostaining (markers of activated macrophage) was observed in the liver and lung of 9V/null and 9V/9V mice expressing GCStg compared to their non-transgenic littermates. The 9V/9V mice without the transgene do not show macrophage infiltration into tissues before 8-9 months of age. Overall, the presence of GCStg increased the rapidity of disease development and its progression in this mouse model of Gaucher disease. (RO1 NS/DK 36681).

## 346/W/Poster Board #4

**Interrogation of the Pathogenesis of Loeys-Dietz Syndrome Using an Allelic Series of Mutant Mice.** *D. Loch[1], J. Habashi[1], H. Dietz[1,2].* 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) Howard Hughes Medical Institute.

Loeys-Dietz syndrome (LDS) is a recently described systemic connective tissue disorder with significant phenotypic overlap with Marfan syndrome (MFS) but significant differences including more widespread and aggressive vascular disease and frequent death in childhood, highlighting the need for elucidation of disease pathogenesis that would inform the development of novel medical therapies. LDS is caused by heterozygous mutations in the genes encoding transforming growth factor-beta receptors 1 and 2 (TGFBR1/Alk5 and TGFBR2, respectively). Expression of mutant receptor subunits in cells naïve for the corresponding receptor fails to support TGFβ signalling. However, a number of observations argue against a simple haploinsufficency/loss-of-function model of disease pathogenesis. First, MFS has been unequivocally associated with increased TGFβ signalling in many tissues including the aortic wall. Second, LDS is overwhelmingly associated with missense mutations in the kinase domains of either receptor subunit; the few nonsense mutations occur at the extreme 3'-end, precluding mutant transcript clearance by nonsense-mediated decay. Finally, analysis of LDS patient aortic tissue has shown paradoxically enhanced TGFβ signalling in the aortic wall. To definitively address this critical issue, we have created three mutant mouse models of LDS; two knock-in strains with missense mutations in Tgfbr1 (M318R) or Tgfbr2 (G357W) and a transgenic strain that ubiquitously over-expresses the mutant Tgfbr2 (G357W). We have also analyzed mouse strains heterozygous for null alleles of either Tgfbr1 or Tgfbr2. Initial phenotyping of both knock-in mouse strains has confirmed recapitulation of the LDS vascular phenotype, with widespread arterial disease including arterial tortuosity, aneurysm and dissection. G357W transgenic mice also develop vascular disease, with increased severity seen in homozygosity. In contrast, both haploinsufficient mouse strains show no evidence of vascular disease and normal longevity. Mice with severe vascular disease show increased canonical TGFβ signalling in the cardiovascular system (phosphorylated Smad2) and activation of noncanonical TGFβ signalling cascades (e.g. Erk1/2), concordant with our recent findings in MFS. Taken together, these data definitively exclude haploinsufficiency and are most suggestive of a gain-of-function mechanism of disease pathogenesis. On this basis, we are initiating pharmacologic trials in these mouse models of LDS.

### 347/W/Poster Board #5

**The transcriptional pathways underlying heart development are defective in Ofd1 mutant animals.** *A. Vitale[1], A. Barra[1], A. Baldini[1,2], B. Franco[1,3].* 1) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Istituto di Genetica e Biofisica Adriano Buzzati Traverso via Pietro Castellino 111, 80131 Naples, Italy; 3) Medical Genetics, Department of Pediatrics, Federico II University, via Pansini 5, 80131 Naples, Italy.

Oral-facial-digital type I (OFDI; MIM 311200) syndrome is a male lethal X-linked dominant developmental disorder characterized by malformations of the face, oral cavity and digits. CNS abnormalities and cystic kidney disease can also be part of this condition. This rare genetic disorder is due to mutations in the OFD1 gene that encodes a centrosome/basal body protein necessary for primary cilium assembly and for left-right axis determination, thus ascribing OFDI to the growing number of disorders associated to ciliary dysfunction. We present the characterization of the cardiac phenotype observed in mutant animals bearing ubiquitous inactivation of the gene responsible for this rare genetic disease. Male mutants display randomization of heart-looping (47%) and an enlarged aortic sac revealed by intracardiac ink-injections. Female mutants displayed a reduced left pulmonary lobe. In situ hybridization analysis revealed aberrant expression of transcription factors critical for appropriate heart development including Nkx2.5, Tbx5, Mef2c, Hand1/2 and Wnt11, while markers strongly expressed in the cardiac field such as Mlc2v, Tbx20 and Anf displayed a normal pattern of expression. Taken together our results strongly suggest a specific alteration of the cardiac transcription program resulting in a severely compromised cardiac function in Ofd1 mutant animals. Immunoistochemical studies revealed increase of proliferating cells and reduction of apoptotic nuclei in the entire heart suggesting that Ofd1 may play a role in the cell proliferation/apoptotic events underlying heart morphogenesis. Our results indicate that Ofd1 has a critical role for the correct development and specification of the heart that goes beyond the expected involvement in left-right asymmetry.

### 348/W/Poster Board #6

**Loss of *Tbx22* causes submucous cleft palate, ankyloglossia and choanal atresia.** *P. Stanier[1], A. Hoshino[1], C. Keller[2], G.E. Moore[1], E. Pauws[1].* 1) Inst Child Hlth, Univ College London, London, United Kingdom; 2) Greehey Children's Cancer Research Institute, The University of Texas Health Science Center, San Antonio, TX, USA.

Cleft palate (CP) is a common birth defect affecting around 1 in 1,500 births. Submucous cleft palate (SMCP) forms a clinically important subgroup, which although more rarely reported, may be at least as common as open CP. X-linked cleft palate and ankyloglossia (CPX, MIM303400) is characterized by submucous or overt clefts of the secondary palate, showing that they are different manifestations of the same disorder. CPX is caused by loss-of-function mutations in the *TBX22* gene. Studies indicate that *TBX22* mutations are found in at least 4% of all CP. Here, we show that mice deficient for *Tbx22* have a classic SMCP or rarely an overt cleft palate. In addition to ankyloglossia, we also find oronasal defects including choanal atresia. Analysis of the craniofacial skeleton demonstrates reduced bone formation in the posterior hard palate, resulting in the classic 'notch', associated with SMCP. Osteogenesis is markedly reduced after condensation of the palatal mesenchyme, resulting in a significantly delay in the differentiation and/or maturation of osteoblasts. Rather than being involved in palatal shelf closure, we show that TBX22 is a key determinant for intramembranous bone formation at the posterior hard palate boundary, which is required for correct palate function. The *Tbx22* null mouse therefore offers an important and novel opportunity to study the molecular mechanisms underpinning SMCP.

### 349/W/Poster Board #7

**Implication of LGI1 in autosomal dominant temporal lobe epilepsy.** *E. Chabrol[1], G. Provenzano[1], V. Navaro[1,2], I. Cohen[1], R. Miles[1], M. Baulac[1,2], E. Leguern[1], S. Baulac[1].* 1) Inserm, UMR_S975,Centre de Recherche - Institut du Cerveau et de la Moelle,Hop. Pitie-Salpetriere, NEB, Paris, France; 2) Center for Epilepsy AP-HP, Hop. Pitie-Salpetriere, Paris, France.

Epilepsy consists in a wide range of syndromes, all associated with abnormal synchronous neuronal firing in one or more brain regions. Genetic factors play an increasingly recognized role in idiopathic epilepsies, i.e epilepsies without neurological abnormalities. To this date, a dozen of genes have been implicated in monogenic autosomal dominant idiopathic epilepsies. Until recently, human hereditary idiopathic epilepsies were thought to be exclusively channelopathies, since all mutated genes encoded subunits of neurotransmitter receptor (GABA and acetylcholine receptor) or ion channels (sodium and potassium channels). LGI1 (Leucine-rich glioma inactivated 1) gene was the first non-ion channel gene identified in monogenic human idiopathic epilepsy. Mutations in the LGI1 gene are the major cause of autosomal dominant lateral temporal epilepsy (ADLTE). ADLTE referrers to a familial epileptic syndrome characterized by an age at onset typically in late adolescence, focal and secondarily tonic-clonic generalized seizures with stereotyped auditory auras. We have investigated the functional consequences of several disease-causing LGI1 missense mutations and demonstrated that they markedly decrease protein secretion by immortalized cells in culture. Our findings suggest that LGI1-related epilepsy results from a haploinsufficiency of LGI1. In order to clarify the function of this newly identified protein in brain development, neuronal excitability and epileptogenesis, we generated a knockout mice model for LGI1. Heterozygote and homozygous mice were successfully obtained according to Mendelian expected ratio. We present the phenotype and morphological data of these animals.

### 350/W/Poster Board #8

**NEMO point mutation mouse models are more severe than human counterparts.** *Y. Gu, D.L. Nelson.* Dept Molec & Human Gen, Baylor Col Med, Houston, TX.

Several human disorders have been associated with mutations in NF-Kappa-B Essential Modulator (*NEMO* or *IKBKG*), including Incontinentia Pigmenti (IP), X-linked anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) and EDA-ID with osteopetrosis and lymphoedema (OL-EDA-ID). Molecular analysis demonstrates that IP is caused by the loss of the function of NEMO protein, while EDA-ID results from a variety of point mutations in *NEMO* gene. Intriguingly, OL-EDA-ID is associated with stop codon mutation, which results in translating the entire NEMO protein followed by 27 additional amino acids. Nemo deficient mouse models recapitulated the human IP disorder, including skin phenotypes of female heterozygous animals and embryonic lethality in males. In this study we created two point mutation mouse models by knockin mutations of nucleotides in exon 10 to model human EDA-ID and OL-EDA-ID. To our surprise, unlike human counterparts, males carrying either of these two point mutations die in the early stages of embryonic life and heterozygous females exhibit phenotypes. The EDA-ID model, with an insertion at the location corresponding to the human dup C 1161 in exon 10, resulting in a truncated NEMO-EGFP fusion protein showed normal skin and no macroscopic abnormalities in heterozygous females. In contrast, hemizygous males die between embryonic day 12.5 -13.5 due to apoptosis in liver, similar to Nemo deficient male mice. In the OL-EDA-ID model, where the stop codon is mutated to add a novel amino acid sequence to the C terminus of the protein, heterozygous females and chimeras showed skin phenotypes and growth retardation. Most died between postnatal days 10 and 14. Histological examination indicated that there are multiple organ development defects in these heterozygous females involving liver, spleen, intestines, heart and lung. Surviving females developed skin problems again between 3 and 4 months of age. Our initial data in these Nemo mouse models suggest that NEMO may play distinct roles in early embryonic development in humans compared to mice. Interestingly, the stop codon mutation exhibited more severe phenotypes than any other point mutation models, in accord with phenotypes seen in humans with NEMO mutations. These two murine models provide new tools to further study NEMO function in the canonical NFkB pathway and other non-canonical signal transduction pathways.

## 351/W/Poster Board #9

**A new mouse model for Marfan Syndrome recapitules all the clinical variability of the disease.** *B.L. Lima, E.J.C. Santos, G.R. Fernandes, L.V. Pereira.* Department of Genetic, Instituto de Biociências - USP, São Paulo, SP, Brazil.

Marfan Syndrome is an autossomal dominant disorder associated with pleiotropic manifestations affecting the skeletal, ocular and cardiovascular systems. Mutations in the FBN1 gene, which encodes the fibrillin-1 protein, were associated with clinical manifestations on MFS patients. In 1997, a murine model for MFS - mgΔ lineage - was designed. Approximately 6 kb of Fbn1 encompassing exons 19-24 were replaced by a neomycin-resistance expression cassette (neo). Surprisingly, these animals were histologically indistinguishable from wild-type mice and no skeletal manifestation, lung emphysemas or aortic alterations were noted. It was postulated that the presence of the neo cassette sequence interfered with allele expression, consequently restricting the dominant-negative effect of the mutation. Here we report the generation of a variation of the mgΔ mouse model carrying the same mutant Fbn1 allele, but with neo flanked by lox-P sequences (mgΔloxPneo). Unexpectedly, heterozygous mgΔloxPneo mice present some of the MFS phenotypes, even before the removal of neo sequence. Moreover, these phenotypes presented significant variability in two different mouse strains, 129/Sv and C57Bl/6. We analyzed 45 mutant and 20 wild-type animals, on three different ages (3, 6 and 9 months). The main difference observed in the phenotypes of both strains, is on the onset of symptoms. While 129/Sv animals, with 3 months of age, presents severely affected individuals, not only on skeletal system, but also on aortic and pulmonary, all animals from B6 strain (3 months), presents mild alterations in pulmonary system, and are completely asymptomatic for bone changes. Immunofluorescence analysis of cultured fetal fibroblasts showed that, while wt cell cultures present an elaborated network of immunoreactive microfibrils, homozygous mgΔloxPneo cells present a more diffuse pattern. We also note that the mutant molecules are retained inside the cell, possibly in the endoplasmic reticulum. Several studies suggest that maintenance of proteins, inappropriately folded, inside the reticulum can result in an oxidative stress, which could be related to a patohgenical mechanism. Our results indicate that the mgΔloxPneo model seems to be an extraordinary tool in the screening of modifier genes in MFS, and to the study of its pathogenical mechanism.

## 352/W/Poster Board #10

**Neurodegeneration in mouse models of CMT4J and ALS.** *M.H. Meisler, C.J. Ferguson, G.M. Lenk.* Dept Human Gen, Univ Michigan, Ann Arbor, MI.

*FIG4* is a phospholipid phosphatase that functions as part of a protein complex regulating the cellular abundance of the signaling phosphoinositide $PI(3,5)P_2$. We described mutations of human *FIG4* in patients with Charcot-Marie-Tooth Type 4J and ALS (Chow et al, Nature 2007; Chow et al, AJHG 2009). We have recently identified several new disease mutations in *FIG4* and related genes. Mouse models of CMT4J and ALS with mutations in *Fig4* have been developed and are being characterized. The CMT4J mice express a transgene carrying the missense mutation I41T on a null background. The ALS model is heterozygous for a null allele of *Fig4*. The CMT4J allele I41T rescues the lethality of null mice, which usually occurs between 3 and 6 weeks of age. Mice from transgenic line 705 with 3x normal expression of the I41T transcript survive for 5 months. Mice from transgenic line 721 with 5x normal expression survive beyond 18 months. Thus, rescue by the partially functional I41T allele is dose-dependent. We also generated congenic lines carrying the *Fig4* null allele on strain C57BL/6J or strain C3HeB/FeJ. Survival on the C57BL/6J background is reduced to two hours postnatal. We are mapping the modifier loci responsible for the perinatal lethality of C57BL/6J null homozygotes. Analysis of these mouse models is providing insight into the cellular and neurological pathogenesis of CMT4J and ALS.

## 353/W/Poster Board #11

**AMPD3 Deficient Mice Exhibit Increased Erythrocyte ATP but Do Not Improve Anemia due to PK Deficiency.** *T. Morisaki[1,2], J. Cheng[1], K. Toyama[1,2], M. Ikawa[3], M. Okabe[3], H. Morisaki[1].* 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan; 3) Genome Information Research Center, Osaka Univ, Suita, Osaka, Japan.

AMP deaminase (AMPD) catalyzes AMP to IMP and plays an important role in energy charge and nucleotide metabolism. Human AMPD3 deficiency are known as erythrocyte-specific enzyme AMPD deficiency and found in individuals without any clinical symptom, though the increased erythrocyte ATP level was reported. To better understand physiological and pathological role of AMPD3, we established AMPD3 deficient mouse [A3(-/-)]. No AMPD activity and high ATP level as well as high ADP and AMP level were observed in erythrocyte of this mouse like human AMPD3 deficiency. Also, A3(-/-) mouse was unremarkable otherwise. Then, we generated AMPD3 and pyruvate kinase (PK) double deficient mouse [PKA(-/-,-/-)] by mating A3(-/-) mice with CBA-Pk-1slc/Pk-1slc (PK(-/-); spontaneous PK deficient mice showing hemolytic anemia). In PKA(-/-,-/-) mice, the level of ATP in RBC was increased 1.5 times compared with that of PK(-/-) mice, though no improvement of hemolytic anemia was found in those animals. Next, we tested erythrocyte fragility. We observed the osmotic fragility of erythrocytes in A3(-/-) mice when mice was in the fasting condition, though the erythrocyte ATP level was found to be still higher in A3(-/-) mice than in the control. From these results, AMPD3 deficiency in murine model resulted in the increased erythrocyte ATP level as in human, but it could not improve anemia due to PK deficiency and rather caused erythrocyte dysfunction.

## 354/W/Poster Board #12

**A VCP R155H Knock-In Mouse Model mimics human IBMPFD (Inclusion Body Myopathy and Paget disease of bone and Frontotemporal Dementia) disease.** *M. Badadani[1], J. Vesa[1], H. Su[1], G.D. Watts[2], V.J. Caiozzo[3], V.E. Kimonis[1].* 1) Dept. of Pediatrics, Div. of Genetics and Metabolism, University of California, Irvine, CA; 2) Dept. of Orthopedic Surgery, Children's Hospital Boston, Harvard Medical School, Boston, MA; 3) Dept. of Physiology and Biophysics, and Dept. of Orthopedics, College of Health Sciences, University of California, Irvine, CA.

Dominant mutations in the Valosin Containing Protein (VCP/p97) gene cause Inclusion Body Myopathy Associated with Paget's Disease and Frontotemporal Dementia (IBMPFD), which is characterized by progressive muscle weakness, dysfunction in bone remodeling, and frontotemporal dementia. VCP plays an essential role in the endoplasmic reticulum associated degradation of misfolded proteins by binding to ubiquitinated substrates via co-factors and transferring them to the 26S proteasomes of the ubiquitin proteasome system. The majority of mutations are located in the ubiquitin-binding domain of VCP, R155H being the most common disease mutation. To elucidate the pathological mechanisms underlying disease progression, we have generated a knock-in mouse model with the R155H mutation and analyzed the progression of disease up to 15 months of age. Muscle strength measurements demonstrated progressive muscle weakness in mutant mice starting before the age of 6 months (6% decrease) and reaching the 18% decrease by the 15 months of age. Motor coordination and fatigue, analyzed by the Rotarod analysis showed progressive decline beginning at 6 months of age (10% decrease) and reaching 22% decline by the age of 15 months. Structural analyses of mutant muscle performed by hematoxylin and eosin staining and electron microscopy, showed vacuolization of myofibrils (2% of cells), centrally located nuclei (2% of cells), and disorganized muscle fibers. Further, immunohistochemical analyses of the quadriceps muscle tissues from mutant mice showed accumulation of TDP-43- and ubiquitin-positive inclusion bodies in 3.9% of quadriceps myofibrils, thus replicating the muscle pathology typically seen in patients. These results were confirmed by Western blotting using TDP-43 and ubiquitin antibodies. Increased apoptosis was observed by elevated Caspase-3 activity (12-fold increase) and increased number of TUNEL-positive nuclei in mutant quadriceps. Additionally, the micro PET and micro CT analyses and histological analysis of bone showed increased bone turnover and Pagetic lesions in mutant bones suggestive of Paget's disease of bone. In conclusion, the R155H knock-in generated mouse model replicates human disease, and therefore can be used to clarify the mechanisms causing IBMPFD. The knock-in mice can also be used in the development of novel therapies for this disease.

## 355/W/Poster Board #13

**Loss of the Frizzled-4 receptor causes significant skeletal muscle atrophy: A potential new model for Facioscapulohumeral Muscular Dystrophy (FSHD)?** *E.M. MacDonald[1], J.L. Simmers[1], T.N. Burks[1], E. Andres-Mateos[1], R. Marx[1], R. Tawil[3], R.D. Cohn[1, 2].* 1) McKusic-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Pediatrics and Neurology, Johns Hopkins University, Baltimore, MD; 3) University of Rochester Medical Center, Neuromuscular Disease Center, Rochester, NY.

The canonical Wnt pathway is characterized by signal transduction events that begin when the Wnt molecule binds to a Frizzled receptor on the cell surface. This binding induces a signaling cascade that leads to the stabilization of non-phosphorylated β-catenin and activation of target genes in the nucleus. Three phenotypically similar human primary vascular retinopathies are caused by loss of function mutations of Wnt pathway genes including the Frizzled-4 receptor gene as well as its co-receptor LRP5/6 and its ligand, Norrin. Interestingly, an identical retinal phenotype is also seen in Facioscapulohumeral Muscular Dystrophy (FSHD) raising the possibility the Wnt pathway is also involved in FSHD. Previous work has demonstrated that Wnt signaling plays a functionally significant role in muscle regeneration and in the maintenance of skeletal muscle mass. In order to further delineate the functional role of Wnt signaling in vivo, we performed a dedicated analysis of skeletal muscle from Frizzled-4 receptor knock-out mice. When compared to wild-type littermates, the Fz4(-/-) mice are smaller, appear to be significantly weaker, and have reduced survivability. Moreover, these mice also exhibit marked kyphosis throughout life which further interferes with their mobility. Biochemical analyses of steady-state muscle of Fz4(-/-) mice reveal an increase in the phosphorylated form of β-catenin. This indicates that knock down of the Frizzeled-4 receptor decreases the total amount of Wnt signaling in the skeletal muscle as compared to wild-type mice. Morphological assessment of skeletal muscle from the Fz4-null mice demonstrates significant variation in fiber size with multiple small and angulated muscle fibers. In addition, occasional fibers with centrally located nuclei are observed. Assessment of muscle fiber typing suggests a specific Type IIa (fast twitch) muscle fiber atrophy. In addition to the pathological changes in muscle and similar to human patients with FSHD, Fz4(-/-) mice also exhibit a progressive loss of auditory function throughout life. Thus, the combination of the retinal, auditory, and skeletal muscle phenotype suggests that Fz4-null mice may represent a novel animal model for studying the pathogenesis of FSHD.

## 356/W/Poster Board #14

**Residual laminin-binding activity and enhanced dystroglycan glycosylation by LARGE in novel model mice to dystroglycanopathy.** *M. Taniguchi[1,2], M. Kanagawa[1], S. Takeda[3], Y. Miyagoe-Suzuki[4], S. Takeda[4], T. Endo[5], K. Kobayashi[1], K.P. Campbell[6], T. Toda[1].* 1) Divison of Molecular Brain Science / Neurology, Kobe University Graduate School of Medicine, Hyogo, Japan; 2) Division of Clinical Genetics, Osaka University Graduate School of Medicine, Osaka, Japan; 3) Otsuka Pharmaceutical Co. Ltd, Otsuka GEN Research Institute, Tokushima, Japan; 4) Department of Molecular Therapy, National Institute of Neuroscience, National Center, Tokyo, Japan; 5) Glycobiology Research Group, Tokyo Metropolitan Institute of Gerontology, Foundation for Research on Aging and Promotion of Human Welfare, Tokyo , Japan; 6) Howard Hughes Medical Institute, Roy J. and Lucille A. Carver College of Medicine, The University of Iowa, Iowa, United States.

Hypoglycosylation and reduced laminin-binding activity of alpha-dystroglycan are common characteristics of dystroglycanopathy, which is a group of congenital and limb-girdle muscular dystrophies. Fukuyama-type congenital muscular dystrophy (FCMD), caused by a retrotransposal insertion in the fukutin gene, is a severe form of dystroglycanopathy. To better understand the molecular pathogenesis of dystroglycanopathies and to explore therapeutic strategies, we generated knock-in mice carrying the retrotransposal insertion in the mouse fukutin ortholog. Knock-in mice exhibited hypoglycosylated alpha-dystroglycan; however, no signs of muscular dystrophy were observed. More sensitive methods detected reduced levels of intact alpha-dystroglycan, and solid-phase assays determined laminin binding levels to be approximately 50% of normal. In contrast, intact alpha-dystroglycan is undetectable in the dystrophic Large(myd) mouse, and laminin-binding activity is markedly reduced. These data indicate that a small amount of intact alpha-dystroglycan is sufficient to maintain muscle cell integrity in knock-in mice, suggesting that the treatment of dystroglycanopathies might not require the full recovery of glycosylation. To examine whether glycosylation defects can be restored in vivo, we performed mouse gene transfer experiments. Transfer of fukutin into knock-in mice restored glycosylation of alpha-dystroglycan. In addition, transfer of LARGE produced laminin-binding forms of alpha-dystroglycan in both knock-in mice and the POMGnT1 mutant mouse, which is another model of dystroglycanopathy. Overall, these data suggest that even partial restoration of alpha-dystroglycan glycosylation and laminin-binding activity by replacing or augmenting glycosylation-related genes might effectively deter dystroglycanopathy progression and thus provide therapeutic benefits.

## 357/W/Poster Board #15

**Postnatal *Sim1*Deficiency Causes Hyperphagic Obesity.** *A.R. Zinn[1,2], K.P. Tolson[1], T. Gemelli[1], B.M. Kublaoui[1,3].* 1) McDermott Center for Human Growth & Development, University of Texas Southwestern Medical School, Dallas, TX; 2) Department of Internal Medicine, University of Texas Southwestern Medical School, Dallas, TX; 3) Department of Pediatrics, University of Texas Southwestern Medical School, Dallas, TX.

Single-minded 1 (*SIM1*) encodes a hypothalamic transcription factor (1) and is one of only a handful of genes associated with nonsyndromic human monogenic obesity (2,3). *Sim1* homozygous mice (*Sim1*$^{-/-}$) die perinatally and lack paraventricular (PVN) and supraoptic (SON) hypothalamic nuclei (4). *Sim1* heterozygotes (*Sim1*$^{+/-}$) show hyperphagic obesity, increased linear growth and enhanced susceptibility to diet-induced obesity, consistent with defective melanocortin 4 receptor signaling (5,6,7). Whether the obesity phenotype of *Sim1*$^{-/-}$ mice is a caused by a developmental or post-developmental defect has yet to be determined. In order to dissociate the neuroanatomic and physiologic functions of *Sim1* in feeding regulation, we used a CamKII-cre transgene to conditionally delete *Sim1* in the postnatal brain. CamKII-cre/*Sim1*$^{+/flox}$ mice became obese on both high and low fat diets, and exhibited the same hyperphagic behavior previously observed in *Sim1*$^{+/-}$ mice. *Sim1* transcripts were decreased by about 50% in CamKII-cre/*Sim1*$^{+/flox}$ mice compared to control littermates, as were hypothalamic oxytocin levels, similar to *Sim1*$^{+/-}$ mice (8). Stereology data support the previous conclusion from less precise methods (7) that heterozygous *Sim1* deficiency does not affect PVN cellularity. Our results indicate that haploinsufficiency of *Sim1* after the PVN and SON are fully formed is sufficient to cause hyperphagic obesity, pointing to a post-developmental role of *Sim1* in feeding regulation.

**Removal of Hsf4 leads to cataract development in mice through down-regulation of gamma S-crystallin and Bfsp expression.** *L. Hu, X. Shi.* Hlth Sci Ctr, Sibs, CAS, Shanghai, China.

BACKGROUND: Heat-shock transcription factor 4 (HSF4) mutations are associated with autosomal dominant lamellar cataract and Marner cataract. Disruptions of the Hsf4 gene cause lens defects in mice, indicating a requirement for HSF4 in fiber cell differentiation during lens development. However, neither the relationship between HSF4 and crystallins nor the detailed mechanism of maintenance of lens transparency by HSF4 is fully understood. RESULTS: In an attempt to determine how the underlying biomedical and physiological mechanisms resulting from loss of HSF4 contribute to cataract formation, we generated an Hsf4 knockout mouse model. We showed that the Hsf4 knockout mouse (Hsf4-/-) partially mimics the human cataract caused by HSF4 mutations. Q-PCR analysis revealed down-regulation of several cataract-relevant genes, including gamma S-crystallin (Crygs) and lens-specific beaded filament proteins 1 and 2 (Bfsp1 and Bfsp2), in the lens of the Hsf4-/- mouse. Transcription activity analysis using the dual-luciferase system suggested that these cataract-relevant genes are the direct downstream targets of HSF4. The effect of HSF4 on gamma S-crystallin is exemplified by the cataractogenesis seen in the Hsf4-/-,rncat intercross. The 2D electrophoretic analysis of whole-lens lysates revealed a different expression pattern in 8-week-old Hsf4-/- mice compared with their wild-type counterparts, including the loss of some alpha A-crystallin modifications and reduced expression of gamma-crystallin proteins. CONCLUSION: Our results indicate that HSF4 is sufficiently important to lens development and disruption of the Hsf4 gene leads to cataracts via at least three pathways: 1) down-regulation of gamma-crystallin, particularly gamma S-crystallin; 2) decreased lens beaded filament expression; and 3) loss of post-translational modification of alpha A-crystallin.

**Down regulation of Hccs in medaka recapitulates the phenotype observed in Microphthalmia with linear skin lesions (MLS) syndrome.** *A. Indrieri[1,2], I. Conte[1], G. Chesi[1], P. Bovolenta[3], B. Franco[1,4].* 1) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) European School of Molecular Medicine (SEMM), Naples, Italy; 3) Instituto Cajal, CSIC, Madrid, Spain; 4) Medical Genetics, Department of Pediatrics, Federico II University, Naples, Italy.

The Microphthalmia with linear skin defects (MLS) syndrome is an X-linked dominant male-lethal neuro-developmental disorder associated to mutations in the holocytochrome c-type synthetase (HCCS) transcript. Female patients display unilateral or bilateral microphthalmia and linear skin defects, additional features include CNS malformation and mental retardation. HCCS codifies a mitochondrial protein that catalyzes the attachment of heme to both apocytochrome c and c1 necessary for proper functioning of the mitochondrial respiratory chain. The molecular mechanisms underlying the eye and brain developmental anomalies in this disease are still unknown. Previous studies demonstrated the early lethality of mouse embryonic Hccs knock-out stem cells. We thus decided to generate a model for this disease in medaka fish (Oryzia latipes). This model will allow us to overcome the possible embryonic lethality using graded concentrations of either the mutated mRNA or the morpholinos. Specific morpholinos directed against the HCCS transcript have been designed and injected. Our experiments have determined that the morpholinos effectively downregulate the expression of the olhccs gene. Gain of function studies did not result in an aberrant phenotype. Instead injection of both the mutated protein (dominant-negative) and two different morpholinos resulted in a pathological phenotype, which resembles the human condition. As expected, morphants displayed microphthalmia, coloboma, and microcephaly. In addition, unexpectedly, absence of blood pigmentation was also observed. Analysis with specific markers (e.g, Pax6, Six3.2, Otx2, Rhodopsin, Crx, Chx10, Ath5, Syntaxin) showed an abnormal formation of the retinal-pigmented epithelium (RPE) and defects in differentiation of the ventral neural retina. RNA in situ hybridization studies revealed an abnormal domain of expression for connexin43, recently shown to be important for cell proliferation and apoptosis. Tunel and pHH3 assayes on morphants, revealed abnormalities in cell proliferation and programmed cell death. Altogether this data suggest a possible role of these mechanisms in the pathogenesis of MLS syndrome and further studies are ongoing to explain the pathogenetic link between Hccs inactivation and the eye abnormalities observed in morphants and affected patients.

**Improved colorimetric (TBA) sialic acid assay validated by GNE transduction of Gne-null Lec3 CHO cells.** *C. Saechao[1,4], Y. Valles-Ayoub[1,2], A. Haghighatgoo[1,2], Z. Khokher[1,3], D. No[1,3], S.L. Martinez[1], I. Shah[1,4], S. Esfandiarifard[1], A.C. Riley-Portuges[1], C. Jay[5], M. Pietruszka[1], D. Darvish[1,2].* 1) HIBM Research Group, Inc., Encino, CA; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA; 3) Los Angeles Mission College, Sylmar, CA; 4) California State University, Northridge (CSUN), Northridge, CA; 5) Gradalis, Inc., Dallas, TX.

To improve the sensitivity of colorimetric sialic acid (Sia) quantitation by a thiobarbituric acid (TBA) based assay, we optimized Leonard Warren's method for detection of physiologic tissue Sia levels. The role of Sia is diverse and essential to cellular stabilization, signaling functions, and biochemical modulations of cell membranes, lysosomal membranes, and glycol-proteins. UDP-GlcNAc 2-Epimerase/ManNAc Kinase (GNE) is the rate-limiting enzyme of Sia biosynthesis. In humans, GNE mutations may lead to either recessive muscle wasting disease (HIBM, IBM2, DMRV) caused by hypomorphic GNE, or dominant sialuria caused by hypermorphic GNE. Using our modified TBA assay, the results from triplicates of a standard curve show an R2 value of 0.994 in linear correlation with absorption at 549nm wavelength, allowing accurate lower detection limits of 0.5nmol/50μL (10μM) Neu5Ac. Subsequently, we transduced Gne-null Lec3 CHO cells with wild-type or sialuria (R266Q) GNE expression plasmids, and measured cell lysate Sia levels. The assay reliably and reproducibly showed an appropriate elevation of cellular Sia production in GNE transduced CHO cells. This assay is optimized at physiologic tissue levels of Sia (1-20nmol), and may be used as a rapid, economical, and reliable alternative to widely accepted HPLC methods.

### 361/W/Poster Board #19

**Molecular mechanisms underlying the skin disease erythrokeratoderma variabilis.** *C.A. Scott[1], D. Tattersall[1], T. Corbett-Jones[2], D.P. Kelsell[1].* 1) Centre for Cutaneous Research, Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, 4 Newark Street, London, United Kingdom; 2) Neuroscience Centre, Genome Biology Laboratory, Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, 4 Newark Street, London, United Kingdom.

Erythrokeratoderma variabilis (EKV) is a monogenic skin disease characterized by fixed hyperkeratotic plaques and transient erythema. Mutations in the genes encoding Connexin 31 (Cx31) and Cx30.3 are associated with EKV but can also cause hearing loss with/without neuropathy but no skin disease. Cx proteins form gap junctions, which are aqueous pores allowing the intercellular transfer of ions and small molecules between cells. Mutations in other Cx genes are implicated in a range of human disorders. The aims of this study are twofold, firstly, to identify new genetic loci associated with EKV and, secondly, characterize the mechanisms underlying different disease-associated Cx31 mutants. We and others have shown that approximately half of EKV patients do not harbour mutations in *GJB3* or *GJB4* encoding Cx31 and Cx30.3 respectively indicating genetic heterogeneity. We are performing a number of genetic studies to identify these other EKV associated gene(s). For example, cytogenetic investigations in one patient with recessive EKV reveals a chromosome translocation between chromosome 2 and 22. FISH mapping has reduced the break-point region significantly and may lead to the identification of a new genetic locus for EKV. The second aspect of this study is revealing both similar and distinct properties of Cx31 mutant proteins. When expressed *in vitro*, EKV associated mutants, for example, (R42P)Cx31 and (C86S)Cx31 plus the peripheral neuropathy and hearing loss mutant (66delD)Cx31), misstraffic and have a predominantly cytoplasmic localization in contrast to the wild-type protein which is characterized by punctuate aggregates between cells, indicative of gap junction plaques. In contrast, (R42P)Cx31 and (C86S)Cx31 but not (WT)Cx31 or (66delD)Cx31 cause elevated levels of cell-type specific cell death. Our immunocytochemical data suggests this skin mutant specific cell death phenotype is due to endoplasmic reticulum (ER) stress from the accumulation of unfolded proteins inducing the unfolded protein response (UPR) which can alleviate protein accumulation or lead to, in this case, cell death. This indicates that ER stress may result in aberrant keratinocyte differentiation and hyperproliferation in EKV patient skin *in vivo*.

### 362/W/Poster Board #20

**The $GABA_A$ receptor as a potential target for therapy of the fragile X syndrome.** *F. Kooy[1], C. D'Hulst[1], I. Heulens[1], K. Van Laere[2], C. Bagni[3], B. Hassan[3], P.P. De Deyn[4].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Division of Nuclear Medicine, KU Leuven, Belgium; 3) Dept of Human Genetics & VIB, KU Leuven, Leuven, Belgium; 4) Dept of Neurochemistry and Behavior, Univ Antwerp, Antwerp, Belgium.

The fragile X syndrome is a common form of inherited mental retardation. Patients suffer from mild to severe cognitive impairment, recognizable facial features, behavioural abnormalities and an increased rate of spontaneous epilepsy. A mouse model has been developed that mimics the cognitive and clinical symptoms of the disorder. FMRP, the RNA-binding protein missing in fragile X syndrome, regulates mRNA localization to dendrites as well as mRNA translation and so influences local protein synthesis. Previously we have shown that a dysfunction of the GABAergic system is involved in the clinical presentation of the disorder. We demonstrated a 35-50% reduced expression of 8 of the 18 subunits that make up the GABA receptor and of enzymes involved in GABA synthesis (GAD), transport (GAT1 and GAT44) and degradation (SSADH). A reduction of corresponding genes was observed in the fragile X fly model, indicating decreased GABAergic expression is an evolutionary conserved hallmark of the fragile X syndrome. We demonstrated that FMRP binds several components of the GABAergic system resulting in an apparent increase in stability of these mRNA transcripts. In addition, we show that the previously reported under expression of specific subunits of the $GABA_A$ receptor can be corrected in a YAC transgenic mouse model, containing the full length human FMR1 gene in a knockout background. These results suggest that under expression of the $GABA_A$ receptor is a result of a direct interaction of FMRP with the encoding mRNAs. PET scans in human patients with labelled flumazenil were performed to measure the occupancy of the $GABA_A$ receptor in diverse brain regions. A comparison of 5 patients with 10 controls was indicative for a reduced quantity of $GABA_A$ receptors in specific cortical regions, mimicking our observations in animal models. We ague that the malfunction of the GABAergic system underlies many of the clinical symptoms of fragile X patients. Despite the altered composition of the $GABA_A$ receptor in the fragile X syndrome, rotarod and elevated plus maze experiments in mice performed by us showed that these are still functional. We postulate that the well described $GABA_A$ receptor pharmacology might open new powerful opportunities for treatment of the behavioural and epileptic phenotype associated with fragile X syndrome.

## 363/W/Poster Board #21

**Differential expression of micro RNAs regulating cell cycle in facioscapulohumeral muscular dystrophy.** *Y.-W. Chen[1,2], N. Harafuji[1], R. Shi[1].* 1) Research Center for Genetic Medicine, Children's National Medical Center, Washington, DC; 2) Department of Pediatrics, George Washington University Medical School, Washington DC.

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant muscular dystrophy that is characterized by progressive weakness and atrophy of the muscles from face, upper-arm and shoulder girdle to lower limb. The genetic cause of FSHD is associated with a shortening of the 3.3 kb D4Z4 repeat array from 11-100 to 1-10 copies on the subtelomeric region of chromosome 4q35. Several studies suggested that defects in cell cycle regulation might play a critical role in FSHD. In addition, microRNAs differentially expressed in FSHD muscles were reported previously. In this study, we hypothesized that some of the misregulated miRNAs are responsible for the cell cycle defects in FSHD. To identify miRNAs differentially regulated in FSHD myoblasts, we performed miRNA expression profiling using TaqMan Human MicroRNA Array v1.0 (ABI). Two time points, 0 hour and 48 hours post differentiation (PD), of eight primary human myoblasts (four controls and four FSHD) were analyzed. We identified 11 and 6 miRNAs significantly changed in expression in FSHD myoblasts at 0 and 48 hours PD, respectively. Among those, miR-411 was found up-regulated at both time points (2.1 and 1.5 fold). Expression levels of six miRNAs (let-7e, miR-99b, miR-143, miR-411, miR-532 and miR-601) were validated by individual TaqMan miRNA assay. The changes of let-7e, miR-99b, miR-411, and miR-601 were confirmed by the individual assay. To identify miRNA target genes that are differentially regulated in FSHD myoblasts, we expression profiled mRNA of the myoblasts collected at 48 hours PD using Affymetrix GeneChip Human Genome U133 Plus 2.0 Array. With p value less than 0.05, 1,090 transcripts were identified as differentially expressed in FSHD myoblasts. Among them, predictive miRNA targets of seven miRNAs (let-7e, miR-99b, miR-143, miR-369-3p, miR-411, miR-532, and miR-601) were searched using on-line target prediction software, miRNAMap. Potential mRNA targets were categorized into functional groups using DAVID/NIAID, NIH. The results showed that cell cycle-related genes were most over-represented in targets of let-7e, miR-411, and miR-532. The finding suggested that microRNAs might play an important role in the defects of cell cycle in FSHD.

## 364/W/Poster Board #22

**Mutation Analysis of PLOD1 gene in Ehlers-Danlos Syndrome Type VI.** *K. Damjanovich[1], T. Caine[1], L. Schwarz[1], M. Pasquali[1,2], N. Longo[1,2,3], P. Bayrak-Toydemir[1,2].* 1) ARUP Institute of Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, Utah; 3) Department of Pediatrics, University of Utah, Salt Lake City, Utah.

Ehlers-Danlos syndrome type VI (EDS VI) is a recessively inherited connective tissue disorder characterized by kyphoscoliosis and muscular hypotonia starting at birth along with later signs of skin extensibility, tissue fragility, joint laxity, and ocular involvement. It is caused by a deficiency of collagen lysyl hydroxylase due to mutations in procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (PLOD1) gene. This enzyme is necessary for the formation collagen cross-links which provide the strength and elasticity to many body tissues. In this study, we characterize mutations in the *PLOD1* gene in 14 patients with EDS VI. Their diagnosis was established either by enzyme assay (decreased lysyl hydroxylase activity in fibroblasts) or by abnormal urinary pyridinium cross-links (increased doxypyridinoline with increased ratio deoxypyridinoline/pyridinoline). Primers were designed to detect mutations in the coding regions of the *PLOD1* gene and correlated with RNA and biochemical studies. DNA sequencing identified 8 novel mutations (p.Q49X, p.A72S, p.V380M, p.Y511X, p.R670X, c.580+1G>A, c.1651-2A>G, c.1677_1678dupC). Sequencing alone failed to identify mutations in patients with the duplication of exons 10-16. Most mutations introducing a premature STOP codon resulted in decreased levels of PLOD1 mRNA. There was no clear correlation between type of mutations and biochemical abnormalities in fibroblasts from these patients. These results show that DNA sequencing can be used to confirm the diagnosis of EDS VI and a multitier approach is required to identify causative mutations/rearrangements.

## 365/W/Poster Board #23

**Defective Mechanisms and Signaling Pathways in Inclusion Body Myopathy (IBMPFD) Muscle.** *J. Vesa[1], H. Su[1], G.D. Watts[2], S. Krause[3], M.C. Walter[3], D.C. Wallace[4,5,6], V.E. Kimonis[1].* 1) Dept. of Pediatrics, University of California, Irvine, Irvine, CA; 2) Dept. of Orthopedic Surgery, Children's Hospital Boston, Harvard Medical School, Boston, MA; 3) Dept. of Neurology, Ludwig-Maximillians-University, Munich, Germany; 4) Center for Molecular and Mitochondrial Medicine and Genetics, University of California, Irvine, CA; 5) Dept. of Biological Chemistry, University of California, Irvine, CA; 6) Depts of Ecology and Evolutionary Biology and Pediatrics, University of California, Irvine, CA.

Inclusion body myopathy associated with Paget's disease of the bone and frontotemporal dementia (IBMPFD) is caused by mutations in the Valosin Containing Protein (VCP) gene. Mutations typically in the ubiquitin binding domain of the gene result in progressive, proximal muscle weakness, inclusions and vacuoles in muscle fibers, malfunction in the bone remodeling, and premature frontotemporal dementia. VCP is involved in several cellular processes including the endoplasmic reticulum-associated degradation of defective proteins. We have studied molecular and cellular consequences of VCP mutations in primary myoblasts and muscle tissues from IBMPFD patients and control subjects. Our studies revealed that patients' myoblasts accumulate large ubiquitin-positive vacuoles that are able to fuse with lysosomes. Lysosomal membrane proteins Lamp1 and Lamp2 were defectively N-glycosylated in patients' myoblasts. The maturation processes of mutant cells to myotubes were also affected, which may be due to the down-regulation of the cell adhesion molecule M-cadherin. Additionally, mutant myoblasts demonstrated increased autophagy when cultured in the absence of nutrients, as well as increased apoptosis. To elucidate the affected signaling cascades in IBMPFD, we determined expression profiles by microarray technology using quadriceps muscle samples from patients and unaffected relatives. Statistical and pathway analyses of the obtained expression data revealed that 279 genes were differentially expressed in patients' muscle ($p<0.001$). Most of these dysregulated genes were shared with other muscle dystrophies. An exception was Platelet-Derived Growth Factor Receptor Alpha (PDGFR-$\alpha$), which showed 7.5-fold down-regulation in IBMPFD patients' muscle. This finding was confirmed by qRT-PCR and Western blotting. These findings, combined with the reports showing that defective PDGFR-$\alpha$ expression is involved in the progression of muscular dystrophies and the promotion of muscle fibrosis as well as in the active stage of tissue destruction, suggest that PDGFR-$\alpha$ may play a significant role in the development of progressive muscle pathology in IBMPFD patients. We hypothesize that affected PDGFR-$\alpha$-mediated signaling may result in defective autophagosomal functioning and accumulation of still uncharacterized storage material in patients' cells. This is associated with increased apoptosis and defective myotube formation, which eventually result in muscle weakness in IBMPFD patients.

## 366/W/Poster Board #24

**The research on gene mutation analysis of SPG4 and SPG3A in Chinese hereditary spastic paraplegia patients.** *L. Shen[1,2], YG. Wang[1], C. Chen[1], J. Du[1], YY. Luo[1], JL. Wang[1], ZQ. Xiao[1], XX. Yan[1,2], BS. Tang[1,2,3].* 1) Department of Neurology, Central South University, Changsha, HUNAN, China; 2) Neurodegenerative Disorders Research Center, Central South University, Changsha, China;; 3) National Laboratory of Medical Genetics of China, Central South University, Changsha, China.

Hereditary spastic paraplegias (HSPs or SPGs) are a heterogeneous group of inherited neurodegenerative disorders characterized by slowly progressive spasticity and weakness of the lower extremities. They are divided into pure and complicated forms depend on whether the paraparesis exists in isolation or with other major clinical features, such as dementia, mental retardation, ataxia, deafness, epilepsy, peripheral neuropathy, extrapyramidal disturbances, and skin lesions. HSPs can be inherited in an autosomal dominant (AD), autosomal recessive (AR), or X-linked manner. So far, at least 37 distinct HSP loci designated SPG have been assigned with 19 disease-associated genes identified. SPG4 and SPG3A are the common subtypes, which account for 40% and 10% of AD-HSP patients, respectively. The rearrangment mutation on SPG4 gene have been reported abroad, however there was no rearrangment mutation detection of AD-HSP patients performed in Asia. Objective: To investigate the mutation frequencies of SPG4 and SPG3A gene in AD and sporadic HSP patients in China. Methods: PCR and direct sequencing were carried out to detect the micro-mutation of SPG4 and SPG3A gene in 21 Chinese AD-HSP patients and 44 isolated cases; MLPA technology and capillary electrophoresis were undertook to detect rearrangment mutation of SPG4 and SPG3A gene in 21 Chinese AD-HSP patients. Results: Five families had micro-mutations on SPG4 gene, and another five families carried rearrangment mutations of SPG4 gene. In addition, one individual had micro-mutation in 44 sporadic cases. Altogether, we found 10 mutations on SPG4 gene, which comprised of 1 missenses, 2 nonsenses, 2 micro-deletions, 1 micro-insertion, 3 exon deletions and 1 exon duplication, and five of them were novel. Among 11 SPG4 probands, 9 cases presented pure spastic paraplegia, and 2 cases showed complicated forms. One family and one isolated case had missense mutations on SPG3A gene, respectively. One of the two missense mutations was novel. Two SPG3A probands also presented pure spastic paraplegia, and the SPG3A family showed incomplete penetrance. Conclusions: The mutation frequencies of SPG4 were 47.6% in AD-HSP patients and 2.3% in isolated cases in Chinese Han people. The mutation frequencies of SPG3A were 4.8% in AD-HSP patients and 2.3% in isolated cases in Chinese Han people.

## 367/W/Poster Board #25

**Screening for the GJB2 c.-3170 G>A (IVS 1+1 G>A) mutation in Brazilian deaf individuals by Multiplex Ligation-Dependent Probe Amplification (MLPA).** *A.P. Marques-de-Faria[1], S.M. Silva-Costa[2], F.B. Coeli[2], C.R. Lincoln-de-Carvalho[1,2], M. Kurc[3], M.C.A. Pomilio[4], E.L. Sartorato[2].* 1) Department of Medical Genetics, State University of Campinas (UNICAMP) School of Medicine; 2) Center for Molecular Biology and Genetic Engineering (CBMEG) - UNICAMP; 3) Albert Einstein Hospital; 4) Therapeutic Association for Language and Auditory Stimulation.

Mutations in *GJB2* gene are the most common cause of nonsyndromic sensorineural recessive hearing loss. One specific mutation, c.35delG, is the most frequent in the majority of Caucasian populations and may account for up to 70% of all *GJB2* mutations. However, 10% to 40% of patients have a single pathogenic mutation in the *GJB2* gene. Deletions del (*GJB6*-D13S1830) and del (*GJB6*-D13S1854) truncating the *GJB6* gene have been detected in patients heterozygous *GJB2* in different populations. The IVS 1+1 G>A splice site mutation in the non-coding region of the *GJB2* gene has been found in heterozygous state in addition to c.35delG mutation. This mutation has not been reported in Brazilian deaf patients. In the present study we investigated the presence of the IVS 1+1 G>A mutation by Multiplex ligation-dependent probe amplification (MLPA) in 185 unrelated Brazilian patients with autosomal recessive nonsyndromic sensorineural hearing loss (43 heterozygous patients and 142 without any pathogenic mutation in the *GJB2* coding region). We have found two patients (4.6%) carrying the IVS 1+1 G>A mutation in compound heterozygous with c.35delG mutation. The use of this technique as a screening method is discussed. (*supported by CNPq*).

## 368/W/Poster Board #26

**Molecular Genetic Studies of Inherited Alopecia.** *A. Azhar[1], J. Klar[2], S. Nawaz[1], M. Tariq[1], A. Ali[1], I. Ahmad[1], M. Rasool[1], N. Dahl[2], S. Baig[1].* 1) Human Molecular Genetics Lab, National Inst for Biotech and Genet Eng (NIBGE), Faisalabad, Punjab, Pakistan; 2) Department of Genetics and Pathology, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden.

There are several forms of inherited isolated alopecias with variation in age of onset and severity. The main cause is consanguineous marriages in Pakistan. There are many consanguineous families with different types of alopecia including autosomal recessive hypotrichosis, congenital atrichia with papular lesions, autosomal recessive wooly hair and alopecia universalis etc. Unfortunately, there is no therapy for majority of such genetic disorders. However, these disorders can be controlled through carrier screening, genetic counseling, mutation detection and prenatal diagnosis. To establish such programs it is mandatory to understand the molecular basis of these disorders. In this study we ascertained thirteen consanguineous alopecia families with multiple affected members from northern part of Pakistan. The disease segregates in all families in autosomal recessive fashion. We used candidate gene approach for this study and selected five genes including HR, P2RY5, LIPH, DSG4 and FOXI3. Linkage analysis was performed by PCR using the STR (short tandem repeats) microsatellite markers for the known loci. Five families showed linkage to P2RY5 gene, two families with LIPH gene whereas only one family of Alopecia linked to HR gene. Direct sequencing of the PCR products was carried out and identified the pathogenic mutations. We found a mutation in P2RY5 gene in five families with autosomal recessive wooly hair (ARWH). Haplotype analysis identified same disease haplotype in all these families which showed the common ancestor for them. Along this mutation, we also identified three recurrent mutations in LIPH and HR genes. This molecular knowledge will help in the establishment of carrier screening and prenatal diagnosis tests for prevention of above diseases and to understand the molecular basis involved in the gene function.

## 369/W/Poster Board #27

**A novel homozygous missense variation in HR gene caused Atrichia with Papular lesion.** *S. Baig[1], J. Klar[2], A. Azhar[1], M. Tariq[1], A. Ali[1], I. Ahmad[1], J. Schuster[2], N. Dahl[2], S. Nawaz[1].* 1) Human Molecular Genetics Lab, Natl Inst Biotech/Genetic Eng, Faisalabad, Pakistan; 2) Department of Genetics and Pathology, Uppsala University, Uppsala, Sweden.

Atrichia with papular lesions (APL) is a rare autosomal recessive form of congenital Alopecias characterized by onset of complete or near to complete irreversible alopecia or loss of hair soon after birth or in first few months of life. Only difference in Alopecia universalis Congenita (AUC) and Atrichia with popular lesions (APL) is the papules or milia in APL. APL has been mapped to 8p12 and identification of Human Hairless (HR) gene mutations are associated with its pathogenesis. Diagonisis of APL involves autosomal recessive form of transmittance of disease with possible consanguinity of parents, hair either present at birth or not that never regrows and presence of papules. Although cases with compound heterozygous mutations are emerged to challenge the criteria due to increasing number of sporadic cases. Atrichea with papules have equal prevalence in both men and women but its exact prevalence is still a question. Here we report a novel homozygous missense c.2427 C>T transition in exon10 of HR gene that results in p.A765V substitution and small variation of phenotype in a consanguineous Pakistani family in all affected individuals. This missense variant was excluded on 200 control chromosomes of Pakistani origin and 200 control chromosomes of Swedish origin.

## 370/W/Poster Board #28

**A Novel Approach to Mapping Causal Variants in a Family with Extreme Iron Overload.** *J.M. Brew[1,2], J.A. Cavanaugh[2], M.L. Bassett[3].* 1) John Curtin School of Medical Research, Australian National Univ, Canberra, Australia; 2) Medical Genetics Research Unit, ANU School of Biology and ANU Medical School, Australian National University, Canberra, Australia; 3) ACT Health, Canberra, Australia.

Hereditary haemochromatosis (HH) is usually a late onset autosomal recessive disorder of excess iron storage that may lead to severe organ damage if left untreated. In 1996 two causative mutations (C282Y and H63D) in the *HFE* gene were shown to explain ~85% of HH cases. A recent recruit to our 20 year study of HH was an affected individual of Croatian origin who was diagnosed at ~55 years and had a serum ferritin of >9000 micrograms/L, which is significantly higher than in any other patients in our study (reference range for males is <300μg/L). Analysis of serum from his brother gave a similar result. DNA sequencing ruled out any known mutations or likely causal variants in the exons and 500bp in the 5' region of both *HFE* and *HAMP* (hepcidin antimicrobial peptide - sometimes called the master regulator of iron homeostasis). In addition, haplotype analysis across the *HFE* gene demonstrated that the brothers have only one haplotype in common. We hypothesized that other genes in the iron pathway may be responsible for the disorder in these two brothers. As no members of their extended family are available for traditional mapping, we have developed an innovative approach to identifying the causal variant(s) in these genes using lymphoblastoid cell lines (LCL) established from both brothers. Our results show that the expression levels of *HFE*, *TFRC* (transferrin receptor) and *HAMP* are more similar to those observed in LCLs from affected (YY) individuals than those from normal (CC) individuals. In particular, the expression of transferrin receptor 2 (*TFR2*) is significantly reduced in these two patient lines in comparison to all other samples. We have also assessed the impact of ferrous sulfate in the culture media and have demonstrated a similar mortality in the brothers' LCLs to that observed in LCLs from YY individuals (but not CC individuals). To follow up on these exciting results, we are currently sequencing other genes in the iron pathway, particularly focusing on variants in the *TFR2* gene as the likely explanation of the extreme iron overload in these brothers.

## 371/W/Poster Board #29

**Posterior polymorphous corneal dystrophy - copy number, gene expression and candidate gene analyses within the PPCD1 candidate region on chromosome 20p 11.2.** *L. Noskova[1], P. Liskova[2,4], V. Stranecky[1], H. Hartmannova[1], R. Ivanek[1,5], K. Jirsova[2,3], S. Merjava[2,3], M. Filipec[4,6], S. Kmoch[1,7].* 1) Institute of Inherited Metabolic Disorders, Charles University, Prague, Czech Republic; 2) Laboratory of Biology and Patology of the Eye, General Teaching Hospital, Charles University, Prague, Czech Republic; 3) Ocular Tissue Bank, General Teaching Hospital, Charles University, Prague, Czech Republic; 4) Department of Oftalmology, General Teaching Hospital, Charles University, Prague, Czech Republic; 5) Institute of Molecular Genetics, Academy of Sciences, Prague, Czech Republic; 6) Eye Clinic Lexum, Prague, Czech Republic; 7) Center for Applied Genomics, Prague, Czech Republic.

Posterior polymorphous corneal dystrophy (PPCD) is a genetically heterogeneous autosomal dominant disorder characterised by epithelisation of the endohelium and irregular thickening of Descemet's membrane. It often leads to irreversible corneal edema and requires corneal transplantation. The genetic heterogeneity of PPCD is currently known to be represented by three loci on chromosomes 20, 1, and 10 and several disease causing genes (COL8A2, ZEB1/TCF8) have been identified. We have previously shown linkage in two Czech PPCD1 families to chromosome 20p11.2. To further narrow the PPCD1 candidate interval we used Affymetrix Genome-Wide Human SNP Array 6.0 and genotyped family members demonstrating critical recombination events by STR analysis. Haplotype analysis narrowed the critical region to a 2.1Mb interval delimited by markers D20S114 and rs7509232. In parallel we used the genotyping data, assesed copy number status and found no indication for deletions/duplications within the candidate region. We have also manufactured custom oligonucleotide array and analysed expression changes of all genes located within the candidate region in samples of corneal tissues obtained from patients undergoing corneal transplantation and controls. This analysis showed significantly reduced amounts of destrin (DSTN) transcript in corneal tissues of four patients compared to healthy control tissue. However, subsequent sequencing analysis of the coding and promotor regions of DSTN did not reveal any potential disease causing mutation. As no mutations were found by sequencing of genomic coding regions of other genes in candidate region, we decided to sequence whole 2.1Mb candidate region by combination of NimbleGen Sequence Capture array and next-gen sequencing approach.

## 372/W/Poster Board #30

**Narrowing the critical regions associated with SHFM1 and SHFM3 forms of ectrodactyly through array-based comparative genomic hybridisation.** *S. Raskin[1,2], A. Bonalumi[1], J. Souza[1].* 1) Pontificia Universidade Catolica do Paraná, Curitiba, Parana, Brazil; 2) Laboratory Genetika, Curitiba, Parana, Brazil.

Introduction:Split-hand/foot malformation (SHFM), or ectrodactyly, is characterized by underdeveloped or absent central digital rays, clefts of the hands and feet, and variable syndactyly of the remaining digits. SHFM occurs as both an isolated finding and a component of many syndromes. SHFM is a heterogeneous condition caused by multiple loci, including SHFM1 (chromosome region 7q21-q22), SHFM2 (Xq26), SHFM3 (10q24), SHFM4 (3q27), and SHFM5 (2q31). The recent identification of submicroscopic tandem chromosome duplications affecting the SHFM3 locus in several families with non-syndromic SHFM has helped to further unravel the molecular basis of this malformation. We report two unrelated families, one with two brothers affected with non-syndromic SHFM and the other, a sporadic case with ectrodactyly-deafness syndrome, both investigated by CGH-array. Methods:Patients and their parents were investigated using a commercial DNA microarray constructed from large insert clones spaced across the genome. Array-based comparative genomic hybridization was performed with a targeted bacterial artificial chromosome (BAC) microarray. In addition to known clinical loci, other regions of the genome have been included on the microarray to help identify chromosome abnormalities outside of these known regions, for a total of 622 discrete loci. Conclusion: We found that the brothers with non-syndromic ectrodactyly have a small duplication of 273Kb at 10q24.32, including the genes BTRC, POLL, FBXW4, FGF8, NPM3 and MGEA5, therefore narrowing the citical region of SHFM3.Furthermore, the fact that their both parents are normal, shows that reduced penetrance should be considered in SHFM3. We speculate that one of the parents may have a somatic mosaicism for the mutation. In the second family, the finding of a deletion of 13.1 Mb at 7q21.11q21.3, including the genes SHFM1, DLX5, DLX6 and FZD1 also helps to narrow the critical region for SHFM1. These results show that array comparative genomic hybridisation should be considered to be an essential aspect of the genetic analysis of patients with different types of SHFM. Moreover, besides their importance for diagnosis and genetic counselling, they may allow the identification of critical regions associated with SHFM. Finally, the detailed molecular analysis of the rearranged regions may help to further unravel the molecular basis of this malformation and finally lead to the identification of SHFM causing genes.

Omphalocele is a congenital birth defect characterized by the presence of some of the internal organs located outside of the ventral wall. The size of the omphalocele varies, depending on the presence of which internal organs, (liver, spleen, intestines) are herniated into the umbilical cord. We have conducted a linkage study in a large family with autosomal dominant omphalocele using a genomewide SNP array. Our analysis revealed significant evidence of linkage (nonparametric NPL = 6.93, P = 0.0001; and parametric LOD = 2.70 under a fully penetrant dominant model) at chromosome 1p31.3. Haplotype analysis narrowed down the locus to a 2.74 Mb region between markers rs2886770 (63014807bp) and rs1343981 (65757349bp). Molecular characterization of this interval using array CGH followed by Quantitative Microsphere Hybridization (QMH) analysis revealed a 944 kb duplication between 63,561,322bp-64,505,749bp. All affected individuals who had an omphalocele and shared the affected haplotype were positive for this duplicated region and are not duplicated for probes around the region at chr1:63,495,050bp and chr1:65,004,750bp spanning 1509kb. Multipoint linkage analysis using the duplication as a marker yielded a maximum LOD score of 3.2 at 1p31.3 under a dominant model. The 944 kb duplication on 1p31.3 contains eight known genes including FOXD3, ALG6, ITGB3BP, KIAA1799, PGM1, ROR1, DLEU2L and UBE2U. The present study suggests that development of an omphalocele in this family is controlled by over expression of one or more genes in the duplicated region. To our knowledge, this is the first reported linkage and molecular characterization for the omphalocele phenotype.

## 374/W/Poster Board #32

**Identifying genes for cleft lip with or without palate using chromosomal abnormalities detected by array comparative genomic hybridization (CGH).** *K.M. Dipple[1, 2], J. Peredo[2], R. Jarrahy[3], J.P. Bradley[3], F. Quintero-Rivera[4].* 1) Deptartment of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Department of Pediatrics, David Geffen School of Medicine at UCLA, Mattel Children's Hospital at UCLA, Los Angeles, CA; 3) Department of Surgery, Division of Plastic & Reconstructive Surgery, David Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Department of Pathology & Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.

To identify novel genes predisposing families to cleft lip with or without cleft palate (CL/P), we have been analyzing patients with syndromic CL/P. We report a patient with multiple congenital anomalies including cleft lip and palate who had several genomic copy number imbalances. The proband presented at birth with multiple congenital anomalies including unilateral incomplete left cleft lip, a notch in the left alveolus, and a complete cleft of the secondary palate. In addition there was mild hypertelorism, bilateral undescended testes and a sacral dimple. He developed renal insufficiency due to obstructive uropathy secondary to posterior uretheral valves. He had bilateral hydronephrosis and bilateral grade 5 vesico-ureteral reflux. Echocardiogram revealed a patent foramen ovale but otherwise normal intracardiac anatomy. Head ultrasound showed some punctate lesions in the lateral ventricle. Spinal ultrasound showed no tethered cord. FISH analysis on interphase nuclei detected the presence of an extra X chromosome and there were no numerical aberrations of chromosomes Y, 13, 18 and 21. Chromosome analysis confirmed 47, XXY complement consistent with Klinefelter syndrome. Because of the atypical clinical presentation of Klinefelter's in this patient, a comparative genomic hybridization (CGH) array analysis was also performed. The aCGH detected the extra X chromosome, as well as a 5.8 Mb terminal deletion spanning bands 7p22.1-7p22.3, and a 2.6 Mb chromosome 16 terminal duplication at band 16p13.3. Parental chromosomes and CGH array were normal. Analysis of these genomic regions identified novel genes that may be involved in the formation of cleft lip with or without cleft palate, including *FAM20C, UNCX, LFNG,* and *UBE2I*.

## 375/W/Poster Board #33

**Mutations in *DNAH11* are exclusively seen in primary ciliary dyskinesia patients with normal ciliary ultrastructure: Deciphering the effect of splice mutations on the transcript.** *M. Zariwala[1], M. Leigh[2,5], J. Carson[2], M. Hazucha[3], S. Minnix[3], K. Burns[3], M. Armstrong[3], A. Lori[3], H. Metjian[3], N. Loges[4], H. Olbrich[4], A. Becker[4], M. Schmidts[4], H. Omran[4], M. Rosenfeld[5], T. Ferkol[5], S. Dell[5], K. Olivier[5], S. Sagel[5], M. Knowles[3,5].* 1) Department of Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, NC; 2) Department of Pediatrics, University of North Carolina, Chapel Hill, NC; 3) UNC School of Medicine, University of North Carolina, Chapel Hill, NC; 4) Department of Pediatrics, University Hospital, Freiburg, Germany; 5) Genetic Disorders of Mucociliary Clearance Consortium, USA.

Primary ciliary dyskinesia (PCD)/Kartagener syndrome is an autosomal recessive, genetically heterogeneous disorder characterized by oto-sino-pulmonary disease due to the abnormal structure and function of cilia. The current method of diagnosis is ultrastructural analysis of the cilia and majority of the PCD patients (80-90%) have either defective outer dynein arm (ODA), or inner dynein arm (IDA) or both dynein arms (DA). The definitive diagnosis of PCD becomes challenging in patients who present with the compatible clinical phenotype, low nasal nitric oxide levels that are commonly seen in PCD, but normal ciliary ultrastructure. Although 10 PCD-causing genes have been described, two genes (*DNAI1* and *DNAH5*; both encode ODA proteins) account for 17-38% of PCD. The genetic etiology in majority of the PCD patient is still elusive. Two unrelated families with PCD and normal DA have been described to have biallelic mutations in *DNAH11* (encodes ODA heavy chain), but large scale studies were missing. Hence, to test *DNAH11* as a candidate gene for PCD, we carried out mutation analysis of 82 coding exons and intron/exon junctions in 164 well-characterized unrelated PCD patients (59 had normal DA, 74 had ODA defect, 8 had central pair defects and 23 ultrastructure unavailable). Biallelic mutations were seen in 13 of 59 (22%) patients with normal DA. Two additional patients (ciliary ultrastructure unavailable) had biallelic mutations. Of the total 31 mutant alleles, 9 were nonsense, 6 were frame-shift, 7 were splice site and 9 were missense mutations. We carried out the analysis of mRNA (from transformed lymphocytes) on 5 splice site mutations and found that splice mutations caused: 1) in-frame deletion of an exon (n=2); 2) out-of-frame deletion of an exon (n=2); and 3) out-of-frame deletion of the four exons (n=1). In conclusion, our results show that in the absence of ultrastructural defects, genetic analysis can confirm the diagnosis of PCD. In addition, we demonstrate that splice site mutations resulted in the abnormal transcripts that would be predicted to cause loss-of-function for protein. This abstract was funded by RR00046, 1 RO1 HL071798, 5 U54 RR019480. Resequencing was provided by NHLBI N01-HV-48194R99 NHLBI RS&G Services.

## 376/W/Poster Board #34

**Frequency of 35delG mutations in cochlear implant recipients.** *M. Falah[1], M. Houshmand[2], s. Akbaroghli[3], M. Farhadi[1].* 1) Department and Research Centr, Genetic, Tehran, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Tehran, Iran, Tehran, Iran, Islamic Republic of; 3) 3Tehran welfare Organization, Tehran, Iran, Islamic Republic of, 4National institute of genetic.

Hearing impairment is the most common sensory disorder, present in 1-4 of every 1000 newborns. Nonsyndromic sensorineural hearing loss(NSHL) impairment is inherited in a predominantly autosomal recessive manner in up to 70% of cases. It is also an extremely heterogeneous trait. The gene more often involved is GJB2, encoding the protein Connexin 26. In most populations a single mutation, 35delG, accounts for most cases of NSHI . 100 patients receiving cochlear implants were ascertained through research centre of ENT & head and neck surgery .After genetic counseling for them DNA isolated from the peripheral blood, all patients were molecularly evaluated for the presence of the 35delG mutation by ARMS /PCR. We investigated 100 patients , 45% male and 55% female , The age distribution was: Min.= 1 ; Max.= 28 and Mean:7±5 72% of these patients were born on consanguine family and 87%of them were nonsyndromic hearing loss. Among these patients 86% were normal, 10 % homozygote and 4% heterozygote for 35delG mutation. Conclusion The most frequent genes implicated in autosomal recessive nonsyndromic hearing loss are GJB2, which is responsible for more than half of cases.In our study, there was a significant relationship between consanguineous marriage in our evaluated group and express of NSHI .( PV#0/00 and O.R= 3.64 , 2.30< OR <5.79 ). but there was not any significant relationship between inheritance pattern and consanguineous marriage with 35delG mutation. These data can help genetic counselor and otologist for setting priority in evaluation, prevention and even treatment in these patients.

## 377/W/Poster Board #35

**Further genetic heterogeneity in Emery-Dreifuss muscular dystrophy.**
*M. Wehnert[1], M. Hoeltzenbein[1], S.S. Wehnert[1], M. Sukalo[1], B. Budde[2], P. Nürnberg[2], T. Voit[3].* 1) Inst Human Gen, Ernst-Moritz-Arndt Univ, Greifswald, Germany; 2) Max-Delbrück Center for Molecular Medicine, Berlin, Germany; 3) Institut de Myologie, Université Pierre et Marie Curie, Paris, France.

Emery-Dreifuss Muscular Dystrophy (EDMD) is a rare muscular disorder characterized by early joint contractures, slowly progressive muscular dystrophy, cardiac involvement including conduction defects and arrhythmias. So far only approx. 40% of the EDMD cases can be associated with LMNA, EMD, SYNE1 or SYNE2 gene mutations, suggesting the existence of additional genes involved. By a genome wide scan in a large German family, we found by multipoint linkage analysis a LOD score of 3.6 to the region Xq26. Using a candidate gene approach we found a mutation c.61559 T>C, p.C209R in the FHL1-gene. The mutation co-segregated with the disease in the family studied. The disease phenotype was compatible with EDMD unless a pronounced cardiac and shoulder girdle hypertrophy, which is compatible with a previously described phenotype - XMPMA - associated to a c.61559 T>C, p.C224W mutation in FHL1. Moreover, in our EMD and LMNA negative cohort of 198 patients, we identified the FHL1 mutation c.61606 C>G, p.C224W in four unrelated males suggesting a mutational hot spot. Thus FHL1 is a further major gene involved in the pathogenesis of an additional 2,5 % of our EDMD cases. It should strongly be considered as a diagnostic tool in all EMD and LMNA negative patients with EDMD or EDMD like phenotypes.

## 378/W/Poster Board #36

**Mapping of a novel locus for orbital innervation to chromosome 4q24-25.**
*N.A. Al Tassan[1], D.S. Khalil[1], L.J. Al Sharif[1], J.M.A. Shinwari[1], A.O. Khan[2].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Center, P.O Box 3354 Riyadh 11211,Saudi Arabia; 2) Division of Pediatric Ophthalmology, King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia.

Orbital dysinnervation can cause incomitant strabismus and/or ptosis, such as congenital fibrosis of the extraocular muscles, Duane retraction syndrome (DRS), and Moebius syndrome. We identified a consanguinous family in which 3 siblings exhibited a unique form of orbital dysinnervation without other clinical findings. The oldest affected brother had right congenital ptosis. His sister had bilateral congenital ptosis. Their brother had DRS IV (synergistic divergence) in his right eye and DRS I in his left eye. Genome-wide linkage analysis using the Affymetrix GeneChip® Human Mapping 250K Sty Array suggested a novel recessive disease locus on chromosome 4q24-25 with a maximum multi-point LOD score of 2.5. This region comprises 40 genes of which selected candidate genes were sequenced. Several variants were identified. The genetic defect in this family likely affects a mechanism responsible for orbital innervation.

## 379/W/Poster Board #37

**Identification of a candidate locus in familial systemic lupus erythematosus by homozygosity mapping.**
*A. Kitamura[1], Y. Yoshida[2], M. Nakamura[3], K. Yasutomo[1].* 1) Department of Immunology and Parasitology, Institute of Health Biosciences, The University of Tokushima Graduate School, Tokushima, Japan; 2) Department of Human Genetics, Institute of Health Biosciences, The University of Tokushima Graduate School, Tokushima, Japan; 3) Department of Neuropsychiatry, Toho University, Tokyo, Japan.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by high fever, erythema, arthritis, renal dysfunction and elevated serum autoantibodies. SLE is a multifactorial disease in which both genetic and environmental factors are involved. Indeed, SLE patients with autosomal dominant or recessive inheritance have been reported. Recent studies have revealed many genetic predisposing factors from a large-scale candidate gene or genome wide association analysis in familial and sporadic cases. However, the genetic basis of SLE remains unclear. We identified one consanguineous Japanese family, which consists of 3 affected and 1 unaffected siblings. Affected siblings presented psychological disorders and multiple autoimmune diseases such as SLE, Sjögren's syndrome and Hashimoto thyroiditis. To identify an underlying gene, we performed a genome-wide homozygosity mapping using the high density SNP microarray (HumanCNV370-Quad, Illumina) in the four siblings and revealed two homozygous regions (FSLE-1, FSLE-2) that spanned 0.7 Mb and 1.1 Mb, respectively. Next, we confirmed and refined with flanking microsatellite markers spanning the 10-cM each homozygous region. Multipoint parametric linkage analysis and haplotype reconstruction were performed with the Genehunter program, under the assumption of autosomal recessive inheritance with complete penetrance and a disease allele frequency of 0.001. Haplotype reconstruction was consistent with autosomal recessive inheritance and showed that the affected siblings were homozygous by descent for the allele within the critical region. The FSLE-1 did not contain any gene, but the FSLE-2 region contained 40 known and predicted genes annotated in the UCSC database. We selected several genes from FSLE-2 region based on the available data on immunological functions and are now doing DNA sequence of those genes. The identification of the candidate gene of those SLE patients would provide crucial insights into not only pathogenesis of SLE but also regulation of immune systems.

## 380/W/Poster Board #38

**Disease mutation detection by next generation sequencing platforms.**
*H. Wang[1,2], K. Zhang[3], F. Yu[1,2], M. Bray[4], R. Lewis[2,5,6], J. Lupski[2,6,7], G. Mardon[2,7,8,9,10], D. Muzny[1,2], R. Gibbs[1,2,], R. Chen[1,2,10].* 1) Human Genome Sequencing Center, Baylor College of Medicine, houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, houston, TX; 3) Department of Bioengineering, University of California at San Diego, La Jolla, California, USA; 4) Children's Nutrition Research Center, Baylor College of Medicine, houston, TX; 5) Department of Ophthalmology, Baylor College of Medicine, houston, TX; 6) Texas Children's Hospital, Baylor College of Medicine, houston, TX; 7) Department of Neurology, Baylor College of Medicine, houston, TX; 8) Department of Neuroscience, Baylor College of Medicine, houston, TX; 9) Department of Pathology, Baylor College of Medicine, houston, TX; 10) Program in Developmental Biology, Baylor College of Medicine, houston, TX.

Next-generation high-throughput DNA sequencing techniques have great potential to dramatically accelerate the discovery of mutations which cause human diseases. To test this approach, both targeted capture sequencing (TCS) and whole genome shotgun sequencing (WGS) strategies were tested on three sequencing platforms, including 454, Illumina GAII, and SOLiD, to identify novel mutations in patients with Leber congenital amaurosis (LCA). LCA is a clinically and genetically heterogeneous disorder characterized by severe vision loss at birth. Several novel LCA disease loci have been identified by our group via homozygosity mapping using genome high density SNP genotyping. The size of these loci ranges from 10Mb to 100Mb, making PCR followed by Sanger sequencing strategy cost prohibitive. Depending on the size of each locus, either TCS or WGS were performed. In the case of TCS, exons within the candidate locus were captured and sequenced using both the 454 and the Illumina GAII platform. Our preliminary data indicate that high sensitivity and specificity can be reached by this method. More than 90% of the exons can be captured and sequenced to sufficient depth. In addition, about 95% of sequencing reads can be mapped to the targeted regions, indicating very little off targets effect. In parallel, WGS was performed on two patient samples using the SOLiD platform. About 7x sequencing coverage were generated for each individual and a list of potential variations, including missense and nonsense changes, has been identified. Further validation and analysis of these potential changes are currently underway and will be reported. In addition, systematic comparison of TSC and WGS as well as the three NextGen sequencing platforms will also be performed on our data set.

**Autosomal-Dominant Retinitis PIgmentosa is caused by mutations in a BTB-Kelch Protein, KLHL7.** *J.S. Friedman[1], J.W. Ray[2], N. Waseem[3], K. Johnson[4], M.J. Brooks[1], T. Hugosson[5], K.E. Branham[6], D.S. Krauth[1], S.J. Bowne[2], L.S. Sullivan[2], V. Ponjavic[5], A.R. Webster[3], D.G. Birch[7], G.R. Abecasis[8], Y. Fann[4], S.S. Bhattacharya[3], S.P. Daiger[2], J.R. Heckenlively[6], S. Andréasson[5], A. Swaroop[1,6,9].* 1) NEI/NNRL, NIH, Bethesda, MD; 2) Human Genetic Center, The University of Texas Health Science Center, Houston, TX; 3) Department of Molecular Genetics, Institute of Ophthalmology, London, UK; 4) Bioinformatics Section, Division of Intramural Research, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD; 5) Department of Ophthalmology, Lund University Hospital, Lund, Sweden; 6) Department of Ophthalmology, University of Michigan, Ann Arbor, MI; 7) Retina Foundation of the Southwest, Dallas, TX; 8) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 9) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Retinitis pigmentosa (RP) encompasses a group of progressive retinal diseases that lead to the loss of photoreceptors in the retina. To date, 18 genes have been associated with autosomal dominant (ad) RP. Through linkage analysis of a large Scandinavian family, we identified an adRP locus (RP42) at chromosome 7p15. We determined the disease-causing mutation to be c.449G/A (p.S150N) in exon 6 of the KLHL7 gene. Six independent families with three different missense mutations were subsequently uncovered from a large screen of 502 retinopathy probands. KLHL7 is broadly expressed and encodes a protein with homology to the BTB-Kelch family. Homology modeling of the three mutations located in the conserved BACK domain suggests that mutant amino acid side chains can potentially fill the cleft between two helices. Gigaxonin, another BTB-Kelch protein, has been previously shown to cause giant axonal neuropathy. We are currently exploring KLHL7 protein interactors through immunoprecipitation and yeast-two hybrid experiments of bovine retina. Based on other BTB-Kelch family members' functions, we hypothesize that KLHL7 is involved in ubiquitin-proteasome protein degradation pathway and may interact with one or more E3 ligases. Further elucidation of KLHL7 interactors will assist in understanding of the biology and disease processes of the retina.

## 382/W/Poster Board #40

**Hunting down the last Meckel syndrome genes in the Finnish population.** *J. Tallila[1], E. Jakkula[1], T. Varilo[1,2], L. Peltonen[1,2,3], R. Salonen[4], M. Kestila[1].* 1) 1National Institute of Health and Welfare, Public Health Genomics Unit and FIMM, Institute for Molecular Medicine Finland, Helsinki 00290, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki 00290, Finland; 3) The Wellcome Trust Sanger Institute, Hinxton CB10 1SA, UK; 4) Department of Medical Genetics, Väestöliitto, Helsinki 00100, Finland.

Meckel syndrome (MKS, [MIM 249000]) is an autosomal recessive, early lethal disorder characterized by a combination of severe malformations. Minimum diagnostic criteria are cystic dysplasia of the kidneys with fibrotic changes in the liver and occipital encephalocele or some other central nervous system malformation. Polydactyly is also a frequent finding in MKS. The number of disease genes and loci has increased rapidly in the past few years. To date, five genes, six loci and over 50 mutations have been implicated in MKS. These findings have demonstrated that MKS genes are not restricted to certain populations and that MKS is an allelic disorder with several other syndromes with overlapping phenotypes, e.g. Joubert syndrome. Unraveling the molecular background of MKS has revealed that it is caused by primary cilia dysfunction. These findings have had a great impact on studies of MKS as well as on studies of cilia. In the Finnish population 90% of the MKS cases are caused by homozygous mutations in either *MKS1* or *CC2D2A* genes: a 29 bp intronic deletion in the *MKS1* gene (c.1483-7_35del) and a C>T substitution in the coding region of *CC2D2A* (c.1762C>T), respectively. Both of these mutations result in abnormal splicing. In addition, systematic sequence analysis of the established MKS genes showed that one Finnish MKS case is a compound heterozygote for mutations in MKS1 and one for mutations in *CEP290* (*MKS4*). As we still have six typical MKS families without a known mutation, we are currently hunting for a new MKS locus (or loci). Instead of a traditional linkage analysis, we are applying homozygosity mapping with affected MKS cases using Illumina genome-wide SNP arrays, method which we have used successfully previously in identification of the fifth MKS gene, *CC2D2A* (*MKS6*). To evaluate which families would share the same founder mutation with a common homozygous region, we are genealogically tracing the consanguinities of the families and using dense SNP-data to estimate identity-by-descent (IBD) sharing between affected individuals. Combining of genealogical data, current genome-wide SNP technology and improved ciliary database information provide us effective tools to first identify additional MKS locus (or loci) and then proceed with further functional studies and improved knowledge of MKS pathogenesis.

## 383/W/Poster Board #41

**Non-syndromic X-linked deafness (DFN2) is caused by decreased functional mutations in PRPS1.** *H. Yuan[1], X. Liu[1,2], J. Li[1], B. Han[1], J. Cheng[1], Y. Wang[3], J. Chen[1], Y. Liu[3], P. Dai[1], D. Han[1].* 1) Inst Otolaryngology, Chinese PLA General Hospital, Beijing 100853, China; 2) Department of Otolaryngology, University of Miami, Miami, FL 33136, USA; 3) Hearing Center, Guizhou Provincial People's Hospital, GuiYang 550002, China.

Hereditary nonsyndromic hearing loss (NSHL) is extremely heterogeneous. During the past decade, remarkable progress has been made towards determining the deafness-causing genes. To date, over 110 loci have been mapped for NSHL, and 47 deafness genes from these loci have been identified. The vast majority of cases of NSHL are associated with mutations in autosomal genes. X-linked deafness is clinically and genetically a heterogeneous disorder accounting for about 5% of all congenital deafness, and for less than 2% of non-syndromic hearing impairment. The first deafness-causing gene, POU3F4, was identified in a family with X-linked non-syndromic hearing loss in 1995. Although seven non-syndromic deafness loci (DFN2-8) have been mapped to the X chromosome over the last 15 years, the second X-linked deafness gene has not yet been identified. The DFN2 locus was mapped to Xq13-q24 and previously defined by three different families. The age at detection of the hearing loss in affected males in these families varied from birth to 20 years of age, indicating that DFN2 can cause either congenital or post-lingual deafness. In the present study, we ascertained a five generation Chinese family characterized by X-linked postlingual, progressive, non-syndromic sensorineural hereditary hearing impairment. We mapped the disease locus to a 5.4 cM region on Xq22 between DXS8020 and DXS8055 overlapping with the known DFN2 locus. Mutations in the phosphoribosyl pyrophosphate synthetase 1 (PRPS1) gene were found in all identified DFN2 families, demonstrating that PRPS1 is likely the gene responsible for DFN2 deafness.

## 384/W/Poster Board #42

**Gene Scanning Of The Interleukin 2 Receptor Gamma (IL2RG) By High Resolution Melting.** *M.A. Liew[1], K.V. Voelkerding[1,2], C.T. Wittwer[1,2].* 1) ARUP Laboratories, Salt Lake City, UT; 2) University of Utah, Department of Pathology, Salt Lake City, UT.

X-linked Severe Combined Immunodeficiency Disease (X-SCID) affects approximately 1/50000-1/100000 newborns. It is characterized by the presence of persistent opportunistic infections. Individuals with X-SCID have mutations primarily in the interleukin 2 receptor gamma (IL2RG) gene, which leads to the loss of this receptor. IL2RG is an important part of the pathway that regulates lymphocyte maturation so without this receptor the immune system does not function properly and infections are able to persist and cause severe disease.

Primers for the 8 exons (8 amplicons), 3'-untranslated region (2 amplicons) and a gender typing control (amelogenin, 1 amplicon) were pre-spotted on 96-well plates and stored until needed. Genomic DNA was purified from whole blood by silica-based automated DNA extraction (40 min), followed by standard PCR in generic thermal cyclers (60 min). High resolution melting analysis was then performed on a dedicated 96-well platform (15 min) for increased throughput. Variants were detected by a change in shape of the melting curves compared to wild type controls. Common polymorphisms were distinguished from mutations by rapid cycle PCR and melting of small amplicons, unlabeled probes, or snapback genotyping (30 min). Only the rare variants were sequenced by standard dideoxytermination (45 min) and capillary electrophoresis (45 min).

A common PCR annealing temperature was identified for all amplicons using a gradient 96-well PCR instrument, melting analysis and agarose gel electrophoresis. Common variants were identified by analyzing 96 female control subjects. Based upon the workflow wild type samples are completed in <4 hours. Common variant genotyping requires an additional hour, and rare variant identification by sequencing requires an additional 2 hours. Scanning for mutations in IL2RG by high resolution melting enables a significant reduction in sequencing for improved turnaround time and cost reduction.

## 385/W/Poster Board #43

**Homozygosity mapping of primary microcephaly in 86 Iranian families: novel mutations and phenotypes.** *H. Darvish[1], S. Esmaeeli Nieh[1,2], G. Bahrami Monajemi[1], M. Mohseni[1], F. Behjati[1], S. Ghasemi Firouzabadi[1], P. Jamali[1], S. Azimi[1], F. Mojahedi[1], A. Jankhah[1], I. Bahman[1], M. Ghani Kakhki[3], M. Garshasbi[2], S.S Abedini[1], A. Naghavi[1], A.W. Kuss[2], H.H. Ropers[2], H. Neitzel[3], K. Kahrizi[1], H. Najmabadi[1,4].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany; 3) Institute of Human Genetics, Charité Medical University of Berlin, Germany; 4) Kariminejad-Najmabadi Pathology and Genetics Center, Tehran, Iran.

Primary microcephaly (MCPH) is a genetically heterogeneous disorder showing an autosomal recessive mode of inheritance in the majority of cases. Affected individuals present with head circumferences more than three standard deviations below the age- and sex-matched population mean, accompanied by mental retardation without further associated malformations. Five genes (*MCPH1*, *CDK5RAP2, ASPM, CENPJ* and *STIL*) and two additional genomic loci (MCPH2 and 4) have been identified so far. In this study, we investigated all six loci in patients with primary microcephaly and other family members from 86 Iranian families with 2 or more affected individuals. Thorough clinical characterization and karyotype analyses were performed for all patients. For linkage analyses, several microsatellite markers were selected for each locus and used for genotyping. Our investigation enabled us to detect linkage to the *ASPM* region in thirteen families. Three families showed linkage to MCPH2. Seven families were linked to *MCPH1* and four to *CENPJ*. The remaining 59 families were not linked to any of the six known loci. Subsequent sequencing revealed 10 novel mutations in *ASPM*, seven novel mutations in *MCPH1* and one novel mutation in *CENPJ*. Additional clinical features accompanying microcephaly and MR were observed in some patients. While confirming the general prevalence of *ASPM* mutations, our results indicate that these are comparatively less frequent in the Iranian population than in others. This and the high proportion of families without apparent linkage to known loci suggest the presence of additional, probably population specific loci.

## 386/W/Poster Board #44

**Refinement of the LGMD1 locus on 7q36 - genotyping new informative families.** *JP. Hackman[1], S. Sandell[2,3], J. Sarparanta[1], H. Luque[1], S. Huovinen[2,4], PH. Jonson[1], A. Paetau[5], I. Mahjneh[6], B. Udd[1,2,7].* 1) Folkhälsan Institute of Genetics and Department of Medical Genetics, University of Helsinki, Finland; 2) Neuromuscular Research Center, Dept of Neurology, University Hospital and University of Tampere, Finland; 3) Department of Neurology, Seinäjoki Central Hospital, Finland; 4) Department of Pathology, Centre for Laboratory Medicine, Tampere University Hospital, Finland; 5) Department of Pathology, Helsinki University Hospital, Finland; 6) Department of Neurology, University of Oulu, and MHSO hospital, Finland; 7) Vaasa Central Hospital, Finland.

We have described the clinical and morphological phenotype of an autosomal dominant limb-girdle muscular dystrophy in a large Finnish family. Molecular genetic analyses confirmed linkage of the disease to a locus on chromosome 7q36 with a LOD score 3.76 for marker D7S1823 and a LOD score 3.07 for marker D7S2465. Patients had onset of muscle weakness in the pelvic girdle between the fourth and the sixth decade, and the first symptoms were difficulties in running and climbing stairs. Later on the upper limb-girdle muscles were involved. The progression of the disease was relatively mild and patients were still able to walk with marked difficulty in the eighth decade. Muscle biopsy showed myopathic and/or dystrophic features with rimmed vacuolation and some minor myofibrillar disintegration and protein aggregations. We were now able to include three additional Finnish LGMD1 families with similar clinical genetic and morphological features in the study. They show linkage to the same locus, as identified by identically segregating alleles on a common haplotype in the patients. Genotyping members of these new informative families with additional microsatellite and SNP markers for the linked region, the locus on chromosome 7q36 was considerably narrowed down from >6 Mb to < 3.3 Mb. The region is now located between the marker D7S3037 and the telomere on chromosome 7q. Finemapping is ongoing to further reduce the linked area. Twelve described genes, including some fairly good candidate genes for LGMD1, as well as 15-17 hypothetical genes/pseudogenes are reported in this refined linked area. The sequencing of the genes is ongoing aiming to identify the underlying genetic defect of 7q36 linked LGMD1. Two American families have previously been linked to an overlapping locus on 7q36. ENMC reports and later reviews defined the 7q36 locus as LGMD1E while the OMIM database defines this locus as LGMD1D.

## 387/W/Poster Board #45

The molecular mechanisms of brain development and function are largely unknown. The normal structural organization and maturation of the brain are the result of a precisely orchestrated series of developmental processes. Despite its fundamental importance, a mechanistic understanding of brain development at the level of the gene is generally lacking and only recently has begun to be elaborated in a broad fashion. One approach to obtain such insight is to identify genes that play a key role in this process specifically and directly within the human brain through molecular genetic studies of human brain malformations. Structural brain abnormalities represent disruptions of normal cerebral or cerebellar cytoarchitecture and often lead to severe neurological disorders including epilepsy, mental retardation and global developmental delays, as well as cognitive deficits and other motor and sensory neurological deficits. We collected 250 patients from consanguineous families mainly from Eastern Turkey, where the consanguineous marriages are common. Those patients consisted of malformations of cortical development (MCD), sub-classified into three broad categories reflecting the developmental steps at which the cortical development was first disrupted: (i) neural cell proliferation or apoptosis (ii) neuronal migration and (iii) cortical organization. We performed whole-genome genotyping using Illumina Human CNV370 or Human610 beadchips and then conducted homozygosity mapping. Using Plink Software, we performed runs of homozygosity analysis and determined individual homozygous segments greater than 1.5 million base pairs. We then sought for the overlap among the identified segments with and without shared haplotypes to evaluate both identity by decent and identity by state. We developed an R script to visualize the overlapping segments and plot them across the genome to manually evaluate the segments. We also used HapMap Phase III CEU genotype information to determine common regions of homozygosity and exclude them from further analysis. The analysis revealed multiple loci of homozygosity shared by more than 10 patients. To screen for mutations, we selected the genes that are expressed in the brain, especially during brain embryogenesis. Mutational screening is currently underway.

## 388/W/Poster Board #46

**Novel FGD1 Mutation Underlying Aarskog-Scott Syndrome with Myopathy and Distal Arthropathy.** *S. Majid[1], A. Al-Semari[2], M. Muhaizea[2], M. Dabobo[3], R. Omar[1], F. Al-Kuraya[1], B. Meyer[1].* 1) Genetics,Functional Genomics, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) Department of Neurosciences, King Faisal Specialist Hospital & Research Centre; 3) Department of Pathology and Laboratory Medicine, King Faisal Specialist Hospital & Research Centre.

Aarskog Scott Syndrome (AAS) is described as an X-linked disorder which is characterized by ocular hypertelorism anteverted nostrils, broad upper lip, digital abnormalities and peculiar penoscrotal morphology. Mutations in FGD1 the only known cauasative gene are found in about one fifth of AAS cases. FGD1 is a guanine nucleotide exchange factor that specifically activates the RhoGTPase Cdc42 via its RhoGEF domain. The Cdc42 pathway is involved in skeletal formation and multiple aspects of neuronal development. We describe a kindred with five affected males manifesting many of the well recognized features of AAS. Linkage analysis localized the disease in this family to Xp11.3-q13.3 with FGD1 present in the critical region. The diagnosis was confirmed by the identification of novel nonsense mutation which resulted in substitution of tryptophan by a stop residue 447 (W447X). This mutation segregated within the family in a manner fully consistent with an X-linked pattern of inheritance. In addition to the other features of AAS seen in this family, this novel mutation may underlie the electromyographic evidence of myopathy we observed in the affected members which we suggest may be an under-recognised feature of the syndrome.

## 389/W/Poster Board #47

**Mutation of *ACTA2* Gene as a Major Cause for Non-Syndromatic Thoracic Aortic Aneurysm and/or Dissection in both Familial and Sporadic Cases.** *H. Morisaki[1], K. Akutsu[2], H. Ogino[3], N. Kondo[4], I. Yamanaka[1], Y. Tsutsumi[2], T. Yoshimuta[2], T. Okajima[2], H. Matsuda[3], K. Minatoya[3], K. Sasaki[3], H. Tanaka[3], H. Ueda[5], T. Morisaki[1,6].* 1) Dept Bioscience, Natl Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Cardiovascular Medicine, Natl Cardiovasc Ctr, Suita, Osaka, Japan; 3) Dept Cardiovascular Surgery, Natl Cardiovasc Ctr, Suita, Osaka, Japan; 4) Dept Cardiovascular Surgery, Aomori Municipal Hosp, Aomori, Japan; 5) Dept Pathology, Natl Cardiovasc Ctr, Suita, Osaka, Japan; 6) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan.

Approximately 20% of thoracic aortic aneurysm and/or dissection (TAAD) cases result from inherited disorders including several syndromatic connective-tissue disorders such as Marfan syndrome, Ehlers-Danlos syndrome and Loeys-Dietz syndrome, which are caused by mutations in the *FBN1*, *COL3A1*, and *TGFBR1*&*TGFBR2* genes, respectively. Also up to 20% of non-syndromatic TAAD has a familial background. Recent study revealed that mutations of *TGFBR2*, *MYH11*, *SLC2A10*, and *ACTA2* genes cause familial non-syndromatic TAAD. In order to elucidate the contribution of these genes to TAAD in the absence of known genetic syndromes, we conducted a genetic study of *FBN1*, *TGFBR1*, *TGFBR2*, *ACTA2* and *SLC2A10* genes, in 44 unrelated Japanese patients with non-syndromatic TAAD, 17 familial and 27 sporadic and young-onset (≤50 y.o.). By directly sequencing all exonic regions of those genes, we identified 4 mutations in *ACTA2* and one in *TGFBR2* in 17 probands with familial TAAD, and two mutations in *ACTA2* in 27 sporadic TAAD. No mutations in *FBN1*, *TGFBR1* or *SLC2A10* were identified in this study. All six mutations in *ACTA2*, including 4 novel, were expected to disturb the highly conserved structure of actin molecule. Reported cardinal features, iris cysts and livedo reticularis, were identified only in one pedigree with reported mutation, R149C. We did not find any specific clinical feature suggesting premature onset of coronary artery disease or premature ischemic stroke in 14 mutation carriers, though two of the family members with R212Q mutation died suddenly with chest pain in their 40s. In our study, genetic penetrance seemed to be higher than that in the previous report, since we found aortic involvement in all mutation carriers but one. Histopathologically, aortic tissues from affected individuals showed aortic medial degeneration and focal SMC loss or disarray, but we did not observe any SMC hyperplasia or occlusive/stenotic change of vasa vasorum as reported in the previous report. In conclusion, we confirmed that *ACTA2* mutations are the major cause in both familial and sporadic TAAD. Since the first and only clinical symptom can be life-threatening aortic aneurysm or dissection, genetic analysis of family members of patients with *ACTA2* mutations would be beneficial for improved surveillance and awareness of treatment. We think that genetic analysis of *ACTA2* should be recommended for all patients with familial or young-onset TAAD.

## 390/W/Poster Board #48

**A novel SNP genotyping array analysis yields linkage for a rare medial arterial calcification disorder in five siblings.** *S.G. Ziegler[1], M.P. Siegenthaler[2], D. Adams[1], C.E. Wahl[3,4], C. Groden[3,4], M. Anahtar[1], T.C. Markello[3,4], W.A. Gahl[1,3,4].* 1) Human Biochemical Genetics Section, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD; 2) Office of the Clinical Director, NHLBI, NIH, Bethesda, MD; 3) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD; 4) Undiagnosed Diseases Program, NIH, Bethesda, MD.

Sharp (1954) described a syndrome (OMIM 211800) in a pair of siblings from a consanguineous marriage with an unusual type of calcification of joint structures and medial walls of medium sized arteries. Two previous cases had been independently reported. Here we report five affected siblings with the same clinical findings who were examined as part of the NIH Undiagnosed Diseases Program. Two sisters were initially referred for peripheral vascular disease secondary to presumed “tumoral calcinosis”. Bone surveys revealed marked calcification following the distributions of the iliac, femoral, popliteal, and proximal tibial arteries. Additionally, there was subtle juxtaarticular calcification present in the wrists and ankles, the interphalangeal and metacarpophalangeal joints of the hands and feet, and the tarso-metatarsal joints. There was narrowing of interphalangeal joint spaces, without gross osteophyte formation or erosions. The medical history confirmed similar symptoms in three other siblings, but not in the parents, who are third cousins. DNA from siblings and parents was collected and genotyped on a 1 million multiplex SNP array. B allele plots (to determine genotype frequency at individual SNPs) identified one 22MB region on chromosome 6 with consecutive uninterrupted homozygosity for 7977 SNPs; this defined a potential region of identity by descent. Further analysis, using the ENT program (a genotype phasing algorithm based on entropy minimization) to find paternal and maternal haplotypes, confirmed linkage in this region; identical maternal and paternal haplotypes extended proximally across the centromere for an additional 40.3MB, indicating a linkage region of identical heterozygosity or identity by state (log score = 3.0 across this entire 62.3MB region). Sequencing studies on selected candidate genes are being performed to identify a causal mutation in this linked region. The molecular cause of calcification in medium sized vessels will provide new insights into extramedullary calcification of specialized connective tissue and explain this unique connection between the arterial wall and joint capsule ligament matrix.

## 391/W/Poster Board #49

**Molecular genetic analysis in app. 300 patients with Congenital Hyperinsulinism.** *K. Brusgaard[1], H. Christesen[6], K. Hussain[2], A. Molven[4], A. Angham[5], M. Melikian[3].* 1) Clinical Genetics, Odense University Hospital, Odense, Fyn, Denmark; 2) HC Andersen Children’s hospital, Odense University Hospital, Denmark;; 3) London Center for Paediatric Endocrinology and Metabolism, Great Ormond Street Hospital, London, UK; 4) Section for Pathology, the Gade Institute, University of Bergen, Norway; 5) Department of Molecular Pathology and Laboratory Medicine, King Abdulaziz Medical City, Riyadh, Saudi Arabia; 6) Endocrinology research centre, Moscow, Russia.

Background Congenital hypoglycemic hyperinsulinemia (CHI) is a clinical and genetic heterogeneous entity. Clinical manifestations can vary from serious life threatening to milder difficultly identifiable cases. Children who don’t react adequate to medical treatment are subject to pancreatic recession. The molecular ethiology are from recessive mutations of the ABCC8 (SUR1) and KCNJ11 (Kir6.2) to dominant mutations of the GCK or GDH genes. Focal dysplasia characterised by loos of maternal Chromosome 11 and hereby ABCC8 and KCNJ11 is a common cause of CHI. In some studies mutations in the ABCC8 promotor have been shown to cause CHI. In approximately 50% of the incidences the disease is still genetically unexplained necessitating the search for other genetic factors. 5n recent studies mutations in other MODY genes have been shown to cause severe forms of transient CHI. The purpose of the present study was to identify the genetic cause of CHI in a large group of patients with CHI. Materials: More than 300 children were tested for mutations in the ABCC8, KCNJ11 and/or GCK, GDH, HAD and TCF1, by sequencing. Results: We found mutations in ABCC8, KCNJ11, GCK, GLUD1 and TCF1. A number of previously undescribed mutations were detected. Several mutations including variants of ABCC8, KCNJ11 and GCK were functionally described expressing the mutated allele in in vitro systems using patch clamping, FISH staining and Rb+ flux. Discussion: ABCC8 mutations constituted the large majority of CHI causing mutations.The majority of ABCC8 positive individuals only carried one paternal mutation. Tissue collected from pancreaectomised individuals pointed to loss of maternal 11p15 in combination with the paternal mutation was the cause of the CHI phenotype. Still app. 50% of CHI cases are not explained by mutations in the genes analysed.

## 392/W/Poster Board #50

**Both recessive and dominant INS gene mutations are a common cause of neonatal diabetes.** *S. Ellard, E.L. Edghill, J. Locke, S.E. Flanagan, A.-M. Patch, L.W. Harries, O. Rubio-Cabezas, A.T. Hattersley.* Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, United Kingdom.

In 2008 we reported that heterozygous missense mutations in the INS gene are the second most common cause of permanent diabetes diagnosed before 6 months of life (PNDM). Mouse models suggest that these mutations cause misfolding of the proinsulin molecule, evoking the endoplasmic reticulum stress response which leads to apoptosis of the pancreatic beta cells. We hypothesised that homozygous loss-of-function INS mutations might cause PNDM in consanguineous pedigrees. We investigated 42 patients of consanguineous descent for mutations in the four genes known to cause isolated PNDM (INS, GCK, KCNJ11 and ABCC8). Mutations were identified in 22/42 probands. These included 7 homozygous GCK mutations, 4 homozygous ABCC8 mutations, 2 heterozygous KCNJ11 mutations and one heterozygous INS mutation. Eight patients had novel homozygous INS mutations; c.-331C>G (n=3), c.331C>A, M1I (n=2), Q62X and a large deletion (p.M1_Q62del) that was confirmed by MLPA analysis of the parental DNA samples. Patients with homozygous INS mutations were diagnosed earlier than those with heterozygous mutations (median age at diagnosis 6 days vs 9 weeks; p=0.005) and had a lower centile birth weight (<1st vs <5th; p>0.0001). Both recessive loss-of-function and dominantly acting misfolding mutations are common causes of isolated permanent neonatal diabetes. Recessive mutations were associated with an earlier age at diagnosis and lower birth weight, suggesting a more severe insulin secretion defect.

## 393/W/Poster Board #51

**Neonatal Hyperpigmentation - Diagnosis of FGD with a novel mutation in *MC2R*.** *Y. Anikster[1,2], E. Jacoby[1], O. Pinhas-Hamiel[1,2], S. Padeh[1,2], J. Laufer[1,2].* 1) Metabolic Disease Unit, Safra Children's Hosp, Tel-Hashomer Ramat-Gan, Israel; 2) Sackler Faculty of Medicine, Tel-Aviv University. Tel-Aviv.

Background: Familial Glucocorticoid Deficiency (FGD) is a rare autosomal recessive disorder of insensitivity to ACTH, characterized by isolated glucocorticoid deficiency while mineralocorticoid production is preserved. Clinical features include hypoglycemia and its sequels, hyperpigmentation, failure to thrive and recurrent infections. Genetic mutations have been identified in 40-45% of patients.

We describe a 3-month-old infant with hypoglycemia, anemia and hyperpigmentation. The patient's parents are first-degree cousins, and two out of 3 siblings died in infancy. The patient and both of the deceased siblings were noticed to have dark skin and mucous membranes present already at birth, while both parents and sister have a much lighter skin complexity. Diagnosis of FGD was suggested based on the clinical findings. Elevation of morning ACTH levels and low cortisol levels supported the diagnosis.

Methods: Genomic DNA was extracted from the family member's peripheral blood. The ACTH receptor exons were sequenced directly.

Results: The patient was found to be homozygous for a novel mutation in *MC2R* (635insC, I153-167X). His mother and sister are heterozygote for the mutation.

Follow up and Conclusions: Four months after initiation of corticosteroids treatment hyperpigmentation faded, the infant thrives without any hypoglycemia. A positive family history of neonatal hyperpigmentation and unexplained infant deaths should suggest the diagnosis of FGD. Early recognition and treatment prevent mental disability and fatal outcome. The finding of the mutation in this family enables prenatal diagnosis.

## 394/W/Poster Board #52

**Olfactory defects, pubertal delay, and erratic estrus cycles in *Chd7* deficient mice indicate underlying mechanisms of Kallmann-like features in CHARGE syndrome.** *W. Layman[1], E. Hurd[2], D. Martin[1,2].* 1) Dept Human Genetics, Univ Michigan, Ann Arbor, MI; 2) Dept Pediatrics, Univ Michigan, Ann Arbor, MI.

Mutations in *CHD7*, a chromodomain protein, are present in 60-80% of individuals with CHARGE syndrome, a multiple anomaly disorder characterized by ocular Coloboma, Heart defects, choanal Atresia, Retardation of growth and development, Genital hypoplasia with hypogonadotropic hypogonadism and delayed puberty, and inner Ear defects including hearing and balance disorders. CHARGE individuals also have olfactory impairments and delayed puberty, with decreased circulating levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Mutations in *CHD7* are present in patients with idiopathic hypogonadotropic hypogonadism (IHH) and olfactory impairment (Kallmann Syndrome), which is thought to result from deficiency of hypothalamic gonadotropin releasing hormone (GnRH) secretion or function. GnRH producing neurons originate in the olfactory placode in humans, and in the vomeronasal organ in mice. *Chd7* is highly expressed in the embryonic and adult mouse vomeronasal organ, hypothalamus and pituitary, suggesting it may have critical roles in these tissues. We recently showed that CHD7 is a positive regulator of neural stem cell proliferation and olfactory sensory neuron formation in the mouse olfactory epithelium, indicating that the deleterious effects of CHD7 deficiency may be mediated in part by defects in stem cell division and/or maintenance. Based on these observations, we further hypothesized that loss of CHD7 disrupts GnRH neuronal development and signaling, either directly or indirectly via defects in neural stem cells. We found that female mice with heterozygous loss of *Chd7* ($Chd7^{Gt/+}$) have delayed vaginal opening and erratic estrus cycles. GnRH neurons are present in the olfactory bulb in $Chd7^{Gt/+}$ mice, suggesting that initial formation and migration are unchanged. However, circulating levels of LH and FSH in six week old $Chd7^{Gt/+}$ mice are variable, and correlate with altered levels of hormone expression in the pituitary as measured by qRT-PCR. Collectively, these studies demonstrate that defects in GnRH signaling to the pituitary may contribute to the reproductive and endocrine dysfunction seen in humans with *CHD7* mutations.

## 395/W/Poster Board #53

**Identification of a novel SRY-mutation causing 46,XY complete gonadal dysgenesis in two half-sisters by paternal gonadal mosaicism.** *P. Miny[1], I. Filges[1], N. Boesch[1], C. Kunz[2], S. Tschudin[3], G. Szinnai[4], F. Wenzel[1], U. Zumsteg[4], K. Heinimann[1].* 1) Division of Medical Genetics, University Children's Hospital and Department of Biomedicine, Basel, Switzerland; 2) Molecular Genetics, Department of Biomedicine, University Basel, Basel, Switzerland; 3) Department of Obstetrics and Gynecology, University Hospital, Basel, Switzerland; 4) Division of Pediatric Endocrinology, University Children's Hospital, Basel, Switzerland.

Mutations and deletions in the SRY-gene have been identified in about 15% of individuals with 46,XY complete gonadal dysgenesis (CGD). The SRY gene (Yp11.3) encodes the testis- determining factor (TDF), a transcription factor that is a member of the high mobility group (HMG)-box family of DNA-binding proteins. Mutation of SRY results in complete gonadal dysgenesis. Familial cases with confirmed paternal mosaicism have been rarely reported. Here we describe the clinical, endocrinological and molecular characteristics of two half-sisters, related by their common but deceased father, with complete gonadal dysgenesis. Genetic investigations were performed after one sister was diagnosed for primary amenorrhea and infantilism of secondary sexual development, hypergonadotropic hypogonadism, infantile uterus and hypoplastic bilateral gonads. One sister delivered a healthy girl after egg donation. The karyotype revealed 46,XY. SRY deletion was excluded by FISH analysis of the Yp11.3 region. Direct SRY gene sequencing was performed according to standard PCR and DNA-sequencing methods. Direct sequencing of the SRY coding region revealed a novel, hemizygous missense mutation c.347T>C resulting in an amino acid replacement of Leucin to Serin at position 116 (p.Leu116Ser). The mutation is located in the HMG-domain, an evolutionary conservated region responsible for DNA-binding, with in silico analysis (PolyPhen software) predicting a pathogenic impact. Therefore, p.Leu116Ser is likely to adversely affect SRY's DNA-binding capacity. The same mutation could be identified in the affected half-sister, but not in 100 fertile male control individuals. DNA from the deceased father was available after extraction from formalin-fixed tissue of a biopsy of inflammatory infiltration after hip surgery. Mutation analysis of this DNA revealed the familial mutation in a mosaic state. Functional analysis of the mutation is ongoing. We describe a novel missense mutation in the SRY gene, p.Leu116Ser causing Swyer syndrome phenotype in two half-sisters related by their common father. The rare finding of paternal mosaicism has been confirmed in the father, so that the recurrent phenotype in this family is most likely due to paternal gonadal mosaicism.

**Molecular analysis of the CYP21 gene in patiens with 21-hydroxylase deficiency in western Turkey.** *F. Ozkinay[1,2], H. Onay[2], F. Hazan[2], S. Ozen[3], O. Cogulu[1,2], S. Darcan[3], D. Goksen[3], C. Ozkinay[2].* 1) Department of Pediatrics, Ege University, Izmir, Turkey; 2) Department of Medical Genetics, Ege University Medical Faculty, Izmir, Turkey; 3) Department of Pediatric Endocrinology, Ege University Medical Faculty, Izmir, Turkey.

Congenital adrenal hyperplasia (CAH) caused by 21-hydroxylase deficiency is one of the most frequent autosomal recessive disorders. The aim of the study was to detect the frequencies of CYP21 gene mutations and to study the genotype-phenotype correlation in a group of 21-hydroxylase deficienct patients from western Turkey. Molecular analysis of CYP21 gene for the detection of 11 most common mutations (large deletion, P30L, I2G, del-8bp, I172N, E6 cluster, V281L, F30+T, Q318X, P453S and R356W) was performed in 20 clinically diagnosed CAH patients using real time PCR method. In 25 (25%) of the patients none of the 11 mutations analysed was detected. Six of the patients (30%) were homozygous, 1 patient (5%) compound heterozygus, 4 patients (20%) heterozygous for one of the mutations covered by the test. Four patients carried complex alleles. The most common mutation in the CYP21 gene of the study group was the I2G (in 35% of the patients). Genotype-phenotype correlations of the patients were similar to the results of previous studies from different populations except one case with homozygous I2G mutation which showed simple virilizing phenotype. To our knowledge, this is the first study showing the mutation spectrum of CYP21 gene in patients from western Turkey.

## 397/W/Poster Board #55

**Insights into the molecular mechanism of hypopituitarism caused by *Otx2* and *Prop1* mutations.** *A.H. Mortensen, S.A. Camper.* Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Mutations in a variety of transcription factors cause pituitary hormone deficiency. *HESX1* and *OTX2* mutations cause variable, syndromic effects, including brain and ocular malformations and pituitary hormone deficiencies, while *PROP1* and *POU1F1* mutations affect pituitary function specifically. The mechanism whereby *OTX2* mutations cause hypopituitarism is not clear, but regulation of *HESX1* and *POU1F1* transcription have been suggested. Mice with mutations in these genes reveal genetic background influences and generally recapitulate the human phenotypes. Both *Otx2* and *Prop1* mutant pituitaries are dysmorphic, but *Pou1f1* pituitaries have normal shape and size at birth. The pituitary hypoplasia characteristic of both adult *Prop1* and *Pou1f1* mutants arises from reduced cell proliferation in the anterior lobe after birth. We hypothesize that *Prop1* controls the expression of genes that regulate progenitor production, cell migration, survival, and differentiation, and vascularization. To identify genes involved in these processes we used microarray analysis of gene expression to compare pituitary RNA from newborn *Prop1* and *Pou1f1* mutants. Significant differences in gene expression were noted between the mutants. *Otx2* expression was elevated specifically in *Prop1* mutant pituitaries, suggesting that *Prop1* normally suppresses *Otx2* transcription. We analyzed the spatial and temporal expression of *Otx2*. It is normally expressed in the neural ectoderm and the prospective posterior pituitary when BMP, WNT, and FGF signaling are inducing anterior pituitary gland growth. *Otx2* is also transiently expressed with *Hesx1* in the anterior pituitary primordium, but it is extinguished long before the initiation of *Pou1f1* expression. This suggests that the ectopic posterior lobe and small anterior lobe in *Otx2* mutants result from early effects on pituitary gland induction and growth, with some potential downstream targets in the neural ectoderm. There is a temporal delay between normal *Prop1* transcriptional activation and the elevated, ectopic expression of *Otx2* in the anterior lobes of *Prop1* mutants, which suggests that *Prop1*-mediated suppression is indirect. This discovery provides support for our hypothesis that identifying molecular differences in mouse mutants will contribute to understanding the molecular mechanisms that control pituitary organogenesis and uncover candidate genes for human pituitary disease. ## 398/W/Poster Board #56

**Pathways involved in Cayman Ataxia.** *K.M. Ito[1], V. Strumba[2], M. Hortsch[3], M. Burmeister[4].* 1) Program in Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI; 2) Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI; 4) Molecular & Behavioral Neuroscience Institute, Psychiatry, University of Michigan, Ann Arbor, MI.

Cayman Ataxia is a rare, non-progressive, congenital, recessive cerebellar ataxia that has no known treatment. Our group has found two mutations in the Cayman Ataxia gene, ATCAY/Atcay, in all individuals with Cayman Ataxia. This gene encodes the protein, Caytaxin, which we've shown to be absent in naturally-occurring ataxic mouse mutants that display a strong phenotype (sidewinder and jittery) and markedly decreased in mutants that display a mild phenotype (hesitant). In addition, we have also generated transgenic mice expressing a BAC that encodes human Caytaxin and rescues the mutant phenotype. Despite the 30 fold over-expression of the protein, these mice are healthy and have no indications of neurological dysfunction by 1.5 years. Mice that fail to express Caytaxin have normal brain weight, external brain morphology, regional and cellular architecture suggesting that this protein is not involved in brain development. We have generated a set of monoclonal antibodies, which detect Caytaxin as three different major proteins on a western blot, irrespective of developmental stage or brain region. Affinity purification of Caytaxin using one of these antibodies detected a direct association between Caytaxin and kidney-type glutaminase (KGA), an enzyme abundant in the brain that acts to hydrolyze glutamine to glutamate. Glutamate is the most abundant excitatory neurotransmitter in the brain and is required for synaptic transmission. These results confirm reports from Buschdorf et al (2006) who show this association through co-immunopreciptation. Immunocytochemistry in differentiated SH-SY5Y cells detects strong staining near the growth cones preceding synapse formation. We also used microarray analysis to identify genes whose expression is altered in response to a lack of Caytaxin. Interestingly, only very few genes were identified. The most significantly down-regulated gene is Carbonic Anhydrase Related protein 8 (Car8), which is mutated in the naturally occurring ataxic mouse mutant waddles. Recently, Robinson et al (2009) have described mutations in the Car8 gene in a consanguineous family in Iraq. All affected individuals display a form of congenital ataxia characterized by mild mental retardation and a quadrupedal gait. In addition to Car8, microarray analysis also identified several proteins in glutamate signaling pathways. Together, these results suggest that Caytaxin plays a role in glutaminase transport to the synapse or glutamate signaling.

## 399/W/Poster Board #57

***DFNA5*, a hearing loss gene, encodes an apoptosis-inducing protein.** *L. Van Laer[1,2], K. Op de Beeck[1], S. Thys[3], N. Cools[4], I. Callebaut[5], K. Vrijens[1], L. Van Nassauw[3,6], V.F.I. Van Tendeloo[4], J.P. Timmermans[3], G. Van Camp[1].* 1) Center of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Present address: Center of Medical Genetics Ghent, University of Ghent, Ghent, Belgium; 3) Laboratory of Cell Biology & Histology, University of Antwerp, Antwerp, Belgium; 4) Vaccine & Infectious Disease Institute (VIDI), Laboratory of Experimental Hematology, University of Antwerp, Antwerp, Belgium; 5) Department of Structural Biology, Institute of Mineralogy and Physics of Condensed Media, Université Pierre et Marie Curie-Paris, Université Paris Diderot-Paris, Paris, France; 6) Laboratory of Human Anatomy & Embryology, University of Antwerp, Antwerp, Belgium.

Mutations in *DFNA5* are responsible for an autosomal dominant, nonsyndromic, sensorineural type of hearing loss with an onset age of 5-15 years. Hitherto, four *DFNA5* mutations have been described. Despite being different at the genomic DNA level, all mutations result in exon 8 skipping at the cDNA level. These findings have led to the hypothesis that DFNA5 associated hearing loss is attributable to a highly specific gain-of-function mutation. We previously provided the first experimental evidence for this hypothesis; transfection of mutant *DFNA5* caused cell death in both yeast and mammalian cells. Little is known about the molecular function of DFNA5, but a clear link with cancer exists. As such, DFNA5 was implicated in the p53-mediated cellular response to DNA damage and was epigenetically silenced in primary gastric tumors and colorectal carcinomas. In the current study, EGFP constructs containing different DFNA5 parts were transfected in HEK293T cells. Cell viability was assessed using flowcytometry and cytochemistry. The type of cell death was evaluated by annexin V and TUNEL assays. Interestingly, our experiments prove that the domain of DFNA5 responsible for cell death is located in a region that is shared by wild type and mutant protein, indicating that the observed toxicity is an intrinsic part of the physiological function of DFNA5. In addition, we show that sequences in exon 2 and exon 6 are essential for the toxic activity. Finally, we demonstrate that cells transfected with mutant DFNA5 are committed to an apoptotic cell fate. We conclude that DFNA5 contains an apoptosis inducing domain, suggesting a role in cell survival pathways. We hypothesize that this apoptosis inducing domain is activated by the hearing loss mutations, leading to accidental hair cell death.

## 400/W/Poster Board #58

**Expression of CACNA2D3 in Gingival Fibroblasts.** *T.C. Hart[1], T. Han[1], X. Liu[2], I. Ambudkar[2], P.S. Hart[3].* 1) Human Craniofacial Genetics Section, NIDCR, NIH, DHHS, Bethesda, MD; 2) Molecular Physiology and Therapeutics Branch, NIDCR, NIH, DHHS, Bethesda, MD; 3) Office of the Clinical Director, NHGRI, NIH, DHHS, Bethesda, MD.

CACNA2D3 on chromosome 3p21.1-p14.3 encodes an alpha-2/delta subunit of a voltage-dependent calcium channel. Calcium channels control the influx of calcium ions into the cell upon membrane polarization and consist of a complex of alpha-1, alpha-2/delta, beta, and gamma subunits in a 1:1:1:1 ratio. Recently disruptions in CACNA2D3 have been reported in two patients with Zimmerman-Laband syndrome, a syndromic condition which includes gingival overgrowth. Because of this, we characterized expression of CACNA2D3 in normal gingival fibroblasts. Gingival fibroblasts were obtained from 3 control individuals undergoing gingivectomy. Three CACNA2D3 isoforms (A-C) have been reported in the literature. Isoform A is the refseq isoform and is encoded by the full length transcript. Isoform B has skipping of exon 20 with the introduction of an immediate stop codon. Isoform C has a novel first exon. These isoforms, including a novel isoform D, were evaluated in the control gingival tissues by quantitative PCR. The predominant isoform in all gingival samples was isoform B (~70%), followed by isoform D (~20%) and isoform A (~10%). The novel isoform D includes a portion of intron 20 that introduces an immediate stop codon. This isoform was found in several other tissues, including skin, kidney and brain. Isoform C was not present in gingival tissue. Next calcium signaling was investigated in the cells. $2.5 \times 10^5$ cells were plated in 35mm optical dishes in 2ml of media and incubated overnight. 1.5ml media was removed the next morning and 5μl Fura-2 AM dye was added. Plates were incubated for 1 hour at 37C and 5%CO2. Media was removed and cells were washed with PBS to remove excess Fura-2. Bayk-8644, an agonist for L-type calcium channels, was added to stimulate $Ca^{2+}$ entry into the cell. Fluorescence was measured. Two distinct populations of cells were noted in all 3 control lines. Both populations showed a rapid influx of calcium. The fist population had initial total fluorescence about half that of the other population followed by a rapid decrease in fluorescence back to baseline levels. The second population had a sustained response, with fluorescence levels slowly returning to baseline. Results indicate tissue specific isoforms and altered functioning of CACNA2D3 may contribute to gingival overgrowth.

## 401/W/Poster Board #59

**High-resolution breakpoint mapping of novel rearrangements involved in alpha- and beta-thalassemia using array-Comparative Genomic Hybridization (aCGH).** *M. Phylipsen[1], I.P. Vogelaar[1], Y. Ariyurek[2], J.T. den Dunnen[2], P.C. Giordano[1], C.L. Harteveld[1].* 1) Hemoglobinopathies Laboratory, Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Leiden Genome Technology Center, Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Thalassemias are hereditary microcytic hypochromic anemias characterized by abnormalities in hemoglobin production due to reduced expression of either the beta-globin gene, leading to beta-thalassemia, or the alpha-globin genes, giving rise to alpha-thalassemia. About 10% of the beta-thalassemias and 90% of the alpha-thalassemias are caused by deletions in either globin gene cluster. In a previous study, we applied Multiplex Ligation-dependent Probe Amplification (MLPA) to characterize large rearrangements in the alpha- and beta-globin gene cluster. Several new deletions and duplications were found, however, the exact breakpoint sequences are still unknown. To facilitate confirmation by breakpoint PCR and to gain more insight in the mechanisms causing these rearrangements we decided to determine the precise location of breakpoints. Array Comparative Genomic Hybridization (aCGH) measures DNA copy number differences between a reference and a patient's genome sample thereby detecting and mapping deletions and duplications. We used high resolution tiling arrays with 135,000 probes spaced at a density of ~15 bp to map the breakpoints to an interval that can be validated by PCR and sequencing. The array was hybridized to a set of 55 thalassemia patients who were found to carry a deletion in the alpha- or beta-globin gene cluster. The fine mapping results were used to design breakpoint PCRs and resulting fragments were sequenced to determine the precise breakpoint.

## 402/W/Poster Board #60

**Examination of PMP22 involvement in deafness by comparative analysis of protein localization and gene expression patterns throughout murine development.** *T.A. Carver, M.J. Kovach.* Biol & Enviro Sci/ 2653, Univ TN at Chattanooga, Chattanooga, TN.

A genetic variant of the Charcot-Marie-Tooth (CMT Type 1E) disease, which causes profound deafness in addition to progressive peripheral neuropathy, has been linked to a unique point mutation in the PMP22 gene rather than gene duplication. PMP22, also known as peripheral myelin protein-22, is a 22 kD glycoprotein classified as a Growth Arrest specific (Gas) gene. Members of the Gas gene family have been shown to regulate gene expression, cell division and cell death. Although PMP22 is largely expressed in Schwann cells, it also has been found in other tissues such as cochlea, lungs and intestines at critical times during development. Thus, PMP22 appears to play a role in myelination of neural tissues, as well as in cell growth regulation of non-neural tissues. This dual expression is consistent with the description of both neural and cochlear components to hearing loss in CMT1E patients. This study was designed in order to gain a better understanding of the cochlear involvement of PMP22 in the normal function and development of the inner ear. We hypothesize that in the cochlea, PMP22 is acting as a transcriptional regulator, and mutations in PMP22 lead to abnormal gene expression patterns that characterize the deafness phenotype. The Trembler-J mouse was chosen as a model for PMP22-associated auditory dysfunction. Differences in protein localization and gene expression profiles were characterized in control and experimental groups by immunohistochemistry (IHC) and differential display (DD), respectively. IHC of the cochlea confirms expression of PMP22 protein in non-neural regions. In general, staining of the PMP22 protein in the Tr-J mouse is reduced in the cochlear nerve but more pronounced in the sensory and non-neural tissues of the inner hair, hensen and spiral prominence cells in a developmental-specific manner. These cells have been proposed to be involved with the $K^+$ recycling pathway. Differences were also noted for Type IV spiral ligament and marginal cells of the stria vascularis, which are also involved with $K^+$ recycling and cochlear homeostasis. DD analysis of lung tissue collected at different time points during inner ear development has identified a number of differentially expressed genes in the Tr-J, with slightly more than 50% being upregulated. Sequence analysis of some of these transcripts has determined genes with functions important in neurogenesis and cell development such as apoptosis, signal transduction and $K^+$ transport.

## 403/W/Poster Board #61

**Decreased Expression of Heat Shock Protein 27 and phosphorylated Hsp27 in Cellular Models of MERRF (A8344G) disease.** *M. Hsieh[1], C.Y. Chen[1], S.J. Gi[1], Y.H. Wei[2].* 1) Department of Life Science, TungHai University, Taichung, Taiwan; 2) Department of Biochemistry and Center for Cellular and Molecular Biology, National Yang-Ming University, Taipei, Taiwan.

Mitochondrial DNA (mtDNA) mutations are responsible for human neuromuscular diseases caused by mitochondrial dysfunction. Myoclonus Epilepsy associated with Ragged-Red Fibers (MERRF) is a maternally inherited mitochondrial encephalomyopathy with various syndromes involving both muscular and nervous systems. The most common mutation in MERRF disease, A8344G, has been associated with severe defects in protein synthesis, which impaired assembly of complexes in Electron Transport Chain and resulted in decreased respiratory chain activity. In this study, we showed a dramatic decrease of Heat shock protein 27 (Hsp27) in lymphoblastoid cells derived from a MERRF patient and in cybrid cells with MERRF A8344G mutation. However, reverse transcriptase PCR showed no difference in the mRNA level between normal and mutant cell lines, indicating that alterations may occur in the protein level. In addition, normal cytoplasmic distributions of Hsp27 and normal heat shock responses were observed in both wild type and mutant cybrid cells. Overexpression of Hsp27 in mutant MERRF cells significantly decreased cell death under staurosporine treatment, suggesting a protective function of Hsp27 in cells harboring MERRF mutation. Meanwhile, it was noted that the phosphorylated Hsp27 was also markedly decreased in cells harboring MERRF mutation. Given that the phospho-Hsp27 in mutant cells has no response to exogenous ATP addition and the similar levels of phospho-ERK,-JNK and -p38 between MERRF and wild type cells, the possibility of low ATP content leads to decreased phospho-Hsp27 may be excluded. Furthermore, evidenced by the decreased levels of Hsp27 upon starvation, proteasome inhibitor and rapamycin treatments, Hsp27 may be degraded by the autophagic pathway. However, phospho-Hsp27 was accumulated under proteasome inhibition, and shown no alternation during starvation or rapamycin treatment. Thus, the degradation of Hsp27 and phospho-Hsp27 may go through different pathways. To further understand the relationship between phospho-Hsp27 and the cell viability, we are establishing stable cells expressing different forms of Hsp27 with mutations on the phosphorylated sites. Stable clones expressing mutant forms of Hsp27 will serve to better understand the roles of Hsp27 in MERRF disease.

## 404/W/Poster Board #62

**Functional analysis of *UBE2A* c.382C-T mutation: evidence for functional specificity between the two human *RAD6* homologs.** *R.M.P. Nascimento, G. Monteiro, N.M. Vieira, L.E.S Netto, A.M. Vianna-Morgante.* Genetics and Evolutionary Biology, Institute of Bioscience, University of São Paulo, São Paulo, Brazil.

We have previously described a nonsense mutation (c.382C>T) in the *UBE2A/ HHR6A* gene (ubiquitin-conjugating enzyme 2A) as the cause of a novel X-linked mental retardation syndrome. It was the first description of a ubiquitin-conjugating enzyme mutation as the cause of a human disease. *UBE2A* is one of the two human homologs of the Saccharomyces cerevisiae RAD6 gene. In humans and other mammals, the RAD6 ortholog is duplicated, with one X-linked (*UBE2A*) and one autosomal (*UBE2B*) copy, both able to complement the rad6-null yeast strain phenotypes. The mutation found in our patients introduces a premature stop codon (Q128X) and abolishes the 25 C-terminal amino acids of the protein. Here we report on the effect of this mutation on UBE2A function. Functional complementation in a rad6-null yeast strain and *in vitro* ubiquitin-conjugating activity assays towards histone H2A revealed that the defective protein is toxic and, although capable of interacting with the ubiquitin molecule, it is unable to transfer ubiquitin to histones. Our data also indicate that the mutated protein undergoes poli-ubiquitination and proteasomal degradation *in vivo*. The fact that the loss of function of UBE2A causes a neurodevelopmental syndrome points to function specificity between the human paralogs, both expressed in brain. This conclusion is further supported by the finding of completely skewed X-chromosome inactivation, with the normal *UBE2A* allele being the active one in the heterozygous mothers, likely the result of selection against cells harboring the mutated allele on the active X, although having normal *UBE2B* expression.

## 405/W/Poster Board #63

**KIRREL3, a putative synaptic molecule, with a potential role in intellectual disability.** *A. Srivastava[1,2], Y. Luo[1].* 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, South Carolina; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, South Carolina.

Intellectual disability (ID), formerly known as mental retardation, is the most frequently reported developmental disability, affecting cognitive function in about 2-3% of the population. Growing evidence indicates that defects in synapse formation and plasticity are major causes of ID. We have recently identified a gene, *KIRREL3* at 11q24, encoding a putative synaptic molecule of the immunoglobulin (Ig) superfamily, that was disrupted by a balanced t(11;16) translocation in a patient with ID. We also identified three nonsynonymous *KIRREL3* variants that were apparently rare and unique to ID (Bhalla et al. Am J Hum Genet 83: 703-713, 2008). The *KIRREL3* gene is predicted to encode a type 1a membrane protein of 778 amino acids containing five Ig-like domains in its extracellular portion and a PDZ domain-binding motif in its cytoplasmic portion. We characterized the human KIRREL3 and determined the protein is primarily located in the neuronal cell membrane. *KIRREL3* mutations identified in patients with ID appear to have no effect on its cellular localization. Based on a previous report (Gerke et al. J Comp Neurol 498: 465-475, 2007), we showed that human KIRREL3 colocalizes and interacts with the synaptic scaffolding protein, CASK, recently implicated in X-linked brain malformation and ID conditions. In HT22 and PC12 neuronal cells, KIRREL3 and CASK both showed overlapping signals. We confirmed the presence of CASK in immunoprecipitates of KIRREL3. Furthermore, we determined that the extracellular domain of KIRREL3 is post-translationally modified by N-glycosylation and is cleaved after expression in neuronal cells. Thus, identification of the extracellular binding partner(s) of KIRREL3 in neuronal cells will help to further define the mechanism underlying its physiological function and the potential role of KIRREL3 in neuronal function.

## 406/W/Poster Board #64

**Functional characterization of mutations in the ATP-binding loop of ATP7B, the Wilson disease gene.** *L. Luoma, T.M.M Deeb, G. Macintyre, D.W. Cox.* Dept Med Gen, Univ Alberta, Edmonton, AB, Canada.

Wilson disease (WND) is an autosomal recessive disorder of copper homeostasis characterized by accumulation of excess copper in the liver, brain and kidneys, leading to tissue damage. Onset is highly variable and can be neurological, hepatic, renal or a combination of all. The primary means for maintaining copper homeostasis in mammals is through export of copper from the liver into the bile for excretion. The defective gene in WND is *ATP7B*. Previously WND diagnosis has been complicated by extensive clinical and biochemical heterogeneity of the disease. Complete sequencing of *ATP7B* has become a major means of WND diagnosis. Sequencing has resulted in the identification of over 580 *ATP7B* variants. As such novel missense variants can be diagnostically ambiguous. When functional data for missense variants is unavailable, predictive algorithms such as SIFT, PolyPhen and Align-GVGD, may be used to classify new ATP7B variants, although their accuracy is unknown. *ATP7B* encodes a P-type copper transporting ATPase, ATP7B. The yeast orthologue of ATP7B is Ccc2. If *Ccc2* is deleted, yeast cannot grow under iron limiting conditions. Their high affinity iron uptake complex is unable to assemble and function, as copper is an essential cofactor for iron oxidization and uptake. This growth deficit can be complemented by transformation of Δ*ccc2* yeast with *ATP7B*. Relative complementation of *ATP7B* variants identified in patients is a good indicator of the consequence of these variants on copper transport function. Twelve patient variants localized to the ATP-binding loop of ATP7B were tested in our yeast model system for their effect on copper transport. L1043P, G1000R, G1101R, I1102T, V1239G, D1267V were found to be deleterious to function, E1173G is temperature sensitive, G1176E and G1287S are intermediate. T991M and I1148T are mildly defective while R1228T is neutral. Protein modelling suggests possible consequences of specific amino acid changes. Comparison of functional results with predictive algorithms showed that PolyPhen was the most accurate, with 74% accuracy. SIFT and Align-GVGD were accurate 64% of the time. Through our functional studies we can determine whether novel patient variants are disease-causing or rare normal, assisting in diagnosis of WND. Furthermore, we find that computational predictive algorithms, while a useful adjunct, cannot replace functional data for designating the status of novel variants.

## 407/W/Poster Board #65

**Functional assessment of N-terminal *ATP7B* variants identified in patients with Wilson disease.** *G. Macintyre, J.J. Goodall, A.N. Szava-Kovats, M.A. Benusic, D.W. Cox.* Department of Medical Genetics, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Wilson disease (WND), an autosomal recessive disorder of copper transport, results in liver and/or neurological disease and can be fatal if left untreated. ATP7B, defective in Wilson disease, is the main copper transporter that eliminates copper via the liver and facilitates copper incorporation into copper-requiring proteins (eg. ceruloplasmin). Mutation studies have identified 642 *ATP7B* variants, listed in our WND database, http://www.wilsondisease.med.ualberta.ca. Functional testing is necessary to ensure identification of WND-causing variants. The ATP7B N-terminus (ATP7B-N) consists of 653 amino acids and contains six copper binding domains, each ~70 residues in length with an MXCXXC motif that binds copper. Additional motifs and domains, important for protein trafficking and copper transport, are located within ATP7B-N. Chinese Hamster Ovary (CHO) cells do not express endogenous ATP7B and are sensitive to copper. Using a tetracycline-inducible Flp-In FRT system (Invitrogen), we generated stable transfectants of *ATP7B* and *ATP7B-N* variants to measure CHO cell viability (CHO-CV) over a range of copper concentrations (0-500 micromolar), using Alamar Blue. Wild-type ATP7B protects CHO cells from copper. We tested 14 missense ATP7B-N variants, identified either by our group or others, for their ability to confer protection from high concentrations of copper. Nine exhibited normal function (N41S, G85V, D196E, I381S, A486S, E541K, R616W, L641S, M645R), four partial function (G96D, L492S, A604P, H639Y) and one, R616Q, a variable phenotype. The five defective ATP7B variants showed partial mislocalization by immunofluoresence microscopy (IFM), supporting their designation as WND-causing variants. Our findings agree with functional scores predicted by the Sorting Tolerant from Intolerant (SIFT) algorithm for 9 of 14 variants. However, three ATP7B variants, G85V, I381S and R616W, predicted to be defective, exhibited normal CHO-CV in the presence of copper. G96D and A604P, abnormal in the CHO-CV assay, were predicted to have normal ATP7B function. SIFT shows a poor success rate (65%) for the prediction of deficits in ATP7B-N. Four ATP nonsense variants, Q457X, C490X, L523X, Q544X, did not confer protection from high copper concentrations. Q457X and C490X produced truncated ATP7B proteins detectable by Western blot analysis, and were mislocalised by IFM. The contribution of stable truncated ATP7B proteins to WND severity requires further investigation.

**Functional consequences of a germline mutation located in the leucin rich repeat domain of NLRP3 identified in an atypical form of autoinflammatory disorder.** *E. Cochet[1], I. Jéru[1,2], S. Marlin[1], G. Le Borgne[1,2], P. Duquesnoy[1], F. Dastot-Le Moal[1], L. Cuisset[3], V. Hentgen[4], R. Dhote[5, 6], G. Grateau[7,2], S. Amselem[1,2].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM) U.933, Paris, France; 2) Université Paris 6 Pierre et Marie Curie, Paris, France; 3) Service de Biochimie et Génétique moléculaire, Hôpital Cochin, Assistance publique-Hôpitaux de Paris, Paris, France; 4) Service de Pédiatrie, Centre Hospitalier de Versailles, Le Chesnay, France; 5) Service de Médecine Interne, Hôpital Avicenne, Assistance publique-Hôpitaux de Paris, Bobigny, France; 6) Université Paris 13, Bobigny, France; 7) Service de Médecine Interne, Tenon, Assistance publique-Hôpitaux de Paris, Paris, France.

We investigated the pathophysiology of an atypical familial form of periodic fever syndrome (PFS) characterized by autosomal dominant sensorineural hearing loss, systemic inflammation but without any cutaneous manifestation. Microsatellites were used to test the segregation of the NLRP3 locus with the disease phenotype. All NLRP3 exons were screened for mutations by direct sequencing. A heterozygous missense mutation (p.Tyr859Cys) was identified. This mutation, which segregated with the disease phenotype within the family, is located in the leucin rich repeat (LRR) domain of the protein. Functional assays were performed in HEK293T cells to determine the effects of normal and mutated NLRP3 proteins on NF-kB activation and caspase 1 signaling. The mutation activates speck formation and procaspase 1 processing, but does not alter the inhibitory properties of NLRP3 on NF-kB signaling. This study identifies the first familial form of cryopyrinopathy associated with a mutation located outside exon 3 of NLRP3, thereby underlining the importance to screen other exons of the NLRP3 gene in patients presenting atypical manifestations. Our data, which assess the relevance and limitations of in vitro functional assays, also provide the first evaluation of the functional consequences of a missense mutation involving the LRR domain of NLRP3. This mutation readily explains, through a gain of function,the pathophysiology of this autoinflammatory syndrome.

## 409/W/Poster Board #67

**GLUT10 Located on the Mitochondria Facilitates Dehydroascorbate Transport and Protects Cells from Oxidative Stress: A New Insight into Arterial Tortuosity Syndrome.** *Y. Lee[1], H. Huang[1], C. Chang[1], C. Cheng[1], J. Wu[1], Y. Chen[1,2].* 1) Institute of Biomedical Sciences, Taipei, Taiwan; 2) Department of Pediatrics, Duke University Medical Center, Durham, NC, 27710, USA.

Glucose transporter 10 (GLUT10) is a member of the class III facilitative glucose transporter family. Mutations of the GLUT10 cause arterial tortuosity syndrome (ATS), an autosomal recessive disorder with tortuosity and elongation in the major arteries due to disorganization of elastic fibers in the arterial wall and laxity of skin and joints. However, the physiological function of GLUT10 and the molecular mechanisms of ATS caused by GLUT10 deficiency remain unclear. Here, we showed that GLUT10 mRNA was highly expressed in white adipose tissue and aortic smooth muscle cells. In addition, we found that GLUT10 was located on mitochondria of the aortic smooth muscle cells, and its subcellular location in adipocytes was on Golgi but translocated to mitochondria upon insulin stimulation. We identified the pheylalanin/tyrosine (YXXΦ)- based motif on C-terminus of GLUT10 is critical for mitochondria targeting. We further found that GLUT10 mediated transport of L-dehydroascorbic acid (DHA), an oxidized form of ascorbic acid (AA), but not glucose into mitochondria, and resulted in significant reduction of the reactive oxygen species (ROS) in cells under oxidative stress. We proposed that loss-of-function mutations of GLUT10 impair DHA transport into mitochondria, which affects the redox homeostasis and vitamin C recycling. These in turn lead to the disturbance of elastin and collagen synthesis and result in arterial tortuosity and laxity of skin and joint in human ATS.

## 410/W/Poster Board #68

**DUX4 Promotes FSHD-Associated Pathology *In Vivo.*** *L. Wallace[1,3], S. Garwick[3], W. Mei[4], A. Belayew[5], J. Yang[4], S.Q. Harper[1,2,3].* 1) MCDB, The Ohio State University, Columbus, OH; 2) Department of Pediatrics, The Ohio State University, Columbus, OH; 3) Center for Gene Therapy, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 4) Center for Cell and Developmental Biology, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 5) Laboratoire de Biologie Moléculaire, Université de Mons-Hainaut, Académie Universitaire Wallonie-Bruxelles, Mons, Belgique.

Facioscapulohumeral muscular dystrophy (FSHD) is a dominant genetic disorder caused by D4Z4 repeat contraction on chromosome 4q35. Current evidence supports that FSHD is an epigenetic disorder, in which FSHD-associated deletions produce chromatin changes that aberrantly upregulate myotoxic genes. Although the primary mutation was identified nearly two decades ago, the pathogenic mechanisms underlying FSHD are unclear. We hypothesize that the DUX4 gene is involved in FSHD pathogenesis because of its location in the D4Z4 repeat, elevated expression in FSHD myoblast cultures, and pro-apoptotic function *in vitro*. However, the in vivo effects of DUX4 over-expression in muscle have not been reported. Here, we describe the first *in vivo* evidence that DUX4 over-expression causes histological and functional deficits consistent with muscular dystrophy in zebrafish and mice. In fish, muscle-specific DUX4 expression produced body malformations, impaired mobility, somite defects, and myofiber degeneration. These results are consistent with abnormalities reported in other zebrafish models of muscular dystrophy and indicate that DUX4 is toxic to developing eukaryotic muscle. To confirm DUX4 toxicity in a mammalian model more closely related to humans, we delivered adeno-associated viral vectors (AAV6) carrying DUX4 or control GFP vectors to neonate or adult mouse muscle. In neonatal mice, DUX4 caused significant muscle atrophy, increased central nucleation, myofiber size variability, fibrosis, fat replacement of muscle, and inflammatory cell infiltration, while control GFP or untransduced muscles were unaffected. These results confirm our findings in zebrafish, and indicate that DUX4 toxicity to developing muscle is conserved between eukaryotic species. In adult muscle, AAV6.DUX4 caused massive, dose-dependent myofiber degeneration, apoptosis, histological evidence of muscle turnover, mononuclear cell infiltration, and gross muscle weakness. Untransduced or GFP transduced myofibers were normal. Importantly, expression of structurally intact but functionally inactive DUX4 mutants eliminated DUX4 toxicity *in vitro* and *in vivo*, supporting our hypothesis that DUX4-associated dystrophic phenotypes are related to DUX4 function as a transcription factor. Together, these data support DUX4 muscle toxicity *in vivo*, and justify further investigation of DUX4 in FSHD pathogenesis.

## 411/W/Poster Board #69

**Transcriptional profile of the embryonic myosin heavy chain gene *MYH3* responsible for two congenital distal arthrogryposis syndrome subtypes.** *A.E. Beck[1], A.W. Ward[2], M.J. Rieder[3], M. Regnier[2], M.J. Bamshad[1].* 1) Dept Pediatrics, University of Washington, Seattle, WA; 2) Dept Bioengineering, University of Washington, Seattle, WA; 3) Dept Genome Sciences, University of Washington, Seattle, WA.

The distal arthrogryposis (DA) syndromes are a group of 10 dominantly inherited disorders characterized by multiple congenital contractures such as camptodactyly and clubfoot. DA syndromes are caused by mutations in at least seven different genes that encode components of the contractile apparatus of fast-twitch myofibers including genes for troponin I, troponin T, tropomyosin, and myosin heavy chains. Mutations in *MYH3*, which encodes embryonic myosin heavy chain, cause both the most common DA, Sheldon-Hall syndrome, and the most severe DA, Freeman-Sheldon syndrome. To better understand the mechanism by which *MYH3* mutations cause contractures, we sought to first describe the spatial and temporal expression patterns of *MYH3* in human fetal skeletal muscles in the upper and lower limbs. As a screen, we first examined mRNA transcripts derived from the skeletal muscles from both the lower arm and the lower leg of two human fetal samples aged 103 and 124 days gestation using an Illumina Human HT-12 whole transcriptome array. *MYH3* was the predominant myosin heavy chain gene expressed in all skeletal muscles studied. Next, we sought to determine which specific fetal muscle groups in the lower limb expressed *MYH3* and whether expression levels varied among muscles and/or gestational age. To this end, we prepared cDNA from individual skeletal muscles dissected from normal human fetal samples aged from 11 to 23 weeks gestation and "control" tissues including adult skeletal muscle. As assessed by amplifying intron-spanning amplicons, *MYH3* was highly expressed in all fetal skeletal muscles studied, not expressed in cardiac muscle, and expressed at a low level in kidney, spleen and liver. Surprisingly, *MYH3* was also expressed in adult human skeletal muscle. To verify the universality of this finding, we determined that *MYH3* expression is found in adult mouse and rabbit skeletal muscles as well. The demonstration that transcription of normal *MYH3* continues into adulthood suggests that mutations in *MYH3* may affect both prenatal and adult DA skeletal muscle. Understanding transcription patterns of the genes involved in DA syndromes may allow us to better understand the mechanism underlying the development of congenital contractures.

## 412/W/Poster Board #70

**Tissue specific splicing of mutant transcript in patients with Hereditary Myopathy with Lactic acidosis (HML).** *A. Olsson[1], L.-E. Thornell[2], M. Holmberg[1].* 1) Department of Medical Bioscience, Umea University, Umea, Sweden; 2) Department of Integrative Medical Biology, Umea University, Umea, Sweden.

Hereditary Myopathy with Lactic acidosis (HML) is an autosomal recessive disorder with its origin in the northern part of Sweden. HML patients are exercise intolerant and will, even at a low work load, present symptoms such as muscle cramps, tachycardia, dyspnea and increased release of lactate and pyruvate. In severe cases, which can be triggered by fasting or hard exercise, the patients can develop severe acidosis which can prove fatal. We have previously identified an intronic mutation (G→C) in the *ISCU* gene in patients with HML. The mutation results in aberrant splicing of the IscU RNA introducing 100bp of intron RNA into the IscU mRNA. This in turn gives rise to a dysfunctional IscU protein which causes impaired energy metabolism. The IscU protein is involved in the assembly of iron-sulfur clusters, which are necessary for the function of several proteins in the respiratory chain and the TCA cycle. One would expect that a defect in such a general process would affect all energy demanding tissues but the phenotype is limited to the patients' skeletal muscles, while organs such as the heart and the brain are unaffected. We have shown by RT-PCR and western blot that the IscU mRNA and protein is expressed in all tissues examined, including heart. We therefore speculate that the fact that skeletal muscle is particularly vulnerable to the IscU defect is due to alternative splicing of the IscU RNA. We have studied the IscU transcripts in tissues from both patients and controls and preliminary data show that the mutant transcript is indeed alternatively spliced in a tissue specific manner in HML patients.

## 413/W/Poster Board #71

**Mitochondrial UBIAD1 Pore Function is Predicted to be Altered by Schnyder Corneal Dystrophy Mutations.** *M.L. Nickerson[1,5], B. Kostiha[2,5], W. Braun[3], W. Fredericks[4], B. Gold[5], B. Malkowicz[4], L. Wessjohann[3], H. Kruth[6], M. Dean[5], J.S. Weiss[7].* 1) Graduate Partnership Program, NIH, Bethesda, MD 20892, USA; Molecular Medicine Program, Institute for Biomedical Sciences, George Washington University, Washington, DC 20037, USA; 2) Biomedical Science Graduate Program, Hood College, Frederick, MD 21701, USA; 3) Leibniz-Institute of Plant Biochemistry Department of Bioorganic Chemistry, Weinberg 3,0612 0 Halle/Saale, Germany; 4) Department of Surgery, Division of Urology, University of Pennsylvania, Philadelphia, PA 19104, USA; 5) Cancer and Inflammation Program, National Cancer Institute, National Institutes of Health, Frederick, MD, 21702, United States of America; 6) Section of Experimental Atherosclerosis, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, USA; 7) Kresge Eye Institute and Departments of Ophthalmology and Pathology, Wayne State University School of Medicine, Detroit, MI 48201, USA.

Schnyder corneal dystrophy (SCD, MIM: 121800) is a rare autosomal dominant disease characterized by abnormal deposition of cholesterol and phospholipids in the cornea leading to progressive corneal opacification and loss of visual acuity. A novel gene mutated in SCD, UBIAD1, was recently independently identified by two groups using classic positional cloning methodology. UBIAD1 was predicted to contain a prenyl-transferase domain and eight transmembrane spanning regions. Examination of protein homology showed that UBIAD1 is an outlier when compared to proteins involved in sterol and cholesterol metabolism. This may indicate a novel function for the enzyme. The current study presents examination of ten newly recruited SCD families. One represents a first report of SCD in a family of Native American ethnicity. Clinical manifestations of SCD in proband cornea are described. We report five novel UBIAD1 genetic alterations: A97T, D112N, V122E, V122G, and L188H. Five families possessed the hotspot alteration, N102S, bringing the total number of SCD families with this alteration to 41%. Mutated amino acids were observed to be highly conserved across species, and to date, 88% (15/17) of residues mutated in SCD are completely conserved from sea urchin to mammals. To assess the impact of SCD mutations on protein function, a three-dimensional model of UBIAD1 in a lipid bilayer was developed using protein threading. A model obtained using the Molecular Operating Environment was refined using the molecular dynamics refinement tool, YASARA. Stereochemical quality of the model was analyzed with PROCHECK. The model indicates the protein forms a potential pore structure composed of a circle of eight transmembrane helices. Amino acid, N102 appears to occupy a critical position within the pore as part of a previously identified enzyme active site. Docking simulations with various substrates were conducted and these indicate favorable interaction with oligoprenyl diphosphates. Naphthalin-1,4 diol also fit well when docked into the putative active site of the model. Significantly, changing N102 to N102S altered the binding of naphthalin-1,4 diol completely, rendering its prenylation impossible. Lastly, we demonstrate subcellular localization of UBIAD1 to the mitochondria in normal and SCD keratocyte cell lines.

## 414/W/Poster Board #72

**Gene expression signatures of primary colonic tissue from control, FAP and AFAP patients.** *D.W. Neklason[1,2], B.A. Milash[1], E.J. Manos[1], T.M. Tuohy[1], J. Lilley[1], R.W. Burt[1,3].* 1) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT; 2) Department of Oncological Sciences, University of Utah, Salt Lake City, UT; 3) Department of Medicine, University of Utah, Salt Lake City, UT.

Familial adenomatous polyposis (FAP) is a colon cancer syndrome with a prevalence of 1:10:000. Patients have 100's to 1000's of precancerous colonic polyps and nearly 100% risk of developing colon cancer at an average age of 39 years in the absence of colon surveillance and surgery. Mutations in the *APC* gene lead to FAP as well as an attenuated form (AFAP) which presents with variable phenotypic expression, reduced polyp numbers and reduced cancer risk as compared to FAP. Current methods for the clinical diagnosis of genetic diseases most commonly involve analysis of germline DNA. Germline DNA-based diagnosis can be incomplete, for example no mutation is found in approximately 20% of FAP and 50% of AFAP patients. The objective of this study is to determine a molecular profile of the colonic epithelia from patients with *APC* mutations leading to FAP or AFAP then to use this information to establish a gene expression signature for diagnosis and for better understanding of the disease in the primary affected tissue. Aglient 44K RNA microarrays were run using mRNA from fresh normal-appearing colonic epithelia obtained as biopsies during endoscopy from FAP patients (n=6), AFAP patients (n=14) and control patients (n=12). Analysis using the Rank Product method found 48 mRNA probes with statistical significance (p<0.001) that consistently distinguish between control, FAP and AFAP normal appearing colonic tissue. These probes are up in FAP vs. control but low in AFAP vs. control or vice versa and will be tested for their accuracy to classify FAP and AFAP patients. Differential expression was also evaluated to better understand the phenotypic variability within AFAP using 5 individuals with > 100 adenomas versus 6 individuals with < 20 adenomas with the identical APC mutation. Differential expression identified 245 probes with a p-value of <0.05. The most striking were *DEFA5* and *DEFA6*, encoding microbicidal defensins involved in host defense, which consistently showed increased expression in the >100 adenoma group. It is not clear if this reflects a host or an environmental difference and will require further study. In conclusion, a distinct gene expression signature can be identified in FAP vs. AFAP patients that, in turn, can be applied to diagnostics. A separate set of genes can also distinguish phenotypic classes of individuals with the identical *APC* mutation.

## 415/W/Poster Board #73

**Molecular and Clinical Findings of Patients Referred for UGT1A1 Mutation Analysis.** *B. Durmaz[1], H. Onay[2], A. Alpman Durmaz[2], U.S. Akarca[3], F. Ozgenc[4], M. Baran[4], F. Ozkinay[1,2].* 1) Department of Pediatrics, Division of Genetics, Ege University, Izmir, Turkey; 2) Department of Medical Genetics, Ege University, Izmir, Turkey; 3) Department of Gastroenterology, Ege University, Izmir, Turkey; 4) Department of Pediatrics, Division of Gastroenterology, Ege University, Izmir, Turkey.

Gilbert syndrome (GS) is an inherited disorder characterized by unconjugated hyperbilirubinemia without any liver pathology or hemolysis. Hepatic UDP-glucuronosyltransferase enzyme activity is decreased to its 30% of normal levels leading to a defect of biluribin uptake into the liver resulting in unconjugated hyperbilirubinemia. UGT1A1 gene which is found to be associated with GS is located on 2q37. Increase in the number of TA repeats in the TATAA element of the promoter region of the UGT1A1 gene results in decrease of the enzyme activity leading to decreased bilirubin conjugation. A(TA)6TAA allele is seen in normal individuals whereas A(TA)7TAA or A(TA)8TAA alleles are found to be associated with hyperbilirubinemia. Here, we present 8 suspected Gilbert syndrome patients who were referred to us for molecular analysis of UGT1A1 gene. The sequence analysis of the promoter region of the UGT1A1 gene in these 8 patients revealed a normal A(TA)6TAA allele in homozygous state in 4 patients, (TA)7/(TA)7 in 2 patients, (TA)6/(TA)7 in one patient and (TA)7/(TA)8 in one patient. The clinical spectrum of the patients according to their genotypes of the UGT1A1 gene are discussed.

## 416/W/Poster Board #74

**Novel mutations underlying familial enteropathies.** *D. Monies[1], Z. Rahbeeni[2], H. Al-Zaidan[2], A. Mehaidib[3], M. Al-Edreesi[4], M. Faqih[5], B.F. Meyer[1].* 1) Genetics, King Faisal Specialist Hospital and Research Centr, Riyadh, Riyadh, Saudi Arabia; 2) Medical Genetics, King Faisal Specialist Hospital and Research Centr, Riyadh, Riyadh, Saudi Arabia; 3) Pediatrics, King Faisal Specialist Hospital and Research Centr, Riyadh, Riyadh, Saudi Arabia; 4) Saudi Aramco Medical Services Organization; 5) Anatomic Pathology, King Faisal Specialist Hospital and Research Centr, Riyadh, Riyadh, Saudi Arabia.

Microvillous Inclusion Disease (MVID) and Congenital Tufting Enteropathy (CTE) are congenital disorders of the intestinal epithelial cells that cause an intractable watery diarrhea with usual onset near birth. MVID is characterized by lack of microvilli on the surface of enterocytes with the occurrence of intracellular vacuolar structures containing microvilli. Whereas pathologic studies for CTE patients demonstrate villi with crowded epithelial cells forming tufts. MVID and CTE are very rare disorders and are inherited as autosomal recessive traits. Recently, mutations of MYO5B and EpCAM were identified as the underlying lesion resulting in MVID and CTE, respectively. Four Saudi families were investigated, three with children affected by MVID and one with a child affected by CTE. Five patients and available unaffected individuals were subjected to genome-wide homozygosity scans using the Affymetrix 250K SNP array. Analysis with the copy number tool CNAG identified shared homozygous regions unique to the affected subjects. Of the three families with MVID, homozygosity was observed in two families at a locus on chromosome 18 which included MYO5B. Sequencing of MYO5B in individuals from these families identified two novel nonsense mutations in exons 24 and 36 (Q1047X and E1589X). In the other family homozygosity was absent at the MYO5B locus. However, a locus on chromosome 2 which included EpCAM was found to be homozygous in this family. Sequencing of EpCAM identified a 1bp insertion (c.499insC) in exon 5 resulting in premature truncation of the mature protein. This was consistent with this family being classified as having CTE rather than MVID. The fourth family studied was referred with a diagnosis of CTE and was found to have the same 1 bp insertion consistent with a common founder. The present study has identified novel nonsense mutations in MYO5B and EpCAM associated with autosomal recessive entheropathies in Saudi families. Our findings expand the limited spectrum of MYO5B and EpCAM mutations associated with gastrointestinal genetic disorders and provide an opportunity to investigate phenotype/ genotype correlations.

## 417/W/Poster Board #75

**Novel *SLC26A3* mutations in patients with congenital chloride diarrhea.** *S. Wedenoja[1,2], P. Höglund[1], C. Holmberg[2], J. Kere[1,3].* 1) Dept Medical Genetics, Univ Helsinki, Helsinki, Finland; 2) Hospital for Children and Adolescents, Univ Helsinki, Helsinki, Finland; 3) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden.

The rare autosomal recessive disease congenital chloride diarrhea (CLD) is caused by mutations in the solute carrier family 26 member 3 (SLC26A3) gene. This gene resides on chromosome 7q31 and belongs to the human solute carrier family 26 (SLC26) with 11 structurally homologous anion exchangers, at least 3 of them causing rare autosomal recessive diseases. SLC26A3 encodes for an apical epithelial $Cl^-/HCO_3^-$ exchanger which shows expression in the surface epithelium of the ileum and colon, and in a few extraintestinal tissues including the sweat gland, male reproductive tract, and kidney. Intestinal loss of SLC26A3 results in profuse $Cl^-$-rich diarrhea, secondary loss of sodium, and a tendency to hypochloremic and hypokalemic metabolic alkalosis. The life-saving therapy for CLD, salt substitution with NaCl and KCl, allows favorable long-term outcome. CLD diagnosis is based on its typical clinical picture and a high concentration of fecal $Cl^-$, exceeding 90 mmol/L after correction of the fluid and electrolyte depletion. Although genetic testing for CLD is possible, the simple measurement of fecal $Cl^-$ is still sufficient to confirm the diagnosis in most of the cases. Differential diagnosis includes the rare entity of other inherited diarrheas. While most of the 250 cases reported so far arise from Finland, Poland, and Arabic countries, single cases with this rare autosomal recessive disorder appear worldwide. Such CLD infrequency makes diagnostics challenging but necessary, as untreated disease is usually lethal in early infancy. As a part of our research program, we have been characterizing mutations for CLD in patients from all over the world. After our mutation update in 2002, we have found altogether 16 novel mutations behind CLD by direct sequencing. The aim of this study is to report novel SLC26A3 mutations and assess their types and distribution in different regions of the SLC26A3 gene. These mutations add important data on SLC26A3 genetics but despite the spectrum of tens of mutations, evidence of genotype-phenotype differences remain non-existent. It is worth remembering, however, that most clinical data on CLD stem from a relatively homogenous population of Finnish patients with an identical genetic background for CLD (p.V317del mutation in 97%). Therefore, future work is necessary to assess possible phenotypical differences, if any, in CLD.

## 418/W/Poster Board #76

**Are endothelial nitric oxide synthase (eNOS) gene VNTR genotypes risk factors in the etiology of Necrotizing enterocolitis (NEC) in premature infants?** *K. Yanamandra[1], J. Aryama[1], D. Napper[1], H. Chen[1], S.A. Ursin[1], A. Pramanik[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Dept Pediatrics, LSU Med Ctr, Shreveport, LA; 2) Dept Pediatrics, UT Health Science Center, Memphis, TN.

Necrotizing enterocolitis (NEC) is a severe GI disease of the premature infants. Although the precise etiology of NEC is unknown, suspected pathopyhisological mechanisms include prematurity, formula feeding, infection and bacterial translocation, ischemia, hyperosmolar load, and disruption of mucosal integrity in the GI tract. The disease could be fatal if untreated. It is a multifactorial disorder with fragile intestine susceptible to microbial infections culminating in ischemia and necrosis in premature infants. Nutritional factors were reported to be involved in the etiology of NEC, such as low Arginine. Also several investigators have reported the advantages of L-Arginine supplementation with a caution on the dose. L-Arginine is a precursor of endogenous nitric oxide (NO) through nitric oxide synthase (NOS). There are three forms of NOS, neuronal and endothelial being constitutive and the third inducible form. Endothelial nitric oxide (eNO) serves as a vasodilator, relaxes smooth muscle, prevents platelet aggregation, and facilitates improved blood flow, vascular tonicity. Reduced nitric oxide levels result in vasoconstriction and weak tone leading to decreased blood flow and hypoxia. Mutant eNO synthetase (eNOS) genotypes result in reduced nitric oxide levels by decreasing the enzyme activity. In the present investigation we have studied the association of eNOS variable number of tandem repeats (VNTR) of 27bp in intron 4 region of the gene. We have collected peripheral blood specimens from a total of 147 premature infants consecutively from our NICU facility and genotyped by PCR. The frequency of rear allele *a* consisting of 4 repeats was elevated over the common *b* allele consisting of 5 repeats in NEC patients as compared to controls (0.56 vs. 0.36, odds ratio 2.2). Clinical data of the infants from NICU with ethnic stratification and distribution of alleles and genotypes and their significance will be presented.

## 419/W/Poster Board #77

**Evaluation of 263 patients referred for molecular analysis of Alpha 1 antitrypsin gene.** *C. Ozkinay[1], E. Karaca[1], A. Alpman Durmaz[1], H. Onay[1], B. Durmaz[2], O. Cogulu[1,2], F. Ozkinay[1,2].* 1) Department of Medical Genetics, Ege University Medical Faculty, Izmir; 2) Department of Pediatrics, Ege University Medical Faculty, Izmir, Turkey.

Alpha 1 antitrypsin (AAT) enzyme deficiency is one of the most common autosomal-codominant genetic disorderand is characterized by early onset rapidly progressive emphysema. The variants within the AAT1 gene are classified according to the protease inhibitor (PI) system in which M is the normal allel and the inheritance of S and Z alleles is associated with decreased levels of the protein. The Z genotype is associated with liver cirrhosis in contrast to S genotype. The objctive of this study is to investigate the presence of S and Z alleles in patients with various indications. In this report we present the AAT1 genotypes of 263 patients referred for molecular analysis with various indications. The indications for AAT1 genotyping were chronic lung disease, chronic liver disease, cirrhosis, hepatitis, Wilson disease and some other entities. Among 263 patients, 252 patients were found to be normal MM genotype, whereas 4 pateints were PIMZ, 4 patients were PIZZ and 3 pateints were PIMS. The clinical features of the patients having mutant alleles are discussed. The frequencies of the mutant alleles were found to be rare among the patients referred to molecular analysis in the study group.

## 420/W/Poster Board #78

**Adult-onset leukoencephalopathies with vanishing white matter with novel missense mutations in *EIF2B2* and *EIF2B5*, and decreased eIF2B activity.** *T. Matsukawa[1], X. Wang[2], R. Liu[2], A. Hida[1], A. Kubota[1], Y. Fukuda[1], H. Kowa[1], Y. Takahashi[1], S. Aoki[3], J. Shimizu[1], J. Goto[1], CG. Proud[2], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Dept Biochemistry and Molecular Biology, Univ British Columbia, Vancouver, Canada; 3) Dept Radiology, Univ Juntendo, Tokyo, Japan.

Background: Leukoencephalopathy with vanishing white matter (VWM) is a leukoencephalopathy with autosomal recessive inheritance. MRI shows diffuse leukoencephalopathy with cystic lesions. The onset is usually at age 2-6 with cerebellar ataxia, spasticity and intellectual decline. The course is chronic-progressive with episodes of rapid deterioration following minor head trauma. Mutations in each of eIF2B subunit genes, *EIF2B1-5*, have been identified as causative for VWM. Thus far, the cases of 8 adult patients with VWM have been reported. Material & method: 10 Japanese adult patients with leukoencephalopathy of unkown origin in our hospital aged 28 to 70 years (mean age; 50.9) were investigated. Parents were first cousins in two patients. Brain MRI showed diffuse leukoencephalopathy with cystic lesions in 4 patients. We performed mutational analyses of *EIF2B1-5* of the patients using direct nucleotide sequence analysis. Functional assays of mutant eIF2B was accomplished by the analysis of the activity of complexes of eIF2B subunits containig the mutant eIF2B subunit. Results: We detected novel homozygous missense mutations in *EIF2B2* (p.Val85Glu) in one patient with severe intellectual decline and ataxia, and in *EIF2B5* (p.Asp270His) in one patient with only mild cognitive impairment, ataxia and spasticity. Both of their parents are consanguineous. In addition, we detected novel SNPs in introns of *EIF2B3-5*. These novel SNPs in introns are unlikely to be associated with splicing abnormalities. Analysis of eIF2B subunits containing the mutant eIF2B subunit was conducted in the adult case of VWM with a novel missense mutation in EIF2B2, and the results confirmed decreased activity of eIF2B. The decrease in the activity of the eIF2B containing the mutant eIF2B subunit is milder than observed for mutations tested previously. This was the second case among the adult-onset cases with the mutation in *EIF2B2*. The onset of the adult case of VWM with a novel missense mutation in *EIF2B5* was at age 50 and this was the latest among adult-onset cases of VWM. Conclusion: In our study, we detected 2 adult-onset cases of VWM out of 10 cases of leukoencephalopathy of unkown origin. Both of two adult-onset cases of VWM showed cystic lesions on MRI. To investigate the genotype-phenotype correlation of the cases of VWM and whether the level of residual activity is related to the variability of VWM phenotype, investigation on larger number of cases of VWM will be needed.

## 421/W/Poster Board #79

**Comprehensive functional analysis of human radiosensitive cell lines enables a molecular diagnosis of DNA repair disorders.** *S.A. Nahas, F. Fike, k. Nakamura, L. Du, R.A. Gatti.* Pathology and Lab Medicine, UCLA, Los Angeles, CA.

In an effort to unravel the many possible etiologies of human radiosensitivity, we studied a unique panel of 26 radiosensitive (RS) human lymphoblastoid cells (RS-LCLs) from individuals with undiagnosed diseases. Our comprehensive approach tested the integrity of known functional pathways for sensing and repair of DNA double strand breaks. We first categorized the RS-LCLs by assessing the kinetics of phosphorylation of SMC1 followed by radiation-induced DNA damage over 24-hours. We further interrogated cell cycle checkpoints, Non Homologous End Joining DNA ligation (NHEJ), mitochondrial respiratory integrity, and the chromatin ubiquitin ligase cascade. These results implicated specific repair pathways and protein defects. From among the cell lines with an S-phase checkpoint defect, we identified a Chk2- related deficiency that impaired the degradation of the Cdc25A phosphatase protein and phosphorylation of BRCA1 by Chk2. In another cell line absence of IR-induced 53BP1 foci implicated a portion of the recently described chromatin ubiquitin ligase pathway. A third RS-LCL unexpectedly lacked aprataxin, a deficiency not previously associated with RS. These studies provided proof of principle that a hypothesis-driven dissection of RS mechanisms can lead to improved diagnoses of DNA repair disorders.

## 422/W/Poster Board #80

**Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay (ARSACS): expanding the genotype in the French-Canadian population.** *I. Thiffault[1, 2], M. Tetreault[1,2], J. Demers-Lamarche[1,2], M.J. Dicaire[1,2], L. Loiselle[1,2], J. Mathieu[3], J.P. Bouchard[4], G.A. Rouleau[2], B. Brais[1,2].* 1) Lab Neurogenetics, M4211-L4, CRCHUM-Notre Dame Hospital, Montreal, PQ, Canada; 2) 2) Centre of Excellence in Neuromics of Université de Montréal, CRCHUM, Hospital Notre-Dame, Montreal, QC, Canada; 3) Carrefour de la Santé de Jonquière, Saguenay, QC, Canada; 4) Department of Neurology, CHUL, Quebec City, QC, Canada.

Recessive ataxias are a heterogeneous group of neurodegenerative diseases. Autosomal Recessive Spastic Ataxia of Charlevoix-Saguenay (ARSACS, MIM 270550) is one of the classical recessive diseases more frequent in the French-Canadian (FC) population due to a founder effect. Is has an estimated mutation carrier rate of 1/22 in the Saguenay-Lac Saint-Jean (SLSJ) region of Northern Quebec. First described in 1978, ARSACS manifests itself in childhood by a spastic paraparesis that evolves into a progressive spastic cerebellar ataxia accompanied by a sensory-motor neuropathy that ultimately leads to a loss of walking at a mean age of 41 (17-57 years). In 2000, two nonsense mutations in the SACS gene were found to be responsible for 92.6% and 3.7% of Quebec carrier chromosomes. Despite the fact that ARSACS is a common recessive disease in Quebec, our specific aim is to uncover the full spectrum of mutations in French Canadians to better delineate the clinical variability of the ARSACS phenotype. DESIGN/METHODS: RT-PCR, long-range PCR and extensive sequencing of all cDNA and genomic fragments were performed. We also designed two custom panels encompassing all variants reported in the literature and novel French-Canadian mutations using Sequenom iPLEX technology (N=63 variants) to investigate the frequency of SACS mutations in sporadic/idiopathic ataxia cases and validate it use for mutation detection. In order to better delineate rearrangement and asses the frequency of these events in SACS patients, we designed an Illumina GoldenGate array to interrogate 96 loci (SNPs and mutations). RESULTS: Mutation analysis was performed in 32 ARSACS patients with only one mutation identified or a classical phenotype and 127 spastic ataxia cases. We identified 18 mutations in the SACS gene. Most mutations are loss of function mutations (90%). Large deletion encompassing the entire SACS coding sequence and surrounding genes seems to be more common than expected (5/32 ARSACS cases). CONCLUSIONS/RELEVANCE: The prevalence of ARSACS in the French-Canadian population seems even higher than previously estimated. The phenotype of ARSACS patients seems less uniform than originally described. Multimodal molecular screening is required to improve the sensitivity of SACS mutation analysis. The Illumina Goldengate custom array that we designed could help international colleagues to better assess the role of SACS mutations in ataxia cohorts.

## 423/W/Poster Board #81

**FREQUENCY OF Q829X MUTATION IN OTOF GENE AMONG 650 INDIVIDUALS WITH NONSYNDROMIC DEAFNESS: GENOTYPE- PHENOTYPE CORRELATION.** *N. Gelvez[1], L. Morales[1], S. Florez[2], V. Rodriguez[3], M. Olarte[1], M.F. Leiva[4], M.L. Tamayo[1].* 1) Inst Genetica Humana, Univ Javeriana, Bogota, 1, Colombia; 2) Fundaciòn oftalmològica Nacional FUNDONAL, Bogotà, Colombia; 3) Hospital universitario San Ignacio, Bogotà, Colombia; 4) UDES, Universitaria de Santander, Cúcuta, Colombia.

Introduction: Non-syndromic deafness affects 1 to 1000 or 2000 newborn infants. The most common form is autosomal recessive with genetic heterogeneity. At least 16 genes have been implicated in the aetiology of deafness. The OTOF gene is one of the most important implicated in the nonsyndromic deafness of neural type, codifies for the Otoferlin protein with expression in cochlea, vestibule and brain. Alterations in this protein cause auditory neuropathy and deafness; the Q829X mutation is the third most frequent causing deafness. Objective: To determine the frequency of Q829X mutation among 650 individuals with nonsyndromic deafness; and to offer a genotype-phenotype correlation in positive cases. Methods: Complete clinical, genetic and ocular evaluation to 650 Colombian deaf individuals attending schools for the deaf throughout the country in order to confirm the diagnosis of Non-syndromic deafness. Blood samples were obtained from selected individuals, to identify the Q829X mutation, choosing children without mutation in the GJB2 and GJB6 genes (Cx26, Cx30), or deaf individuals heterozygous for any mutation in GJB2 or GJB6 genes. Results: Among 650 deaf children, the Q829X mutation was identified in 11 individuals: 7 homozygous and 4 heterozygous. The frequency for this mutation was 1.69% among deaf institutionalized population with Non-syndromic deafness. Discussion: These results indicate that Q829X mutation has a significant frequency among deaf Colombian population. It is important to include the Q829X mutation as a part of a future diagnostic panel in Colombia, based on molecular screening among hearing impaired individuals, in order to offer an early and reliable diagnosis, which is important to start an earlier rehabilitation in this population.

**Computational Re-Examination of Tyrosinase Mutations in Oculocutaneous Albinism.** *D.R. Adams, W.A. Gahl.* Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

INTRODUCTION: Oculocutaneous albinism (OCA) is an autosomal recessive condition causing decreased pigment production. Four genes are known to cause OCA, the most common being *TYR* (tyrosinase) and *OCA2* (OCA2). Sequence analysis in affected individuals has up to 85% sensitivity, with the remainder unexplained. Recent human whole-genome sequencing data suggests that rare, non-synonymous sequence variants (nsSNPs) are more common than previously thought. To help understand the pathogenicity of nsSNPs in OCA, we re-analyzed the published *TYR* mutations using pathogenicity prediction software. METHODS: The analyzed set of variants was collected from published literature, and included only non-frameshifting single amino acid changes. Each variant was tested using the published programs SNAP, PolyPhen and Panther. The results were compared with the published pathogenicity assessment, the proximity to tyrosinase protein functional elements, and the nsSNP frequency among affected individuals. The pathogenicity assessments of the three software programs was compared by ranking the assessments within each method and comparing the rankings using Spearman rank correlation. RESULTS: 20% of the variants that had been reported to be pathogenic were assessed as non-pathogenic. Another 20% were assessed as indeterminate. Pair wise correlations between the method rankings averaged 80% with a P-value of less than 1 x 10-7. 13/15 mutations that were reported separately in 3 or more papers were classified as pathogenic. Mutations that disrupted known structural elements were classified as pathogenic. CONCLUSIONS: Some reportedly pathogenic mutations found in persons with OCA are likely to be rare, non-pathogenic nsSNPs. Pathogenicity prediction software has false-positive and false-negative rates that are substantial (10-20%). In addition, there is significant overlap among the different programs' usage of assessment techniques such as multiple alignment. However, such programs would be expected to perform relatively well with TYR given a large number of available distant orthologs and a well characterized structure. While software pathogenicity prediction is not currently reliable enough for the assessment of individual nsSNPs, it can provide valuable categorization of groups of variants. Future refinement of pathogenicity assessment techniques, including functional assays, will be required to differentiate rare non-deleterious nsSNPs from deleterious mutations.

## 425/W/Poster Board #83

***ZNF469* mutations in patients with brittle cornea syndrome.** *F. Malfait[1], Ph. Vlummens[1], L. Van Laer[1], S. Ceylaner[2], G. Ogur[3], A. De Paepe[1].* 1) Centre for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Zekai Tahir Burak Womens Health and Education Hospital, Department of Genetics, Ankara, Turkey; 3) Department of Paediatric Genetics, Medical Faculty, Ondokuz Mayis University, Samsun, Turkey.

Brittle cornea syndrome (BCS) is an autosomal recessive (AR) condition characterized by a thin, fragile cornea that tends to rupture upon minor trauma and blue sclerae. Additional systemic symptoms, such as joint and skin hyperlaxity place BCS among the heritable disorders of connective tissue (HDCT). BCS shows considerable overlap with the kyphoscoliotic type of Ehlers-Danlos syndrome (EDS type VI), based on its AR transmission, joint and skin hyperlaxity and rupture of the eye. In general however, EDS VI patients have more severe muscle hypotonia, as well as kyphoscoliosis, atrophic scarring and arterial rupture. EDS VIA is caused by deficient activity of lysyl hydroxylase-1 (LH-1; encoded by *PLOD1*), which hydroxylates specific collagen lysines. EDS VIB patients have an identical phenotype but normal LH activity. Recently two homozygous 1 bp deletions were identified in the *ZNF469* gene in 6 unrelated BCS families. *ZNF469* encodes Zinc finger 469, a protein of unknown function which belongs to the C2H2-zinc finger (ZNF) family of proteins. ZNFs are abundant in eukaryotic proteins and generally function as sequence-specific DNA-binding motifs, although they can be involved in recognition of RNA and proteins. Here we present 2 consanguineous Turkish families, with respectively two (P1&2) and one (P3) affected children, all of them previously diagnosed with EDS VIB. They presented blue sclerae and corneal rupture after minor trauma, joint and skin hyperlaxity and marfanoid habitus. P1&2 were more severely affected with multiple dislocations, muscle hypotonia and kyphoscoliosis. LH-1 activity was normal in all patients. Direct sequencing of *ZNF469* revealed 2 homozygous duplications generating a premature stop codon: in P1&2 a c.6509_6512dupTCTT (p.Leu2171PhefsX99), and in P3 a c.9792dupT (p.Ala3265CysfsX6). Interestingly, molecular analysis of *PLOD1* revealed a previously unreported heterozygous variant c.79A>C (p.N27H) in P1&2. In conclusion, we identified 2 novel *ZNF469* mutations in 3 BCS patients. In one family, a potentially deleterious, heterozygous amino acid substitution in LH-1 was identified as well. Although LH-1 activity was normal, this variant may have an aggravating effect, accounting for the more severe EDS VI-like phenotype of P1&2. Further studies are needed to unravel the function of ZNF469. This will provide insight into the molecular pathways involved in the development of connective tissues and in the pathogenesis of HDCTs.

## 426/W/Poster Board #84

**Atlastin-1 (SPG3A) mutations in Portuguese families with dominantly inherited spastic paraplegia.** *A.F. Brandão[1,2], J.L. Loureiro[2,3], J. Pinto-Basto[1,2,4], P. Coutinho[2,3], J. Sequeiros[1,2,4], I. Alonso[1,2].* 1) CGPP, IBMC, Porto, Portugal; 2) UnIGENe, IBMC, Porto, Portugal; 3) Serviço de Neurologia, Hospital de São Sebastião, Feira, Portugal; 4) ICBAS, Universidade do Porto, Porto, Portugal.

Hereditary spastic paraplegias (HSPs) are a very heterogeneous group of neuro-degenerative disorders. Clinically, they are divided in pure and complex forms. Pure HSPs are characterized mainly by slowly progressive weakness and spasticity of the lower limbs; complex forms show additional neurological features, like ataxia, epilepsy and/or non-neurological signs. Genetically, HSPs are also very heterogeneous, and all modes of inheritance have been described: autosomal dominant (AD), autosomal recessive (AR) and X-linked (XL). Among the dominant forms, SPG3A is the second most common, responsible for about 10% of AD-HSP (SPG4 represents 40% of AD-HSP). Mutations in SPG3, encoding atlastin-1, a Golgi transmembrane GTPase involved in vesicle trafficking, are mainly associated with early onset. We ascertained 40 Portuguese families clinically with AD-HSP: 14 with pure HSP, 7 with complex form and 19 unclassified; and performed mutation analysis in SPG3A gene. Mutation analysis was carried out by PCR amplification of the entire coding region and consensus flanking sequences, followed by bidirectional direct sequencing. In patients in whom no mutation was found, MLPA was also performed to detect large deletions/duplications. Analysis identified two missense mutations in SPG3A: one replacing a highly conserved tyrosine by a histidine, at codon 336 (Y336H), while the second replaced an arginine by a cysteine, at codon 239 (R239C), in one family each. Both are predicted by Polyphen to be probably damaging to atlastin-1 function. The Y336H mutation was found in a family with onset on the first year of life and R239C mutation in a family with onset on the early infancy. No other mutations, including large deletions or duplications were identified in the other patients studied. We plan to enlarge our sample of HSP families to assess the frequency of SPG3A among the Portuguese families and functionally characterize the Y336H and R239C mutations identified.

## 427/W/Poster Board #85

**Legius Syndrome in the University of Utah Neurofibromatosis Clinic.** *TM. Muram-Zborovski[1], DA. Stevenson[3], AR. Wilson[2], M. Procter[2], BW. Shirts[1], L. Chou[2], D. Viskochil[3], R. Mao[1,2].* 1) Department of Pathology, The University of Utah, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) Department of Pediatrics, The University of Utah, Salt Lake City, UT.

Legius syndrome, originally "neurofibromatosis type 1-like syndrome", is caused by SPRED1 mutations. The original report of Legius syndrome (Brems et al. 2007) suggested phenotypic overlap with NF1 without the more severe complications, specifically tumorigenesis. Patients often meet the diagnostic criteria for NF1 based on pigmentary findings, but appropriate classification is important since they are unlikely to require the same medical management. The aims of this study were to identify the frequency of Legius syndrome within an NF1 clinic population. The overlap of pigmentary findings in young children without other manifestations of NF1 may require the implementation of SPRED1 mutation analysis to establish the diagnosis of Legius syndrome. Patients fulfilling the NIH clinical diagnostic criteria for NF1 were enrolled from the University of Utah NF Clinic. Bidirectional Sanger sequencing for the coding regions and intron/exon boundaries of SPRED1 was performed. We sequenced 151 unselected patients with the clinical diagnosis of NF1 and identified 2 individuals (1.3%) with novel SPRED1 mutations, p.R18X and p.Q194X. The phenotype for the first patient (10 yrs.) included >10 café-au-lait spots, intertriginous freckling, learning disabilities, and no neurofibromas. The phenotype for the second patient (12 yrs.) included 10-20 café-au-lait spots, intertriginous freckling, single reported Lisch nodule, no learning disabilities, and no neurofibromas. A specific haplotype allele was identified in 27 individuals, allele frequency of 9.6%; (29/302). An unselected population showed a slightly decreased haplotype allele frequency of 6.3%; (4/64 alleles, p=0.049). However, because ethnicity data for the unselected population are not available, ethnicity may be a confounding factor. Statistical analysis, correcting for age, showed that the haplotype is associated with various phenotypes of NF1. The association was strongest for hypertension (p=0.003), but was also significant for the Riccardi severity score (p=0.049). We identified Legius syndrome in 2 of 151 patients who fulfilled the clinical diagnostic criteria of NF1 in our Neurofibromatosis Clinic. We identified a haplotype seen more frequently in our NF1 cohort than the unselected population. The association of a more severe NF1 phenotype in carriers of this SPRED1 haplotype suggests that it may have functional significance in Ras signaling or be linked to another modifier gene.

## 428/W/Poster Board #86

**Spatacsin (SPG11) mutations in Portuguese patients with hereditary spastic paraplegia.** *M.C. Pereira[1], J.L. Loureiro[2,3], J. Pinto-Basto[1,3,4], P. Coutinho[2,3], J. Sequeiros[1,3,4], I. Alonso[1,3].* 1) CGPP-IBMC, Porto, Portugal; 2) Serv. Neurologia, Hosp. São Sebastião, Feira, Portugal; 3) UnIGENe, IBMC, Porto, Portugal; 4) ICBAS, Univ.Porto, Portugal.

Hereditary spastic paraplegias (HSPs) are a group of neurodegenerative diseases with clinical and genetic heterogeneity. SPG11 is the most frequent autosomal recessive form of these disorders, and is characterized by signs such as cognitive impairment, along with the traditional spasticity of the lower limbs. A thin corpus callosum (TCC) is a common feature of SPG11, proposed as a marker for its diagnosis. We selected 11 families with autosomal recessive pattern, as well as sporadic cases of spastic paraplegia with thin corpus callosum and/or consanguineous parents. Mutation screening was performed by direct sequencing of the SPG11 gene, to detect point mutations, followed by MLPA analysis for detection of large gene rearrangements, deletions or duplications. Sequencing was performed in 26 individuals (8 families and 14 sporadic cases), allowing the detection of five pathogenic mutations, previously described, which result in truncated spatacsin. These were found in 62.5% of the families, and only in 14.3% of the sporadic cases. Interestingly, there seem to be two recurrent mutations in the AR-HSP Portuguese families (c.733_734delAT [40%] and c.529_533delATATT [30%]). A thin corpus callosum was present in 60% of the families and 50% of the sporadic cases with SPG11 molecularly confirmed; mental impairment occurred in 40% of the SPG11 families and none of the sporadic cases. MLPA analysis, performed in 3/8 of the affected families and 7/14 sporadic cases, showed no gene rearrangements. Our results show that SPG11 is frequent among Portuguese patients with AR-HSP and two previously described mutations are highly recurrent in Portuguese families.

## 429/W/Poster Board #87

**Interstitial Lung Disease in Hermansky-Pudlak Syndrome-2.** *B. Gochuico[1], M. Huizing[1], G. Golas[2], R. Hess[1], W. Gahl[1].* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Intramural Program of the Office of Rare Diseases, OD, NIH, Bethesda, MD.

There are eight known human subtypes of Hermansky-Pudlak syndrome (HPS), an autosomal recessive disorder characterized by aberrant biogenesis of lysosome related organelles. Progressive pulmonary fibrosis is a leading cause of mortality in people with HPS-1 and HPS-4, which are associated with defective Biogenesis of Lysosome-related Organelles Complex-3 (BLOC-3). HPS-2, which is associated with mutation of ADTB3A, is characterized by abnormal function of the adaptor-3 (AP-3) complex. Investigators have shown that the pearl mouse, a model for HPS-2, is highly susceptible to pulmonary fibrosis induced by bleomycin. Consistent with these data, we report that humans with HPS-2 have interstitial lung disease. Three individuals with HPS-2 were evaluated at the National Institutes of Health. Subject 1 is an 8-year old male with a history of neutropenia, sepsis, and severe pneumonias, including influenza, respiratory syncytial virus, and enterococcal sepsis. Subject 2 is a 27-year old male smoker with a history of neutropenia and no history of pneumonia. Subject 3 is a 22-year old nonsmoking male who is a brother of subject 2; he has a history of neutropenia and no history of severe infection, including pneumonia. None of these individuals has a history of dyspnea, cough, or significant environmental exposures associated with interstitial lung disease. Pulmonary function tests from subjects 2 and 3 reveal normal lung volumes and normal diffusion capacity. High-resolution computed tomography of the chest reveals bilateral ground glass opacification and thickening of interlobular septa in subjects 1 and 2; there is minimal thickening of interlobular septa in subject 3. Thus, human HPS-2 disease is associated with radiographic findings of interstitial lung disease. Taken together, these data indicate that children and young adults with HPS-2 are at risk for development of interstitial lung disease. The young age of these subjects may indicate that functional defects of AP-3 complex are associated with susceptibility to an aggressive form of interstitial lung disease.

## 430/W/Poster Board #88

**The deletion of *CCM2* is not uncommon in patients with Greig cephalopolysyndactyly contiguous gene syndrome: Recommendations for diagnosis and management.** *J.J. Johnston, J. Turner, J.C. Sapp, J.A. Butman, A. Gropman, L.G. Biesecker.* NHGRI, NIH, Bethesda, MD, USA.

The Greig cephalopolysyndactyly contiguous gene syndrome (GCPS-CGS) is a multiple malformation syndrome caused by haploinsufficiency of *GLI3* and adjacent genes. Deletions in our GCPS-CGS cohort range in size from less than 1 Mb to greater than 12 Mb with each patient having a unique set of haploinsufficient genes. Several of the genes in this region, including *TBX20*, *GCK*, and *CCM2*, have been implicated in disease phenotypes that are inherited in a dominant pattern and can be due to haploinsufficiency. A single individual in our cohort has a deletion that includes *TBX20*, a gene known to cause congenital heart disease, this individual presented with both a VSD and coarctation of the aorta. Nine individuals in our cohort have deletions that include both *GCK* and *CCM2*. Heterozygous mutations in *GCK* cause MODY, a form of NIDDM, however mutations in this gene typically lead to a mild form of nonprogressive hyperglycemia. In contrast, heterozygous mutations in *CCM2* cause cerebral cavernous malformations (CCM). CCMs are vascular malformations consisting of clustered malformed blood vessels without normal intervening brain tissue or mature vessel walls. Individuals with these malformations can present with a variety of symptoms including seizures, focal neurologic deficits, headaches and cerebral hemorrhage. In rare instances these malformations can cause cerebrovascular accidents leading to death. Approximately 50-75% of individuals with CCMs become symptomatic and it is therefore important when diagnosing an individual with GCPS-CGS to determine if *CCM2* is disrupted by the deletion. In cases where *CCM2* is deleted the patient should be followed for CCM development using susceptibility weighted MRI sensitive to the microhemorrhage associated with tiny CCMs. These data lead to several conclusions; 1) molecular diagnosis for patients with GCPS is important for management and prognosis 2) patients with deletion of *CCM2* must be followed closely with specific MRI protocols to anticipate and treat CCMs, 3) *TBX20* deletions may cause septal defects in patients with GCPS-CGS and 4) *TBX20* likely causes septal defects via haploinsufficiency in patients with GCPS-CGS.

## 431/W/Poster Board #89

**Genomic deletions in *OPA1* are common in Autosomal Dominant Optic Atrophy.** *G.J. Almind[1], M. Larsen[1,2], K. Brondum-Nielsen[1], J. Ek[1].* 1) Medical genetics lab , Kennedy Center, Glostrup, Glostrup, Denmark; 2) Department of Ophthalmolgy, Glostrup Hospital, University of Copenhagen, Denmark.

**Background:** Autosomal Dominant Optic Atrophy (ADOA, OMIN #165500), also known as Kjer's optic atrophy is the most common form of hereditary optic neuropathy. The characteristic expression is characterized by bilateral subnormal visual acuity, deficient color vision, central visual field defects, and optic nerve pallor. The prevalence is relatively high in Denmark (1/12,000) compared to other countries (1/50,000). Large family studies have found that the OPA1 locus on chromosome 3q28 is the predominant gene-locus for the disease and more than 200 mutations in *OPA1* have been identified. However, the mutations only explain between 60 and 80% of the cases of ADOA. Therefore we initiated a study of copy number variation and other genomic rearrangements at the OPA1 locus to supplement the results of direct sequencing.

**Aim/Purpose:** The aim of this study was to identify and report copy number variation in the *OPA1* gene in Danish patients with ADOA without demonstrable mutations in *OPA1* and to describe the phenotypic association with the rearrangements.

**Methods:** 42 unrelated probands clinically diagnosed with ADOA were analyzed for genomic rearrangements in *OPA1* by means of multiplex ligation probe amplification (MLPA). Abnormal results were confirmed by additional manually added probes and by long distance PCR. The results were compared with visual acuity and color vision data.

**Results:** Among 42 patients with clinically diagnosed ADOA but no identifiable mutation in *OPA1* we identified 9 patients (21%) with genomic rearrangements in OPA1. These included two independent probands with deletions of exon 26, two with deletions of exon 9-15, two with deletions of intron 28, and one patient with deletion of exon 17. In addition, we identified two probands harboring deletions of the entire OPA1 gene on one allele. Phenotypically, the patients were comparable to patients with point mutations in OPA1.

**Conclusion:** *OPA1* deletion is a frequent cause of ADOA, contributing substantially to the established linkage to 3q28.

## 432/W/Poster Board #90

**Identification of Sulfonylurea Receptor SUR1 and Potassium Inward Rectifying Receptor Kir6.2 genes mutations in saudi patients with persistent hyperinsulenimic hypoglycemia of infancy (Nesidioblastosis).**

*D. Bakheet[1], N. Tassan[2], B. Bin Abbas[3].* 1) Gen, King Faisal Spec Hosp & Res Ctr, Riyadh, Saudi Arabia; 2) Genetics, KFSH & RC, Riyadh, Saudi Arabia; 3) Pediatrics Department, king Faisal Hospital, Riyadh Saudi Arabia.

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) (MIM 256450) formerly called nesidioblastosis is an autosomal recessive disorder of pancreatic B-cell function. It is mainly characterized by inadequate suppression of insulin secretion in the presence of severe fasting hypoglycemia. Clinical presentation of this disease, which occurs predominantly in neonates and infants under the age of one year, includes seizures and coma. Mutations within B-cell plasma membrane ATP-sensitive potassium (KATP) channel which is encoded by two adjacent genes on chromosome 11p15.1: SUR1 (sulfonyl urea receptor) ABCC8 and Kir6.2 (inward rectifying potassium channel) KCNJ11 gene were identified in patients with PHHI. Fifteen patients diagnosed with PHHI, were enrolled in this study. Screening of the whole open reading frame (ORF) for both SUR1 and Kir6.2 genes has been performed. Three patients showed small deletions in the ABCC8 gene that requires further investigations. Twenty five novel and reported misense, silent and splice variants were identified in those genes. Some of these variants were known to be associated with other disorders such as Type II diabetes mellitus and hyperinsulinemia.

**Modifying effect of common type 2 diabetes associated variants on HNF1A MODY age of onset.**

*M.N. Weedon[1,2], S. Johansson[3,4], S. Ellard[2], J.K. Hertel[3,4], B. Shields[2], H. Raeder[3,5], K. Colclough[2], A. Molven[6,7], T.M. Frayling[1,2], P.R. Njolstad[3,5], A.T. Hattersley[2], H. Lango Allen[1,2].* 1) Peninsula Medical Sch, Exeter, United Kingdom; 2) Diabetes Genetics, Peninsula Medical School, Exeter, UK; 3) Department of Clinical Medicine, University of Bergen, Bergen, Norway; 4) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 5) Department of Pediatrics, Haukeland University Hospital, Bergen, Norway; 6) Section for Pathology, the Gade Institute, University of Bergen, Bergen, Norway; 7) Department of Pathology, Haukeland University Hospital, Bergen, Norway.

Mutations in hepatocyte nuclear factor-1alpha (*HNF1A*) are the most common cause of maturity onset diabetes of the young (MODY). There is a substantial variation in the age of diabetes onset, even within families where diabetes is caused by the same mutation. Common genetic factors are likely to explain some of this variation but none have been described to date. We hypothesized that common genetic variants that predispose to type 2 diabetes might have a modifying effect on the age of diabetes diagnosis in *HNF1A* MODY.

Sixteen robustly associated type 2 diabetes variants were successfully genotyped in 407 individuals from 196 families, from two study centers in the UK and Norway. We assessed their individual and combined effect on the age at diagnosis, by summing up the number of risk alleles carried by each individual to form a genetic risk score.

We confirmed the strong effects of social, environmental and genetic factors known to modify the age at diabetes onset in HNF1A MODY, namely the age at study or genetic testing (0.31 years, $P=8.9x10^{-44}$), *HNF1A* mutation position (-5.1 years if at least two isoforms affected, $P=9.3x10^{-3}$), and intrauterine hyperglycemia (-5.9 years if present, $P=4.4x10^{-14}$). Additionally, there was a strong effect of gender in our data, with females diagnosed 3.7 years earlier than males ($P=1.0x10^{-4}$). We included these variables and study as covariates in the subsequent individual and joint SNP analyses.

There were no strong individual SNP effects, although the variants in *HNF1B*, *SLC30A8* and *CDKAL1*, known beta cell genes, showed strongest associations (all P<0.01, unadjusted for multiple testing). In the combined genetic score model, each additional risk allele was associated with 0.33 years earlier diabetes diagnosis ($P=4.4x10^{-3}$).

In summary, we show that type 2 diabetes risk variants of modest effect sizes reduce the age at diagnosis in HNF1A diabetes. This is one of the first studies to demonstrate that clinical characteristics of a monogenic disease can be influenced by common variants associated with the polygenic form of that disease.

## 434/W/Poster Board #92

**Characterization of intragenic deletions and duplications in the *NIPBL* gene in patients with Cornelia de Lange syndrome.**

*E.V. Haverfield, R.J. Alva, A.J. Whited, S. Das.* Department of Human Genetics, University of Chicago, Chicago, IL.

Cornelia de Lange syndrome (CdLS) is a rare developmental disorder characterized by distinctive facial features, growth retardation, hirsutism, and upper limb reduction defects. Mutations in the *NIPBL* and *SMC1A* genes have been identified in patients with CdLS with a frequency of ~50% and 3-5%, respectively. Intragenic deletions and duplications of the *NIPBL* gene are thought to contribute to the molecular basis of CdLS, although very few have been described to date. Our molecular diagnostic laboratory has identified 5 intragenic deletions and 1 intragenic duplication in 189 individuals tested by *NIPBL* deletion/duplication analysis, a detection rate of 3.2%. The incidence of intragenic *NIPBL* deletions and duplications in CdLS patients is likely to be higher as the patient population studied includes patients with a suspicion of CdLS and many of whom likely do not have this diagnosis. The 5 intragenic deletions and 1 duplication identified in our laboratory span from two to ten exons, and occur in different regions of the gene. An intragenic deletion spanning exons 46 and 47, the two terminal exons of the *NIPBL* gene, has been identified in two patients. As this class of mutations has not been well described in CdLS, we will present data further characterizing these intragenic deletions and duplications, including the size of each intragenic deletion or duplication and delineation of breakpoints, which may likely help with the understanding of the potential mechanisms mediating these mutation events. Detailed clinical information on patients with intragenic deletions or duplications in the *NIPBL* gene will also be presented. This clinical information is obtained via a questionnaire that is submitted to our laboratory with the patient sample at the time of test request. Our findings represent an update on the molecular basis of CdLS and highlight that intragenic deletions and duplications are a significant contributor to CdLS etiology.

## 435/W/Poster Board #93

**Toward comprehensive molecular diagnosis of Retinitis Pigmentosa.**

*J. Sutherland[1], E. Heon[1], E.L. Burner[2], A.C.-H. Tsai[3], J.B. Bateman[4], T.L. Young[2], E.B. Spector[5], P.-W. Chiang[5].* 1) Ocular Genetics, Ophthalmology, Hosp Sick Children, Toronto, ON, Canada; 2) Duke Eye Center, Duke School of Medicine, Durham, NC; 3) The Children's Hospital, Department of Pediatrics, UC Denver School of Medicine, Aurora, CO; 4) Denver Health Medical Center, Denver, CO; 5) UC Denver DNA Diagnostic Laboratory, Department of Pediatrics, UC Denver School of Medicine, Aurora, CO.

Retinitis pigmentosa (RP) is a genetically heterogeneous group of inherited retinal disorders affecting the photoreceptors or retinal pigment epithelium (RPE) and usually leads to progressive visual loss. Clinical severity and onset of RP can be variable even in the same family. RP can be inherited along autosomal dominant (adRP), recessive (arRP) or X-linked recessive patterns. Molecular diagnosis of RP can use different approaches. We provided mutational analysis of patients with RP using a newer approach of simultaneously sequencing every coding exon from 18 genes in which mutations are known to be associated with RP as listed in RetNet. To analyze every coding exon and exon/intron borders from these genes, a total of 137 polymerase chain reactions (PCR) were performed and the products subjected to bi-directional DNA sequencing. Mutations and novel SNPs could be identified with this approach. We hypothesized that some of the novel SNPs cause clinical variability in patients. We present preliminary data from three families supporting our hypothesis. Family 1 is a large family with 4 generations affected; varying age of onset and phenotype. Families 2 and 3 are isolated cases and the proband in each family is an only child. A reported mutation, namely *RHO* p.A164V, was identified in the proband of Family 1; in addition, four novel variations also were identified in other retinal genes, one each in *IMPDH1*, *ROM1*, *RP9* and *SEMA4A*. A reported mutation, namely CRX p.A158T, was identified in the proband of Family 2; five novel variations also were also identified, one each in *CA4*, *FSCN2*, *PRPF8*, *ROM1* and *RP9*. No known mutation was identified in Family 3; however, seven novel variations including *CRX* p.G122D and *NR2E3* p.R125Q were identified in the proband. We are investigating the biological significance of these sequence changes in these three families by studying additional family members. Potential modifiers may also be present in genes associated with arRP. RP may be an excellent disease model to elucidate phenotypic modifiers due to the large numbers of known genes involved in the specific pathway.

## 436/W/Poster Board #94

**Mutation analysis of the ATP7B gene in patients with Wilson disease from northeast China.** *S. Li[1], M. Sun[1,2], J. Niu[2], W. Xu[1], L. Wang[2], F. Wang[2].* 1) Dept Ped/Gen, BSEB 224, Univ Oklahoma Hlth Sci Ctr, Oklahoma City, OK; 2) The Department of Infectious Diseases, the First Hospital of Jilin University, Changchun, Jilin, P.R. China.

Introduction The worldwide prevalence of Wilson disease is estimated to be 1 in 30,000-100,000, and it is more frequent in China. The majority of patients with Wilson disease have a mutation of the ATP7B gene; this causes a defect of copper excretion, leading to copper accumulation in the liver, brain and cornea. Since ATP7B was cloned in 1993, more than 379 variants have been reported to be causative of Wilson disease; variant p.R778L was the most common mutation among Chinese people of the Han Nationality. The frequency of this mutation in patients with Wilson disease was between 28.8-39.4%. The majority of published mutation studies were based on the investigation of common mutations, not whole coding sequences. Here we present our sequencing findings of the whole coding region of the ATP7b gene in Chinese patients with Wilson disease. To determine the mutation spectrum of the ATP7b gene and the frequency of each mutation identified in our Chinese patients from northeastern China, as well as a possible correlation between gene mutation and disease severity. Materials and Methods A total of 17 patients with Wilson disease were included in this study; four of these were sporadic cases. All of the patients involved are of the Chinese Han Nationality. After our consent form was approved by the Ethnic, Medical Affair and Research committee of the First Hospital of Jilin University, 5 cc of peripheral blood was drawn from each patient, and DNA was extracted from these samples based on standard laboratory protocols. DNA samples were amplified by PCR using primers corresponding to all 21 exons and they were subsequently sequenced. Results: Thirteen out of 17 patients had two disease-causing mutations; another three had only one mutation found, one patient had no mutation identified Also, we have identified three new mutations and two new polymorphisms (Figure 1). Conclusions: Our results suggest that heterogeneity of the mutation exists in our small patient population in northeast China. At the same time, we have noticed there might be a correlation between the p.R778L mutation and liver impairment, and p.R778L homozygotes are associated with an early onset of hepatic symptoms. Another interesting finding is the fact that affected patients within the same family who have the same mutation can have very different phenotypes. This suggests that there are other factors impacting the presentation of the autosomal recessive disorder.

## 437/W/Poster Board #95

**Dysfunction of protein synthesis mediated by mTOR-dependent signaling in Fragile X syndrome.** *C. Hoeffer[1], E. Klann[1], H. Wong[1], R.J. Hagerman[2,3], F. Tassone[2,4].* 1) Center of Neural Science, New York University, NY , USA; 2) M.I.N.D. Institute, University of California Davis Medical Center, Sacramento, CA, USA; 3) Department of Pediatrics, University of California, School of Medicine, Davis, CA, USA; 4) Department of Biochemistry and Molecular Medicine, University of California, School of Medicine, Davis, CA, USA.

Multiple studies have revealed the important role played by the mTOR (mammalian target of rapamycin) signaling pathway in learning and memory. All components of the mTOR pathway, which is involved in protein synthesis-dependent phase of synaptic strengthening, are present in dendrites suggesting a role for mTOR in local translation. mTOR drives local translation through phosphorylation of its downstream targets, including the eukaryotic initiation factor 4E-binding protein (4E-BP)s, which permits eIF4E to bind to eIF4G and be phosphorylated by Mnk1. The 70kD ribosomal protein S6 kinase (S6K1) and the eukaryotic elongation factor 2 (eEF2) are two additional mTOR substrates involved in translation control. These substrates in turn regulate translational initiation and rates of peptidyl elongation. Hypophorylated 4E-BPs inhibit translation of a number of mRNAs, mRNAs by sequestering eIF4E. Loss of eIF4E activity especially impacts mRNAs with high CGG content and complex 5'UTR structure via steric hinderance. The mRNA encoded by the Fragile X gene (FMR1) bears these features. FMR1 contains a CGG repeat element in the 5'UTR. Expansion above 200 CGG repeats leads to Fragile X syndrome (FXS) through hypermethylation of the promoter, silencing and consequent absence of the encoded protein, FMRP. FMRP is an RNA-binding protein, which plays an important role in translational repression. Thus, we have investigated whether altered mTOR signaling is present in subjects with FXS. Our preliminary findings indicate that translation control mediated by the mTOR pathway is compromised in FXS. Peripheral blood leukocytes of FXS subjects, who lack of FMRP, displayed phosphorylation of translation factors and kinases involved in translation control. Specifically, a significant increase in the phosphorylation of both S6K1 and eIF4E, which is consistent with elevated basal translation, was detected in FXS subjects. The observed increases in translational signaling suggest excessive basal translation in FMRP-deficient cells, and this activity may contribute to the cognitive and behavioral deficits observed in subjects with FXS. Thus, altered phosphorylation of mTOR substrates and their effectors could represent putative biological markers of cognitive impairment in FXS and the assessment of their levels in FXS lymphocytes could complement existing molecular testing.

## 438/W/Poster Board #96

**A novel missence ABCA12 mutations lead to nonbullous congenital ichthyosiform erythroderma (NBCIE).** *S. Nawaz[1], J. Klar[2], A. Azhar[1], M. Tariq[1], A. Ali[1], I. Ahmad[1], J. Qureshi[1], J. Schuster[2], J. Qureshi[1], S. Baig[1].* 1) Human Molecular Genetics Lab, National Inst for Biotech and Genet Eng (NIBGE), Faisalabad, Punjab, Pakistan; 2) Department of Genetics and Pathology, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden.

Lamellar ichthyosis was a broad term initially used for all nonbullous autosomal recessive ichthyoses other then harlequin ichthyosis and ichthyosis syndromes, but now a days nonbullous autosomal recessive ichthyoses have been divided into 2 major clinical groups , nonbullous congenital ichthyosiform erythroderma NBCIE and Lamellar Ichthyosis (LI) with a prevalence of lamellar ichthyosis of approximately 1 in 200,000 persons. A considerable number of cases, however, show an intermediate phenotype, and neither histopathologic findings nor ultra structural features clearly distinguish between NCIE and LI. Nonbullous congenital ichthyosiform erythroderma (NBCIE) is autosomal recessive congenital ichthyosis with prominent features of generalized severe white scaling all over the body and erythrodermic skin without blister formation . ABC12, causal gene here, localized on chromosome 2q33-35 belongs to a subfamily of ATP-binding cassette (ABC) transporters which implicate in some autosomal recessive disorders pertaining to lipid metabolism. Here we report a large consanguineous Pakistani family exhibiting autosomal recessive inheritance and classic phenotype of NBCIE. A novel homozygous missense 1241 G to V transition in exon 31 of ABCA12 gene in all affected members was identified which showed exclusion to 200 Pakistani and 200 Swedish controls.

## 439/W/Poster Board #97

**Functional characterization of chronic pancreatitis-associated variations in the 5' regulatory region of the *SPINK1* gene.** *A. Boulling[1,2,3], J.M. Chen[1,2,3], C. Ferec[1,2,3,4].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U613, Brest, France; 2) Université de Bretagne Occidentale (UBO), Faculté de Médecine et des Sciences de la Santé, Brest, France; 3) Etablissement Français du Sang (EFS) - Bretagne, Brest, France; 4) Centre Hospitalier Universitaire de Brest, Hôpital Morvan, Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Brest, France.

Introduction: The SPINK1 gene, which encodes the pancreatic secretory trypsin inhibitor, is one of the major genes predisposing to chronic pancreatitis. To date, a dozen of variations have been described in the 5' regulatory region (RR) of SPINK1 but their functional effects remain unknown. The aim of this study was to systematically characterize all these currently known 5' RR variants. Method: The wild-type 5' RR of SPINK1 was firstly cloned into the pGL3-Basic Luciferase Reporter Vector. All the 5' RR variations in the SPINK1 gene were then introduced into the pGL3-SPINK1 construct, respectively, by means of site-directed mutagenesis. SPINK1 promoter activities were determined in human pancreatic COLO 357 cells. Functional relevance of some variants was further evaluated by EMSA. Results: The 5' RR variations can be divided into three categories in terms of luciferase expression, which correlated well with clinical findings. The variants that caused a decreased expression often show consistent disease association among different studies whilst those that had no effect on expression often show equal allele distribution between patients and controls. The variants that caused an increased expression are, in fact, in cis with a known disease-causing mutation. EMSA assay demonstrated that variations located in well defined regulatory motifs affected protein-DNA interactions. Conclusion: This work was the first to assess the functional impact of the 5'-RR's SPINK1 variations. Our finding clarified the role of the diverse SPINK1 5' RR variants in the etiology of chronic pancreatitis and resulted in a better understanding of the genotype/phenotype relationship.

**Molecular aspect of carnitine palmitoyltransferase II deficiency.** *J.H. Ding, N.H. McNeill, B.Z. Yang.* Inst Metabolic Disease, Baylor Res Inst, Dallas, TX.

Carnitine palmitoyltransferase II (CPT II) deficiency is an autosomal recessive disorder of mitochondrial long-chain fatty acid oxidation. CPT II deficiency has three distinct clinical forms: the adult-onset form characterized by episodes of muscle pain; milder infantile form, and severe neonatal form which may result in sudden unexplained death. In this report, eleven patients with CPT II deficiency had been investigated to identify the molecular defect. All five CPT II exons and their flanking intronic sequences were amplified from proband's DNA. The PCR products were purified and sequenced. The sequencing analysis revealed that ten novel mutations were identified, including R290X and D390fs. The novel mutations were also verified by DNA amplification/enzyme digestion method, but were not detected in the normal control subjects. In our group, The CPT II activities in patients' lymphocytes have also been tested and summarized with mutations and clinical presentation. This study demonstrated the genetic heterogeneity that may underlie the clinical variation in CPT II patients.

**The Spectrum of Mutational Genes and Alleles in Chinese OCA Patients.** *W. Li[1], A. Wei[2], Y. Wang[2], Y. Long[3], Y. Wang[1], X. Guo[1], Z. Zhou[1], X. Bian[3], S. Lian[2].* 1) Insttitute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing, China; 2) Department of Dermatology, Xuan Wu Hospital, Capital Medical University, Beijing, China; 3) Department of Obstetrics and Gynecology, Union Hospital, Peking Union College, Beijing, China.

Oculocutaneous albinism (OCA) is a heterogeneous Mendelian recessive disorder with hypopigmentation in the skin, hair, and eyes. At least sixteen different genes have been identified as causative genes for human OCA. OCA1 is the most common type of OCA in some populations. Several novel mutational alleles of TYR, P and MATP have been identified in Chinese population. However, no comprehensive analysis has been conducted to reveal the spectral distribution of Chinese OCA. We have screened unrelated and unselected 127 Chinese OCA patients for the mutations in TYR, P, TYRP1, MATP, HPS1 gene. We found that OCA1 is the most common form of OCA in Chinese population (70.1%), while OCA2 and OCA4 account for 10.2%, 12.6% respectively. Only one HPS1 patient is identified in our OCA repository. No apparent pathological mutation on TYRP1 has been found in these OCA patients. In this study, 41 novel mutational alleles have been reported which were not found in 100 non-albinism subjects. Potential mutational hotspots on TYR and MATP have been characterized in Chinese OCA patients. Genotype-phenotype relationship analysis revealed that clinical diagnosed OCA1 or OCA2 patients are mixed types of OCA1, OCA2, OCA4 and HPS1. These results provide useful information for the establishment of an optimized strategy of gene diagnosis and genetic counseling of Chinese OCA patients. In addition, to simplify the conversion of a mutation from cDNA to protein by following the common rules in mutation nomenclature, we developed a user-friendly tool, MutConv, which is freely accessed at http://liweilab.genetics.ac.cn/mutconv/.

### 442/W/Poster Board #100

**DNA and RNA analysis of COL6A genes in a cohort of 73 patients with collagen type VI related myopathies.** *F. Gualandi[1], E. Martoni[1], C. Trabanelli[1], M. Bovolenta[1], M. Neri[1], A. Venturoli[1], M. Fabris[1], S. Falzarano[1], A. Urciuolo[2], P. Sabatelli[3], E. Bertini[4], E. Mercuri[5], P. Bonaldo[2], L. Merlini[1], A. Ferlini[1].* 1) Dept Exp Diagn Med, Medical Genetics Section, Ferrara, Italy; 2) Dipartimento di Istologia, Microbiologia e Biotecnologie Mediche, Università di Padova; 3) IGM-CNR, Unità di Bologna c/o IOR; 4) Unità di Medicina Molecolare, Ospedale Bambino Gesù, Roma; 5) Istituto di Neurologia, Università Cattolica, Roma.

The collagen VI related myopathies include Bethlem (BM) and Ullrich (UCMD) muscular dystrophies, a pure limb girdle presentation (LGMD) and the Myosclerosis Myopathy. We have fully screened by genomic sequencing COL6A1-2-3 genes in a total of 73 patients with collagen VI related myopathies (36 UCMD, 35 BM, 1 myosclerosis, 1 LGMD). The causative mutation was identified in 55 patients, with a detection rate approximating 75%; for both UCMD and BM patients. Among UCMD genotypes, 74% consisted of de novo heterozygous mutations. We identified 3 BM patients (11.5%) compound heterozygous for recessive mutations, pioneering autosomal recessive inheritance for Bethlem myopathy. 60 different mutations were detected, the large majority (52/60) representing previously unreported changes. The prevalent mutation type is represented by missense changes (66.6%), followed by mutations affecting splicing (20%), in frame deletions (5%), nonsense mutations (5%) and ins/dup causing frameshifting (1.7%). The identified mutations are distributed preferentially within N-Terminal and triple helix (TH) domains of COL6A1 and COL6A3 genes. In the COL6A2 gene, the mutations are clustered in the TH and C-Terminal domains. Among a total of 12 mutations affecting splicing, 9 were outside the invariant GT-AG dinucleotides. These non-canonical splicing mutations affect fairly degenerated sequences and the distinction between SNPs and pathogenic mutations is often challenging. RNA analysis was performed in all cases revealing unpredictable splicing phenotypes with single and multiple exons skipping, intron retention and cryptic splice site activation/usage. Non sense mediated decay of aberrant transcript turned out to represent a frequent event, often hampering the detection of mutated transcripts. A quantitative RNA assay revealed a reduced level of the in-frame mRNA originating from a COL6A2 mutation at intronic position +3. The transcription level of the in-frame mRNA originating from a genomic deletion removing the splicing sequences of COL6A1 exon 8 was normal. These findings support a different transcriptional efficiency of a regulatory splicing mutation compared to a genomic deletion causing a splicing defect and point to the reciprocal coupling between transcription and splicing as a possible modifier of pathogenic consequences of splicing mutations in collagen VI related myopathies. This study was supported by the Italian Telethon Foundation grant GUP07004 (to FG).

### 443/W/Poster Board #101

**Severe Factor V Deficiency caused by a Novel Frameshift Mutation, 5493insA.** *M.H. Al-Hamed, M. Al-Mansoori, H. Al-Saud, A. Al-Musa, B.F Meyer.* Genetics Department, King Faisal Specialist Hospital and Research Centr, Riyadh, Saudi Arabia.

Factor V deficiency is a rare autosomal recessive coagulation disorder (OMIM 227400) with an incidence of about 1 in 106, affecting both sexes equally and diagnosed in multiple ethnic groups. The factor V gene (F5) encodes a 330 kd single chain glycoprotein consisting of three homologous A-type domains, a heavily glycosylated B-domain and two smaller homologous C-type domains. We report on a family in which the proband had severe bleeding and a subnormal FV antigen level. The proband, a Saudi female whose parents were first cousins, presented at age two weeks with convulsions and a coagulopathy with a highly prolonged PT (71.4 seconds; control= 13.8 seconds) and APTT (150 seconds; control= 29.5-42.7 seconds). Plasma FVIII, vWF antigen and activity levels were within the reference (control) range. Factor V antigen was <0.01U/L in the proband's plasma. Computerized tomography scan (CT) and magnetic resonance imaging (MRI) revealed a massive intracranial haemorrhage (ICH) with no vascular malformations. She had three attacks of ICH within a 3-week interval all presenting with convulsions and coagulopathy. Sequencing of F5 in the proband identified a novel homoallelic single base insertion in exon 16 at nucleotide position 5493 (5493insA) predicting a premature stop codon at position 1776. Screening of members of the family for the mutation showed that both parents and the probands twin brother were heterozygous for the 5493insA mutation with both sisters homozygous for the wild type allele The premature stop at position 1776 predicts a 1775 residue protein lacking a significant part of the FV light chain and a molecular weight of approximately 200 kd. Presence of the heavily glycosylated B-chain in the truncated protein is consistent with FV antigen levels in the patient's plasma being severely reduced but detectable.

### 444/W/Poster Board #102

**Manifesting and asymptomatic females in families with OTC deficiency. Does X-inactivation status in blood cells correspond to phenotype?** *L. Dvorakova[1], M. Hrebicek[1], L. Stolnaja[1], J. Minks[1], E. Hruba[1], M. Bouckova[1], H. Treslova[1], H. Vlaskova[1], V. Stranecky[1], R. Ivanek[1], S. Kmoch[1], O. Luksan[2], M. Jirsa[2].* 1) Inst. Inherited Metabolic Disorders, 1st Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Czech Republic; 2) Laboratory of Experimental Hepatology, Inst.Clinical and Experimental Medicine, Prague, Czech Republic.

Ornithine carbamoyltransferase deficiency (OTCD;OMIM 311250) is the most common inherited defect of the urea cycle. Mutation analysis in OTC gene (Xp21.1) revealed a causative mutation in 27 patients from 24 families from Czech Republic and Slovakia (22), Japan (1) and Hungary (1). Patients from 8 and 10 families manifested neonatal and late onset form, respectively, 6 probands were heterozygous females. There were other 3 symptomatic heterozygotes among OTCD family members, while the other identified carriers were asymptomatic. Manifesting heterozygotes carried 4 missense, 3 nonsense and one splicing mutation and one gross deletion. Mutation analysis was based on direct sequencing, MLPA assay and DNA array analysis (Affymetrix SNP 6.0). We analyzed skewing of X-inactivation in OTCD heterozygotes by HUMARA assay in peripheral blood cells (PBC), although OTC is expressed almost exclusively in liver. We presume, that PBC can be used as the results of X-inactivation study performed in 21 necroptic tissues including liver and PBC from 5 individuals showed no substantial organ differences. To evaluate the results we classified the severity of mutations: severe (SM) - obviously deleterious mutations and missense mutations causing neonatal form of OTCD; mild mutations (MM) causing late onset form. Of the 5 informative symptomatic heterozygotes 4 carried SM with either random inactivation or preferential inactivation of WT allele and one was heterozygous for a MM with the X inactivation skewed in favor of the mutant allele. In 7 of the 12 asymptomatic carriers SMs were found. Six of them had substantial skewing (>75:25) favoring the wild type allele; the remaining carrier had random inactivation - this patient preferred diet with lower protein intake. Of the 5 heterozygotes with MM three had random inactivation patterns and in two the inactivation was skewed in favor of WT allele. Although the cohort is small, the results suggest that patients carrying SM do not develop symptoms only if the mutant allele is preferentially inactivated (with possible modification of the phenotype by dietary habits). Patients heterozygous for mild mutations tend to be asymptomatic with random inactivation and the symptoms may develop only if the WT allele is preferentially inactivated. More research is needed to better understand if this hypothesis is valid and can be included in phenotype prediction. Support: IGA MZ CR NR/9364-3, VZ MSM CR 0021620806 and VZ MZ CR 64165.

## 445/W/Poster Board #103

**Molecular Analysis of AGPS in two probands with RCDP type 3 reveals two novel alleles.** *B.J. Itzkovitz[1], S. Jiralerspong[1], M. Potti[3], S. Steinberg[2], N. Braverman[1,3].* 1) Human Genetics,Mcgill University, Montreal , Quebec, Canada; 2) Neurogenetics, Kenedy Krieger Institute, Baltimore, MD USA; 3) Institute of Genetic Medicine, John Hopkins Medical Center, Baltimore, MD, USA.

Rhizomelic chondrodysplasia punctata (RCDP) type 3 is caused by a deficiency of alkylglycerone phosphate synthase (AGPS), the second enzyme in the committing steps of plasmalogen synthesis in the peroxisome. It physically interacts with the first enzyme of this pathway, glycerone-phosphate acyltransferase (GNPAT), deficient in RCDP type 2. RCDP types 2 and 3 are responsible for ~5% of RCDP. Thus far only 2 probands with RCDP3 have been reported. We report here the biochemical and molecular analysis of 2 additional probands. Fibroblasts from patient 1 had mean GNPAT activity of 2.2 nmol/2h/mg protein, or 61% of the simultaneous normal control (3.6). Plasmalogen synthesis was 1.5 (normal values are <1). RBC plasmalogen level was 0.028 for C16:0 DMA/C16:0 (normal .051-.090). Patient 2 had mean GNPAT activity of 1.8, or 56% of the normal control; plasmalogen synthesis was 18, and RBC plasmalogen level was 0.003. These values show that there is a similar reduction in GNPAT activity in both patients, but plasmalogen synthesis is more severely impaired in patient 2, compared to patient 1. PCR amplification of all exons and intronic flanking regions for the AGPS gene was performed according to our protocol, and directly sequenced. AGPS encodes a 3.3 kb mRNA and a 658 amino acid protein. Results in patients 1 and 2 showed presumed homozygous point mutations causing E471K and T568M substitutions, respectively. The parents of patient 1 are consanguineous. No other changes were identified in the coding regions and UTR. Immunoblotting of whole cell lysates from primary patient fibroblasts indicated patient 1 had complete absence of detectable AGPS protein, whereas patient 2 had near normal levels of mature protein. Homology analysis shows that the amino acids at the mutation site are evolutionarily conserved, and both are located in a putative FAD-linked oxidase domain. The absence of detectable AGPS protein in the E471K mutant suggests a destabilizing effect leading to protein degradation, possibly due to disruption of ionic interactions in the protein structure. These results, along with the measured reduction in GNPAT activity, confirm previous studies suggesting that AGPS protein is necessary to stabilize GNPAT in the peroxisome. Unexpectedly high levels of plasmalogen synthesis and comparable GNPAT activity in the E471K vs. T568M mutants suggest that the E471K protein has residual function, the cause of which is currently under investigation.

## 446/W/Poster Board #104

**Clinical and genetic heterogeneity in a Swedish family with Retinal Degeneration.** *F. Jonsson[1], O. Sandgren[2], A. Hollander[3], I. Golovleva[1].* 1) Dept Medical Biosciences/Medical and Clinical Genetics, Univ Hosp Umea, Umea, Sweden; 2) Dept Clinical Sciences/Ophthalmology, Univ Hosp Umea, Sweden; 3) Human Genetics, Nijmegen Center for Molecular Life Sciences, Nijmegen, Netherlands.

Retinal degenerations represent a heterogeneous group of disorders affecting the function of retina. The frequency of retinitis pigmentosa (RP) is 1/3500 worldwide, however, in northern Sweden it is 1/2000 due to limited migration and "founder" effect. Using large families of Swedish origin we identified underlying genetic mechanisms in a local form of RP (RLBP1 gene), cone dystrophy (PITPNM3 gene) and an autosomal dominant form of RP with reduced penetrance (PRPF31 gene). In this study we aimed to undercover genetic mechanisms underlying recessive form of retinal degeneration in one large family from northern Sweden. Patients admitted to the University Hospital were examined clinically and family history was collected. Genotyping of the DNA from three affected siblings done with SNP-array (Affymetrix) revealed homozygosity region on 1q31-q32.1 harbouring a gene known as a cause of a severe form of autosomal recessive RP and Leber Congenital Amaurosis (LCA). The gene, CRB1, 'crumbs' of Drosophila melanogaster is known to be involved in cell-cell interaction affecting of cell polarity of photoreceptors. Mutation analysis of the CRB1 gene done by sequencing resulted in a novel mutation c.2557C>T (p.Gln853X). Family testing showed that four individuals with clinical appearance of LCA were homozygous while two other carried only wild type alleles. One of these patients tested for 848 known mutations in 29 genes performed by arrayed primer extension (APEX) technology revealed presence of a mutation in the ATP-binding cassette transporter - retinal gene (ABCA4 IVS10-T>C) also known as a cause of autosomal recessive RP and Stargardt disease. Further analysis of the family members showed absence of the ABCA4 IVS10-T>C in carriers of the CRB1 c.2557C>T mutation, presence of biallelic mutation in one patient and one affected allele in another patient. Carriers of the ABCA4 IVS10-T>C have a distinct phenotype which was different from the phenotype of the CRB1 c.2557C>T mutation despite they belong to the same family. In conclusion, we identified a novel mutation in the CRB1 gene and demonstrated that in the same family two different genetic mechanisms causing different types of retinal degenerations can co-exist. Clinical and genetic heterogeneity can result in difficulties for both clinical geneticists and ophthalmologists.

## 447/W/Poster Board #105

**Serum cholinesterase activity: a phenotype-genotype study.** *M.L. Parnas[1], M. Procter[2], M.A. Schwarz[2], R. Mao[1,2], D.G. Grenache[1,2].* 1) Department of Pathology, University of Utah Health Sciences Center, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT.

Pseudocholinesterase (PChE), or serum cholinesterase, is one of two enzymes that hydrolyze choline esters. Encoded by the *BCHE* gene and synthesized in the liver, the function of PChE remains unknown although it is implicated in the metabolism of the neuromuscular blocking agent succinylcholine. Prolonged blockade and apnea with succinylcholine occurs in individuals with reduced PChE activity due to genetically determined variants. Phenotypic identification of variants is achieved by measuring PChE activity in the presence of the inhibitor dibucaine, which, together with total activity, is used to calculate a dibucaine number (DN). Assignment of PChE phenotypes requires well-defined, phenotype-specific PChE and DN reference intervals. Method-specific reference intervals are not available due to the number of biochemical methods for determining PChE activity and the lack of assay standardization. The goal of this study was to perform genotype-phenotype correlations of serum PChE to validate existing reference intervals and/or establish more appropriate intervals. Cell free DNA was extracted from 44 serum specimens for which total enzyme activity, DNs, and phenotypes were known. Phenotypes were assigned based on our laboratory criteria. PCR of the *BCHE* gene coding region was performed, followed by bidirectional DNA sequencing using BigDye® terminator chemistry. Sequencing data analysis was achieved using Mutation Surveyor® software. Phenotype-genotype agreement occurred in 36% of specimens. Of these, 38% were wild-type (UU) and 62% were heterozygous for a common PChE variant (UA). For 32% of specimens a PChE phenotype was not assigned due to inconsistencies between the PChE biochemistry and our interpretive criteria. Of these, 50% were genotypically UU or UA. Discordance between phenotype and genotype occurred in 32% of specimens, for which the inaccurately assigned phenotype either did not change the likelihood of succinylcholine susceptibility or implied a slightly increased risk when there was none. One discordant specimen was phenotyped as AS (high risk) and sequencing revealed a recently reported mutation that imparts low PChE activity. These data highlight the inability to assign an accurate phenotype based solely on PChE activity and the DN. Method-specific biochemical reference intervals based on PChE genotype are necessary. PChE gene sequencing combined with biochemical testing could provide improved and accurate assessment of patient risk.

## 448/W/Poster Board #106

**Assessment of the Pathogenic Contribution of Individual Recessive Disease Alleles in *ABCA4*-Associated Retinal Degeneration.** *E.I. Schindler[1,2,3], A.C. Ko[3], A.V. Drack[3], A.V. Cideciyan[4], T.S. Aleman[4], S.G. Jacobson[4], R.G. Weleber[5], G.A. Fishman[6], V.C. Sheffield[1,7,8], E.M. Stone[1,3,8].* 1) Genetics Program, University of Iowa, Iowa City, IA; 2) Medical Scientist Training Program, University of Iowa, Iowa City, IA; 3) Department of Ophthalmology and Visual Sciences, University of Iowa, IA; 4) Department Ophthalmology, Scheie Eye Institute, University of Pennsylvania, Philadelphia, PA; 5) Macular Degeneration Center, Casey Eye Institute, Oregon Health and Science University, Portland, OR; 6) Department of Ophthalmology and Visual Sciences, University of Illinois at Chicago, Chicago, IL; 7) Department of Pediatrics, University of Iowa, Iowa City, IA; 8) Howard Hughes Medical Institute, Iowa City, IA.

**Purpose:** Numerous studies have shown extensive allelic heterogeneity in *ABCA4*-related eye disease. Most individuals with disease-causing variations in this gene are compound heterozygotes and many of the variations they harbor are quite uncommon. For these reasons it has been difficult to establish genotype-phenotype correlations for *ABCA4* disease. However, if one has access to a sufficiently large number of subjects who share one disease allele, the phenotypic differences observed among the members of the group can be used to estimate the pathogenic contribution of their second disease alleles. **Methods:** An inexpensive high-throughput allele-specific assay was designed for the detection of 19 of the most common disease-causing alleles in the *ABCA4* gene. This assay was used to screen 351 patients with the clinical features of Stargardt disease, 238 with cone-rod dystrophy, 237 with retinitis pigmentosa (RP) and 253 controls. The clinical data from patients found to harbor two *ABCA4* mutations were then used to devise an empiric quantitative model of the relative pathogenic contributions of these 19 variations. An additional group of patients were found to harbor two disease-causing variations in *ABCA4* by using a combination of SSCP and automated DNA sequencing. These individuals were used to increase the resolution of the model as well as to estimate the pathogenicity of some more rare disease alleles. **Results:** Two of the most common disease-causing alleles (G1961E and G863A) were found to be the least pathogenic. These alleles rarely cause disease in the homozygous state or in the compound heterozygous state with each other. The four most virulent alleles (R152X, C1490Y, C1488R, and IVS14-1 G>A) were each found more commonly in cone-rod dystrophy or RP patients than in patients with Stargardt disease. **Conclusion:** The differences in disease severity among a group of patients who share one allele can be assigned, at least in relative terms, to their second allele. As the number of clinically well-characterized patients with two detectable alleles increases, the precision with which one can predict the pathogenicity of specific genotypes will also increase. Such predictions will be useful for a variety of purposes ranging from genetic counseling to the design and execution of clinical trials.

## 449/W/Poster Board #107

**Niemann-Pick type C1 patients carrying apparently only one mutant allele: Are there dominant negative variants?** *H. Vlaskova, M. Bouckova, L. Dvorakova, A. Hnizda, J. Sikora, M. Hrebicek, M. Elleder.* Institute of Inherited Metabolic Disorders, 1st Faculty of Medicine, Charles University and University Hospital, Prague, Czech Republic.

Niemann-Pick disease type C (NPC, OMIM 257220, 607625) is a severe autosomal recessive neuro-visceral disorder characterized by progressive neurological deterioration and hepatosplenomegaly. A defect in transport of unesterified cholesterol leads to its accumulation in lysosomes/late endosomes. The patients carry mutations either in NPC1 (18q11) or NPC2 (14q24.3). The molecular defect corresponds to two complementation groups NPC1 and NPC2, identified by biochemical assays. Both genes encode two late endosomal/lysosomal functionally linked proteins. We present the results of mutation analysis performed by sequencing of genomic PCR products in 42 probands from Czech and Slovak republic, Poland, Germany and Brasil. We have detected both mutant alleles in 39 patients and identified 43 different NPC1 mutations, 23 of them being novel. In 3 patients only one mutation was detected. One of these patients with severe clinical signs of NPC had classical biochemical phenotype of complementation group NPC1 (dr. M. T. Vanier, Lyon) and inherited mutation p.R1186H from her asymptomatic father; the maternal mutation was not identified. The patient was heterozygous for three common polymorphisms, two of them were exonic (p.Y129Y, p.I642M). The exonic polymorphisms as well heterozygous mutation p.R1186H were detected by direct sequencing of RT/PCR products. The presence of both alleles in the transcript analysis excluded splicing errors or deletions that could be missed by analysis of genomic DNA. This result also makes improbable the possibility that the level of transcription is affected. Although the complementation study indicated NPC1 group, we have also analysed NPC2 gene. The only change found by analysis of genomic DNA and cDNA was a novel polymorhism p.H150H. The presence of only one mutated allele in patients in whom NPC was proved by biochemical methods was reported by several authors. This raises the question if some of the mutations may not function as dominant-negative variants in this recessive disorder. Our data do not support this hypothesis as asymptomatic father of the patient carries the same mutation. Our data also do not support the possibility that polymorphisms p.Y129Y, p.I642M could modify the phenotype. Therefore, we suggest that some other process affecting NPC1 protein (e.g. translation defect) or defect in other gene may be in play. Support: VZ MSM CR 0021620806, VZ MZ CR 64165.

## 450/W/Poster Board #108

**A rare BCHE deficient allele, R386C, confirmed by phenotype-genotype correlation case study.** *J.E. Whittington[1], H.D. Pham[2], M. Procter[3], D.G. Grenache[1,3], R. Mao[1,3].* 1) Department of Pathology, University of Utah, Salt Lake City, UT; 2) Department of Anesthesiology, University of Minnesota, Minneapolis, MN; 3) ARUP Institute for Clinical and Experimental Pathology and ARUP Laboratories, Salt Lake City, UT.

*Background:* Pseudocholinesterase (PChE), or butyrylcholinesterase (BChE), catalyzes the hydrolysis of choline esters. Encoded by the *BCHE* gene and synthesized in the liver, PChE's function is unknown although it metabolizes the neuromuscular blocking agent succinylcholine. Extended blockade and apnea with succinylcholine occurs in individuals with reduced PChE activity due to genetically determined enzyme variants. Phenotypic identification of variants is achieved by measuring PChE activity in the presence of the inhibitor dibucaine, which, together with total activity, is used to calculate a dibucaine number (DN). Assignment of PChE phenotypes requires well-defined, phenotype-specific PChE and DN reference intervals which are lacking due to numerous biochemical methods for determining PChE activity and lack of assay standardization. *BCHE* sequencing can be used to infer a phenotype from the genotype. *Patient & Methods:* An adult Asian male underwent an emergent laparoscopic appendectomy. Intubation was facilitated with 1 mg defasciculating dose of vecuronium followed by 120 mg of succinylcholine. 1.7 hours later the patient remained paralyzed with no muscle twitches, small spontaneous inspiratory efforts, and no protective airway reflexes. Complete recovery was achieved 4 hours after succinylcholine administration. A serum specimen for PChE testing was collected 14 days later. The PChE activity and DN were determined using acetylthiocholine substrate at 37°C on a Roche cobas c501 analyzer and a PChE phenotype assigned based on these data. DNA was extracted from the serum by MagNAPure followed by bidirectional sequencing of the entire coding region and intron/exon boundaries to determine the *BCHE* genotype. *Results:* PChE activity was 89 U/L and the DN was <5 [reference intervals: 2900-7100 and 83-88, respectively]; consistent with a silent PChE phenotype. BCHE sequencing identified a unique apparent homozygous mutation: 1240 C>T (p.R414C, known as R386C) in exon 2. This rare mutation has been previously reported in a heterozygote with unknown clinical significance (Yen et. al, *Clin Chem* 2003; 49:1297). *Conclusions:* Genotype R386C is associated with a silent PChE phenotype and extended succinylcholine-induced paralysis. A complete family pedigree would allow further definition of the assigned mutation phenotype-genotype correlation. This case highlights the clinical significance of mutations in the *BCHE* gene and emphasizes the need for screening.

**Systematic Classification of the Human Mitochondrial Phenome.** *C. Scharfe[1], H.H.S. Lu[2], J.K. Neuenburg[3], E.A. Allen[1], G.C. Li[4], T. Klopstock[5], T.M. Cowan[6], G.M. Enns[7], R.W. Davis[1].* 1) Genome Technology Ctr, Stanford Univ, Palo Alto, CA; 2) Institute of Statistics, National Chiao Tung University, Hsinchu, Taiwan; 3) BioMarin Pharmaceutical Inc. Novato, CA; 4) Department of Operations Research, University of California, Berkeley, CA; 5) Friedrich-Baur-Institute, Department of Neurology, Ludwig Maximilians University, Munich, Germany; 6) Departments of Pathology and Pediatrics, Stanford University, Stanford, CA; 7) Department of Pediatrics, Medical Genetics Division, Stanford University, Stanford, CA.

Mitochondrial diseases are caused by an abnormal function of mitochondria. They may be the result of spontaneous or inherited mutations in the mitochondrial genome or in nuclear genes that code for mitochondrial components, but may also be acquired secondary to adverse effects of drugs, infections, or other environmental causes. Even with years of experience, recognizing and diagnosing mitochondrial diseases is still a major hurdle in clinical medicine. Computational tools supporting clinicians not only help identify affected individuals, but also guide studies of the genetic and biological causes of these disorders. In the Mitochondria Phenome knowledgebase (www.mitophenome.org), we established a clinical phenotype catalog of 174 mitochondrial disease genes and study associations of diseases and genes. Phenotypic features such as clinical signs and symptoms were manually annotated from full-text medical articles and classified based on the hierarchical MeSH ontology. This classification of phenotypic features of each gene allowed for the comparison of diseases between different genes. In turn, we were then able to measure the phenotypic associations of disease genes for which we calculated a quantitative value that is based on their shared phenotypic features. The results showed that genes sharing more similar phenotypes have a stronger tendency for functional interactions, proving the usefulness of phenotype similarity values in disease gene network analysis. Our study of a large functional network of mitochondrial genes revealed distinct properties that differentiate disease and non-disease genes. Disease genes showed a lower average total connectivity but a tendency to interact with each other; a finding that we used to predict 168 high-probability disease candidates. Mitophenome allows for easy navigation between clinical phenotype and gene information and promises to aid in the recognition and diagnosis of mitochondrial disorders.

## 452/W/Poster Board #110

**Mutation analysis in patients with GSD III and correlation with clinical subtype.** *D. Bali[1], J. Goldstein[1], S. Austin[1], K. Boyette[1], A. Kanaly[2], C. Rehder[2], P. Kishnani[1].* 1) Division of Medical Genetics, Dept. of Pediatrics, Duke University Medical Center, Durham, NC; 2) Clinical Molecular Diagnostics Laboratory, Duke University Medical Center, Durham, NC.

Glycogen storage disease type III (GSD III; limit dextrinosis; Cori or Forbes disease) is an autosomal recessive disorder of glycogen metabolism caused by deficient activity of glycogen debranching enzyme (GDE). Patients with GDE deficiency in liver and muscle have GSD IIIa (85%), while those with only liver deficiency have GSD IIIb (15%). Clinical symptoms include hepatomegaly, hypoglycemia, short stature and, in patients with GSD IIIa, myopathy and cardiomyopathy. Both GSD IIIa and IIIb are caused by mutations in a single gene, amylo-1,6-glucosidase (AGL), which encodes GDE. The molecular basis behind differences in tissue-specific expression of GDE activity in patients with GSD IIIa and IIIb is not yet clearly understood. However, previous studies have shown that two mutations in exon 3, c.17_18delAG (p.Q6HfsX25) and c.16C>T (p.Q6X), are associated specifically with GSD IIIb. The large size of the AGL gene (35 exons) and the absence of common mutations, except those associated with GSD IIIb, present a diagnostic challenge. The goal of this study was to investigate clinical, biochemical and molecular characteristics of GSD III patients in order to examine genotype-phenotype correlation. We have sequenced the AGL gene in 21 patients with enzymatically confirmed GSD III. Eighteen patients had GSD IIIa and 3 had GSD IIIb. Two known or possible pathogenic mutations were found in 18 patients; 2 patients had 3 possible deleterious variants each, and a single mutation was found in another patient. In total, 26 different sequence changes were identified, 11 of which were previously cited. In patients with GSD IIIa, most mutations were nonsense (13 alleles), and splice site (11 alleles); whereas frameshift (5 alleles), missense (4 alleles), exon 3 deletion (2 alleles), and a duplication (1 allele) were seen less often. Each of the three GSD IIIb patients had one common exon 3 mutation (c.17_18delAG in two patients and p.Q6X in one), and other mutations elsewhere in the gene. Two mutations (p.W680X and p.R864X) were identified in patients with both GSD IIIa and IIIb. In conclusion, GSD III is a highly heterogeneous condition. Our results suggest that the GSD IIIb subtype can be predicted if the patient carries either the c.17_18delAG or p.Q6X mutation, however other mutations do not seem to be predictive of subtype or isolated to a specific part of the gene.

**Homozygous mutations in the 5' region of the *JUP* gene result in cutaneous disease but normal heart development.** *R. Cabral[1], L. Liu[8], C. Hogan[9], P.J.C. Dopping-Hepenstal[8], B.C. Winik[2], R.A. Asial[3], R. Dobson[4], C. Mein[4], P. Baselaga[5], J.E. Mellerio[7], A. Nanda[10], M.delC. Boente[6], D.P. Kelsell[1], J.A. McGrath[7], A.P. South[1,9].* 1) Centre for Cutaneous Research, Institute of Cell and Molecular Science, Barts and The London, Queen Mary's School of Medicine and Dentistry, University of London, London, UK; 2) Servicio de Microscopía Electrónica, INSIBIO, Universidad Nacional de Tucumán - CONICET, Tucumín, Argentina; 3) Facultad de Medicina, Universidad Nacional de Tucumán, Tucumán, Argentina; 4) Genome Centre, Barts and The London, Queen Mary's School of Medicine and Dentistry, University of London, London, UK; 5) Department of Cardiology, Hospital del Niño Jesús, Tucumán, Argentina; 6) Department of Dermatology, Hospital del Niño Jesús, Tucumán, Argentina; 7) Genetic Skin Disease Group, St John's Institute of Dermatology, The Guy's, King's College and St Thomas' School of Medicine, London, UK; 8) National Diagnostic Epidermolysis Bullosa Laboratory, St John's Institute of Dermatology, The Guy's, King's College and St Thomas' School of Medicine, London, UK; 9) Surgery & Molecular Oncology, University of Dundee, Ninewells Hospital & Medical School, Dundee, UK; 10) Asad Al-Hamad Dermatology Center, Salmiya, Kuwait.

Desmosomes are specialized cell junctions which mediate strong intercellular adhesion and connect intracellularly to the intermediate filament (IF) cytoskeleton. Desmosomes are prominent in the epidermis and heart, which are tissues that constantly experience physical stress. The constitutive desmosomal protein plakoglobin (PG) is involved in linking transmembrane desmosomal components to IFs. PG also contributes to intercellular adhesion through adherens junctions and has additional signaling roles. To date, two mutations have been found in the gene encoding PG (*JUP*), and in each case patients suffer from arrhythmogenic right ventricular cardiomyopathy (ARVC). Recently, reduced or absent PG expression in heart biopsy has been suggested as an ARVC diagnostic test. We have investigated the genetic basis of disease in three unrelated Argentinean patients and two patients from a Kuwaiti family. All patients had the distinct cutaneous phenotype of skin fragility, diffuse palmoplantar keratoderma and woolly hair (notably sparse in Kuwaiti patients) with no symptoms of cardiomyopathy. We describe two novel homozygous mutations in the 5' region of *JUP*; a nonsense mutation, p.S24X, in all three Argentinean patients and a splice site mutation, c.468G>A, in both Kuwaiti patients. By immunohistochemistry with three different PG antibodies, we show virtually absent PG expression in the skin of all patients. c.468G>A is predicted to abolish the donor splice site in exon three. RT-PCR and cDNA sequencing from p.S24X skin reveals normal 5' splicing of *JUP* and no loss of mutant transcript. Western blotting (WB) of skin proteins with a PG C-terminal antibody reveals low levels of a truncated protein in p.S24X patients and heterozygous carriers of the mutant allele. We demonstrate by WB and quantitative PCR that recombinant p.S24X PG is efficiently translated in dermal fibroblasts. These results show that p.S24X mRNA is expressed at similar levels to wild type mRNA and that an alternative translation start site, using an in-frame internal AUG codon downstream of the mutation, results in the expression of an N-terminal truncated protein. PG is required for correct maintenance of skin integrity and the absence of heart phenotype in patients suggests that aberrant PG expression does not compromise normal human heart development in children. Our findings provide new insight into the distinct roles PG plays in the epidermis and heart.

## 454/W/Poster Board #112

**Evaluation of the RP1 gene in Chinese Patients with Retinitis Pigmentosa.** *L.J. Chen, P.O.S. Tam, X. Zhang, S.W.Y. Chiang, T.Y.Y. Lai, C.P. Pang.* Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong S.A.R.

Purpose: RP1 is a major gene responsible for both autosomal dominant (ADRP) and autosomal recessive retinitis pigmentosa (ARRP). In this study, we evaluated the contribution of RP1 gene mutations in Chinese patients with retinitis pigmentosa (RP). Methods: Genomic DNA of 56 RP patients were analyzed and the coding sequences and the exon-intron boundaries of RP1 were screened by direct sequencing. The amplicons containing the mutation candidates were resequenced in 190 normal controls. Pedigree analysis was performed after the identification of the nonsense mutations in a proband with ARRP. Computer programs were applied in silico for mutational analyses of the missense variants. Results: Sixteen sequence changes were identified, in which seven were novel and absent in controls. Two nonsense mutations (c.5_6delGT, c.4941_4942insT) were found to coexist in a proband with ARRP. In the patient's family, members compound heterozygous for the two nonsense mutations have early-onset and severe RP, while those with only one mutation did not develop RP. Two missense variants (K1370E and R1652L), which were found in patients with simplex RP, were predicted to have functional impact on the RP1 protein, being candidate disease-causing mutations. The other three variants (IVS3+34T>C, I408L and L2015L) were considered benign. Conclusions: In this study, we had for the first time reported ARRP associated with compound heterozygous nonsense mutations in RP1. Identification of the nonsense-mediated mRNA decay (NMD) sensitive mutation c.5_6delGT provided genetic evidence that haploinsufficiency of RP1 is not responsible for RP. We had also identified novel RP1 mutations likely to play a role in the genetics of simplex RP. Our results also indicate high mutability of the RP1 gene in the Chinese RP population.

## 455/W/Poster Board #113

**Evaluation of the NR2E3 and NRL genes in Chinese Patients with Retinitis Pigmentosa.** *P.O.S. Tam, X. Zhang, Y.P. Yang, L.J. Chen, S.W.Y. Chiang, T.Y.Y. Lai, C.P. Pang.* Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong S.A.R.

Purpose: Disease-causing mutations in the NR2E3 and NRL genes have been implicated in both autosomal dominant and autosomal recessive retinitis pigmentosa (RP) in non-Chinese populations. In this present study, the mutation profiles of these two genes were investigated in Chinese RP patients. Methods: 172 RP patients with varied inheritance patterns and 180 normal controls from Hong Kong, and an addition of 180 control subjects from Beijing were recruited. All received complete ophthalmic examinations. The coding exons and the exon-intron boundaries of NR2E3 and NRL were screened in the Hong Kong subjects by direct DNA sequencing. Any possible mutations detected were additionally screened in the control subjects from Beijing. Association analysis was performed for common SNPs while analysis of variants was performed for rare missense variants using in silico programs. Results: In NR2E3, a total of 20 sequence changes had been identified, with 14 being novel. Eight variants (IVS1-47C>T, IVS1-28T>C, IVS1-28_IVS1-13del, IVS2+75G>A, IVS3+8G>A, IVS8-87C>T, IVS8-47G>A, and c.1230+53C>T) were non-coding, four (I61I, L277L, P281P and C321C) were synonymous, and eight (G56R, V118M, E121K, E140G, M163T, T300M, V302I and P374L) were missense changes. Two missense variants, G56R (reported) and V118M (novel), were exclusively found in RP patients. Analysis of variants showed that these two missense variants might have functional impacts on the NR2E3 protein, suggesting a role of disease-causing, being responsible for 1.16% (2/172) and 1.74% (3/172) of patients, respectively. Notably, the E121K variant, which has been reported to be responsible for Enhanced S-cone Syndrome (ESCS), was found simultaneously in RP patients (13.4%) and control subjects from Hong Kong (10.0%) and Beijing (12.2%), being not associated with the disease. The rest missense changes were not significantly associated with RP. In NRL, seven sequence changes were identified, all were novel. Among them, four (W32S, P35P, T36T, S38P) and three (Y42Y, R233R, c.853C>T) were exclusively found in controls and RP patients, respectively. Conclusions: In this study, NR2E3 mutations (G56R, V118M) were found to be responsible for approximately 2.9% of overall RP. The ESCS-causative variant E121K was a common SNP in Chinese, suggesting an ethnic difference in the role of this variant on the pathogenesis of retinal degeneration. By contrast, none of the NRL variants was likely to be disease-causing.

## 456/W/Poster Board #114

**FAMILIAL EXUDATIVE VITREORETINOPATHY (FEVR): MOLECULAR AND CLINICAL-GENETIC CORRELATION IN A COLOMBIAN FAMILY.** *M. Tamayo[1], J.H. Montoya[1], N. Gelvez[1], C.L. Varón[2].* 1) Dept Genetics, Inst de Genetica Humana, Bogota, Colombia; 2) Fundación Oftalmológica de Santander, Clínica Ardila Lulle (FOSCAL). Bucaramanga, Santander. Colombia.

Introduction: The familiar exudative vitreoretinopaty, also called Criswick-Schepens disease, is caused by a genetic alteration producing a bilateral, asimetric and progressive ocular damage; this disorder has specially an autosomal dominant inheritance. OBJECTIVE: Genotype-phenotype correlation previous clinical analysis and molecular studies of the FZD4 gene to identify the causal mutation, in a extensive family from Colombia with confirmed diagnosis of familial exudative vitreoretinopathy disease (FEVR). METHODS: Initial complete ophthalmologic evaluation to the whole family; with special examination of the 32 individuals with diagnosis of FEVR. Ocular ecography, angiography and, optical coherent tomography (OCT) were performed to each one. DNA sample was taken after sign the informed consent, in order to perform DNA extraction and sequencing of the coding region of FZD4 gene. RESULTS: By ocular examination we defined that eleven individuals were affected, while the reminder 21 were non-affected. Molecular studies let us to identify the "1501delCT" mutation in the FZD4 gene, in all affected individuals. Autosomal Dominant inheritance was confirmed and, at least in this family, we can postulate the hypothesis that non-affected relatives did not present partial manifestations of the disease. CONCLUSION: We present here a complete clinical description with report of findings of angiography, optical coherent tomography and ocular echography. This exams showed the clasical peripheral changes in retinal vascularization. The Autosomal Dominant inheritance was defined in this family, as well as the causative mutation in the FZD4 gene. We were able to offer a complete genetic counseling in all evaluated individuals, after analysis of the clinical and molecular results.

## 457/W/Poster Board #115

**GLI3 Gene Mutation Spectrum of the patients with Pallister-Hall syndrome.** *Y-G. Xie[1,2,3], J. Cui[1], G. Sun[2], F-Y. Han[1,2].* 1) Discipline ofLaboratory Medicine, Memorial University, St John's, NL, Canada; 2) Discipline of Genetics, Memorial University,St John's, NL, Canada; 3) Discipline of Pediatrics, Memorial University,St John's, NL, Canada.

Pallister-Hall syndrome (PHS) is characterized with polydactyly, cutaneous syndactyly and hypothalamic hamartoma. Other clinical features include bifid epiglottis, imperforate anus, and kidney abnormalities. PHS is a rare autosomal dominant inherited disorder, and is caused by mutations in the GLI3 gene. Most cases are sporadic and the result of new mutations and the gene manifests variable expressivity. Although the typical patients can be diagnosed based on the classic signs of PHS, the patients with ambiguous or mild clinical findings can only be diagnosed by the detection of mutant GLI3 gene. The current known about the causative GLI3 mutations is very limited, and the genotype/phenotype correlation is even more not clear yet. Therefore, the study on more PHS patients for the causative mutations is urgently appreciated. To determine the mutation spectrum of GLI3 gene for PHS, we have collected DNA samples from 20 unrelated patients with clinical suspicion of PHS. The collected patients are originated from four countries including Canada, USA, Australia, and Turkey. Comprehensive mutation scan of entire GLI3 gene was carried out for all of the collected patients by using DNA direct sequencing analysis. Five nonsense mutations and one RNA processing mutation were identified from the six unrelated patients. The identified mutations include c4774 G>T (pE1592X); c4774 G>T (pE1592X), c2610 C> A (pC870X), c4774 G>T (pE1592X), c49 G>T (pE17X) and c1028+1G>T. Detailed clinical information from all patients is being further collected, and genotype /phenotype correlation analysis is under the way. Identification of as many as possible causative mutations for PHS will help to further understand the molecular pathogenesis of PHS and determine the genotype/phenotype correlation as well.

## 458/W/Poster Board #116

**Evidence suggesting a new inheritance pattern for subgroups of patients with the Oculocutaneous Albinism Spectrum.** *P.-W. Chiang[1], R. Smith[2], R.E. Longman[3], E. Burner[4], C.S. Walton[5], E.B. Spector[1], A.C.-H. Tsai[5].* 1) UC Denver DNA Diagnostic Laboratory, Department of Pediatrics, UC Denver School of Medicine, Aurora, CO; 2) Maine Medical Center, Department of Pediatrics, Portland, ME; 3) Department of Pediatrics, Division of Genetics, University of Michigan, Ann Arbor, MI; 4) Duke Eye Center, Duke School of Medicine, Durham, NC; 5) The Children's Hospital, Department of Pediatrics, UC Denver School of Medicine, Aurora, CO.

Pigmentation is a polygenic trait determined primarily by the amount and type of pigment present in an individual. Many genes are involved and interactions among genes are essential in the determination of pigmentation. Disorders associated with Oculocutaneous albinism (OCA) spectrum are characterized by hypopigmentation of eyes, skin and hair, and are considered to be autosomal recessive disorders. One of the remaining unsolved puzzles for the study of the OCA spectrum is that a significant portion of Caucasian patients with OCA1 or OCA2 have only one identifiable mutation. Large deletions are unlikely due to the presence of heterozygous SNPs in most of these patients. Here, we provide evidence suggesting that a specific *OCA2* haplotype in *trans* to a severe mutation in *OCA2* or the *OCA1* p.R402Q/rs1126809 allele is associated with Caucasian patients with only one identifiable mutation in *OCA2* or *OCA1*, respectively. We studied four Caucasian patients with a clinical diagnosis of OCA2. DNA sequencing of the following 6 genes was performed on genomic DNA extracted from each patient; *OCA1*, *OCA2*, *OCA3*, *OCA4*, *GPR143* (X-linked OA) and *MITF*. A rare, severe mutation in *OCA2* was found in each patient, namely p.L734R, IVS10+2T>C, 2055insT and p.Q106X. An identical *OCA2* haplotype in trans to the mutation was also present in each patient. However, it appears that additional unknown modifier(s) is (are) also required in order to present the typical OCA eye phenotype, as shown by a sibs who inherited the same two OCA chromosomes but with only one sibling demonstrating the typical OCA eye findings. Similarly, even though the *OCA1* p.R402Q/rs1126809 allele is strongly associated with Caucasian OCA1 patients with only one identifiable mutation, the p.R402Q/rs1126809 allele cannot produce the typical OCA eye findings as shown by a sib who inherited the same two OCA chromosomes but with no typical OCA eye finding. These findings confirmed our previous hypothesis, namely the clinical spectrum of patients with OCA spectrum depends upon the combined effects of mutation(s) acting with various modifiers and crossing a threshold to produce a phenotype in a patient. In some Caucasian patients with OCA, the presence of one mutation, a hypomorphic allele/haplotype and extra unknown modifier(s) from other gene(s) are the likely cause of OCA spectrum in these patients. Therefore, OCA spectrum should not be treated as a purely recessive disease.

## 459/W/Poster Board #117

**Homozygous promotor mutation [-30/-30] of beta-globin gene caused by maternal uniparental isodisomy of chromosome 11 in a fetus.** *I. Keser[1,3], T. Bilgen[1], Y. Arikan[1], I. Mendilcioglu[2], A. Yesilipek[3], G. Luleci[1].* 1) Medical Genetics, Faculty of Medicine, Akdeniz University, Antalya, Turkey; 2) Perinatology, Faculty of Medicine, Akdeniz University, Antalya, Turkey; 3) Thalassemia Unit, Faculty of Medicine, Akdeniz University, Antalya, Turkey.

The homozygosity or compound heterozygosity for beta-globin gene mutations (HBB gene) can cause beta-thalassemia major phenotype. Most cases are inherited from parents who both have diseased alleles of the HBB gene. We report a fetus with homozygous -30 (T>A ) mutation that evolved from beta-thalassemia minor in which only one of its parents had the diseased HBB gene using DNA sequencing. To study the cause of homozygous -30 (T>A ) in this fetus, we performed the intragenic single nucleotide polymorphism genotyping assay, the STR analysis of the parental origin, and high resolution chromosome analysis of deletion of the HBB gene lokus. The results showed that homozygous -30 mutations were perfectly originated from one allele of its mother. Our study demonstrates that maternal uniparental isodisomy (iUPD) of chromosome 11 is associated with the homozygous -30/-30 mutation in this fetus.

## 460/W/Poster Board #118

**Verbal intelligence quotient (VIQ) is associated with FMR1 repeat size and reproductive cycling characteristics in women.** *E.G. Allen, A. Abramowitz, K. Charen, D. Hamilton, M. Leslie, R. Letz, G. Novak, M. Rusin, L. Shubeck, J. Juncos, S.L. Sherman.* Dept Human Genetics, Emory Univ, Atlanta, GA.

A CGG repeat sequence located in the 5' untranslated region of the FMR1 gene when expanded leads to fragile X-associated disorders. When greater than 200 repeats, the gene is silenced due to hypermethylation, and the lack of protein leads to fragile X syndrome (FXS). Alleles with 55-200 unmethylated repeats, termed premutation alleles, have been associated with ovarian insufficiency (FXPOI) and a late-onset tremor/ataxia syndrome (FXTAS). Several groups have reported neuropsychological deficits among carriers of the premutation, particularly among males with FXTAS. We have previously shown a subtle but significant effect of FMR1 repeat size on verbal intelligence quotient (VIQ) as measured by the Wechsler Adult Intelligence Scale - III (WAIS-III) among women between the ages of 18 and 50 years. We have confirmed this association, and expanded the model by including a variable for reproductive cycling characteristics in women. All subjects completed a neuropsychological test battery including WAIS-III, a reproductive questionnaire, and provided a blood sample for hormone measurement. We have completed testing on 232 women, and they have been categorized as having normal cycles (non-carriers n=48; premutation carriers n=52), irregular cycles (non-carriers n=43; premutation carriers n=44), and being menopausal (non-carriers n=4; premutation carriers n=41) based on their reproductive questionnaire. In a linear regression model, repeat size, as a continuous variable, explained 4% of the variation in VIQ ($p = 0.002$), and reproductive status explained 3% of the variation in VIQ ($p=0.018$) after adjusting for age, race, and education. Upon further examination of the VIQ index scores, Verbal Comprehension Index (VCI) and Working Memory Index (WMI), an association with repeat size and reproductive status ($p= 0.001$ and $p=0.003$, respectively) was identified for the VCI, but not the WMI. Finally, we stratified the dataset by women with normal cycles and those with irregular cycles and re-examined the model. A significant association with repeat size and VIQ was observed only among the group of women with normal cycles, with 10% of the variance in VIQ being explained (p-value for repeat size=0.002). Hormone replacement did not affect these results. We are in the process of finalizing hormone results and will use these to define reproductive stage in the next series of tests. These findings, including data on individual WAIS-III subtests, will be presented.

## 461/W/Poster Board #119

**Molecular etiology of Stargardt disease in Newfoundland and Labrador.** *J. Green[1], A. Sheaves[1], L. Wilkins[1], K. Hatch[1], D. Galutira[1], J. Whelan[2], D. Bautista[2], B. Younghusband[1], P. Parfrey[3], TL. Young[1].* 1) Discipline of Genetics, Memorial University of Newfoundland, St John's, NL, Canada; 2) Department of Surgery, Memorial University of Newfoundland, St John's, NL, Canada; 3) Department of Clinical Epidemiology, Memorial University of Newfoundland, St John's, NL, Canada.

**Objective**: Our goal was to identify mutations in the ABCA4 gene in Newfoundland (NL) families with Stargardt disease (STGD) and related retinal dystrophies. **Patients and Methods**: 31 families with STGD have been identified in NL since 1978 and members of 22 families were available for molecular analysis. DNA was collected from 37 affected and 27 unaffected consenting members of these families and sequenced on the ABI3130 automated sequencer. Variants were reviewed manually and with Mutation Surveyor, and compared with Asper Ophthalmics and Retina International mutation databases. Clinical records were reviewed for all affected individuals for up to 30 years, and phenotypes for each genotype were compared. The study was approved by the Human Investigation Committee of Memorial University Faculty of Medicine. **Results**: Ancestors of 13/22 families studied came from one isolate in eastern NL. Both disease-causing alleles have been identified in 28 patients, a single mutation in 4 individuals and no mutation for five individuals in five families. The common IVS40+5G>A mutation was homozygous in seven individuals and heterozygous in 11 others all from the same eastern bay. A second mutation, IVS38-10T>C, was present in seven individuals from this same bay. Twelve other mutations were identified in fewer individuals. **Conclusions**: Multiple mutations were identified in NL families, with IVS40+5G>A being the most common mutation. The IVS38-10T>C mutation was seen in seven individuals in two families with severe disease confirming the cone-rod dystrophy presentation previously reported for this mutation. As with other hereditary eye diseases in NL, founder effect and diversity of mutations for STGD was found with a high proportion (70%) of families having the disease-causing ABCA4 alleles identified.

## 462/W/Poster Board #120

**A novel homozygous missense mutation in the HAX1 gene of severe congenital neutropenia patients (Kostmann disease).** *S.H.E. Zaidi[1], A. Al-Jefri[4], H. Abalkhail[2], M.A. Al-Muallimi[2], M. Toulimat[2], M.A. Pulicat[5], A. Gaafar[5], A.A. Alaiya[5], F. Al-Dayel[2], I. Peltekova[6], M. Faiyaz-Ul-Haque[2,3].* 1) Department of Medicine, University Health Network & University of Toronto, Toronto, Ontario, Canada; 2) Department of Pathology and Laboratory Medicine, King Faisal Specialist Hospital & Research; 3) College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 4) Department of Pediatric Hematology/Oncology, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 5) Department of Biological and Medical Research, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 6) Department of Medicine, Queen's University, Kingston, Ontario, Canada.

Autosomal recessive severe congenital neutropenia (SCN) is a rare inherited disorder, which is characterized by an early onset of recurrent infections in the presence of persistent agranulocytosis. This disease is caused by maturation arrest of granulopoiesis at the level of promyelocytes. In SCN patients, several mutations have been identified in the HAX1 and ELA2 genes. In the HAX1 gene, all of the mutations described to date are nonsense mutations that produce frame shifts of the coding region. The HAX1 gene produces two alternatively spliced transcripts, which differ in inclusion of sequences from exon 2. While nonsense mutations specific to the transcript variant 1 of the HAX1 gene only cause neutropenia, nonsense mutations that are common to both transcript variants produce neurological symptoms in addition to neutropenia. This study describes SCN patients who carry a novel homozygous missense, c.421T>C, mutation in the HAX1 gene. This mutation encodes for a p.Phe141Leu change in the HAX1 protein. The mutation affects both transcript variants of the HAX1 gene. No mutation was found in the ELA2 gene of these SCN patients. Interestingly, while patients in the present study exhibit neutropenia and apoptosis of neutrophils, there is no evidence of developmental delay or neurological impairment. We conclude that while p.Phe141Leu substitution is sufficient to produce SCN, this mutation does not cause developmental or neurological manifestations. This is the only known pathogenic missense mutation in the HAX1 gene of SCN patients.

## 463/W/Poster Board #121

**Molecular analysis of 6 Turkish Griscelli Syndrome Patients.** *A. Alpman Durmaz[1], F. Ozkinay[1, 2], H. Onay[1], M. Tombuloglu[3], A. Atay[4], E. Peker[5], M. Atmaca[5], H. Akin[1], C. Ozkinay[1].* 1) Department of Medical Genetics, Ege University Medical Faculty, Izmir, Turkey; 2) Department of Pediatrics, Ege University Medical Faculty, Izmir, Turkey; 3) Department of Internal Medicine, Ege University Medical Faculty, Izmir, Turkey; 4) Department of Pediatrics, Gulhane Military Medicine Faculty, Ankara, Turkey; 5) Department of Pediatrics, Van 100. Yil Medical Faculty, Van, Turkey.

Griscelli syndrome is a rare autosomal resessive disorder associated with various degrees of skin or hair hypopigmentation, hepatosplenomegaly, pansytopenia, immunological and central nervous system abnormalities. RAB27A coding a GTPase in terminal phase of cytotoxic granule/melanosome exocytosis is mutated in the most common GS subtype GSII which mainly is characterized by hemophagocytosis and variable immundeficiency. RAB27 gene is located on chromosome 15q21 and several mutations have been found in affected patients. We present RAB27A mutation analysis of 6 cases diagnosed as Griscelli syndrome type II which were missense mutations (L26P and L130P) in 2 cases, deletion of 5 bases (514delCAAGC) in 2 cases and one base deletion (148delA) in 2 cases. The 514delCAAGC deletion has been detected in only 2 previous cases and is close to a deletion hotspot found in GSII patients. The 2 cases having homozygous 148delA mutation which leads to premature stop codon also had homozygous R50T missense mutation. Mutation analysis of the parents revealed heterozygosity for these 2 mutations and it is considered to be linked changes within RAB27A gene. A similar previous case was reported from Iran and this is the second report defining this comlex genotype in unrelated 2 GS cases. The phenotype-genotype correlation of different types of mutations is also discussed in this presentation within the RAB27A gene in Griscelli Typr II syndrome.

## 464/W/Poster Board #122

**Mutation spectrum of the autoimmune regulator (AIRE) gene in Arab patients affected with autoimmune polyendocrinopathy syndrome type 1 (APS1).** *M. Faiyaz-Ul-Haque[1,2], B. Bin-Abbas[3], A. Al-Abdullatif[1], H. Abalkhail[1], M. Toulimat[1], S. Al-Gazlan[4], A.M. Almutawa[1], A. Al-Sagheir[3], I. Peltekova[5], F. Al-Dayel[1], S.H.E. Zaidi[6].* 1) Pathology & Lab Med, King Faisal Spec Hosp & Res Ctr, Riyadh, Saudi Arabia; 2) College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 3) Endocrine/Metabolism, Department of Pediatrics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Allergy/Immunology, Department of Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 5) Department of Medicine, Queen's University, Kingston, Ontario, Canada; 6) Department of Medicine, University Health Network, Toronto, Ontario, Canada.

Autoimmune polyendocrinopathy syndrome type 1 (APS1) is characterized by the manifestation of at least two out of three disease components, which comprise of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiasis. Additional manifestations include alopecia universalis, diabetes mellitus, onychosis, growth hormone deficiency, nephrocalcinosis, keratopathy, vitamin B12 deficiency, gonadal failure, iridocyclitis, and celiac disease. This disorder is caused by mutations in the autoimmune regulator (AIRE) gene. While AIRE mutations have been described in APS1 patients of various ethnicities, the spectrum of AIRE mutations in Arab APS1 patients has not been determined. This study describes seven Arab families, in which eighteen individuals were diagnosed with APS1. DNA sequencing of these APS1 patients identified one recurrent and four novel mutations in the AIRE gene. These mutations likely result in loss of AIRE function in these patients. An interesting finding in this study is the manifestation of hypoparathyroidism and mucocutaneous candidiasis during the neonatal period in several patients. In addition, alopecia universalis was present in several patients with an onset during the ages of 3-10 years. Scalp biopsies from the patients showed decreased number of hair follicles and peribulbar lymphocytic inflammation. Presence of T-lymphocytes in the peribulbar area of hair follicles was confirmed by immunohistochemical staining for CD3 antigen. We conclude that the Arab APS1 patients carry novel and recurrent AIRE mutations, with early onsets of hypoparathyroidism and mucocutaneous candidiasis, and frequent occurrence of alopecia universalis, which is associated with inflammation of hair follicles.

## 465/W/Poster Board #123

**Genetic investigation of human natural killer lymphocytes deficiency.** *L. GINEAU[1,2], E. Jouanguy[1,2], J. Dunne[3], C. Cognet[4], L. Abel[1,2], S. Aoufouchi[5], E. Vivier[4], C. Feighery[3], JL. Casanova[1,2].* 1) Laboratory of Human Genetics of Infectious diseases, Necker Branch, University of Paris René Descartes INSERM U550, Necker Medical School, Paris, 75015, France, EU; 2) Laboratory of Human Genetics of Infectious diseases, Rockefeller Branch, The Rockefeller University, New York, 10065 NY, USA; 3) Departement of Immunology, St Jame's Hospital, Dublin, Irland, EU; 4) Centre d'immunologie de Marseille-Luminy, Université de la Méditerranée, INSERM U631-Centre National de la recherche scientifique UMR 6102, Marseille 13288 France, EU; 5) Genome plasticity and B cells, University of Paris-Sud, FRE2939, Institut de Cancérologie Gustave Roussy, 94805 Villejuif, France, EU.

Natural killer (NK) cells functions are well characterized in the mouse for their important role in the first line of defence in antiviral and anti-tumoral immunity. In humans, however, little is know mainly because there is no immunological defect restrictive to NK cells. We report six children with a novel primary immunodeficiency, consisting of a specific NK cell deficiency and susceptibility to viral diseases and tumoral proliferation. Indeed, one child developed an EBV-driven lymphoproliferative disorder, another one developed recurrent viral infections by HSV and VZV. The patients are related and they belong to a large inbred kindred of Irish nomadic descent, suggesting autosomal recessive inheritance of this defect. A genome-wide scan identified a single 12 Mb region on chromosome 8 linked to this immunodeficiency and containing 77 genes. The sequencing of the coding region of these genes conducted so far to identify a germline mutation in these patients. Our preliminary data show that the mutated gene seems to be specifically implicated in the development of a sub-population of NK cells. The functional characterization of this mutation will allow us to better understand a crucial regulatory step in NK cell differentiation.

## 466/W/Poster Board #124

**Detection of copy number variation in the beta-globin locus potentially associated with beta thalassemia.** *M. Mikula, A. Buller, W. Sun, C. Strom.* Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

There are an estimated 80 million carriers of beta thalassemia worldwide and more than 200 mutations are known affecting the beta-globin gene. Most mutations are point mutations within the gene or its immediate flanking sequences; deletions only rarely cause the disease. However, deletions account for approximately 20% of beta thalassemia alleles in some populations and more than 40 different beta-globin locus deletions have been reported. A newly developed beta-globin gene dosage assay, specifically a single tube multiplex semi-quantitative fluorescent PCR, can be used to detect deletions and duplications in the beta-globin cluster of genes and the associated locus control region (LCR). The assay detects mutations in 12 amplicons spanning the beta-globin locus and uses 2 internal controls to normalize signal for inter-sample comparison. Anonymized samples (n= 564) previously submitted for beta-globin sequencing from individuals with red cell indices suggestive of beta thalassemia were tested for deletions and duplications in the beta-globin gene cluster. The samples were chosen irrespective of sequencing results. Eleven deletions (2.0%) were detected: 5 deletions involved the beta- globin gene only (3 deletions of the entire gene and 2 deletions of the 5' portion of the gene) and 6 rearrangements that deleted both the delta-globin and beta-globin genes. No duplications were detected. Thus, testing for deletions in the beta-globin gene may reveal novel mutations associated with beta thalassemia. Clinical correlation and confirmation studies are underway to further characterize the detected deletions.

## 467/W/Poster Board #125

**TMPRSS6, the Serine Protease Mutated in Iron-Refractory, Iron Deficiency Anemia, Regulates Systemic Iron Homeostasis by Inhibiting Hepcidin Signaling Through Hemojuvelin.** *K.E. Finberg[1], R.L. Whittlesey[2], M.D. Fleming[3,4], N.C. Andrews[2,5].* 1) Dept Pathology, Duke Univ Med Ctr, Durham, NC; 2) Dept Pharmacology & Cancer Biology, Duke Univ Med Ctr, Durham, NC; 3) Dept Pathology, Children's Hosp Boston, Boston, MA; 4) Dept Pathology, Harvard Medical School, Boston, MA; 5) Dept Pediatrics, Duke Univ Med Ctr, Durham, NC.

Iron-Refractory, Iron Deficiency Anemia (IRIDA) is a familial disorder characterized by iron deficiency anemia unresponsive to oral iron treatment but partially responsive to intravenous iron therapy. Previously, we showed that IRIDA patients harbor loss-of-function mutations in TMPRSS6, a transmembrane serine protease expressed by the liver. Both humans and mice with Tmprss6 mutations show inappropriately elevated levels of hepcidin, a circulating hormone produced by the liver that inhibits iron absorption from the intestine and iron release from macrophage stores; these findings suggest that TMPRSS6 acts to negatively regulate hepcidin expression. We hypothesized that Tmprss6 may negatively regulate hepcidin expression by down-regulating hepcidin signaling through hemojuvelin (Hjv), a membrane-bound protein in hepatocytes that signals to promote hepcidin expression. To test this, we bred Tmprss6-deficient mice to Hjv-deficient mice; the latter are a mouse model of juvenile hemochromatosis characterized by low hepcidin levels and systemic iron overload. Compared to wild type controls, Tmprss6-deficient mice showed iron-deficiency related hair loss, decreased hemoglobin levels ($p<0.0005$), decreased transferrin saturation ($p<0.0005$), elevated hepatic hepcidin mRNA ($p<0.05$), and decreased hepatic iron stores ($p<0.0005$). Mice harboring one defective Tmprss6 allele had a normal coat but moderately decreased hepatic iron stores ($p<0.0005$ vs. wild type) and laboratory signs of iron-restricted erythropoiesis. Mice deficient for both Tmprss6 and Hjv, however, showed a normal coat and normal hemoglobin levels, and like mice deficient for Hjv alone, were systemically iron overloaded compared to wild type mice, displaying elevated transferrin saturation ($p<0.0005$), markedly decreased hepcidin levels ($p<0.005$), and markedly increased non-heme iron content of liver ($p<0.0005$), heart ($p<0.05$), pancreas ($p<0.005$), and muscle ($p<0.0005$). We conclude that TMPRSS6 is an essential regulator of mammalian systemic iron homeostasis that acts functionally upstream of hemojuvelin to negatively regulate hepcidin transcription by hepatocytes. In IRIDA, where TMPRSS6 function is lost, excess hemojuvelin signaling results in elevated hepcidin levels, which in turn promote systemic iron deficiency by reducing dietary iron absorption.

## 468/W/Poster Board #126

**A new concept of Alpha thalassemia: normal alpha locus and mutant Alpha hemoglobin stabilizing protein.** *S. Pissard[1,3], C. Vasseur[2], F. Toutain[5], M. Silva[4], E. Faubert-Laugé[1], MC. Marden[2], H. Wajcman[1,3], V. Baudin-Creuza[2].* 1) Lab Biochemistry & Genetics, Hosp Henri Mondor and Univ Paris 12, Creteil, France; 2) Inserm U779, CHU de Bicetre, Le kremlin Bicetre, France; 3) Inserm U 955 eq11, CHU H mondor, Creteil, France; 4) Hematologie Biologique, Groupe hospitalier du Havre, Le Havre, France; 5) service de Pediatrie, Groupe Hospitalier du Havre, Le Havre, France.

Alpha thalassemias ($\alpha$-thal) form a group of inherited diseases in which the deficit in $\alpha$-globin chain synthesis results in dyserythropoiesis. Due to the sequential activation of the $\alpha$-globin loci during the gestation and the degree of imbalance, the severity of the disease varies from a fetal death or, at birth, to a microcytic anemia with Hb Bart's detected by hemoglobin phenotype studies. Various molecular defects of the $\alpha$-globin locus result in $\alpha$-thal, the most frequent being deletions of the $\alpha$-loci (s). Point mutations are less frequent and, as rare etiologies, deletions of the activating sequence (HS-40) have been reported. $\alpha$-thal is a part of ATR-16 syndrome (large deletion within 16p) and ATR-X syndrome (mutation in the ATRX gene :Xq13) in which thalassemia is associated with mental retardation. Alpha hemoglobin stabilizing protein (AHSP) is a chaperon (16 p11.2) of $\alpha$-Hb described to have a major importance in the folding and stability of the $\alpha$-globin chains. In vitro studies and experiments on mice have shown that default in the folding process results in the degradation of the $\alpha$-chain and thus should lead to $\alpha$-thal. Up to now this has not been found in humans. We have studied the second child of a family originating from SE Asia, who was referred to the hospital one month after birth, because of palor and anemia. Biological tests demonstrated a hemolytic microcytic anemia (Hb 6.9 g/dl, MCV : 73.2 fL and MCH 25 pg), 3% Hb Bart's were detected by CE-HPLC. The molecular screening for $\alpha$-thal, including detection of common and rare $\alpha$ locus deletions using Gap-PCR and MLPA analysis, sequencing of $\alpha$ 1 and $\alpha$ 2 genes, and sequencing of the HS-40 core sequence revealed no abnormality. We then sequenced the AHSP gene and its promoter; the proband was found to be homozygous for a mutation in exon 3 (c.167 T>G) and the parents heterozygous for it. In vitro studies demonstrated a 20% -30% decrease in the association between normal $\alpha$-globin and the mutated recombinant AHSPV56G suggesting that the mutated AHSP could be responsible for the $\alpha$-thal, thus explaining the child's phenotype. Up to now, only 3 mutants have been described in the AHSP gene but none found to impair the association with normal $\alpha$-chain. This case is thus the first evidence of an isolated $\alpha$-thal not linked with $\alpha$-locus but with a mutated AHSP.

## 469/W/Poster Board #127

**Novel and recurrent mutations in the complement component 1 inhibitor (C1NH) gene of Arab patients affected with hereditary angioedema.** *H. Abalkhail[1], S. Al-Gazlan[3], A. Al-Abdullatif[1], M. Toulimat[1], I. Peltekova[4], A.M.R. Khaliq[3], F. Al-Dayel[1], S.H.E. Zaidi[5], M. Faiyaz-Ul-Haque[1,2].* 1) Department of Pathology & Labo, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) College of Medicine, Alfaisal University, Riyadh, Saudi Arabia; 3) Allergy/Immunology, Department of Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Department of Medicine, Queen's University, Kingston, Ontario, Canada; 5) Department of Medicine, University Health Network, Toronto, Ontario, Canada.

Autosomal dominant hereditary angioedema (HAE) is characterized by episodes of subcutaneous edema in various body parts and/or submucosal edema of the upper respiratory or gastrointestinal tracts. This disorder is caused by mutations in the complement component 1 inhibitor (C1NH) gene. While C1NH mutations have been described primarily in European patients, the spectrum of C1NH gene mutations in Arab HAE patients has not yet been determined. In this study, we describe four unrelated Arab families, in which fifteen patients were diagnosed with HAE. These patients exhibited recurrent swelling of the face, lips, limbs, tongue and other body parts, abdominal pain, laryngeal edema, and respiratory distress. DNA from thirteen patients was analyzed for mutations in the C1NH gene by DNA sequencing. Three novel and two recurrent C1NH mutations were found in the HAE patients, which include the c.856C>T, c.1361T>A, c.509C>T, and c.1142delC novel mutations, and the c.1397G>A recurrent mutation. These mutations encode for p.Arg264Cys, p.Val432Glu, p.Ser148Phe, p.Ala359AlafsX15, and p.Arg444His changes in the AIRE protein, respectively. In one family, a single patient was found to be compound heterozygous for a novel and a recurrent missense mutation encoding for p.Arg264Cys and p.Val432Glu, respectively. The five mutations in the present study were not found in 119 control chromosomes of Arab ethnicity. All identified mutations belong to the micro C1NH gene mutation class. This is the first ever report of C1NH gene mutations in Middle Eastern Arab patients. Our study suggests that despite the numerous reports of mutations in the C1NH gene, there exist novel and recurrent mutations in HAE patients of non-European ethnic origins.

## 470/W/Poster Board #128

**Mutation Spectrums of PRF1, MUNC13-4 and STX11 genes in patients with Familial Hemophagocytic Lymphohistiocytosis in North America.**
*K. Zhang[1], J. Meller[3,4], J. Biroschak[1], JA. Johnson[1], Q. Wei[8], C. Liu[1], EM. Uzvolgyi[1], R. Marsh[2], S. Satake[7], A. Grom[5], K. Risma[6], J. Bleesing[2], AH. Filipovich[2].* 1) Division of Human Genetics, Cinncinnati Children's Hospital, Cincinnati, OH; 2) Division of Hematology /Oncology, Cinncinnati Children's Hospital, Cincinnati, OH; 3) Depts. of Environmental Health and Biomedical Engineering, University of Cincinnati College of Medicine, Cincinnati, OH; 4) Division of Biomedical Informatics, Cinncinnati Children's Hospital, Cincinnati, OH; 5) Division of Reumatology, Cinncinnati Children's Hospital, Cincinnati, OH; 6) Division of Allergy, Cinncinnati Children's Hospital, Cincinnati, OH; 7) Section of Hematology/Oncology, University of California, Davis School of Medicine, Davis Medical Center, Sacramento, CA; 8) Department of Biomedical Engineer, Columbia University, New York, NY.

Familial hemophagocytic lymphohistiocytosis (FHL-familial HLH) is a rare disorder of immune regulation, characterized by defects in cell-mediated cytotoxicity that results in fever, hepatosplenomegaly and cytopenias. It is often rapidly fatal unless treated with chemotherapy, immune suppression and followed by bone marrow transplant. FHL is an autosomal recessive disorder. Three genes have been identified to be associated with FHL: PRF1, MUNC13-4 and STX11. From 2004 to 2008, we tested a total of 1,145 patients from North America with the clinical diagnosis of HLH. We found 1) PRF1 mutations in 190 families. PRF1-50delT is found in 32 families (17%). it is the most common mutation in PRF1. All of these patients are of African American descent. 2) For the 845 families available for MUNC13-4 sequence analysis, bi-allelic mutations were found in 38 families (4.5%), and more strikingly, single MUNC13-4 mutations were found in 94 families (11%). MLPA analyses were performed in these patients, and did not find any evidence of gross deletions. Careful examination of the patient's sequences in MUNC13-4, revealed more than three dozen haplotypes in MUNC13-4. One unique haplotype is associated with macrophage activation syndrome, which resembles HLH clinically. We predict that some of these haplotypes might host pathological mutations and contribute to the development of FHL and associated disorders. 3) Mutational analyses of STX11 by direct sequencing were done in the remaining 306 unrelated patients. Two novel nonsense STX11 mutations were identified in two families. Two previously unreported missense mutations are presented in another family. 4) More interestingly, there is an affected individual who is heterozygous for a nonsense STX11 mutation, and also carries heterozygous missense mutation in MUNC13-4 gene. As both STX11 and MUNC13-4 are involved in vesicle trafficking and membrane fusion in perforin mediated cytotoxic pathway, the finding of double heterozygosity of mutations in both STX11 and MUNC13-4 suggests that digenic effects may also lead to FHL. In summary, this is the first large scale genetic study of HLH patients in North America. Single MUNC13-4 mutations were found in a large portion of FHL patients. Certain haplotypes in the MUNC13-4 locus might be associated with FHL and associated disorders. And for the first time, bi-allelic pathological mutations in STX11 can be found in FHL patient without a Turkish/Kurdish background.

## 471/W/Poster Board #129

**Genetic disorders in Tunisia. A systematic review.**
*L. Romdhane, I. Manai, S. Romdhane, S. Abdelhak.* Institut Pasteur de Tunis, Tunis Belvédère, Tunisia.

Tunisia is a North African country, geographically situated at the crossroad between Africa and Europe. Little information is available about genetic diseases in developing countries, especially in Tunisia although hereditary disorders are considered as a real public health problem because of the high rates of consanguinity which may reach 60%. The purpose of the present study is to evaluate the burden of genetic diseases through a review of the literature. A research in OMIM texts was performed. A systematic review of publications using key-words "genetic disease Tunisia" and "Tunisian patient" was done using PubMed. Data from "gray literature" were retrieved through national and international meeting reports, local journals, thesis and monographs. Reports dealing with clinical, epidemiological, genetic and molecular features were selected. Data on genetic diseases among Tunisian population are from patients living in Tunisia and immigrant Tunisians. A non exhaustive list of 251 genetic disorders has been identified. Among those, 66.93 % are autosomal recessive, 21.51 % autosomal dominant, 5.18 % X-linked, 0.4 % Y-linked, 0.8 % mitochondrial, 2 % mixed, 2.4 % sporadic and 0.8 % of unknown mode of transmission. Fifty five per cent of genetic diseases had a defined molecular aetiology and were caused by at least one mutation. No molecular data were available for the remaining diseases with unknown gene or in case mutations are not yet identified in the Tunisian population. A founder effect was noticed in 7.17 %, about 50 % of them are specific to the Tunisian population, the remaining others are founder alleles shared with North African populations. In many cases, genetic heterogeneity is responsible for their high frequency in the Tunisian population. Allelic heterogeneity is also noticed that lead to expression of a single morbid phenotype. As a consequence of the high inbreeding rate in Tunisia combined with a founder effect, many genetic disorders emerged with autosomal recessive inheritance being the most prevalent. Currently in Tunisia, there are several studies on prevention of disabilities through pluridisciplinary networks. Health education early at scholar course seems to be a suitable tool for a developing country as Tunisia in order to prevent such disorders. Because of geographical, historical and socio-cultural reasons, our study has an impact at the regional level, as the population structure is very similar to the neighbouring countries.

## 472/W/Poster Board #130

**Molecular characterization of three Taiwanese families with Lowe syndrome.**
*S. Chang[1,5], Y. Ke[1,2], G. Ma[1], M. Chen[1,3,4].* 1) Center for Medical Genetics, and Department of Medical Research, Changhua Christian Hospital, Changhua, Taiwan; 2) Department of Pediatrics, Changhua Christian Hospital, Changhua, Taiwan; 3) Department of Obstetrics and Gynecology, and Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan; 4) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan; 5) Department of Life Science, National Chung Hsing University, Taichung, Taiwan.

Lowe syndrome is a rare and panethnic X-linked disorder characterized by anomalies in the eye, nervous system and kidney with an incidence of approximately 1 in 500,000 people. Mutations in OCRL gene (localized at Xq26.1) are responsible for the disease. We performed the molecular analysis to screen for mutations in all the coding sequences and exon-intron boundaries of the OCRL gene in three unrelated Taiwanese families. Three novel mutations, including two frameshift mutations (c.1854dupA on the exon 17and c.2309_2312delATTG on the exon 21) and one missense mutation c.1501A>T (p.I501F) on the exon 15 were identified. Familial analyses showed mutations in two of three probands (hemizygous c.1854dupA and c.1501A>T) were maternal origin. The remaining hemizygous frameshift mutation c.2309_2312delATTG (p.Asp619ValfsX54) in a sporadic case is a de novo mutation because it was not found in his parents. Western blotting analyses showed reduction or absence of the OCRL protein expression in all probands, providing evidence that all the three mutations we detected here are disease-causing defects.

## 473/W/Poster Board #131

**Bifid Nose, Renal Agenesis, and Anorectal Malformations Syndrome is Caused by Mutation of *FREM1*.** *A.M. Alazami[1], L. Al-Gazali[2], K. Snape[3], F.S. Alkuraya[1,4,5].* 1) Dept of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Department of Pediatrics, United Arab Emirates University, Al-Ain, United Arab Emirates; 3) North East Thames Regional Genetics Service, Clinical Genetics Unit, Great Ormond Street Hospital NHS Trust, London; 4) Department of Pediatrics, King Khalid University Hospital and College of Medicine, King Saud University, Riyadh, Saudi Arabia; 5) Department of Anatomy and Cell Biology, College of Medicine, Alfaisal University, Riyadh, Saudi Arabia.

In 2002, Al-Gazali et al described an apparently novel autosomal recessive multiple congenital anomalies syndrome comprising bifid nose (with no associated hypertelorism), renal agenesis, and anorectal malformations (MIM 608980). The consanguineous nature of the parents allowed us to implement homozygosity mapping to identify two blocks of shared homozygosity on chromosomes 5 and 9. We hypothesized that the candidate gene will be expressed in the developing kidney and although *FREM1* fit this description, this gene is known to be one of several that are responsible for the spontaneous *bleb* mutant phenotypes in mice, which collectively are believed to be mouse models for Fraser syndrome (MIM 219000), an autosomal recessive condition in which cryptophthalmos and syndactyly are major features. To our surprise, we uncovered two mutations in *FREM1* in both the original family and a new unrelated family. FREM1 is an extracellular matrix protein that is found in close association with two other related extracellular matrix proteins, FRAS1 and FREM2. Only mutations in *FRAS1* and *FREM2* have been identified in human patients with Fraser syndrome and, while specifically pursued, *FREM1* mutations have never been reported in this disorder or any other human disease in general. A re-assessment of the original paper describing the spontaneous *Frem1* mouse mutant revealed no evidence of cryptophthalmos. *In situ* hybridization demonstrated *Frem1* gene expression in the midline of E11.5 embryos, in agreement with the observed cleft nose phenotype of our patients. Given that two of the defining traits of Fraser syndrome, cryptophthalmos and syndactyly, are absent from all our affected individuals, this is therefore the first report to define mutations in the FRAS1/ FREM complex which lead to a human phenotype distinct from Fraser syndrome.

## 474/W/Poster Board #132

**Molecular basis of Melnick-Needles syndrome: first cases with confirmation of mutations in filamin A exon 22 in boys with the perinatal-lethal phenotype.** *M.R.S. Carvalho[1], H.H. Santos[2], P.P. Garcia[3], L. Pereira[1], L.L. Leão[2,5], R.A.P.L. Aguiar[4], A.M.A. Lana[3], M.J.B. Aguiar[2,5].* 1) Departamento de Biologia Geral, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 2) Serviço Especial de Genética do Hospital das Clínicas da Universidade Federal de Minas Gerais, Brazil; 3) Departamento de Anatomia Patológica e Medicina Legal da Universidade Federal de Minas Gerais, Brazil; 4) Departamento de Ginecologia e Obstetrícia da Faculdade de Medicina da Universidade Federal de Minas Gerais, Brazil; 5) Departamento de Pediatria da Universidade Federal de Minas Gerais, Brazil.

Introduction Melnick-Needles syndrome (MNS) is a rare condition with X-linked dominant inheritance, and lethal in males. MNS is caused by mutations in FLNA, which encodes a protein filamina A. Three mutations have been already described, all of them in FLNA exon 22 (D1184E, A1188T and S1199L). Besides, FLNA mutations heve been identified in patients with Otopalatodigital syndromes type 1 and type 2 and Frontometaphyseal dysplasia. Objectives To acertains mutations in FLNA exon 22 in two stillbirth with post-mortem diagnosis of MNS perinatal-lethal phenotype and their mothers with a clinical diagnosis of MNS. Methodology DNA was extracted from paraffin embedded tissues for children and peripheral blood from their mothers. The analysis of the mothers DNA was performed by PCR and direct sequencing. Sequencing of children DNAs was obtained after heminested PCR and cloning into plasmid TOPO2.1 (Invitrogen). Results We identified in one child the mutation 3845C → T (in NCBI reference sequence NM 001456.3) in exon 22 that replaces an serine by a leucine residue at position 1199. In another boy, a double SNP was identified, 3776G → A and 3777G → T - (in NCBI reference sequence NM 001456.3) which lead to the substitution of a glycine by an aspartic acid at position 1176. Conclusion Through genetic and molecular analysis we confirmed the clinical diagnosis of individuals. The mutation 3845C → T, which had been described in literature only in mothers of affected or in mosaics men, it was identified for the first time in a stillbirth affected, confirming its role in the development of the phenotype. The second mutation (G1176D) was identified for the first time in this study and was present both in the mother (in heterozygosis) and in the stillbirth. The replacement of a small and neutral amino acid by a large and acid one is sugestive of gain of function. This is the first study confirming FLNA mutations in boy affected by the MNS perinatal-lethal phenotype.

## 475/W/Poster Board #133

**Pursuit of additional 'Cohesinopathy' loci involved in human developmental disorders.** *M. Deardorff[1], E. Loy[1], M. Kaur[1], M. Berman[1], L. Conlin[1], X. Gai[2], J. Perin[2], T. Shaikh[1], H. Hakonarson[3], L. Jackson[4], I. Krantz[1].* 1) Genetics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Bioinformatics, Children's Hosp Philadelphia, Philadelphia, PA; 3) Center for Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 4) Drexel School of Medicine, Philadelphia, PA.

The Cornelia de Lange syndrome (CdLS) or Brachmann-de Lange syndrome (BDLS) (OMIM 122470) is a multisystem developmental disorder characterized by facial dysmorphia, hirsutism, growth and cognitive retardation, gastrointestinal abnormalities and limb deficiencies. To date, we have identified mutations in approximately 65% of patients with CdLS. These mutations involve the genes NIPBL, SMC1A and SMC3, all of which are involved in sister chromatid cohesion. We have yet to elucidate a cause of CdLS in 35% of patients with typical features of CdLS and nearly 80% of patients with variant features of CdLS. To facilitate identification of genes that may cause CdLS or these variant phenotypes, we have used genome-wide CNV analysis. To date, 269 individuals submitted to our study for whom causative mutations had not been previously identified were analyzed for potentially pathogenic copy number variations using Illumina HapMap550K SNP arrays. Analysis to the level of 2 consecutive abnormal SNPs has revealed 8932 potential variants ranging from 2bp to 20Mb. Of these CNVs, 5191 were 5 SNPs or less. We have identified deletions in 5 patients that include NIPBL and were validated using MLPA. There were no deletions that included SMC1A and SMC3, consistent with previous findings of only missense mutations in these genes. We have identified a number of large chromosomal abnormalities in individuals with phenotypic overlap with CdLS, but who do not meet full clinical criteria. We are hypothesizing that these overlapping clinical features may be similar to CdLS due to the involvement of additional genes involved in the pathogenesis of the 'Cohesinopathies'. In our cohort, we have identified two patients with overlapping de novo deletions on 19p13 and two additional patients with overlapping de novo duplications on 19q13. We have identified six additional patients with overlapping abnormalities from other sources and are working to collect their detailed clinical and cytogenetic data. We speculate that the underlying basis of the clinical features in these and other patients may be related to Cohesin function during human development.

**Transcriptional and Epigenetic Dys-regulation in *NIPBL* and Cohesin Mutant Human Cells - A Comprehensive Genomic Study in Cornelia de Lange Syndrome.** *J. Liu[1], Z. Zhang[2], M. Bando[3], T. Ito[3], M.A. Deardorff[1,4], J.R. Li[1], D. Clark[1], M. Kaur[1], S. Tandy[1], T. Kondoh[5], E. Rappaport[6], N.B. Spinner[1,4], H. Vega[7], L.G. Jackson[8], K. Shirahige[3], I.D. Krantz[1,4].* 1) Division of Human Genetics, Abramson Research Institute, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 2) Center for Biomedical Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 3) Laboratory of Chromosome Structure and Function, Department of Biological Science, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, B-20, 4259, Nagatsuta, Midori-ku, Yokohama City, Kanagawa 226-8501, Japan; 4) The University of Pennsylvania School of Medicine, Philadelphia, PA 19104; 5) Division of Developmental Disability, Misakaenosono Mutsumi Developmental, Medical, and Welfare Center, Konagai-cho Maki 570-1, Isahaya, 859-0169, Japan; 6) NAPCORE, The Children's Hospital of Philadelphia, Philadelphia, PA 19104; 7) Instituto de Genética, Universidad Nacional de Colombia, Bogotá, Colombia; 8) Department of Obstetrics and Gynecology, Drexel University School of medicine, Philadelphia, PA 19104.

Cohesin regulates sister chromatid cohesion during the mitotic cell cycle with NIPBL facilitating its loading and unloading. In addition to this canonical role, cohesin has also been demonstrated to play a critical role in regulation of gene expression in nondividing cells. Heterozygous mutations in the cohesin regulator, *NIPBL*, or cohesin structural components *SMC1A*, and *SMC3*, result in the multisystem developmental disorder Cornelia de Lange Syndrome (CdLS). Genome-wide assessment of transcription in 16 mutant cell lines from severely affected CdLS probands as well as in 17 matched healthy controls has identified a unique profile of dysregulated gene expression that was validated in an additional 101 samples and correlates with phenotypic severity. This profile could serve as a diagnostic and classification tool. Cohesin binding analysis demonstrates a preference for intergenic regions suggesting a *cis*-regulatory function mimicking that of a boundary/insulator interacting protein. However, the binding sites are enriched within the promoter regions of the dysregulated genes and are significantly decreased in CdLS probands, indicating a potential alternative role of cohesin as a transcription factor. Genome wide DNA methylation assays on 63 CdLS probands with *NIPBL*, *SMC1*, or *SMC3* mutations have revealed significant DNA methylation difference at 375 CpG sites ($p<0.01$) between controls and severely affected individuals, DNA methylation levels of 81% (304) of these sites correlate with disease severity as mildly affected probands have less changes than severe probands. Cohesin preferentially binds to hypomethylated DNA and the binding is prohibited by DNA hypermethylation. However, no evidence has been found that gene mis-expression in CdLS is correlated to the levels of DNA methylation, indicating NIPBL and cohesin may regulate transcription and affect DNA methylation through different pathways. Additionally, skewed X inactivation identified among CdLS probands suggests a novel functional role of NIPBL and cohesin involved in the "choice" step during the X inactivation process.

**Identification of *RSK2* mutations in Polish patients with Coffin-Lowry syndrome.** *D. Jurkiewicz, E. Popowska, E. Ciara, D. Piekutowska-Abramczuk, M. Borucka-Mankiewicz, P. Kowalski, A. Tanska, M. Gajdulewicz, M. Kugaudo, K. Chrzanowska, M. Krajewska-Walasek.* Medical Genetics, Children's Memorial Health Institute, Warsaw, Poland.

Coffin-Lowry syndrome (CLS, MIM#303600) is a rare X-linked semidominant disorder. Affected males show severe mental retardation, facial dysmorphism, and various skeletal anomalies. In females the intensity of symptoms is variable. CLS is caused by mutations in the *RSK2* gene (*RPS6KA3*) located in Xp22.2. The gene encodes for a serine/threonine kinase (RSK2) acting in the Ras/MAPK signaling pathway involved in regulating wide range of cellular functions. Mutations in the *RSK2* gene are very heterogenous and lead to premature termination of translation and/or to loss of phosphotransferase activity of RSK2. In this study we present results of the *RSK2* gene mutation analysis in a group of Polish patients with clinically recognized Coffin-Lowry syndrome. Mutation screening of the entire *RSK2* gene was performed in sixteen patients. All twenty-two exons and the intron-exon bounaries of *RSK2* gene were amplified by PCR and subsequently analyzed by SSCP and sequencing technics. The molecular analysis revealed the presence of five different mutations in the *RSK2* gene, including two splice site (c.845+1G>A, c.1842-2A>T), one frameshift (c.896delT, p.Leu299TyrfsX13), one stop codon (c.1672C>T, p.Arg558X) and one missense (c.1610A>G, p.His537Arg) mutation. One splice site mutation was of maternal origin, remaining variants appeared *de novo*. Identified mutations are localized in the regions of the *RSK2* gene coding for N-terminal and C-terminal kinase domains and can be predicted to have a detrimental effect on the RSK2 function. The study was supported by Polish Ministry of Science Project 0624/P01/2006/31 (N40103131/0624).

## 478/W/Poster Board #136

**A Novel Form of Recessive Cerebellar Atrophy Maps To 5q31.1-q33.1.** *Z. Arlier[1,2], A.K. Ozturk[1,2], K. Bilguvar[1,2], K. Yasuno[1,2], L.E. Kolb[1,2], S. Giray[3], R.P. Lifton[4,5,6], M.W. State[2,4,7], M. Gunel[1,2,4,8].* 1) Neurosurgery, Yale University School of Medicine, New Haven, CT; 2) Program on Neurogenetics, Yale University School of Medicine, New Haven, CT; 3) Neurology, Baskent University Faculty of Medicine, Ankara, Turkey; 4) Genetics, Yale University School of Medicine, New Haven, CT; 5) Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT; 6) Internal Medicine, Yale University School of Medicine, New Haven, CT; 7) Child Study Center, Yale University School of Medicine, New Haven, CT; 8) Neurobiology, Yale University School of Medicine, New Haven, CT.

In the absence of associated abnormalities, structural defects of the cerebellum can be non-specific. While certain conditions such as Dandy-Walker syndrome may be readily evident, the majority of cases of structural cerebellar abnormalities pose diagnostic challenges. Broadly, these abnormalities can be divided into those that are unilateral and bilateral. Bilateral abnormalities can further be subdivided into those that are midline (vermian), involve the pons in addition to the cerebellum (pontocerebellar), or mostly affect the cerebellar hemispheres. Genetic causes of cerebellar atrophy tend to be progressive and symmetric. A number of metabolic and genetic causes have now been identified that lead to cerebellar atrophy, and distinguishing between these syndromes clinically can be quite challenging, and if there is an obvious genetic mode of inheritance, then molecular biology and linkage analysis may lead to the most robust results about the etiology of cerebellar atrophy. Here, we present a consanguineous family, a first cousin once-removed union, with three affected and six healthy offspring. All affected demonstrate bilateral cerebellar atrophy in cranial magnetic resonance imaging. They have mental retardation and their gait is ataxic. We performed genome-wide homozygosity mapping and parametric linkage analysis using Affymetrix NSP 250K SNP genotyping chips. Affected only analysis revealed three loci with theoretical maximum LOD score of 2.65. Inclusion of unaffected sibling further refined the linkage, and only one locus on chromosome 5q31.1-q33.1 remained with a LOD score of 3.45. This region spans 14.5 million base pairs and contains 220 genes. There are two entries in OMIM associated with cerebellar ataxia from this genetic locus. Spinocerebellar ataxia 12, which is caused by mutations in PPP2R2B, is inherited in autosomal dominant fashion. Marinesco-Sjorgen Syndrome, a recessive syndrome caused by SIL1 mutations, is characterized by cerebellar ataxia, congenital cataracts, retarded somatic and mental maturation, hypergonadotropic hypogonadism and hypotonia. Although our patients lack the characteristic manifestations of this syndrome, we re-sequenced all the exons, and exon-intron boundaries of SIL1. No variants other than common SNPs were identified. We believe that this family represents a novel recessive form of cerebellar ataxia. Mutation screening is currently underway.

## 479/W/Poster Board #137

**Cerebellar dysfunction and glutamatergic deficits in murine models of spinocerebellar ataxia type 5 (SCA5).** *K.R. Armbrust[1,2], X. Wang[3], T. Obu[1,2], T.J. Ebner[3], L.P.W. Ranum[1,2].* 1) Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN; 2) Institute of Human Genetics, University of Minnesota, Minneapolis, MN; 3) Neuroscience, University of Minnesota, Minneapolis, MN.

Spinocerebellar ataxia type 5 (SCA5) is a slowly progressive neurodegenerative disease of the cerebellum caused by mutations in the *spectrin, beta, non-erythrocytic 2* gene, which encodes the protein β-III spectrin. Here we report the development and characterization of the first transgenic mammalian models of SCA5 which express mutant β-III spectrin in cerebellar Purkinje cells. Behavioral studies with a 3xFLAG-tagged SCA5 murine model and a second conditional murine model that drives expression of untagged β-III spectrin show that overexpressing mutant β-III spectrin in cerebellar Purkinje cells causes cerebellar dysfunction. Histologic analysis of the 3xFLAG-tagged murine model shows that the SCA5 mutation alters the Purkinje cell distribution of the mutant β-III spectrin protein itself. Further studies with the conditional tet-regulated mice show that overexpression of untagged mutant β-III spectrin alters the localization of the glutamate transporter EAAT4 and the metabotropic glutamate receptor mGluR1α. Additionally, *in vivo* optical imaging of flavoprotein autofluorescence shows that the SCA5 mice have a concomitant deficit in mGluR1-mediated long term potentiation (LTP). These findings suggest that abnormalities in perisynaptic glutamatergic transmission contribute to SCA5 pathogenesis.

## 480/W/Poster Board #138

**Spinocerebellar ataxia type 12 identified in two Italian families.** *A. Brussino[1], C. Graziano[2], D. Giobbe[3], E. Dragone[1], M. Ferrone[1], R. Lodi[4], C. Tonon[4], A.S. Gabellini[5], R. Rinaldi[6], S. Miccoli[2], E. Grosso[1], M.C. Bellati[1], L. Orsi[7], N. Migone[1], A. Brusco[1].* 1) Department of Genetics, Biology and Biochemistry, University of Torino, and S.C.D.U. Medical Genetics, A.O.U. San Giovanni Battista, Torino Italy; 2) U.O. Medical Gentics, S.Orsola-Malpighi Hospital, and University of Bologna, Italy; 3) Neurology III, A.O.U. San Giovanni Battista, and Department of Neurosciences, University of Torino, Italy; 4) Dipartimento di Medicina Interna, dell'Invecchiamento,e delle Malattie Nefrologiche, University of Bologna, Italy; 5) U.O. Neurology, Ospedale Maggiore, Bologna, Italy; 6) Neurologic Unit, Policlinico S. Orsola-Malpighi, AOSP di Bologna, Italy; 7) Neurology I, A.O.U. San Giovanni Battista, and Department of Neurosciences, University of Torino, Italy.

SCA12 is an autosomal dominant cerebellar ataxia (ADCA) with onset in the 4th decade, clinically characterized by the association of action tremor of arms and heads, mild ataxia, dysmetria and hyperreflexia. Bradikinesia, and sensory/motor neuropathy are also present, and older subjects may develop cognitive decline. The genetic mutation underlying SCA12 is a ≥51 CAG expansion in the 5' region of the brain-specific regulatory subunit B of the protein phosphatase 2A gene (*PPP2R2B*). SCA12 is very rare, and no patient has been identified in Europe, except for a single ethnic group in India where it accounts for up to 16% of ADCAs probably due to a founder effect. As part of our diagnostic routine, we screened 181 ataxic patients for expansion in the SCA12 gene between 2003 and 2008. The survey comprised cases with autosomal dominant, probably recessive and unknown transmission. We found two carriers of an expanded SCA12 allele (57 CAG). One patient belonged to a family with a clear autosomal dominant transmission; the other was apparently sporadic. Clinical and genetic analyses in the two families revealed the presence of a symptomatic subject carrying the expansion in one and two asymptomatic carriers, aged 68 and 37 yrs, in the other. The two families originated from the Ferrara province, in north-eastern Italy: haplotype reconstruction showed that both shared a common haplotype of four microsatellites (one of which was internal to the *PPP2R2B* gene) and four intragenic SNPs, different from that described in Indian SCA12 patients. In the three affected patients, the disease onset at 53±7,6 yrs (range 45-60) with either action tremor of head and hands, or fine hands movement impairment, or gait instability. Cognitive impairment and psychiatric disorders were not reported. MRI, performed in symptomatic patients, showed mild cortical atrophy in two, associated with mild cerebellar atrophy in the third. These data indicate that, although rare, SCA12 can be found in Italy: considering the results of a previous survey of 225 ataxic patients, performed by our group (Brusco et al., 2004), SCA12 may count for up to 0.5% (2/406) of Italian SCAs. The age at onset and variability of symptoms are in agreement with those already described. Because of the late age at onset and slow progression, SCA12 subjects may be classified as sporadic ataxia: this suggests that SCA12 testing, due to its simplicity, should be routinely extended both to sporadic and familial cases.

## 481/W/Poster Board #139

**Spinocerebellar ataxia type 15: clinical and molecular-genetic features of two Italian families.** *E. Di Gregorio[1], G. Vaula[2], M. Godani[3], L. Orsi[4], S. Jensen[5], E. Salmon[6], G. Ferrari[7], S. Squadrone[8], M.C. Abete[8], C. Cagnoli[1], A. Brussino[1], A. Brusco[1].* 1) Gen Biol & Biochem, Univ Torino, and SCDU Medical Genetics, San Giovanni Battista Hospital, Torino, Italy; 2) Neurology II, A.O.U. San Giovanni Battista, and Department of Neurosciences, University of Torino, Italy; 3) Neurological Department, S. Andrea Hospital, La Spezia, Italy; 4) Neurology I, A.O.U. San Giovanni Battista, and Department of Neurosciences, University of Torino, Italy; 5) Neurological Department, Civic Hospital, Carrara, Italy; 6) Department of Neurology and Cyclotron Research Centre, University of Liege, Liege, Belgium; 7) UO Complessa di Neurologia, Ospedale di Ivrea, Italy; 8) C.Re.A.A., Istituto Zooprofilattico Sperimentale del Piemonte, Liguria e Valle d'Aosta, Torino, Italy.

SCA15 is a pure cerebellar ataxia characterized by onset between 10 and 50 yrs, very slowly progressive gait ataxia, dysarthria, titubation, postural or action tremor of hand, neck and trunk, mild hyperreflexia, gaze-evoked nystagmus, and impaired vestibulo-ocular reflex. MRI shows a marked cerebellar atrophy, particularly in the vermis, whereas the brainstem is not involved. Type 1 inositol 1,4,5-triphosphate receptor (*ITPR1*) is reported as the SCA15 causing gene. At present, six families are described worldwide: five carry a partial deletion of *ITPR1* and one a missense mutation. We examined a four generation Italian family segregating an autosomal dominant form of cerebellar ataxia, and found a positive linkage at the SCA15 locus. In this family and in 43 familial SCA index cases, we performed a gene-dosage sensitive quantitative PCR (qPCR) to search for *ITPR1* gene deletion, using a probe mapping in *ITPR1* exon 3. We identified two families with a deletion that was further characterized by a custom array-CGH spanning 3 Mb centred on the *ITPR1* gene. In one family, the deletion extended over ~238 Kb including *ITPR1* exons 1-39, while in the second it spanned ~447 Kb and comprised *SUMF1* exons 1-7 and *ITPR1* exons 1-59. In these two SCA15 families, clinical data were available for 10 patients and brain MRI for six. The disease onset between 25 and 72 yrs (50 ± 17 yrs, mean ± SD); the first symptoms were unsteadiness, gait ataxia and dysarthria, variably associated with nystagmus, hyperreflexia, dysmetria and dysphagia. In all affected subjects MRI showed cerebellar vermis atrophy with a mild involvement of the hemispheres in some individuals. Overall, the phenotype mainly overlapped known SCA15 cases. However, our data show that this disease may have a greater variability in the age at onset (25-72 yrs) than described and that we also noticed facial dyskinesias in four cases, never reported in SCA15 patients. The variable disease expression mimicked anticipation in one family. Our results further support *ITPR1* gene as causative of SCA15, and describe two novel families in Italy. Clinical signs of pure cerebellar ataxia with slow progression, and MRI showing predominant vermis atrophy, are suggestive of SCA15. In these cases, the search for *ITPR1* deletions by qPCR is mandatory and simple.

## 482/W/Poster Board #140

**Molecular epidemiology of spinocerebellar ataxias in Japanese population.** *Y. Ichikawa, S. Tsuji, J. Goto.* Dept Neurology, Univ Tokyo, Tokyo, Japan.

**Background:** Spinocerebellar ataxias (SCAs) are heterogeneous neurodegenerative diseases characterized by progressive ataxia occasionally accompanied with other features including pyramidal and extrapyramidal signs. At least 26 gene loci associated for autosomal dominant cerebellar atxias (ADCAs) have been mapped. The disease genes have been identified in 15 SCA subtypes : SCA1, 2, Mahdado-Joseph disease (MJD)/SCA3, SCA5-8, SCA10-15, 17, 27 and dentarorubral-pallidoluysian atrophy (DRPLA). A single nucleotide substitution (-16C>T) in the 5'UTR of *PLEKHG4* was identified as the strongly associated with the families linked to chromosome 16q22.1 (16qADCA). **Objectives:** To reveal the frequencies of SCAs in Japanese population. **Patients and Methods:** The subjects include 480 Japanese patients with SCAs during the period 1993 and 2008 on consecutive referral basis for molecular diagnosis. Three hundred and forty subjects from 303 Japanese families had family history, 93 patients were diagnosed as sporadic ataxia, and 47 patient's family history were unclear because of insufficient information. Among the 303 families with hereditary ataxia, 3 families with consanguinity and only siblings in one generation were affected, consistent with an autosomal recessive pattern of inheritance. The gene loci of SCA1-8, MJD/SCA3, SCA12, SCA17 and DRPLA were examined by the fragment analyses of the PCR products containing triplet repeat sequences. Detection of the -16C>T substitution in *PLEKHG4* was accomplished by DHPLC analysis and direct sequencing method. **Results:** Among 303 families and 47 patients with insufficient family history, MJD was the most common inherited ataxias in Japanese population (91 families). The second common was SCA6 (49 families), and followed by DRPLA (48 families), 16qADCA (38 families), SCA1 (17 families), SCA2(10 families), SCA17(7 families) and SCA8(5 families). We found the first Japanese family with SCA12 mutation. SCA7 mutation has not been detected in our cohort. Among 93 patients diagnosed as sporadic ataxia, 17 patients s have expanded triplet repeats. Of these, the SCA6 mutation was the most frequently detected (9 cases, 52.9%). **Conclusion:** The most frequent ADCA in Japanese population was MJD, subsequently SCA6 was ranked at the second. The expanded triplet repeats of ADCAs were detected in sporadic cases. The causative genes of around 17 % of our 303 hereditary ataxias remained to be identified.

**SPG11 - clinical heterogeneity and genetic data in a large international cohort.** *A. Rolfs[1,2], U. Goelnitz[2], P. Bauer[3], K. Boycott[4], A. Dionne[5], N. Dupres[5], J. Girouard[6], P. Huan-Kee[7], W. Kristofertisch[8], L. Krogh[9], B. Lindvall[10], W. Meschino[11], K. Metcalfe[12], I. Meijer[5], I. Navarro Vera[13], A. Summers*[14], L. Velsher[14], M. Wittstock[15].* 1) Albrecht-Kossel-Institute, Univ Rostock, Rostock MV, Germany; 2) Centogene GmbH, Rostock, Germany; 3) Department of Human Genetics, University of Tübingen, Germany; 4) Children's Hospital of Eastern Ontario, Dept of Genetics, Ottawa, ON, Canada; 5) Dept of Neurological Science, Faculty of Medicine, Laval University, CHA-Enfant Jesus, Quebec, Canada; 6) CHA, Hopital Enfant-Jesus, Quebec, QC, Canada; 7) Singapore Baby & Child Clinic, Mount Elizabeth Medical Centre, Singapore; 8) Sozialmedizinisches Zentrum Ost, Donauspital, Wien, Austria; 9) Odense University Hospital, Dept of Clinical Genetics, Denmark; 10) Dept of Neurology, Örebro, Sweden; 11) North York Hospital, Genetics Program, Toronto, Canada; 12) Clincal Genetics, St. Mary's Hospital, Manchester, UK; 13) Centro de Analisis Geneticos, c/Santa Teresa 45, Zaragoza, Spain; 14) North York General Hospital, Toronto, Canada; 15) Dept of Neurology, University of Rostock, Germany.

Spatacsin mutations cause an autosomal - recessive (AR) form of hereditary spastic paraplegia (HSP), SPG type 11 (SPG11). Typically SPG11 is been diagnosed in cases with slight ataxia, thin corpus callosum (TCC), mental impairment, pyramidal signs, increased deep tendon reflexes and only rarely neuropathy. We have analysed in a large cohort of patients with HSP the clinical heterogeneity and the frequency of clinical symptoms. In a cohort of 251 patients with AR-HSP we analysed SPG11 gene by sequencing the gene including the exon-intron boundaries and deletion screening by MLPA. We have been able to detect 82 mutated alleles in 44 patients with 55 different mutations. In 7 cases we found homozygous mutations and in 6 patients we have not been able to detect a second mutation. For 36 patients we got detailed clinical data including MRI results (35 cases). Age at onset ranged from 8 to 38 years with a mean of 22.0+/-9.6. Onset was characterized by gait disorders (21/36, 58%), polyneuropathy (7/36, 19%), dementia, dystonia, tremor and dysarthria (each in three patients). Interestingly only in 15/34 (44%) a thin Corpus callosum (TCC) has been demonstrable. This low frequency of TCC is in contrast to other reports and raises the question of the specificity of TCC for SPG11. Larger deletions seem to correlate with a more severe phenotype including earlier manifestation. Our data demonstrate a great phenotypic variability and a high percentage of large deletions within the SPG11 gene.

**The genetic basis of EAST (Epilepsy, Ataxia, Sensorineural Deafness, Tubulopathy) syndrome.** *H.C. Stanescu[1], S. Feather[2], D. Bockenhauer[1], A.A. Zdebik[1], G. Landoure[1], O. Al Masri[3], Y. Anikster[4], E. Klootwijk[1], M. Arcos-Burgos[5], A. Dobbie[2], W.A. Gahl[6], R. Warth[7], E. Sheridan[2], R. Kleta[1].* 1) University College London / GOSH, London, United Kingdom; 2) Leeds & Bradford Teaching Hospitals / University of Leeds, Leeds, UK; 3) Sheikh Khalifa Medical City, Abu Dhabi, UAE; 4) Sheba Medical Center, Tel-Hashomer, Israel; 5) University of Miami, Miami, FL, USA; 6) National Institutes of Health, Bethesda, MD, USA; 7) University of Regensburg, Regensburg, Germany.

Five patients from two consanguineous families presented with epilepsy beginning in infancy, severe ataxia, moderate sensorineural deafness, and a renal salt losing tubulopathy with normotensive hypokalemic metabolic alkalosis. We investigated the genetic basis of this hitherto unknown autosomal recessive disease, which we call EAST syndrome. Whole genome linkage analysis was performed in an extended inbred family with four affected children. Newly identified mutations in a potassium channel gene were evaluated using a heterologous expression system. Protein expression and function were further investigated in genetically modified mice. Linkage analysis identified a single relevant locus on chromosome 1q23.2 with a LOD score of 4.98. This region contained KCNJ10, which encodes a potassium channel expressed in brain, inner ear, and the kidney. Sequencing of this candidate gene revealed homozygous missense mutations in affected persons in both families. These mutations, when expressed heterologously in Xenopus oocytes, significantly and specifically decreased potassium currents. Mice with Kcnj10 deletions became dehydrated and exhibited definitive evidence of renal salt wasting. In conclusion, mutations in KCNJ10 cause this specific disorder consisting of epilepsy, ataxia, sensorineural deafness, and tubulopathy. Our findings indicate a major role for KCNJ10 in hearing, brain activity, renal salt handling and, hence, possibly also in blood pressure maintenance and its regulation.

## 485/W/Poster Board #143

**SCA8 Generates from homozygous mothers and coexists with several SCA/FRDA gene expansions.** *V. Volpini[1], H.S. Nicolás[1], J. Corral[1], L. De Jorge[1], J. Infante[2], O. Combarros[2], J. Berciano[2], M. Calopa[3], A. Matilla[4], D. Genís[5].* 1) Molecular Genetics Diagnosis, IDIBELL, L'Hospitalet de LLobregat, Barcelona, Spain; 2) Dep. of Neurology, Hosp. Univ. Josep Trueta, Girona, Spain.

Spinocerebellar ataxias (SCA) are a clinically and genetically heterogeneous group of neurodegenerative disorders in which several genes have been cloned: SCAs1-3, SCAs6-7, SCA12 and SCA17; mainly sharing a CAG repeat expansion mutation which generally encodes a polyglutamine tract. In SCA8 the mutation is a CTG/CAG repeat. In our casuistic, over 162 unrelated index cases 6.17% were SCA1; 25.93% SCA2; 33.95% SCA3; 7.41% SCA6; 6.17% SCA7; 15.43% SCA8; 1.85% SCA17; and 3.09% DRPLA. In 25 SCA8 index cases the allele range goes from 85 to 726 repeats (143.27% ±67.47%; Pearson Coef. = 47.09%). Maternal transmissions elongate the CTG combined sequence from +3 to +13 repeats. Paternal transmissions contract from -1 to -17 repeats. We have found several giant SCA8 expansions in two families, with CTG ranging from 375 to 1,126 (N= 12) repeats. All 12 adult carriers remain unaffected until now. All of them have inherited the giant SCA8 CTG expansions from homozygous SCA8 mothers that have genotypes with alleles of moderate size. Studying 90 individuals from general population the distribution of SCA8 results in two major groups: a) 15 to 34 CTGs, with frequency 98%; and b) 77 to 86 CTGs, with frequency 2%. We have found three pedigrees in which SCA8 expansions coexist respectively with SCA2, SCA3 and Friedreich's ataxia (FRDA) in the respective index cases. In all of three families the expansions segregates independently in the rest of relatives. Other family shows SCA8 and SCA1 expansions in several members, but none joint both. The same occurs in a pedigree with FRDA and SCA8 and in other pedigree with SCA6 and SCA8. Our very preliminary data suggest that the familial coexistences could be due to high population prevalence of no penetrant SCA8 alleles. More studies will be necessary to conclude other putative cause-effect relation, if exist, involving SCA8 expansions in the origin of other triplet elongations from a founder common ancestry.

## 486/W/Poster Board #144

**To Screen or not to Screen: *GJB2* in American Minorities.** *J. Samanich[1], J. Shan[2], J. Chobot-Rodd[3], R. Castellanos[2], M. Babcock[2], A. Shanske[1], S. Parikh[4], B. Morrow[2].* 1) Center for Congenital Disorders, Children's Hospital at Montefiore, Bronx, NY, USA; 2) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY, USA; 3) Children's Evaluation and Rehabilitation Center, Albert Einstein College of Medicine, Bronx, NY, USA; 4) Department of Otolaryngology, Montefiore Medical Center, Bronx, NY, USA.

In many ethnic populations, up to 50% of persons with familial autosomal recessive nonsyndromic sensorineural hearing impairment (NSHI) have biallelic mutations in *GJB2*. We reported the paucity of mutations in *GJB2* and deletions in *GJB6* in Caribbean Hispanic and African admixture populations in 2007. We have now collected 102 additional subjects with NSHI, for a total of 209. Of the 209, 36% are inherited and the rest have sporadic occurrence. The hearing impairment ranged from unilateral mild to bilateral profound, with the majority in the latter category. Combining results we sequenced the single coding exon of the *GJB2* gene in 209 subjects, PCR screening for del(GJB6-D13S1830) in 32 NSHI patients with a heterozygous variation in *GJB2*, and Multiplex Ligation-Dependent Probe Amplification (MLPA) testing of *GJB2*, *GJB3* and *GJB6* exon deletions or amplifications (P163- GJB-WFS1 kit) in 70 subjects. Seven unrelated individuals had biallelic *GJB2* mutations of 209 total in both studies representing 3% of our population. Of 418 chromosomes examined, variations of *GJB2* sequence found and (number of chromosomes) were: 35delG (mutation; 10), 94C>T (mutation, R32C; 3), 139G>T (mutation, E47X; 3), 167delT (mutation; 3), 269T>C (mutation, L90P; 1), 427C>T (mutation, R143W; 1), 101T>C (mutation vs. polymorphism; M34T; 1), 109G>A (mutation vs. polymorphism; V37I; 2), -15C>T (polymorphism; 3), 79G>A (polymorphism, V27I; 10), 380G>A (polymorphism, R127H; 8), 457G>A (polymorphism, V153I, 2), 670A>C (indeterminate, K224Q; 2), -3331C>G (novel; 1), -6T>A (novel; 3), 503A>G (novel, K168R; 5), and 684C>A (novel; 1). Of 158 probands of Hispanic or African descent, five (3%) had biallelic pathogenic mutations, four had monoallelic mutations and 149 had no disease-causing mutations in *GJB2*. At the same time, no major deletions were identified either by PCR screening (del [GJB6-D13S1830]) or by MLPA analysis (*GJB2* or *GJB6*). These results re-confirmed our previous report that *GJB2* is not the major contributor to the genetic basis of NSHI for the Bronx minority admixture populations.

## 487/W/Poster Board #145

**Unique spectrum of MYO15A mutations associated with autosomal recessive deafness in Turkey.** *M. Tekin[1,2], F.B. Cengiz[2], D. Duman[2], A. Sirmaci[1,2], S. Erbek[3], H. Ozturkmen-Akay[4], H. Ozdag[5].* 1) Dept Human Genetics, Univ Miami, Miami, FL; 2) Div Pediatric Genetics, Ankara Univ, Ankara, Turkey; 3) Dept Otorhinolaryngology, Baskent Univ, Ankara, Turkey; 4) Dept Radiology, Dicle Univ, Diyarbakir, Turkey; 5) Biotechnology Institute, Ankara Univ, Ankara, Turkey.

Biallelic mutations in the MYO15A gene at DFNB3 locus have been shown to cause nonsyndromic deafness. In order to find causative mutations, we first screened 104 unrelated multiplex Turkish families with nonsyndromic deafness using homozygosity mapping with Affymetrix microarrays or microsatellite markers. Parents were consanguineous and GJB2 mutations were negative in each family. Screening of linked families for mutations in 66 exons and flanking intronic regions of the MYO15A gene using SSCP and DNA sequencing showed five previously unreported mutations in eight families including c.5807_5813delCCCGTGG (p.Ala1936fs) (3 families), c.10002_10003dupCCGGCCC (p.Ser3335fs) (2 families), c.867C>G (p.Tyr289Ter), c.4198G>A (p.Val1400Met), and c.4439T>C (p.Ser1481Pro). Each homozygous mutation cosegregated with deafness and was absent in Turkish hearing controls. Recurrent mutations were associated with conserved haplotypes in unrelated families, suggesting founder effects. Biallelic GJB2 mutations have been reported to present in 18.9% of comparable families in Turkey. In conclusion, we estimate the prevalence of homozygous MYO15A mutations in autosomal recessive nonsyndromic deafness in Turkey as 0.098 (95% CI is 0.041-0.155), which demonstrates their significant contribution. This study was supported by TUBITAK (105S464).

## 488/W/Poster Board #146

**Large international cohort study in CMT - frequency of subtypes and clinical phenotype.** *U. Goelnitz[1], C. Tanislav[2], S. Baker[3], K. Lagerstedt[4], Y. Mehraein[5], M. Wittstock[6], V. Mering[7], H. Kingston[8], L. Krogh[9], T. Boettcher[10], P. Bauer[11], A. Charcot-Marie-Tooth (CMT) disease or hereditary motor and sensory neuropathy (HMSN) is caused by mutations in several genes expressed in myelinating Schwann cells and the axons they ensheathe. CMT include a wide range of pathological disorders characterized by damage of peripheral nerves. So far, there are five different types of CMT (1, 2, 3, 4, X) with more than 35 subtypes, associated with more than 40 genes. The most frequent types are CMT1, CMT2 and CMTX. CMT1A is associated with tandem duplication of a 1.5 Mb DNA fragment on chromosome 17p11.2-p12 that codifies the peripheral myelin protein PMP22. A straight on genetic analysis of the clinically heterogenous cases is hampered by the large number of genes being involved in the pathophysiology. The products of genes associated with CMT phenotypes are important for the neuronal structure maintenance, axonal transport, nerve signal transduction and functions related to the cellular integrity. Here we describe a large international cohort of 1.246 patients with positive family anamnesis for polyneuropathy and where genetic material has been send to us for detailed genetic analysis. In 478 patients (38,4%) we have been able to demonstrate the genetic basis of the polyneuropathy by complete sequencing of the causative genes: CMT1 (including HNPP): 21,9%; CMT2: 12,8%; CMT4: 3.6%. In the CMT1 group pmp22 and MPZ gene cause nearly 60% of all CMT1 cases, followed by CMT1c (LITAF, 25 pts.); CMT1d (EGRS2, 12 pts.) and CMT1f (NEFL, 8 pts.). In CMT2 group we were able to detect the following frequencies: CMT2A2 (MFN2, 42 pts.; 26.3%); CMT2d (GARS, 39 pts.); CMT2k (GDAP1, 21 pts.) and CMT2A1 (KIF1b, 19 pts.); CMT2b, CMT2b1, CMT2e, CMT2f and CMT2i have been detected in less than 5% of all CMT2 cases. CMT4 cases reveal the largest clinical heterogeneity: CMT4a (GDAP1) describes 40,7% of all CMT4 cases and 2.3% of all genetically clarified cases. This is followed by CMT4c1 (LMNA, 6 pts.), CMT4b2 (SBF2, 4 pts.), and CMT4b1, CMT4c and CMT4c4 with less than 4 cases. The results of detailed molecular genetic investigations have impact on the appropriate diagnosis, genetic counselling and possible new therapeutic options for CMT patients.

## 489/W/Poster Board #147

**A comprehensive diagnostic system for hereditary spastic paraplegia employing resequencing microarray, Sanger sequencing and comparative genomic hybridization array allows efficient identification of various types of mutations in the causative genes.** *H. Ishiura, Y. Takahashi, J. Goto, S. Tsuji.* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Objective] To establish a high throughput molecular diagnosis system for hereditary spastic paraplegia (HSP), where various kinds of mutations including point mutations, insertion/deletions and copy number variations have been described. [Background] HSP is a genetically heterogeneous neurodegenerative disorder which is clinically characterized by progressive lower limb spasticity and pyramidal weakness. Up to present, more than 40 (SPGs 1-45) genetic loci and 19 causative genes have been identified. To establish genotype-phenotype correlation and to understand pathophysiology, comprehensive genetic analysis is demanded. [Method] We established a high-throughput DNA microarray resequencing system (Affymetrix) for analyzing complete nucleotide sequences of all the coding exons and splicing junctions of 13 causative genes (*L1CAM*, *PLP1*, *atlastin*, *spastin*, *NIPA1*, *paraplegin*, *KIAA0196*, *KIF5A*, *HSP60*, *BSCL2*, *spartin*, *maspardin*, and *REEP1*). To detect small insertion/deletion mutations frequently found in *spastin* and *REEP1*, Sanger method was employed in these 2 genes. For patients with thin corpus callosum and cognitive dysfunction, *SPG11* was analyzed with Sanger method because SPG11 is frequent in such patients. In addition, to detect large rearrangements, we designed an oligonucleotide CGH array (Agilent, 1 probe / 200bp in average) in which sequences of 16 causative genes (*CYP7B1*, *SPG11*, and *ZFYVE27* in addition to 13 genes above) were tiled. The study enrolled 128 HSP patients: 49 patients with autosomal dominant inheritance (ADHSP), 11 autosomal recessive patients, 6 familial patients with undetermined mode of inheritance, and 62 apparently sporadic patients. [Results] In 49 ADHSP patients, we detected 27 *spastin*, 1 *atlastin*, 2 *KIAA0196*, and 2 *REEP1* mutations, in whom 65% (32/49) were diagnosed in total. *Spastin* mutations were found in familial (1/6) and sporadic (4/62) patients. In addition, 4 SPG11 were found in 12 patients with thin corpus callosum and cognitive dysfunction. Collectively, 33% (42/128) of patients were given diagnosis with various kinds of mutations; 22 point mutations, 14 small insertion/deletions, and 8 large insertion/deletions. [Conclusion] The combination of three methods found nucleotide substitutions, small insertion/deletion mutations, and large rearrangements effectively. The system is suitable for the comprehensive mutational analysis of HSP.

## 490/W/Poster Board #148

**Adult-onset spastic paraplegia type 2 with a novel mutation in the exon 7 of *PLP1*: An autopsy case.** *A. Iwaki[1], S.O. Suzuki[2], K. Arakawa[3], K. Furuya[3], N. Fujii[3], Y. Fukumaki[1], T. Iwaki[2].* 1) Div. Hum. Mole. Genet., Res. Ctr. Genet. Info., Med. Inst. Bioreg., Kyushu Univ., Fukuoka, Japan; 2) Dep. Neuropath., Neurol. Inst., Grad. School of Med. Sci., Kyushu Univ., Fukuoka, Japan; 3) Dep. Neurol., Neuro-Muscular Cent., Omuta Hosp., Fukuoka, Japan.

Spastic paraplegia type 2 (SPG2) and Pelizaeus-Merzbacher disease (PMD) are allelic disorders caused by mutations in the X-linked gene for myelin proteolipid protein 1 (*PLP1*). Different point mutations of *PLP1* lead to a variety of clinical phenotypes from mild form (SPG2) to the most severe dysmyelinating form (connatal PMD). The onset of SPG2 is usually in the first decade of life, and adult-onset is rare. We experienced an autopsy case of adult-onset spastic paraplegia. The patient was a 66-year-old male whose elder brother had died of a similar disease. At the age of 33, he noticed difficulty in walking. He gradually became abasic in 7 years. He also developed progressive dementia and eventually became bed-ridden by 5 years before death. He died of pneumonia. At autopsy, the brain weight was 1275g. Diffuse, moderate atrophy of the cerebrum with the dilated ventricular system and thin corpus callosum was noted. Histopathologically, the central nervous system showed widespread myelin paler in the white matter. By contrast, the gray matter and the peripheral nerves were well preserved. Direct sequencing of the seven exons of the *PLP1* gene revealed a point mutation, Tyr262Cys, located at the C-terminal end of PLP1, which is composed of 276 amino acids. The clinical course suggests that this novel mutation may affect maintenance of myelin rather than maturation of oligodendrocytes.

## 491/W/Poster Board #149

**Loci for human cortical malformations revealed by copy number analysis on high-density SNP array.** *G.M. Mancini[1], R. Schot[1], B.C. Dumee[2], M.C.Y. de Wit[3], I.F.M. de Coo[3], M.H. Lequin[4], W.B. Dobyns[5], P.J. van der Spek[2], J.M.H. Verkerk[2].* 1) Clinical Genetics, Erasmus Univ MC, Rotterdam, Netherlands; 2) Bioinformatics, Erasmus Univ MC, Rotterdam, Netherlands; 3) Child neurology, Erasmus Univ MC, Rotterdam, Netherlands; 4) Radiology, Erasmus Univ MC, Rotterdam, Netherlands; 5) Human Genetics, Univ Chicago, Illinois.

Approximately 220 patients with malformations of cortical brain development (MCD), like microcephaly with simplified gyration, lissencephaly, heterotopia, (non-TSC) focal dysplasia and polymicrogyria, were recruited in 15 years at our academic hospital. An etiological diagnosis was possible in 40 percent of the cases after systematic neuro-radiologic, clinical genetic, routine cytogenetic/FISH and molecular genetic tests (de Wit et al., Archives of Neurology, 2008). In DNA of the remaining circa 140 patients and parents, if available, analysis of copy number variations (CNV) was performed on Affymetrix 250K SNP arrays (CNAG program). Miller-Dieker microdeletions were excluded a priori. CNVs were considered pathogenic if 1) not reported in the Toronto database (DGV) as polymorphic, 2) confirmed by independent techniques (FISH, Q-PCR), 3) included known microdeletion/duplication syndromes or 4) were de novo and included (candidate) genes, and 5) parents were available for testing. We identified pathogenic changes in about 13 percent of the patient samples, mostly from the polymicrogyria and heterotopia group. Additionally, an interesting group was represented by about 10 samples regarding unclassified variants (UVs) and containing 1) inherited homozygous deletions/duplications from heterozygous parents, 2) inherited homozygous small intron deletions in candidate genes, 3) deletions/duplications reported for rare and different clinical phenotypes, 4) de novo deletions in “gene desert” areas linked to disease phenotype, 5) microdeletions smaller than 1Mb including miR loci. Each of these concerned unique patients and MCD phenotypes. Most microarray data concern patients with MR/MCA without brain imaging data. Exchanging results and experience from array data with rare UVs, in properly classifed cohorts, will greatly speed up the process of identifying new genes and disease mechanisms for cortical malformations.

## 492/W/Poster Board #150

**The spectrum of collagen IV alpha-1 and -2 mutations in humans.** *F.W. Verheijen[1], E. Verbeek[1], M.W. Wessels[1], D.J. Licht[2], P. Govaert[3], R. Hintzen[4], M.H. Lequin[5], J. Dudink[3,5], I.F.M. de Coo[4], M. Meuwissen[1], G.M. Mancini[1].* 1) Clinical Genetics, Erasmus Univ MC, Rotterdam, Netherlands; 2) Division of neurology, Children’s Hospital, Philadelphia, Pennsylvania; 3) Neonatology, Erasmus Univ MC, Rotterdam, Netherlands; 4) Neurology, Erasmus Univ MC, Rotterdam, Netherlands; 5) Radiology, Erasmus Univ MC, Rotterdam, Netherlands.

Collagen IV abnormalities have been related to a variety of renal problems and stroke-like events in animal models. Collagen IV is the main non-fibrillary collagen forming a mesh network around vascular endothelia and contributing to the normal resistance of the vascular wall. Six genes (three couples, each couple in tandem on the same chromosome) encode for collagen alpha-IV chains. Col4a1 and col4a2 are mapped to the synthenic area of human chromosome13q34, sharing the same promoter. Procollagen-4alpha1 and -4alpha2 molecules together contribute to the assembly of the collagen IV triple helix, both together with a 2:1 ratio, or associated with procollagen-4alpha-5 chains. Mutations in both col4a1 and col4a2 essentially induce prenatal bleeding in brain and eyes of mouse mutants, documented by weakness and abnormal structure of the extracellular basement membrane of vascular endothelia. In humans, mutations in COL4A1 have been associated with the occurrence of several phenotypes including familial porencephaly, prenatal intraparenchymal hemorrhage, recurrent intraparenchymal stroke, cataract, retinal microbleeds, or with hereditary angiopathy, nephropathy, aneurysms and muscle cramps (HANAC syndrome). Although in mice similar phenotypes have been described for both col4a1 and col4a2 mutations, until now no COL4A2 mutations have been reported. We previously reported pathogenic COL4A1 mutations in four families with intraparenchymal cerebral stroke ranging from documented prenatal bleeding to adult onset stroke. We now report new variants of COL4A1 mutation phenotypes with severe brain and ocular abnormalities and, to our knowledge, for the first time human familial COL4A2 mutations.

## 493/W/Poster Board #151

**Spontaneously active glycine receptors: a novel pathogenic mechanism in hyperekplexia.** *S. Chung[1], J-F. Vanbellinghen[2], J. Mullins[1], D.F. Gilbert[3], J. Hantke[4], R.J. Harvey[4], J.W. Lynch[3], M.I. Rees[1,5].* 1) Dept Neuroscience, Univ Wales, Swansea, Swansea, United Kingdom; 2) Laboratoire de Génétique Moléculaire, University of Liège, Liège, Belgium; 3) Queensland Brain Institute, University of Queensland, Brisbane, Australia; 4) Department of Pharmacology, School of Pharmacy, London, United Kingdom; 5) Institute of Medical Genetics, Cardiff University, United Kingdom.

Hereditary hyperekplexia, or startle disease, is caused by genetic defects in glycinergic inhibitory system. This rare but treatable neurological disorder is characterized by an exaggerated startle reflex and extreme muscle stiffness in response to sudden, unexpected auditory or tactile stimuli. To date, hyperekplexia mutations have been identified in several genes involved in the function of glycinergic synapses. Mutations in GLRA1 encoding the glycine receptor (GlyR) $\alpha$1 subunit are the most common cause, accounting for ~70% of previously reported hyperekplexia mutations, followed by defects in SLC6A5 encoding the glycine transporter GlyT2 accounting for ~20% of cases. Functional analysis of GLRA1 mutations indicated that glycinergic transmission is disrupted by defective allosteric coupling of agonist binding to chloride ion channel gating and/or impaired cell membrane trafficking of GlyRs. In this study, we describe a novel dominant GLRA1 mutation that results in the substitution of a tyrosine to a cysteine at amino acid position 128 (Y128C). Whilst the majority of dominant mutations are located in the pore-forming M2 domain or flanking regions of the GlyR $\alpha$1 subunit, the new dominant mutation Y128C is located in the N-terminal extracellular domain. When transiently expressed in HEK293 cells, either as homomeric $\alpha$1 GlyRs or heteromeric $\alpha$1 $\beta$ GlyRs, the Y128C substitution resulted in spontaneously-opening channels. Although, tonic channel opening has been recognized as one of the common mechanisms underlying channelopathies, this is the first report of a hyperekplexia mutation associated with leaky current. The discovery of mutations associated with hyperekplexia coupled with a detailed understanding of the molecular basis of GlyR impairment provides invaluable insights into the pathophysiology of this disorder.

## 494/W/Poster Board #152

**Severe orthopedic and gastrointestinal complications in a child with generalized myokymia and a *KCNA1* mutation.** *L. Seaver[1,2], K. Nagamori[2], G. Yim[2], E. Raney[3], C. Wang[4], D. Sureka[5], G. Enns[5].* 1) Kapiolani Medical Specialists, Honolulu, HI; 2) Department of Pediatrics, John A. Burns School of Medicine Honolulu, HI; 3) Shriners Hospital, Honolulu, HI; 4) Division of Neurology, Stanford University School of Medicine, Stanford, CA; 5) Division of Medical Genetics, Stanford University School of Medicine, Stanford, CA.

*KCNA1* mutations have been associated with Episodic Ataxia type 1, which can present with symptoms of dizziness, ataxia, seizures and myokymia. We report a case with early onset neuromuscular disease causing significant orthopedic and gastrointestinal complications.

The now 8 year old boy presented with firm abdomen since infancy. He required umbilical and inguinal herniorrhaphy at age 4. Short stature, gross motor delay, joint contractures and a crouched gait were evaluated at age 2-3 yr including normal serum CK and MRI of brain and spine. Muscle biopsy showed fiber type disproportion with type I predominance. Sural nerve biopsy was normal. EMG and NCV showed no evidence of myopathy, but a neuropathic process involving motor nerves with significant axonal loss. Between ages 5-8 yr he has had progressive deformation of his ribs, pectus carinatum, hip dislocation and loss of ambulation due to contractures. He has required soft tissue releases of knees and ankles. Gastroesophageal reflux, episodic vomiting, hypoglycemia and failure to thrive led to the diagnosis of a large hiatal hernia which required surgical repair.

His examination at age 5 yr showed short stature (HA 30 months), weight 50th centile for HA, OFC 25-50th centile, a rigid abdomen, fixed flexion contractures of hips, knees and ankles, finger contractures with full passive range of motion, visible and palpable repetitive muscle contractions of arms and fingers. The diagnosis of hyperekplexia was considered. Family history revealed a father and aunt with hand tremor. *GLRA1* sequencing was negative. A heterozygous mutation (Phe184Cys, c.551T>G) in *KCNA1* was recently identified, confirming the diagnosis of myokymia associated with Episodic Ataxia type 1.

Kinali et al. reported a boy with infantile onset of symptoms including muscle stiffness and motor delay with progressive short stature, kyphoscoliosis, hiatal and inguinal hernias. Spells of dizziness began at age 10 (Neuromuscul Disord 14:689, 2004). Our case has similar but more rapid and severe progression of symptoms. Both cases emphasize significant skeletal and GI complications and extreme variability in familial symptoms suggesting that this diagnosis should be considered in the differential diagnosis of hyperekplexia and neuromyotonia in children.

## 495/W/Poster Board #153

**TOPORS, mutated in retinal degeneration, is a novel centrosomal and ciliary protein.** *A.Z. Shah[1], H. Khanna[2], T. Sedmak[3], K. Nagel-Wolfrum[3], C.A. Murga-Zamalloa[2], I. Lopez[4], M. Papaioannou[1], P. Munro[1], M. Cheetham[1], R.M. Rios[5], R. Koenekoop[4], P. Beales[6], K. Matter[1], U. Wolfrum[3], A. Swaroop[7], S.S. Bhattacharya[1], C. Chakarova[1].* 1) Institute of Ophthalmology, UCL, London EC1V 9EL, UK; 2) Department of Ophthalmology, University of Michigan, Ann Arbor, Michigan-48105, USA; 3) Johannes Gutenberg University of Mainz, Institute of Zoology, D-55099 Mainz, Germany; 4) The McGill Ocular Genetics Laboratory, McGill University Health Centre, Montreal, Quebec H3H 1P3, Canada; 5) CSIC-CABIMER, Seville-41092, Spain; 6) Molecular Medicine Unit, Institute of Child Health, University College London, London, UK; 7) 7Neurobiology-Neurodegeneration and Repair Laboratory (N-NRL), National Eye Institute, NIH, Bethesda, Mariland-20892, USA.

**Purpose:** After identifying mutations in TOPORS which cause autosomal dominant retinitis pigmentosa we undertook this study to better understand the localization and the role of this ubiquitously expressed protein in photoreceptors, dividing and quiescent cells. **Methods:** Subcellular localization of TOPORS was examined in human and mouse retina and in cultured cell lines by confocal immunofluorescence. Light- and dark-adapted mice were used to assess potential light-evoked differential localization of TOPORS in photoreceptors. The effect of TOPORS knockdown was assessed by RNAi. Yeast two-hybrid was used to determine whether TOPORS interacts directly with proteins from retrograde transport that have previously shown to co-IP. **Results:** Here we report for the first time that TOPORS, which is mutated in patients with autosomal dominant retinal degeneration, is a novel component of the centrosome in dividing cells, ciliary basal body in quiescent cells and connecting cilium in photoreceptors. Immunocytochemical studies demonstrate that endogenous TOPORS exhibits cell cycle dependent localization in the nucleus, centrosome and midbody. TOPORS was localized to the inner centriolar cylinder using ninein and $\beta$-arrestin-2 which is suggestive of a role in centriole biogenesis and stability. However, knockdown of expression of TOPORS does not affect the number of centrioles, or microtubule organisation. TOPORS remained associated with the centrosome even when retrograde transport was disrupted by overexpressing p50-dynamitin. TOPORS localizes only to the connecting cilia in light adapted mice and distributes diffusely throughout the whole photoreceptor cell when the mice are dark adapted. Moreover, TOPORS exhibits differential association with visual arrestin and transducin in light-adapted condition. We observed no co-localization of TOPORS with PNA (marker for cone photoreceptors) demonstrating its absence from the cone photoreceptor cells in human and mouse retinas. Yeast two-hybrid results indicated TOPORS does not interact with retrograde transport proteins directly. **Conclusions:** TOPORS is a novel component of the cilia in rod photoreceptor cells and is also localized in the basal body of the cilia in quiescent cells and in the centrosome of dividing cells. Our work highlights the increasing importance of ciliary function and adds to the growing list of ciliopathies.

**NOVEL VLDLR MICRODELETION IDENTIFIED IN TWO TURKISH SIBLINGS WITH PACHYGYRIA AND PONTOCEREBELLAR ATROPHY.** *L.E. Kolb[1,2], Z. Arlier[1,2], C. Yalcinkaya[3], A.K. Ozturk[1,2], O. Erturk[3], F. Bayrakli[1,2], K. Bilguvar[1,2], K. Yasuno[1,2], T. Ozcelik[4,5], B. Tuysuz[6], M.W. State[2,7,8], M. Gunel[1,2,7,9]*. 1) Neurosurgery, Yale University School of Medicine, New Haven, CT; 2) Program on Neurogenetics, Yale University School of Medicine, New Haven, CT; 3) Neurology, Division of Child Neurology, Istanbul University Cerrahpasa Faculty of Medicine, Istanbul, Turkey; 4) Department of Molecular Biology and Genetics, Faculty of Science, Bilkent University, Ankara, Turkey; 5) Institute of Materials Science and Nanotechnology, Bilkent University, Ankara, Turkey; 6) Pediatrics, Division of Genetics, Istanbul University Cerrahpasa Faculty of Medicine, Istanbul, Turkey; 7) Genetics, Yale University School of Medicine, New Haven, CT; 8) Child Study Center, Yale University School of Medicine, New Haven, CT; 9) Neurobiology, Yale University School of Medicine, New Haven, CT.

Congenital ataxia with cerebellar hypoplasia is a heterogeneous group of disorders that presents with motor disability, hypotonia, incoordination, and impaired motor development. These disorders present initially with general symptoms such as delayed motor milestones and hypotonia during the post natal period and early childhood, followed by the gradual onset of ataxic gait during the first few years of life. Some cases improve as motor functions develop, while others worsen early during infancy as motor demands increase on coordination. This heterogeneous group of disorders has been associated with multiple other diseases including brain malformations, genetic syndromes, and congenital infections. It is thought that 4% of cases are due to a perinatal cause, while 45% of the cases are due to prenatal causes. The remaining half is speculated to be of unknown etiology. Of the associated brain malformations, cerebellar hyoplasia seems to be the most common, occurring in slightly less than 50% of cases. The most severe cases have been noted to have marked hyoplasia of the vermis, and mild to moderate involvement of the neocerebellum, but in other cases the imaging findings have not correlated with the severity of the disease. Recently mutations in the Very Low Density Lipoprotein Receptor (VLDLR) have been identified in patients in the Turkish, Iranian and Hutterite populations with cerebellar atrophy and congenital ataxia following an autosomal recessive type of inheritance. The Hutterite and Iranian patients presented with Dysequillibrium syndrome, while the Turkish patients exhibited quadrupedal gait. We present a new Turkish family with two siblings affected with cerebellar atrophy and pachygyria with a novel homozygous deletion in the VLDLR gene identified by using high density single nucleotide polymorphism (SNP) chips for homozygosity mapping and identification of copy number variations (CNV) within these regions. The patients are offspring of a first cousin mating and suffer from ataxia, dysarthria, dysmetria, and dysdiadochokinesis. Magnetic resonance scans of affected siblings show pachygyria and cerebellar atrophy. Mapping and crossing of the breakpoint was performed which revealed a 21,194 bp deletion including exons 2, 3, 4, and part of exons 1 and 5 that begins on 2,612,144 bps and ends on 2,633,338 bps on Chromosome 9. Our findings confirm that VLDLR is an integral part of cerebellogenesis.

## 497/W/Poster Board #155

**Mutations in PCDH19 (protocadherin 19) are a frequent cause of isolated infantile epileptic encephalopathy in females.** *C. Depienne[1, 2, 3], D. Bouteiller[1], B. Keren[2], E. Cheuret[4], K. Poirier[5], O. Trouillard[2], A. Brice[1, 2, 3], R. Nabbout[6], E. LeGuern[1, 2, 3]*. 1) INSERM UMR_S975, Paris, France; 2) AP-HP, Département de génétique et cytogénétique, Fédération de Génétique, Hôpital de la Salpêtrière, F-75013, Paris, France; 3) Université Pierre et Marie Curie-Paris6, CNRS, UMR-S975, Paris, F-75013, France; 4) Service de neurologie pédiatrique, Hôpital des enfants, Centre Hospitalier Universitaire de Toulouse, Toulouse, France; 5) Institut Cochin, Inserm U567, UMR 8104, Université René Descartes, Paris 5, France; 6) Département de Neuropédiatrie, AP-HP, Hôpital Necker-Enfants malades, Paris-Descartes, Paris, France.

Dravet syndrome (DS) is a sporadic, early-onset epileptic encephalopathy characterized by the association of febrile and afebrile seizures of multiple types and cognitive and language impairment; 75% of the patients with DS have de novo mutations in the SCN1A gene. To identify new genes responsible for DS, we screened 41 SCN1A-negative patients for microrearrangements using high-density SNP microarrays. Since a de novo hemizygous deletion encompassing only PCDH19 (Xq22.1) was found in a male patient, we sequenced the coding region of this gene in 73 other SCN1A-negative patients. Nine different point mutations (four missense and five truncating mutations) were identified in 11 unrelated female patients. Patients with PCDH19 and SCN1A mutations had very similar clinical features although there were slight but constant differences in the evolution of the patients, including fewer polymorphic seizures, in particular rare myoclonia and atypical absences, in those with PCDH19 mutations. Mutations in PCDH19 were recently reported to cause EFMR (epilepsy and mental retardation limited to females), a remarkable X-linked disorder with male-sparing. To determine the clinical spectrum associated with PCDH19 mutations, we screened 95 additional patients (56 females and 39 males) who presented various epileptic encephalopathies, most of which had no family history. Five additional point mutations, 2 whole gene deletions, one partial gene deletion and 4 partial gene duplications were found in 12 unrelated female patients. So far, all the patients with PCDH19 mutations but one were females. A possible pathogenic mechanism associated with PCDH19 mutations is cellular interference, postulating that the co-existence of PCDH19-positive and PCDH19-negative cells (due to random X-inactivation in females) is pathogenic. According to this hypothesis, mosaic males could also be affected. Using FISH, we demonstrated that the male patient in whom the gene was deleted was indeed mosaic for the deletion. Together, these results suggest that PCDH19 plays a major role in epileptic encephalopathies, with a wide clinical spectrum encompassing DS and EFMR. This disorder mainly affects females. The identification of an affected mosaic male strongly supports the hypothesis that cellular interference is the pathogenic mechanism.

Epilepsy and Mental Retardation Limited to Females (EFMR) is an intriguing X-linked disorder with paradoxical sex reversal in phenotype, such that females are affected whilst transmitting males are unaffected. Mutations in the protocadherin 19 (PCDH19) gene have been identified in seven unrelated families with EFMR. Here, we assessed the frequency of PCDH19 mutations in individuals with clinical features which overlap those of EFMR. We analysed 185 females from three cohorts: 42 with Rett syndrome (RS) who were negative for MECP2 and CDKL5 mutations, 57 with autism spectrum disorders alone (ASD) and 86 with epilepsy with or without intellectual disability (ID). No mutations were identified in the RS and ASD cohorts. Among the 86 females with epilepsy (of whom 51 had seizure onset before 3 years), with or without ID, we identified two (2.3%) missense changes. One (c.1671C>G, p.N557K), reported previously without clinical data, was found in two affected sisters, and is the first EFMR family identified without a multigenerational family history of affected females. The second (c.826T>C, p.S276P), is a novel de novo missense change identified in a sporadic female. The change S276P is predicted to result in functional disturbance of PCDH19 as it affects a highly conserved residue adjacent to the adhesion interface of EC3 of PCDH19. Two of the 3 girls identified with a PCDH19 mutation had features of ASD in addition to seizures and learning concerns. Whilst we did not identify any mutations in PCDH19 in the ASD-alone cohort, gene expression profiling of EFMR female fibroblasts identified differential expression of Autism associated genes (LAMB1 and MET) when compared to control females, suggesting a convergence between ASD and EFMR at a functional level with probable defects in neuronal migration and synaptogenesis in both disorders. The identification of a De novo PCDH19 mutation in a sporadic female highlights that mutation analysis should be considered in isolated instances of girls with infantile onset seizures and developmental delay, in addition to those with the characteristic family history of EFMR.

## 499/W/Poster Board #157

**Mutation screening of the MAGI2 gene in idiopathic infantile spasms.** *A. Muir[1,2], E. Tam[2], T. Babatz[3], W.B. Dobyns[3], F. Zara[4], P. Striano[4], J. Sa[5], B.A. Minassian[6], L.R. Osborne[1,2].* 1) Molecular Genetics, University of Toronto, Toronto, Canada; 2) Medicine, University of Toronto, Toronto, Canada; 3) Department of Human Genetics, University of Chicago, IL; 4) Muscular and Neurodegenerative Disease Unit, G. Gaslini Institute, Genoa, Italy; 5) Serviço de Genética Médica, Hospital pediátrico de Coimbra, Coimbra, Portugal; 6) Program in Genetics & Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

Infantile Spasms (IS) is a disorder of the developing nervous system that begins in the first year of life. It is characterized by jerks of the neck, trunk and extremities lasting 1-2 seconds, occurring in numerous clusters throughout the day. The spasms must be abolished if the prognosis is to be improved, otherwise the immature brain appears to remain hyperexcitable and proper neurodevelopment is impeded, however current medications are variably effective and have severe side effects. In around half of IS cases, the spasms are merely one part of a much wider spectrum of neurological symptoms, however in the other half of cases IS occurs in the absence of any brain malformation or neurological insult and is classed as idiopathic.

We recently identified a new locus for IS on chromosome 7q11.23-q21.1 through deletion mapping of Williams-Beuren syndrome individuals with or without IS. A single gene, *MAGI2*, was located within the critical interval. MAGI2 is a synaptic scaffold protein previously shown to interact with Stargazin, a protein that is disrupted in an epileptic mouse model, making it an excellent candidate for idiopathic IS. We have now initiated a study to determine whether *MAGI2* mutations can in fact cause idiopathic IS. Sequence analysis was performed on all 22 exons of *MAGI2* in cohorts of children with IS from the US, Italy and Portugal. A total of 82 DNA samples were fully analyzed and five potentially deleterious sequence changes were identified, none of which were found in a panel of 300 control chromosomes. All five changes result in amino acid substitutions, and all were predicted to significantly affect protein function using the SIFT (Sorting Intolerant From Tolerant) program. In two cases the sequence change was inherited from a parent, and in one of these cases the parent also had a positive history of seizures. We hypothesize that since these sequence changes are amino acid substitutions rather than changes that would result in a truncated protein product, the phenotype may not be fully penetrant. In summary, we have identified potentially pathogenic *MAGI2* mutations in 6% of our symptomatic IS cohort through a sequence-based screen of the coding region. We have recently developed an MLPA assay to detect intragenic deletions and this may increase the detection rate of *MAGI2* mutations in this population.

## 500/W/Poster Board #158

**RESCUE OF FMR1 KNOCKOUT PHENOTYPES IN ADULT MICE AFTER RESTORATION OF FMRP.** *R. Zong[1], E.J. Mientjes[2], C.M. Spencer[1], R. Paylor[1], B.A. Oostra[2], D.L. Nelson[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 2) Department of Clinical Genetics, Erasmus University, Rotterdam, The Netherlands.

Absence of FMRP causes fragile X syndrome, the most common inherited form of mental retardation. Fragile X syndrome is widely considered to be a developmental disorder; yet direct evidence to support this argument is limited. We have generated mouse models that allow expression of FMRP to be manipulated in a time-dependent manner to determine FMRP requirement during development. One approach was used to allow restoration of full Fmr1 expression from a gene that has an interfering neomycin cassette in intron 1 that can be removed with Cre recombination. Another approach is the temporal deletion of Fmr1 in mice during postnatal or embryonic development, achieved by in vivo expression of a Tamoxifen-inducible Cre recombinase to ablate the Fmr1 promoter and first exon flanked by lox P sites. With these inducible mouse models, we were able to effectively restore or delete FMRP in adult animals, and to examine a number of known abnormal phenotypes present in Fmr1 KO animals. Our results indicate that restoration of FMRP in adult (4-6 week old) mice resulted in the rescue of several phenotypes including abnormal dendritic spines, deficiency on the accelerating rotarod, and altered expression levels of the FMRP target PSD-95 in the hippocampus. Our findings suggest that defective neurons in fragile X syndrome can be repaired after restoration of FMRP, and that the damage to neurons may not be incurred during development, providing important data in support of the potential for therapies in patients. We also find that adult deletion of FMRP in mice results in the development of abnormal dendritic spines, and abnormal rotarod performance, demonstrating that both of these phenotypes are sensitive to the acute presence of FMRP. Further studies including additional behavioral tests are in progress.

## 501/W/Poster Board #159

**Next Generation Technologies for Gene Discovery in Autosomal Dominant Retinitis Pigmentosa.** *S.P. Daiger[1,2], L.S. Sullivan[1], S.J. Bowne[1], D.G. Birch[3], J.R. Heckenlively[4], S.H. Blanton[5], E.A. Pierce[6], L. Ding[7], E.J. Sodergren[7], R.S. Fulton[7], G.M. Weinstock[7].* 1) Human Genetics Center, School of Public Health, The Univ. of Texas HSC, Houston, TX; 2) Dept. of Ophthalmology and Visual Science, Medical School, The Univ. of Texas HSC, Houston, TX; 3) Retina Foundation of the Southwest, Dallas, TX; 4) Kellogg Eye Center, Univ. of Michigan, Ann Arbor, MI; 5) Miami Inst. for Human Genomics, Univ. of Miami, Miami, FL; 6) Scheie Eye Institute, Univ. of Pennsylvania, Philadelphia, PA; 7) Genome Sequencing Center, Washington Univ., St. Louis, MO.

Autosomal dominant retinitis pigmentosa (adRP) is a heterogeneous set of inherited diseases characterized by night blindness in childhood, followed by progressive retinal degeneration, often culminating in legal or complete blindness by midlife. Although adRP is a single-gene disorder in affected individuals and families, many different genes and mutations are involved; for example, mutations in 19 genes are known to cause adRP and these account for a minor fraction of cases in many populations. AdRP represents a model system for gene discovery and mutation detection using “next generation” methods such as targeted, ultra-high-throughput sequencing and micro-array based detection of deletions.

Over the past decade we have tested a cohort of over 220 adRP families by a variety of methods and detected disease-causing mutations in 60%. The remaining 88 families are likely to harbor non-coding mutations or mutations in novel genes. We selected 21 families without known mutations for the first phase of advanced testing. DNAs from a pair of affected individuals from each family, plus positive controls, were amplified by PCR using 1,000 primer pairs covering 42 adRP genes and candidate genes. The PCR products were sequenced by 454 Titanium pyrosequencing (50X depth) and by Illumina Solexa reversible-dye-terminator sequencing. In addition, selected samples were tested using Affymetrix 6.0 SNP/CNV arrays to detect deletions and validate SNPs found by sequencing. Variants in the resulting data were compared to dbSNP and known mutations, and analyzed for pathogenicity by several methods. Approximately 100 rare, potentially-pathogenic variants were found in affected pairs; of these, 5 segregate with disease in one family each and meet multiple criteria for pathogenicity. Thus we detected mutations in 24% of the test group or 2% of the entire adRP cohort.

In the second phase of the study, we are using capture arrays and targeted enrichment to isolate DNA from over 600 candidate genes covering more than 10 MB of sequence in each affected individual, and sequencing the targeted fragments using ultra-high-throughput methods. DNAs are also being tested using Affymetrix arrays. By this combination of approaches we expect to identify novel adRP genes and mutations, and prepare for the day when inexpensive whole-genome sequencing becomes available.

## 502/W/Poster Board #160

**Genetic spectrum and mitochondrial assessment in Korean patients with early-onset Parkinson disease.** *SY. Kim[1], SY. Kim[2], HS. Ko[2], BS. Jeon[3], MW. Seong[4], JY. Kim[2], SS. Park[1,2].* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Clinical Research Institute, Seoul National University Hospital, Seoul, Korea; 3) Department of Neurology, Seoul National University Hospital, Seoul, Korea; 4) Department of Laboratory Medicine, National Cancer Center, Goyang, Korea.

Parkinson disease (PD) is the most important cause of Parkinsonism defined as common clinical features of tremor, rigidity, bradykinesia, and postural instability. Monogenic mutations have been identified in familial, early-onset PD (EOPD) patients, and evidences indicate that these genes are related with mitochondria. In this study, we aimed to characterize the mutational spectrum of Korean EOPD patients, and to investigate molecular deteriorations in consequence of genetic abnormalities. We enrolled 114 Korean patients clinically diagnosed with PD and with symptomatic onsets younger than 41 years (onset age, median 36, range 12-40). Four causative genes, *PARK2*, *PINK1*, *SNCA*, and *PARK7* (*DJ-1*), were analyzed by direct sequencing, multiplex ligation-dependent probe amplification (MLPA), and RT-PCR. In the mutation-positive individuals, mitochondrial DNA was quantified from leukocyte by real-time PCR, and mitochondrial respiratory chain complex I activity was measured in the lymphoblastoid cell line by automated spectrophotometric method. Genetic analyses revealed that 18.4% (21/114) of Korean EOPD patients had mutations in one of these four genes. The *PARK2* mutations were identified in 19 patients. Fourteen patients were homozygote or compound heterozygote of two causative mutations. Exon deletion was the major type of *PARK2* mutation, occurred within 24 alleles. Two alleles were exon duplications, and two were missense mutations. Two patients had heterozygous duplication or missense mutation in each. Three patients harbored exon deletions, but their heterozygosity could not be confirmed. A heterozygous *PINK1* missense mutation was found in a patient, and the *SNCA* missense mutation was in other patient. No *PARK7* mutation was found in this study. There was no difference in mitochondrial DNA quantity between 14 EOPD patients with *PARK2* mutation, 19 normal controls, and 20 late-onset PD patients (Kruskal-Wallis test, p=0.678). Mitochondrial complex I activity showed no difference between groups of 12 EOPD patients with *PARK2* mutation and eight normal controls (Mann-Whitney test, p=0.624). This study indicated that *PARK2* is the most important gene in Korean EOPD patients. No significant difference was observed in mitochondrial DNA quantity or complex I activity in patients with mutations. The molecular genetic characteristics identified in this study will be helpful for diagnosis and understanding of EOPD.

## 503/W/Poster Board #161

**Novel Progressive Myoclonus Epilepsy Disease Gene or Genetic Conundrum?** *J. Turnbull[1,2], J.M. Girard[1], H. Lohi[1], E.M. Chan[1], S. Omer[3], C. Bennett[4], A. Chakrabarty[5], N. Pencea[1], X.C. Zhao[1], P.X. Wang[1], S.W. Scherer[1,2], C.A. Ackerley[6], B.A. Minassian[1].* 1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Neurology, St George's Hospital, London, England; 4) Department of Clinical Genetics, Leeds General Infirmary, Leeds, United Kingdom; 5) Department of Neuropathology, Leeds General Infirmary, Leeds, United Kingdom; 6) Department of Pathology, Hospital for Sick Children, Toronto, Ontario, Canada.

The progressive myoclonus epilepsies (PMEs) are a group of diseases with myoclonic seizures and progressive neurodegeneration. Lafora disease is an autosomal recessive teenage-onset fatal PME with pathognomonic periodic acid-Schiff (PAS) positive diastase resistant accumulations of abnormally branched glycogen known as Lafora bodies. The disease is caused by mutations in either the EPM2A (laforin) or EPM2B (malin) genes. We identified a consanguineous Pakistani family with three children with classic clinical Lafora disease and no mutations in or linkage to either EPM2A or EPM2B. Muscle biopsy was strongly positive for Lafora bodies, but skin biopsy was equivocal, with extremely small PAS positive diastase resistant structures that could not definitively be called abnormal. In contrast, in common forms of Lafora disease, Lafora bodies are most striking in skin. We performed genome-wide linkage using the Affymetrix 10K SNP chip and found a 7MB region (containing 54 genes) on chromosome 4 that gave the maximum predicted LOD score (2.56) for this family. There are two strong functional candidate genes in this region. STBD1 is one of only three mammalian proteins, including laforin, containing a CBM20 type of carbohydrate binding domain. SCARB2 mutations cause the action myoclonus-renal failure syndrome, a PME associated with renal failure and no Lafora bodies. Extensive mutation screening of both genes and quantitative and functional analyses of STBD1 and SCARB2 in this family revealed no differences between affected and unaffected members. We next sequenced 35 additional genes in the region and identified a Phe to Leu sequence variant in the PRDM8 gene. This variant was not found in 500 ethnic-matched controls including 200 from the same region. The affected residue and the exact nucleotide are conserved across species. In cell culture experiments we found colocalization in the nucleus for both PRDM8/EPM2A and PRDM8/EPM2B. Co-immunoprecipitation experiments showed exogenous interactions between each of the three proteins. It is possible that this sequence change is an extremely rare innocuous variant in the PRDM8 gene and the actual disease gene remains to be uncovered, or an actual disease-causing mutation. While further functional experiments are underway, with this report we seek additional non-EPM2A, non-EPM2B families with Lafora disease and illustrate an example of the difficulties in genetic analysis of extremely rare forms of very rare diseases.

## 504/W/Poster Board #162

**New CMT2C families map to 12q23-24 and narrow the previously published linkage region.** *G. Landoure[1,2,3], H. Stanescu[2,4], Y. Shi[1], A. Taye[1], A. La Pean[1], C. Ludlow[5], C. Sumner[1,6], K. Fischbeck[1], R. Kleta[2,4].* 1) Neurogenetics Branch, NINDS/NIH, Bethesda, MD. 20892; 2) University College London, London UK; 3) Department of Neurology, Hospital of Point "G", Bamako Mali; 4) NHGRI, NIH, Bethesda, MD 20892; 5) Laryngeal and Speech Section, NINDS/NIH, Bethesda, MD 20892; 6) Neurology department, The Johns Hopkins University, Baltimore, MD USA.

Charcot-Marie-Tooth disease type 2C (CMT2C) is a rare autosomal dominant axonal neuropathy with weakness and atrophy in distal limb muscles and diaphragm, vocal fold, and intercostal muscle involvement. Sensory symptoms are usually mild. The disease usually starts in the first decade, but the age of onset and the clinical severity are variable. The locus for CMT2C has been mapped to 12q23-24 with a physical distance of 5.7 Mb between markers D12S105 and D12S1330, and a LOD score of about 5. Subsequently, two other CMT2C families were studied, and narrowed the region to 3.9 Mb between D12S105 and D12S1340 with a LOD score of 2.1. Here we report two families with CMT2C. In addition to the disease manifestations reported earlier, several of our patients had bilateral sensorineural hearing loss and impairment of bladder voiding, and one, the most affected, reported recurrent diarrhea. Because the clinical presentation and the electrophysiological studies were similar to the previous reported CMT2C families, we performed fine mapping with 12 polymorphic markers within the previously defined interval. We found linkage in both families with a total LOD score of about 10. Haplotype reconstruction showed that all affected individuals had the disease allele and narrowed the region from 3.9 Mb to about 2.6 Mb between markers D12S105 and D12S1343. This new region contains 38 protein-coding genes. Three unaffected individuals from one family (the mother of the proband and her 71 year old sister and sister's son) carried the disease-associated haplotype. Although electrophysiological studies were not done, their clinical examinations were completely normal. This may be due to an incomplete penetrance or a new mutation. These studies further refine the location of the gene for CMT2C. Candidate gene sequencing is currently under way to identify the disease gene.

## 505/W/Poster Board #163

**Two novel mutations of the Aristaless Related Homeobox gene *(ARX)*.** *S. Rujirabanjerd[1], U. Intusoma[2], T. Hansakunachai[3], K. Tongsippunyoo[1], O. Plong-on[1], E. Thammacharoen[1], T. Sripo[1], P. Limprasert[1].* 1) Department of Pathology, Faculty of Medicine, Prince of Songkla University, Hat Yai, Thailand; 2) Department of Pediatrics, Faculty of Medicine, Prince of Songkla University, Hat Yai, Thailand; 3) Department of Pediatrics, Faculty of Medicine, Thammasat University, Pratumthanee, Thailand.

Aristaless Related Homeobox gene *(ARX)* is an X-linked mental retardation (XLMR) gene located on the short arm of the X chromosome (Xp22). Mutations in this gene can cause a vast phenotypic spectrum ranging from non-syndromic to syndromic forms of mental retardation. The most common mutation is the c.428_451 dup mutation in exon 2. Since the gene was initially identified, it has been screened in several patients with XLMR. Here we report two novel nucleotide changes in *ARX* coding region, which we speculate to be causative in these XLMR families. The first mutation is a single nucleotide substitution in exon 2 (c.430G>T p.A114S) in a patient diagnosed with autism following DSM IV criteria. This patient also has some degree of intellectual disability (IQ=64). This change occurs at a highly conserved amino acid and could not be detected in 500 normal X chromosomes. Until present, only c.428_451 dup mutation has been reported in autistic patients. Therefore, this is the first missense change in the *ARX* gene detected in patients with autistic features. The second mutation is also a nucleotide substitution in the same exon (c.769C>T p.R257C). This change also occurs at a highly conserved amino acid and could not be detected in normal controls. The patient is a Thai boy with seizure and spastic cerebral palsy. Interestingly, he also has a family history of sensory neural hearing loss which never been reported in families with *ARX* mutations. We conclude that these two novel nucleotide changes are likely to be disease-causing mutations in these families.

## 506/W/Poster Board #164

**A novel *SLC9A6* gene mutation in a Japanese patient resembling Angelman syndrome.** *Y. Takahashi[1], M. Funatsuka[2], K. Hosoki[1], Y. Ueda[1], T. Itoh[1], H. Shiraishi[1], K. Saito[2], S. Saitoh[1].* 1) Department of Pediatrics, Hokkaido Univ Grad Sch Med, Sapporo, Japan; 2) Institute of Medical Genetics, Tokyo Women's Med Univ, Tokyo, Japan.

*SLC9A6* mutations were first reported in families exhibiting an X-linked mental retardation syndrome mimicking Angelman syndrome (AS) that is caused by loss of function of the *UBE3A* gene. The patients have cardinal features similar to those of AS including severe developmental delay, mental retardation with absent or minimal use of words, ataxia, easily provoked laughter, epilepsy, nystagmus and microcephaly. Distinct clinical features of the patients with *SLC9A6* mutations included cerebellar atrophy, and slow progression of symptoms. We examined 22 affected males who were initially suspected to have AS but genetic investigations including the *SNURF-SNRPN* DNA methylation test(identifies deletion, UPD, and imprinting defect classes of AS), and *UBE3A* mutation screening excluded known causes of AS. PCR-amplification and sequencing of coding sequences of the *SLC9A6* gene used genomic DNA derived from peripheral blood of patients. A novel *SLC9A6* gene mutation (c.441delG, p.S147fs)was identified in one patient. The mutation is predicted to introduce a frameshift and subsequently generate a premature stop codon. Our patient has the typical AS phenotype with cerebellar atrophy as seen in a subset of patients with *SLC9A6* mutations. Further investigations of other family members are in progress.

*SLC9A6* has been reported to play a role in the growth of dendritic spines. The function of the product of *UBE3A*, encoding an E3 ubiquitin ligase, is also associated with dendritic spine formation. Therefore, *UBE3A* may regulate the turnover of SLC9A6 polypeptide levels, or localization of the polypeptide, in dendritic spines during formation or function of the developing brain. An involvement in a common biological pathway may thus explain the phenotypic resemblance between patients with AS and those with *SLC9A6* mutations.In conclusion, *SLC9A6* gene mutation screening should be performed in male patients who are suspected to have AS but not confirmed by genetic examination. Neverthless, most male AS-like patiens without known causes of AS do not have *SLC9A6* gene mutations(21 of 22 in our study) and could be explained by small intragenic deletions in *UBE3A*, non-coding regulatory mutations in *UBE3A* or *SLC9A6*, or other genetic or epigenetic abnormalities affecting *UBE3A* or unknown genes.

## 507/W/Poster Board #165

**Two-percent of patients suspected of having Angelman syndrome have *TCF4* mutations.** *K. Takano[1], C. Moyes[2], M.J. Lyons[1], C. Skinner[1], J.R. Jones[1], C.E. Schwartz[1].* 1) Greenwood Genetic Center, Greenwood, SC; 2) Whakatane Hospital, Whakatane, New Zealand.

Haploinsufficiency as well as various mutations in the *TCF4* gene have been found to be associated with the Pitt-Hopkins syndrome (PTHS) [Amiel J, AJHG 80: 988, 2007, Zweier C, AJHG 80: 994, 2007]. PTHS (OMIM 610954) is characterized by severe mental retardation, a wide mouth plus other distinctive facial features (fleshy lips, beaked nose, broad nasal bridge) and breathing abnormalities. Because of some phenotypical overlap with Angelman syndrome, some have suggested that PTHS be considered in its differential diagnosis.

To explore this possibility, we screened 86 patients who were suspected of having Angelman syndrome (AS). All the patients were negative for UBE3A testing and 53 were negative for methylation analysis. We identified 2 mutations in this cohort: one frame shift mutation, c.1151delG (p.S384Tfsx7) and a missense mutation, c. 1745G>C (p.R582P).

Patient 1 (p.S384Tfsx7) is a 7 year old male with global developmental delay, microcephaly, broad nasal bridge, open and wide mouth, prominent lower lip, short stature and staring spells. Patient 2 (p.R582P) is a 16 year old male with severe mental retardation, blond hair, bright red lips and an abnormal gait. He also has frequent cyanotic episodes that have associated abnormal limb movements characterized as ballismus and dystonia. Mild hyperventilation occurs prior to the occurrence of these episodes. The patient also has cryptorchidism, convergent strabismus and planovalgus deformities of his feet.

The *TCF4* gene encodes a basic helix-loop-helix (bHLH) transcription factor which belongs the family of E proteins. The bHLH domain binds to the common DNA sequence called E-box and forms homo-and heterodimers with other classes of HLH proteins. The p.S384Tfsx7 mutation lacks this domain. The p.R582P mutation lies within the bHLH domain in which seven other missense mutations have been reported. Both mutations affect the critical function of the bHLH domain of the TCF4 protein.

In summary we found 2 *TCF4* mutations in 86 patients (2%) suspected to have AS. Screening for mutations in this gene should be considered in patients who present with findings of AS but who have been negative for methylation and UBE3A testing.

## 508/W/Poster Board #166

**Dysfunctional Estrogen Signaling: A Novel Cause of Intellectual Disability**. *C.D. van Karnebeek[1,2], P. Atkins[1,2], C. du Souich[1,2], R. Rupps[1,2], T. Woodward[3], M. Demos[4], C.F. Boerkoel[1,2].* 1) Medical Genetics, B.C. Children's & Women's Health Centre, Vancouver, British Columbia, Canada; 2) Child & Family Research Institute, B.C. Children's & Women's Health Centre, Vancouver, British Columbia, Canada; 3) Department of Psychiatry UBC, Mental Health & Addictions Research Institute, Vancouver, British Columbia, Canada; 4) Department of Neurology, B.C. Children's & Women's Health Centre, Vancouver, British Columbia, Canada.

**Background:** Identification of the underlying cause of intellectual disability (ID) is of fundamental importance for optimizing patient care, but is often forbiddingly complex. New insight in etiology reduces the burden of extensive medical work-up for the affected child and society as a whole. In a non-consanguineous 3-generation family with ID, we identified disruption of the estrogen receptor beta (*ER*β) gene as such a novel cause. **Aim:** To precisely define the molecular defect in the ERβ gene in this family and its role in the pathogenesis of ID. **Methods & Results:** Detailed physical and neurologic examination of the affected family members showed mild dysmorphic features and a moderate learning disability with reduced memory and normal insight. Routine karyotyping (550 bands) identified a reciprocal translocation (14;18) co-segregating with ID. Breakpoints have been mapped with FISH analysis and PCR to a region on chromosome 18 not containing any annotated genes, and to a region on chromosome 14 that only contains the *ER*β gene. Using RNA isolated from their lymphoblastoid cell lines, it will be determined whether the gene disruption results in loss of *ER*β expression, in expression of a truncated ERβ, or expression of an ERβ fusion protein. A customized test will be developed to distinguish the specific neurocognitive profile of the three affected individuals in this family. Using the results of this test and of their fMRI scans, specific regions of the brain affected in the family members with ID, and thus by ERβ deficiency, will be identified. These results will be related to published data on distribution of ERβ in the mouse brain and results of our immunohistochemistry studies of expression in human brain. **Conclusions:** To our knowledge this is the first report of human neurologic disease arising from an ERβ abnormality. A causal relation with ID is highly likely, as knock-out mice display morphologic brain abnormalities and cognitive defects, including impairment of spatial learning in females. Insight in the molecular and physiologic basis of the disease in this family increases our understanding of the genetic causes of ID and the role of estrogen in human physiology. Delineation of the neuropsychiatric profile associated with this ERβ mutation facilitates targeted molecular testing for other patients fitting this profile. Ultimately, therapies improving cognitive functioning in this group may be developed based on this model for disease.

## 509/W/Poster Board #167

**High resolution melt (HRM) analysis of DMD gene variants using whole genome amplified (WGA) samples.** *PS. Lai[1], OS. Yim[1], ZS. Chong[1], PS. Low[1], SKH. Tay[1], EPH. Yap[2,3].* 1) Dept of Pediatrics, Yong Loo Lin School of Medicine, National Univ Singapore, National Univ Hospital, Singapore 119074; 2) Defence Research and Technology Office, Ministry of Defence, Singapore 669645; 3) DSO National Laboratories, Defence Medical and Environmental Institute, Singapore 117510.

Whole-Genome Amplification (WGA) provides a way to generate large amounts of genome-equivalent templates from low starting input DNA. While WGA templates have been used for applications such as genotyping, CGH, DHLC analysis, etc., there are few reports of its application in high resolution melt (HRM) analysis. The latter is a simple, rapid method for mutation scanning of sequence variants based on differentiation of PCR products during thermal denaturation. HRM analysis routinely uses 10-50 ng DNA while WGA allows amplification of DNA from 1-10 pg of starting DNA material. This study investigates the amenability of using WGA samples for HRM to genotype mutations in the DMD (Duchenne muscular dystrophy) gene. Four variants were analyzed; c.77A>G and c.79G>C mutations in exon 2, and two SNPs, rs1800263 (c.4131A>T) and rs1801187 (c.5234G>A), in exons 30 and 37 respectively. Wild-type and mutant homozygotes, and heterozygotes were generated from lymphocyte samples from patients, family members and normal controls. To generate WGA products for use as melt analysis templates, aliquots containing 1.0, 0.1 and 0.01 ng of genomic DNA were amplified by multiple displacement amplification (MDA) technique. Paired genomic DNA and WGA products were then PCR amplified, and the amplicons spanning 141-184 bp were analyzed on the LightScanner (Idaho Technology) in a blind study. The results show that WGA templates exhibited variability and genotype profile overlaps with initially high discordance rate of more than 50%. However, discordant results were eliminated with $MgCl_2$ optimization, and after Exo-SAP1 treatment of WGA products prior to melt analysis. All homozygotes and heterozygotes could be detected with high sensitivity and specificity. Use of WGA samples for DMD mutation screening by HRM can be beneficial for future applications in clinical settings when sources of sampling (eg. invasive tissue sampling or biopsies of single embryos, oral buccal swabs, Guthrie cards, etc.) yield DNA of low quantity or quality.

## 510/W/Poster Board #168

**NDUFS4 mutations cause Leigh syndrome with predominant brainstem involvement.** *D. Lev[1,2], A.S. Lebre[3], L. Minai[3], A. Saada[4], J. Stephan[3], S. Cohen[5], A. Rotig[3], A. Munnich[3], T. Lerman-Sagie[2,6], E. Leshinsky-Silver[2,5].* 1) Inst Medical Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Mitochondrial Disease Center, Wolfson Medical Center, Holon, Israel; 3) Service de Génétique, Hôpital Necker Enfants Malades, Paris, France; 4) Metabolic Unit, Hadassah Medical Center, Jerusalem, Israel; 5) Molecular Genetics Laboratory, Wolfson Medical Center, Holon, Israel; 6) Pediatric Neurology Unit, Wolfson Medical Center, Holon, Israel.

Complex I deficiency is a frequent cause of Leigh syndrome. We describe a non-consanguineous Ashkenazi-Sephardic Jewish patient with Leigh syndrome due to complex I deficiency. The clinical and neuroradiological presentation showed predominant brainstem involvement. Blue Native PAGE analysis revealed a markedly decrease of fully assembled complex I. The patient was found to be compound heterozygous of two mutations in the NDUFS4 gene: p.Asp119His (a novel mutation) and p.Lys154fs (recently described in an Ashkenazi Jewish family). These findings support the suggestion that the p.Lys154fs mutation in NDUFS4 should be evaluated in Ashkenazi Jewish patients presenting with early onset Leigh syndrome even before enzymatic studies. Our results further demonstrated that NDUFS4 presents a hotspot of mutations in the genetic apparatus of oxidative phosphorylation and the subunit it encodes is essential for the assembly of complex I.

## 511/W/Poster Board #169

**Mouse Models for Myotonic Dystrophy Type 2 (DM2) Lacking Aberrant Splicing Implicate Novel Cytoplasmic Pathomechanisms.** *R. Krahe[1], M. Sirito[1], M. Wojciechowska[1], L.L. Bachinski[1], L.T. Timchenko[2], C.S. Van Pelt[1], D.R. Mosier[2], K.A. Sheikh[3], G. Zhang[3], P. Mancias[3], B. Udd[4].* 1) University of Texas M. D. Anderson Cancer Center, Houston, TX; 2) Baylor College of Medicine, Houston, TX; 3) University of Texas Health Sciences Center at Houston, Houston, TX; 4) Tampere University Hospital, Finland.

DM is caused by unstable microsatellite expansions -- in DM1 a $(CTG)_n$ expansion in the 3' UTR of *DMPK*, in DM2 a $(CCTG)_n$ expansion in intron 1 of *ZNF9*. In spite of similar mutations, DM1 and DM2 are clinically distinct diseases. The prevailing paradigm is that DM1 and DM2 are toxic RNA diseases: transcription of these repeats into mutant $(CUG)_n/(CCUG)_n$-containing RNAs is both necessary and sufficient to cause disease by formation of nuclear foci and interference with the splicing of downstream "effector" genes. Consequently, efforts so far to identify therapeutic targets have focused on the disruption of the insoluble nuclear foci and the correction of aberrant splicing. We have generated transgenic mice expressing a mutant DM2 expansions of $(CCTG)_{121}$ in intron 1 of the *human skeletal actin* (*HSA*) gene and knock-in mice expressing $(CCTG)_{189}$ in intron 1 of *Znf9*. Both mouse models show muscle weakness and an overall muscle pathology associated with human DM, including aberrant type 2 muscle fibers, sarcoplasmic masses and central nuclei. The transgenic mice also have myotonia by EMG. Other phenotypic features include cardiomyopathy and sudden cardiac death, suggestive of arrhythmia, abnormalities of lens development and retinal atrophy, and azoospermia in males. Recapitulating pathological features that have been shown for DM patients, both of our transgenic and knock-in DM2 mice show nuclear foci that sequester MBNL1, elevated steady-state levels of CUGBP1, mediated by phosphorylation through phospho-PKC, and dysregulation of CUGBP1 target genes. However, both DM2 mouse models lack aberrant splicing for *Clcn1, Atpa2a1, Ryr1, Tnnt3, Tnnt2, Ank2, Capzb* and *Fxr1*, genes that have been identified as misspliced in DM patients. In addition, our DM2 mice show cytoplasmic foci and other cytoplasmic abnormalities, including activation of the ER stress response, which is predicted to globally attenuate translation. Our mouse models indicate that DM-like progressive myopathy can result in the absence of aberrant splicing. They complement existing mouse models for DM and are uniquely suitable for the dissection of alternative cytoplasmic pathomechanisms in DM.

## 512/W/Poster Board #170

**Genetic heteroneneity in Karak syndrome demonstrated by Linkage analysis and mutation screening in PANK2 and PLA2G6 genes in 8 casanguineous Saudi Arabian families.** *H. Azzedine[1], M.A.M. Salih[2], A. Khan[3], E. Mundwiller[1], A. Aldriss[4], S.A. Elmalik[4], M.M. Kabiraj[5], G. Stevanin[1].* 1) INSERM/UPMC UMRS 975, Hosp de la Salpetriere, Paris, France; 2) Division of Pediatric Neurology , College of Medicine, King Saud University, Riyadh, Saudi Arabia; 3) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 4) Department of Physiology, College of Medicine, King Saud University, Riyadh, Saudi Arabia; 5) Division of Clinical Neurophysiology, Department of Neuroscience, military Hospital, Riyadh, Saudi Arabia.

A heterereogeneous group of severe neurological disorders like Aceruloplasminaemia, Neuroferritinopathy, Hallervorden-Spatz syndrome, HARP syndrome, and Friedreich ataxia involve excess brain iron accumulation. The "eye of the tiger" sign is a common neuroradiological finding in neurodegeneration with iron brain accumulation type 1 and 2 (NBIA1, 2), infantile neuroaxonal dystrophy (INAD) as well as in Karak syndrome (KS). Mutations in PANK2 and PLA2G6 genes were implicated in NBIA, INAD and KS disorders. We describe 8 consanguineous Saudi families with Karak syndrome. These consisted of 13 affected individuals (6 males and 7 females, aged 19 months-24 years). Onset ranged between about 8 months and 7 years with difficulty in walking or progressive cerebellar ataxia and spasticity associated, later, with extrapyramidal signs, intellectual decline and axonal form of Charcot-Marie- Tooth disease (CMT2). Ambulation was lost between 4 1/2 and 15 years. One male patient died at 24 years. Ophthalmic evaluations revealed abnormal vertical saccades and pursuit. Brain MRI showed iron deposition in the putamen in all patients aged more than 4 years. Five of these families were genotyped for PANK2 and PLA2G6 loci using 10 microsatellite markers. PANK2 locus was excluded in all the families while assignment of the families to the PLA2G6 locus was established by homozygocity mapping in 4 of them. Using direct sequencing of the PLA2G6 gene we identified, at a homozygous state, 3 novel mutations and one other already reported in the 4 linked families. One of these 5 families was neither linked to PLA2G6 nor to PANK2 genes demonstrating further genetic heterogeneity. Three new other consanguineous families with the same phenotype and belonging to the same country are under investigation. The final results will be presented during the meeting.

## 513/W/Poster Board #171

**Identification and functional characterization of Lrrk2 N1437H as a novel pathogenic cause of familial Parkinson disease.** *M. Farrer[1], C. Viarino-Guell[1], J.C. Dachsel[1], K. Haugarvoll[1,2], M. Toft[1,2], L. White[2], A. Felic[1,2], J. Kachergus[2], A. Ortolaza[1], S.A. Cobb[1], S. Lincoln[1], O.A. Ross[1], J.A. Aasly[2].* 1) Dept Neuroscience, Mayo Clinic , Jacksonville, Jacksonville, FL; 2) Dept of Neurology, St. Olav's Hospital, Norwegian University of Science and Technology, Trondheim, Norway.

Genealogical investigation of a large Norwegian family (F04) with autosomal dominant parkinsonism (PD) has revealed 15 affected family members over 4 generations. Affected subjects present with typical levodopa-responsive PD, albeit with early onset disease (mean 49 years). Genetic investigation identified a novel *LRRK2* mutation c.4309 C>A (p.Asn1437His) that co-segregates with disease (LOD=3.15). The variant was absent in 623 Norwegian control subjects. One additional Norwegian patient (1/692) was identified as a carrier and shares the same ancestral haplotype as F04. The mutation is located within the ROC domain of the protein, and functional characterization demonstrates it pathogenic effects on Lrrk2 dimerization, GTPase and subsequent kinase activities.

## 514/W/Poster Board #172

**Different origins and demographic histories of the LRRK2 G2019S mutation in Parkinson's disease.** *S. Lesage[1,2], E. Patin[3], C. Condroyer[1,2], A.L. Leutenegger[4,5], E. Lohmann[1,2], S. BACKGROUND: Mutations in the Leucine-Rich-Repeat Kinase 2 (LRRK2) gene have been identified in families with autosomal dominant Parkinson's disease (PD) and in sporadic cases, with G2019S, as the most common mutation. This mutation greatly varies according to ethnicity and geographic origins: it is rare in Asia (<0.1% in Japan), accounts for 1-7% in Europe and 20-40% in PD Ashkenazi Jews and North Africa. Previous studies reported that patients from these populations shared at least three haplotypes. AIM: To assess natural histories of the G2019S mutation in a large multi-ethnic population panel. PATIENTS AND METHODS: We genotyped 74 markers [20 short tandem repeat (STR) and 54 single nucleotide polymorphisms (SNP)] spanning a 16 Mb- genomic region around G2019S in 191 individuals from 126 families with G2019S (121 heterozygous and 5 homozygous). Of 126 families, 70 were from North Africa, 13 from France, 7 from other European countries, 1 from Turkey, 1 from Japan, 2 from South Africa, and 32 were of Jewish origin, mostly from Eastern Europe. The haplotypes were reconstructed using Phase v.2.1.1. The age of G2019S was estimated by 2 different maximum-likelihood methods. The network analyses were performed using NETWORK v.4.5. RESULTS: - We identified 3 different haplotypes: Haplotype 1, which was shared by 95% of mutation carriers, Haplotype 2, which was initially identified in 3 European-American families, was also found in 2 French families; and Haplotype 3, which has been primarily observed in Japanese PD patients, was also shared by a Turkish family. - NETWORK analyses showed that Haplotype 1 and Haplotypes 2 and 3 were placed at each edge of the network, suggesting that G2019S arose independently at least 2 times in humans, on Haplotype 1 and on the revolutionary-related Haplotypes 2 and 3. - Population distribution of the intra-allelic diversity of the most widespread Haplotype 1 showed 25%, 33% and 67% of recombining haplotypes in North-African Arabs, Europeans and Ashkenazi Jews, respectively. - Our G2019S age estimations indicated that the LRRK2 mutation initially arose among Near-Easterners ~6,000 years ago, much earlier than in previous estimations. CONCLUSION: We have shown using a large multi-ethnic population panel that PD-related G2019S mutation has independently appeared in humans at least twice, one of these events having occurred most likely in the Near-East, at least 6000 years ago.

## 515/W/Poster Board #173

**Transgenic mouse model of CUG RNA toxicity in brain.** *D.D. Rudnicki[1], A.I. Seixa[1], K.A. Metcalf Pate[2], D.W. Chung[1], D.A. Swing[3], L. Tessarollo[3], R.L. Margolis[1].* 1) Psychiatry, CMSC 8-121, Johns Hopkins School of Medicine, Baltimore, MD; 2) Molecular and Comparative Pathobiology , Ross 459, Johns Hopkins School of Medicine, Baltimore, MD; 3) Mouse Cancer Genetics Program, Building 560, Room 32-31D, NCI, Frederick.

Our group has previously identified an autosomal dominant disorder, Huntington's disease-like 2 (HDL2), with clinical and pathological features nearly indistinguishable from Huntington's disease (HD). Like HD, HDL2 is a relentlessly progressive adult onset neurodegenerative disorder, and like HD, HDL2 is caused by a CAG/CTG expansion mutation. However, the HDL2 locus is on chromosome 16q24.3, and the repeat falls within a variably spliced exon of junctophilin-3 (JPH3) in the CTG orientation. We have recently discovered that HDL2 brain contains intranuclear RNA foci, detectable by riboprobes against either CUG repeats or against JPH3 sequence flanking the repeat. These foci closely resemble the RNA foci detected in DM1 brain. We have also shown that overexpression of an untranslatable JPH3 construct containing an expanded CUG repeat is toxic to cultured cells. We therefore hypothesized that transcripts with an expanded CUG repeat may be toxic to the mammalian brain. To directly test this hypothesis, we have generated transgenic mice expressing an untranslatable fragment of JPH3 exon 2A, with either 10 or 100 CTG triplets, driven by the mouse prion promoter (PrP) vector. Preliminary data indicate that (CTG)100, but not (CTG)10, mice develop RNA foci by 7 months of age. Unlike HDL2 human brain tissue, we have so far not detected ubiqutin-positive protein inclusions in cerebral cortex of the (CTG)100 mice. Early behavioral analysis suggests impaired motoric function of the (CTG)100 mice by 5 months of age (abnormal performance on the inverted platform cling test). These initial findings suggest that the mouse model may be a useful tool in studying the relationship between expanded CUG repeats and neurotoxicity.

## 516/W/Poster Board #174

**The impact of *Hsp70i* over expression on the CMT peripheral neuropathic phenotype.** *J. Saliba[1], M. Khajavi[1], D. Pehlivan[1], J.R. Lupski[1,2,3].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston TX.

Hereditary peripheral neuropathies encompass a large collection of clinically and genetically heterogeneous disorders. These disorders lead to the deterioration of the peripheral nerves along with secondary muscle wasting. Charcot Marie Tooth disease (CMT) is the most common hereditary peripheral neuropathy with a prevalence of 1 in 2,500. CMT is most often the result of a 1.4 Mb duplication of the 17p11.2-p12 region of chromosome 17 that includes the dosage sensitive peripheral myelin protein 22 gene (*PMP22*). In addition, a number of point mutations in over two dozen genes including *PMP22* have been discovered to be associated with CMT. Current treatments for subjects with CMT are not preventive, but rather are based on mitigation of symptoms to allow the patient to better function with the disease. Therapeutic methods attempting to regulate *PMP22* expression have shown promise, however these methods will not be effective in the alleviation of cellular stress and ultimately Schwann cell apoptosis caused by the aggregation of PMP22 point mutated proteins in the ER. The oral administration of curcumin, a small molecule derived from the curry spice tumeric, has been shown to significantly decrease the percentage of apoptotic Schwann cells and partially alleviates the severe neuropathic phenotype of *Trembler-J* (*Tr-J*) mice in a dose dependent manner. Comparative expression profiling of the sciatic nerves of curcumin treated and untreated *Tr-J* mice revealed the potential specific molecular and cellular pathways affected by curcumin. Curcumin treatment leads to a significant increase in the expression of the heat shock protein, Hsp70i. Reduction of *Hsp70i* dosage in Tr-J mice results in a more severe peripheral neuropathy and upon curcumin treatment a rise in mortality. To investigate if the induction of *Hsp70i* expression can alleviate symptoms of peripheral neuropathies, we have produced *Tr-J* mice that over express *Hsp70i*. The *Tr-J* mice with one copy of transgenic *Hsp70i* present with a visibly healthier clinical phenotype and also display improved neuromotor function as assessed by rotarod testing versus *Tr-J* mice with wild type *Hsp70* expression. These results implicate Hsp70i as a primary component involved in the effectiveness of curcumin treatment in the partial mitigation of peripheral neuropathy.

## 517/W/Poster Board #175

**A novel insertion in GDAP1 gene in a Charcot-Marie-Tooth disease patient.** *A. Abbasi[1], M. Sadeghizadeh[1], M. Behmanesh[1], M. Houshmand[2,3].* 1) Department of Genetics, Faculty of Basic Sciences, Tarbiat Modares University, Tehran, Iran; 2) Diagnostic Molecular Genetics Lab, Special Medical Center, Tehran, Iran; 3) National Institute for Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran.

Hereditary motor and sensory neuropathies (HMSN) in genetic literature called also Charcot-Marie-Tooth disease (CMT) are the most common heterogenous disorders of the peripheral nervous system. CMT disease caused by mutations in the ganglioside-induced differentiation-associated protein 1 (GDAP1) gene is a severe autosomal recessive neuropathy originally reported in families with either demyelinating CMT4A neuropathy or axonal neuropathy with vocal cord paresis which maps to the CMT4A locus on chromosome 8q21.1. GDAP1 is a 358 amino acid protein expressed in both the central and peripheral nervous system and a putative role as glutathione S-transferases has been postulated for it. In this study, blood samples from 32 Iranian families and more than 150 members of their families with diagnosis of CMT disease, either axonal or demyelinating, were obtained for genetic analysis of GDAP1 gene. Total genomic DNA was extracted from all family members using standard procedures. The 1.5 Mb CMT1A duplication and point mutations in PMP22 gene were first excluded using restriction enzymes and then MPZ (CMT1B) and GJB1 (CMTX1) genes were excluded using direct sequencing. The GDAP1 gene was then investigated using linkage analysis with three markers (D8S551, D8S286 and D8S164) linked to the GDAP1 locus in the families. PCR amplification and direct sequencing of whole coding regions and exon-intron boundaries of the gene showed a novel insertion in the first exon of the GDAP1 gene in an Iranian patient (c.98-99 insT) leading to a truncated protein. This mutation was not detected in normal subjects which supports the hypothesis that it is responsible for the CMT4A phenotype.

**Screening Aminoacyl-tRNA Synthetase Genes for Mutations Causing Peripheral Neuropathies.** *A. Antonellis[1,2], H.M. Harville[1], V. Ionasescu[3], J.R. Lupski[4,5,6,7], G. Nicholson[8,9], K. Talbot[10], J. Vance[11], S. Zuchner[11], E.D. Green[12,13], NISC Comparative Sequencing Program.* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Neurology, University of Michigan, Ann Arbor, MI; 3) Division of Medical Genetics, Department of Pediatrics, University of Iowa, Iowa City, IA; 4) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Neurology, Baylor College of Medicine, Houston, TX; 6) Pediatrics, Baylor College of Medicine, Houston, TX; 7) Texas Children's Hospital, Houston, TX; 8) Northcott Neuroscience Laboratory, ANZAC Research Institute and Molecular Medicine Laboratory, Concord Hospital, Concord, New South Wales, Australia; 9) Faculty of Medicine, University of Sydney, Camperdown, New South Wales, Australia; 10) Department of Clinical Neurology, University of Oxford, Oxford, UK; 11) Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 12) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 13) NIH Intramural Sequencing Center (NISC), National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Aminoacyl-tRNA synthetases (ARSs) are a ubiquitously expressed, essential class of enzymes responsible for charging tRNA molecules with cognate amino acids. The human nuclear genome encodes all 37 ARSs, which include 17 enzymes responsible for charging tRNA in the mitochondria, 17 enzymes responsible for charging tRNA in the cytoplasm, and 3 bi-functional enzymes that charge tRNA molecules in both locations. Mutations in five ARS-encoding genes have been implicated in inherited neurological diseases in human and mouse, and two (those encoding glycyl- and tyrosyl-tRNA synthetase) are associated with distinct human peripheral neuropathies characterized by either a primary axonopathy or an intermediate form of Charcot-Marie-Tooth disease. These data suggest that all ARS genes can be considered excellent candidates for harboring mutations in patients with peripheral neuropathy and no known mutation. To study this further, we compiled a cohort of 364 such patients, the majority of which have been diagnosed with axonal peripheral neuropathy by a collaborating physician. We screened this cohort for mutations in the 37 human ARS genes using a high-throughput PCR- and DNA sequencing-based approach. These efforts revealed 146 novel predicted missense variants in 25 different ARS genes. Importantly, missense mutations have been shown to be a hallmark of known disease-causing glycyl- and tyrosyl-tRNA synthetase mutations, making our new findings particularly relevant for follow-up analyses. A major effort is now underway to evaluate these variants for disease association and functional consequences. The patient cohort and sequencing strategy will be presented along with interesting vignettes that are emerging from our genetic and functional characterization studies.

## 519/W/Poster Board #177

**Molecular analysis of spastin gene (SPG4) mutations in patients with familial and sporadic spastic paraplegia.** *D. Di Bella[1], S. Baratta[1], C. Mariotti[1], R. Fancellu[1], N. Nardocci[2], D. Pareyson[3], S. Di Donato[1], C. Gellera[1], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative & Metabolic Diseases, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy; 2) Division of Child Neurology, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy; 3) Unit of Neurology VIII, Fondazione IRCCS Istituto Neurologico Carlo Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Mutations in the SPG4 gene are responsible for ~15-40% of autosomal dominant (AD) HSP cases; HSP due to SPG4 mutations is generally described as a pure form of the disease, but has also occasionally been described in association with additional clinical features. This gene encodes spastin, a member of the AAA family of ATPases. The spastin gene was analysed by dHPLC and/or direct sequencing in 238 unrelated index cases, including 117 AD cases, 19 cases compatible with an autosomal recessive pattern of inheritance and 102 sporadic cases. Moreover, a subgroup of patients was screened for micro-rearrangements in the SPG4 gene by multiplex ligation-dependent probe amplification (MLPA) to assess the frequency of deletions/duplications. Thirty-three different pathogenic mutations (15 missense, 8 frameshift, 5 nonsense, 5 splicing) were found, 21 of which are novel. The mutations were not found in a large control population. Moreover, we identified 7 different heterozygous SPG4 deletions in 13 patients while, interestingly, 3 patients carried 3 different partial duplications of the SPG4 gene, setting at 17.3% the overall frequency of SPG4 rearrangements in the AD group. Overall, in our study, SPG4 point mutations account for 13.9% of spastic paraparesis patients, a frequency which raises to 23.1% if only AD families are considered, consistent with data from other studies. MLPA analysis demonstrates that a relevant proportion (17.3%) of mutation-negative HSP patients in fact carry SPG4 rearrangements, confirming that haploinsufficiency is a major mechanism of disease in SPG4 HSP and indicating that gene dosage analysis should always be performed when screening SPG4 in HSP patients. In conclusion, the data indicate that SPG4 accounts for ~40% of HSP families in the Italian population. [Supported by an Italian Ministry of Health grant (RF Neurodegenerazione ex art 56) to FT].

**Copy number variation analysis in patients with malformations of cortical development.** *A.K. Ozturk[1,2], K. Bilguvar[1,2], L.E. Kolb[1,2], M.L. Diluna[1,2], Y. Bayri[1,2], W. Ho[1,2], Z. Arlier[1,2], F. Bayrakli[1,2], K. Yasuno[1,2], C.E. Mason[2,3,4], S. Sanders[2,3,4], R.P. Lifton[3,5,6], M.W. State[2,3,4], M. Gunel[1,2,3,7].* 1) Neurosurgery, Yale University School of Medicine, New Haven, CT; 2) Program on Neurogenetics, Yale University School of Medicine, New Haven, CT; 3) Genetics, Yale University School of Medicine, New Haven, CT; 4) Child Study Center, Yale University School of Medicine, New Haven, CT; 5) Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT; 6) Internal Medicine, Yale University School of Medicine, New Haven, CT; 7) Neurobiology, Yale University School of Medicine, New Haven, CT.

The molecular mechanisms of brain development and function are largely unknown. Despite its fundamental importance, a mechanistic understanding of brain development at the level of the gene is generally lacking and only recently has begun to be elaborated in a broad fashion. Structural brain abnormalities represent disruptions of normal cerebral or cerebellar cytoarchitecture and often lead to severe neurological disorders including epilepsy, mental retardation and global developmental delays, as well as cognitive deficits and other motor and sensory neurological deficits. Recent studies have linked abnormalities in cerebral development to common neuropsychiatric disorders, including, for example, recent compelling evidence that abnormalities of cortical organization and neuronal migration are involved in some forms of Autism Spectrum Disorders, a constellation of syndromes affecting as many as 1 in 150 individuals. Furthermore, recent publications also demonstrated significant contribution of copy number variations (CNV) to neuropsychiatric disorders. In order to search for CNVs underlying structural brain abnormalities, we collected 250 patients from consanguineous families mainly from Eastern Turkey, where the consanguineous marriages are common. Those patients consisted of malformations of cortical development due to either stage of brain development such as cell proliferation or apoptosis, or neuronal migration or late cortical organization. We performed whole-genome genotyping using Illumina Human CNV370 or Human610 beadchips and then conducted CNV analysis by using PennCNV software as well as in-house algorithms. We then annotated these regions in terms of the genes affected and overlap with previously reported CNV loci in database. We eliminated CNVs based on size, overlap with previous reports and whether or not a coding exon is affected. We then confirmed the homozygous CNVs using quantitative PCR. Mutation screening of additional patients for coding homozygous deletions previously not reported is currently underway.

## 521/W/Poster Board #179

**Multiplexed resequencing analysis to identify rare variants in pooled DNA of barcode-indexed DNAs.** *J. Mitsui[1], K. Azuma[2], H. Tozaki[2], H. Ishiura[1], Y. Takahashi[1], J. Goto[1], S. Tsuji[1].* 1) Neurology, University of Tokyo, Tokyo, Japan; 2) Applied BioSystems Japan, Tokyo, Japan.

Genome-wide association studies employing common single nucleotide polymorphisms (SNPs) have been intensively conducted based on the "common disease-common variants hypothesis". However, little is known about disease susceptible rare variants, and efficient methods of detecting multiple rare variants in a large number of samples need to be established. We performed multiplexed resequencing with next-generation sequencer (SOLiD2) employing pooled DNA of barcode-indexed DNAs. We made several sets of pooled DNA of 96 patients with Parkinson disease and 96 normal control subjects as follows; #1: 96 samples of DNA were mixed into 1 set of pooled DNA followed by amplification of the target gene (GBA); #2: 16 samples in each group were mixed as 8 sets of pooled DNA. Each pooled DNA was subjected to PCR amplification of the target gene (GBA) and pooled in 1 tube with barcode-indexing; #3. 6 samples in each group were pooled as 16 sets of pooled DNA. Each pooled DNA was subjected to PCR amplification of the target gene (GBA) and pooled in 1 tube with barcode-indexing. Libraries of these pooled DNAs were prepared and subjected to target resequencing employing SOLiD2 system. To evaluate the results, individual samples were also subjected to direct nucleotide sequence analysis of the coding exons and the flanking splice sites of GBA to identify all variants. Obtained sequence reads were aligned to the reference sequences allowing mismatched color spaces less than 5. The frequencies of variants in the aligned sequences (total reads of 412,303,305) were determined at each nucleotide position (average read of 71,518). In the case of a set of pooled DNA of 6 samples, all the variants were detected with 100.0% of sensitivity. On the other hand, a "false positive" variant appeared in 0.27 kb on the average. Employing barcode-indexing, we could detect a heterozygous rare variant of 1 sample in the 96 samples. The bar coding-based multiplexing with pooled DNA is a suitable method for resequencing of a large number of samples. However, we should be cautious of the false positive reads if multiplicity of pooling is increased. We need to further optimize the protocols and algorithms to extract rare variants efficiently from a large scale of samples.

## 522/W/Poster Board #180

**Polymorphisms within *ataxin-3* and its interaction partners as genetic modifiers of Spinocerebellar ataxia type 3.** *T. Schmidt[1], V. Schmauke[1], N. Schlipf[1], J. Weber[1], T. Schwab[1], D. Wilkens[1], V. Häfele[1], C. Funke[1], C. Richter[1], A. Pohl[1], D. Lenz[1], I. Mäckle-Jentsch[1], P. Bauer[1], L. Schöls[2], O. Riess[1].* 1) Medical Genetics, Univ Tuebingen, Tuebingen, Germany; 2) Neurology, Univ Tuebingen, Tuebingen, Germany.

Spinocerebellar Ataxia Type 3 (SCA3) or Machado-Joseph disease (MJD) is an autosomal dominantly inherited, neurodegenerative disorder which is caused by the expansion of a CAG repeat in the *MJD1 gene* resulting in an expanded polyglutamine repeat in the encoded ataxin-3 protein. SCA3 therefore belongs to the group of the so called polyglutamine diseases. Statistically, a correlation between the number of CAG repeats and the age at onset exists and patients with a higher number of CAG repeats have first symptoms at earlier ages. However, this correlation is not perfect and the number of CAG repeats contributes only about 55 % to the age at onset. Therefore, the remaining 45 % are influenced by other factors, which we try to identify in this study. The actual function of ataxin-3 is not fully understood. However, interaction partners of ataxin-3 have been identified. In this project, we analyzed the coding genes of ataxin-3 and its interaction partners HHR23A, one human homologue of yeast RAD23, and p97/VCP for single nucleotide polymorphisms (SNP) and their influence on the age at onset. We first analyzed already known polymorphisms published in relevant databases in our cohort of SCA3 patients and later performed own screenings for novel SNP. For these screenings, we first generated PCR conditions for the amplification of all coding exons as well as the 5' and 3' untranslated regions (UTR) and the putative promoter and then established for these 51 PCR products conditions for a mutation screen using dHPLC. After screening of a collection of SCA3 patients, putative polymorphisms were identified via sequencing. Finally, an appropriate assay was generated for the genotyping of all SCA3 patient samples collected within the EUROSCA consortium (more than 500 samples). These results were then correlated with the age at onset in order to analyze its impact on the disease. In our analyses, p97/VCP turned out to be highly conserved and the few polymorphisms within this gene seem not to contribute to the age at onset. Interestingly, in the other analyzed genes some of the SNP turned out to have an impact on the age at onset in SCA3 patients. We will present the statistical correlation between these known and novel polymorphisms and the age at onset. We hope that our results will improve the prediction of clinical symptoms and contribute to the understanding of pathogenic processes in SCA3.

**A Novel X-linked 4-Repeat Tauopathy with Parkinsonism and Spasticity.** *P. Navas[1,2], W.H. Raskind[1,2,3], J.B. Leverenz[1,3,5,6], M. Matsushita[2], C.P. Zabetian[3,4,6], A. Samii[3,6], S. Kim[1], N. Gazi[1], L.M. Tisch[2], J.G. Nutt[7], J. Wolff[2], D. Yearout[3,4], J.L. Greenup[1], E.J. Steinbart[3], T.D. Bird[2,3,4].* 1) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 2) Department of Medicine, University of Washington, Seattle, WA; 3) Department of Neurology, University of Washington, Seattle, WA; 4) Geriatric Research Education Clinical Center, Veterans Affairs Puget Sound Health Care System, Seattle, WA; 5) VISN 20 Mental Illness Research Education Clinical Center, Veterans Affairs Puget Sound Health Care System, Seattle, WA; 6) Parkinson's Disease Research Education Clinical Center, Veterans Affairs Puget Sound Health Care System, Seattle, WA; 7) Department of Neurology, Oregon Health Sciences University, Portland, OR.

The parkinsonian syndromes comprise a highly heterogeneous group of disorders. Although 14 loci are linked to predominantly familial Parkinson's disease (PD) and disease-causing mutations have been identified in eleven genes, additional PD loci are likely to exist. We recently identified a multigenerational family of Danish and German descent with a unique syndrome characterized by parkinsonian features and variably penetrant spasticity (XPDS), in which X-linked disease transmission was suggested. XPDS is unlike idiopathic PD because of prominent spasticity and a lack of LB pathology and is unlike classic hereditary spastic paraplegia because of the co-occurrence of parkinsonian features. Autopsy in one individual failed to reveal synucleinopathy; however, there was a significant 4-repeat tauopathy in the striatum. Our objective was to identify the locus responsible for this unique X-linked parkinsonian disorder. Members of the XPDS family were genotyped for markers spanning the X chromosome. Two-point and multipoint linkage analyses were performed and the candidate region refined by analyzing additional polymorphic markers. A multipoint LODmax score of 2.068 was obtained between markers DXS991 and DXS993. Haplotype examination revealed an approximately 20 cM region bounded by markers DXS8042 and DXS1216 that segregated with disease in all affected males and obligate carrier females and was not carried by unaffected at-risk males. The XPDS locus does not overlap with any known X-chromosome PD or spasticity locus and the 28 Mb critical region contains ~200 RefSeq candidate genes and 118 hypothetical protein genes. Candidate genes within the critical region have been prioritized for sequence analysis based on high levels of CNS expression and protein function. For an X-linked disorder, a LOD score of >2 provides significant evidence ($p \leq .05$) in favor of linkage; however, although unlikely, it remains possible that an autosomal locus is responsible for the disease. With this in mind, we used exclusion mapping or direct sequencing to rule out mutations in several autosomal dominant disease genes known to cause syndromes or phenotypes similar to XPDS including SPG3A, SPG4, FBXO7, PLA2G6, DSC3, PARK2, MAPT, SNCA and LRRK2. In conclusion, we have identified a unique X-linked parkinsonian syndrome with variable spasticity and 4-repeat tau pathology, and defined a novel candidate gene locus spanning approximately 28 Mb from Xp11.2-Xq13.3.

## 524/W/Poster Board #182

**The Polycystic Kidney Disease Mutation Database (PKDB): a locus specific database of genetic variants at the *PKD1* and *PKD2* genes.** *S. Rossetti[1], B. Wilson[2], J.P. Kocher[2], V.E. Torres[1], P.C. Harris[1].* 1) Division of Nephrology, Mayo Clinic College of Medicine, Rochester, MN; 2) Bioinformatics Core, Mayo Clinic College of Medicine, Rochester, MN.

Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a frequent inherited nephropathy characterized by kidney cysts leading to kidney failure. ADPKD is caused by mutations at two genes, *PKD1* and *PKD2*. Screening for mutations in large populations has revealed that ADPKD is characterized by high allelic heterogeneity. Through literature mining, we have collected all the published *PKD1* and *PKD2* mutations in a locus specific database, PKDB [http://pkdb.mayo.edu]. Data were extracted from the original reports, corrected to the standard reference sequences, and organized into a database. To date the PKDB includes 875 variants for *PKD1* and 139 variants for *PKD2*. This large dataset has allowed for the first time analysis of the mutational pattern of both *PKD* genes. Of the 875 *PKD1* variants, 306, in 386 families (135 frameshifts, 17 large deletions, 109 nonsense and 45 splicing changes) are truncating (~35%), while 263 are missense (~30%) and 37 are in-frame deletions, with the remaining variants being polymorphisms. Of the 139 *PKD2* variants, the largest portion is truncating changes, 99 total, in 177 families (50 frameshifts, 1 large deletion, 30 nonsense, and 18 splicing) (71%), while only 23 are missense mutations (16.5%), 6 are in-frame deletions, with the remaining being polymorphisms. The high level of allelic heterogeneity and lack of any appreciably recurrent mutation illustrates the challenge of molecular diagnostics. The high number of missense mutations (~1/4 of the total) and the high level of non disease-associated polymorphisms (~10 polymorphism per patient in PKD, including many non synonymous) underline the challenge to determine the pathogenicity of amino acid substitutions. As part of PKDB version 3, we have developed a scoring system for the evaluation of amino acid substitutions at both genes, using *in silico* predictors (the biochemical/biophysical nature of the substitution (Grantham Matrix), the evolutionary conservation, the overall domain conservation when available, the predicted secondary structure propensity and solvent accessibility, calculated using bioinformatics tools. Contextual issues, such as other detected variants in the patient, segregation data and previous description of the variant, have been taken into consideration. This has allowed a substantial re-classification of missense mutations at these genes (90 *PKD1* and 9 *PKD2* with 99 new classified as likely pathogenic), aiding diagnostic and research applications.

## 525/W/Poster Board #183

**Analysis of patients with renal hypouricemia in Czech population.** *B. Stiburkova[1], I. Sebesta[1,2], M. Hosoyamada[3], K. Ichida[4].* 1) Charles University in Prague, First Faculty of Medicine, Institute of Inherited Metabolic Disorders; 2) Institute of Clinical Biochemistry and Laboratory Medicine; 3) Division of Pharmacotherapeutics, Faculty of Pharmacy, Keio University, Tokyo; 4) Department of Pathophysiology, Tokyo University of Pharmacy and Life Sciences, Japan.

Hypouricemia, defined as a serum urate levels < 2 mg/dl, may results from decreased uric acid production, but is more commonly due to decreased renal tubular urate reabsorption. Renal hypouricemia is heterogeneous inherited disorder characterized by impaired tubular uric acid (UA) transport. Most patients are clinically asymptomatic, but acute renal failure and/or nephrolithiasis may develop. Major causative genes are SLC22A12 and SLC2A9. hURAT1 (encoded by SLC22A12) is the major urate-anion exchanger in the kidney, which regulates blood urate levels and plays the central role in reabsorption of urate from glomerular filtrate on apical membrane of the proximal tubules. Genetic variations of the SLC22A12 are associated with renal hypouricemia (OMIM*607096). We have selected patients for analysis of the SLC22A12 (with repetitive serum UA < 1 mg/dl and $EF_{UA}$ > 43%) from the group of 569 Czech hypouricemic cases. Sequence analysis in the 17 subjects revealed 3 sequence variations in the promotor and 5'-UTR region and 5 in exonic regions. 3 transition and 4 deletions, yet unpublished, were found in 6 patients. The function and immunohistochemistry analysis in *Xenopus laevis* oocytes showed significantly decreased urate transport activities of these variants. Recently, transporter GLUT9 (encoded by SLC2A9) was identified, member of the glucose transporter family, which plays a key role in urate reabsorption on both sides of the proximal tubules. Genetic variations of the SLC2A9 were revealed in renal hypouricemic patients (OMIM*606142). We have diagnosed Czech family suffering from renal hypouricemia with one nucleotide insertion (nonsense seq. variant) in SLC2A9 gene and no sequence variants in urate transporters SLC22A12, SLC2A9, SLC17A3, ABCC4, ABCG2 and MRP4. This finding gives further evidence that SLC2A9 is causative gene of renal hypouricemia and supports the important role of SLC2A9 in regulation of serum urate levels in humans. Our finding supports the prediction that intact function of both SLC22A12 and SLC2A9 is necessary for normal urate reabsorption. In patients with unexplained hypouricemia and elevated urinary excretion of urate the mutational analysis of several genes coding urate transporters should be performed for confirmation of diagnosis. Detection of more patients with hereditary renal hypouricemia is needed for better understanding of renal urate handling. Supported by grant MSM0021620806 Czech Republic.

## 526/W/Poster Board #184

**Identification of the second North American family with *REN*-associated medullary cystic kidney disease.** *J.N. Adams[1], A.J. Bleyer[2], T.C. Hart[4], M. Zivna[3], S. Kmoch[3], P.S. Hart[1].* 1) Office of the Clinical Director, NIH, Bethesda, MD; 2) Section on Nephrology, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Center for Applied Genomics and Institute for Inherited Metabolic Disorders, Charles University in Prague, First Faculty of Medicine, Prague; 4) Human Craniofacial Genetics Section, NIDCR, NIH, Bethesda, MD.

Recently, a Renin (*REN*) mutation was identified in a family of Belgian descent segregating autosomal dominant chronic interstitial kidney disease, anemia, and hyperuricemia. The mutation caused deletion of a single leucine residue in the signal peptide (p.L16del), causing reduced renin biosynthesis. We subsequently identified a North American family with an independent origin of the p.L16del mutation. We now present a North American family with a different mutation in *REN* resulting in a more severe clinical phenotype. The proband presented with acute kidney failure after a viral illness resulting in volume depletion at the age of 3 yr. At 6 yr, she suffered from polyuria, nocturia, and anemia. The blood pressure at that time was 82/52 mm Hg with an unremarkable physical examination. A 24 hr urine collection revealed minimal protein, an elevated urine sodium at 5.2 mEq/kg/day, and an elevated urinary volume at 57 ml/kg/day. Her serum uric acid levels were as high as 7.7 mg/dl (normal <6 mg/dl), with a fractional excretion of uric acid of 3.0% (normal 6-10%). She also suffered from anemia responsive to erythropoietin. At age 10, she underwent a 24 hr urine collection for aldosterone revealing 2 ug/24 hr (normal 2-16 ug/24hr). Her father suffered from anemia since childhood. At age 29, he first suffered from gout. At age 33 he underwent a biopsy for renal insufficiency revealing tubulointerstitial scarring with global glomerulosclerosis. A 24 hr urine collection revealed 3450 ml, urinary sodium elevated at 283 mEq/24 hr, and fractional excretion urate 3% (nl >5%). A 24 hr urinary aldosterone was 9 ug/24 hr (nl 17-44 on a low sodium diet). *REN* was sequenced in the affected proband and father, the unaffected mother and sibling as well as the father's parents and unaffected siblings. A c.58T>C change was identified in the affected individuals, predicting substitution of the terminal cysteine residue of the signal peptide with an arginine residue (p.C20R), but not in the unaffecteds. Thus, the mutation appears to have arisen de novo in the father who then transmitted it to the proband. Haplotype analysis is consistent with the mutation have arisen on the maternal chromosome. To date all *REN* mutations causing hereditary interstitial kidney disease have occurred in the signal peptide. Patients with anemia, hyperuricemia and chronic progressive kidney failure should be tested for *REN* mutations, even in the absence of a positive family history.

## 527/W/Poster Board #185

**Novel uromodulin mutations identified in 8 out of the 21 probands with uromodulin associated kidney disease (UAKD).** *K. Hodanova[1], M. Zivna[1], P. Vyletal[1], M. Votruba[1], G. Venkat-Raman[2], T. Ring[3], S. Kmoch[1].* 1) Inst Inher Metab Dis, Charles Univ, Prague, Czech Republic; 2) Renal Unit, Queen Alexandra Hospital, Portsmouth, United Kingdom; 3) Department of Nephrology - Aalborg Hospital , Denmark.

The term of the uromodulin associated kidney diseases (UAKD) emerged recently for a group of genetically heterogeneous autosomal-dominant tubulointerstitial nephropathies characterized by the variable combination of hyperuricemia, gouty arthritis, decreased urinary uromodulin (UMOD) excretion and abnormal UMOD expression in the kidney. UAKD disease complex comprises phenotypes known as a familial juvenile hyperuricemic nephropathy (FJHN) (OMIM 162000), medullary cystic kidney diseases type 1 (MCKD1) (OMIM 174000) and type 2 (MCKD2) (OMIM 603860) and glomerulocystic kidney disease (GCKD). Following our original report of 19 UAKD families and 6 novel UMOD mutations (Vyletal et al, Kidney Int. 2006), we investigated a further 282 probands showing some of the clinical and biochemical hallmarks of the UAKD phenotype. At first, we performed semi-quantitative and qualitative analysis of UMOD in random urine samples by Western blot. Next, based on the reduction in UMOD excretion amount and/or presence of abnormal UMOD immunopositive forms we selected 21 probands from United Kingdom (9) Czech Republic(9), Denmark (1), Netherlands (1) and Israel (1) for UMOD sequence analysis. In these probands we identified 8 UMOD mutations, 6 of which are novel (C112G, R185C, G210D, W230R, P236R, C306Y) and 2 were previously published (C148Y and 383del12/ins9). In one additional case with otherwise normal UMOD sequence we identified cSNP variation in exon 7 resulting in V458L amino acid exchange. Our work further demonstrates the genetic heterogeneity of UAKD, confirming our previous estimates, that in about 38% of the families the disease is associated with UMOD mutation and stress the utility and importance of urinary UMOD analysis in probands with clinical and biochemical signs of UAKD.

## 528/W/Poster Board #186

**Bladder dysfunction in cystinuria male mice is associated with decreased uroplakin expression.** *A. Sahota[1], D.-Y. Cha[2], M. Yang[1], L. Serrano[1], R.M. Levin[3], J.G. Barone[2], J.A. Tischfield[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Dept Surgery, UMDNJ-RWJMS, New Brunswick, NJ; 3) Dept Pharmaceutical Sci, Albany Coll Pharmacy and Health Sci, Albany, NY.

**Background:** Cystinuria is the most common inherited cause of urinary tract stones in children, with males more severely affected than females. Slc3a1 knockout male mice from age 4 months develop cystine stones in the bladder, but only a small fraction of females (age >20 months) form stones. Cystinuria male mice have partial bladder outlet obstruction, but bladder function in female mice is only mildly affected. The apical layer of the bladder urothelium contains uroplakins that form rigid membrane plaques on the cell surface. These proteins provide a permeability barrier that prevents the leakage of urine into the underlying tissue. The four major uroplakins are UPI(a,b), II, and IIIa and they occur as UPIa/UPII and UPIb/UPIIIa pairs. **Methods:** We examined uroplakin expression in bladders from cystinuria and control mice of different age groups (3-6 animals per group). Total RNA was isolated from fresh bladders after removal of any stone material. Real time PCR was carried out using Syber Green dye and GAPDH was used as an internal control. **Results:** UP1a and UPII were expressed at similar levels in 4-5 and 10-12 months old control male mice. There was a significant, age-dependent reduction in expression of these two transcripts in bladders from cystinuria male mice. The UPIa/GAPDH ratio for the younger age group was 0.55 (p = 0.04) and for the older age group the ratio was 0.07 (p = 0.0002). The corresponding UPII/GAPDH ratios were 0.40 (p = 0.01) and 0.21 (p = 0.0001), respectively. In females, there was no difference in UP1a or UPII expression between control and cystinuria mice among the three age groups tested (4-5, 10-12, and 20-22 months). Expression levels of UPIb and UPIIIa were consistently lower in cystinuria males compared with controls, whereas in cystinuria females the expression of these transcripts was unaffected by phenotype. **Conclusions:** These results demonstrate that the presence of cystine stones in the male bladder is associated with decreased expression of uroplakins, possibly through exfoliation of cells from the urothelial surface expressing these proteins. Breaching of the urothelial barrier may lead to the release of mediators that disrupt bladder function in cystinuria male mice. The lack of a significant effect on bladder function in cystinuria female mice suggests the presence of inhibitors of stone formation. These observations may in part account for the gender differences in disease severity seen in cystinuria patients.

## 529/W/Poster Board #187

**Molecular basis of autosomal polycystic kidney disease (*PKD1, PKD2*): identification of 72 new mutations and two large rearrangements.** *E. CORNEC LE GALL[1,2], MP. AUDREZET[1], B. MERCIER[1], J. CREFF[1], I. QUERE[1], Y. LE MEUR[2], C. FEREC[1].* 1) Inserm U613, Molecular Genetic Laboratory, CHU, Brest, France; 2) Nephrology, Dialysis and Transplantation Unit, CHU, Brest, France.

Autosomal dominant polycystic kidney disease (ADPKD) is the most common monogenic disorder, with an estimated prevalence ranging from 1/500 to 1/1000. Clinical features are highly variable. The disease is characterized by the progressive development of bilateral fluid-filled cysts in the kidney and others organs and it accounts for 5 to 10 % of the causes of end stage renal disease, roughly in the sixth decade of age, but neonatal occurrence are also reported. In addition, non-cystic manifestations are described, such as intracranial aneurysms in 8 % of the patients or mitral valve prolapse. Mutation-based diagnosis in ADPKD is complicated by genetic and allelic heterogeneity, with 2 genes involved, *PKD1* with 314 pathogenic variants described and *PKD2* with 91 mutations reported. Moreover, *PKD1* is duplicated over 2/3 of its length and is extremely rich in GC nucleotides. Besides, diagnosis of ADPKD is based upon the detection of kidney cysts by abdominal ultrasonography, according to age-dependent criteria. All these aspects have contributed to consider mutation screening time-consuming, expansive and irrelevant. However, tremendous progress have been made in the past decade in understanding molecular pathogenesis, and targeted drugs are on the way, which makes crucial the identification of predictive factors of clinical evolution and thus the identification of causing mutation to define genotype-phenotype correlations. We undertaken a comprehensive study of *PKD1* and *PKD2* in a large cohort of 162 unrelated patients, using newly home-designed conditions for specific amplification followed by sequencing analysis, and we proposed for the first time a new approach for the study of large rearrangments by quantitative PCR. This new strategy enabled us to identify 71 new mutations for *PKD1* and 3 new mutations in *PKD2*. The majority of changes in *PKD1* were predicted to truncate the protein, with 51% of frameshift mutations, 31% of nonsense mutations and 12% of splicing changes. We successfully characterized two large rearrangements, one of them erasing almost all the *PKD1* gene. Beyond our cohort, mutation-based diagnosis turned to be relevant for assessment of ADPKD in some particular situations, such as atypical forms or absence of a familial history. Moreover, it's likely to become a very useful tool for clinicians as new therapies are now emerging.

## 530/W/Poster Board #188

**Characterization of a broad spectrum of mutations in cystic fibrosis transmembrane conductance regulatory gene (CFTR) gene: An Indian Scenario.** *R. Prasad[1], N. Sharma[1], M. Singh[1], S.K. Singh[1], G. Kaur[2], B.R. Thapa[1].* 1) Department of Biochemistry, Postgraduate Institute of Medical Education and Research, Chandigarh - 160012; 2) Department of Physiology, Government Medical College and Hospital, Chandigarh - 160032.

Cystic fibrosis (CF) is an autosomal recessive disease caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This study was performed on Indian CF patients (n=50) to investigate the spectrum of mutations in the CFTR gene and their association with intragenic and extragenic marker haplotypes. We report identification of 14 previously known and eight novel mutations, namely 3986-3987delC, 876-6del4, 1792InsA, L69H, S158N, Q493L, I530L and E1329Q. The frequency of delta F508 was found to be 27%. Absolute linkage between delta F508 and the KM.19-GATT-TUB9-M470V-T854T haplotype (2-2-1-1-1) predicts a relatively recent appearance of delta F508 in Indian CF patients. Low frequency of delta F508 mutation and detection of eight novel and thirteen rare mutations reflect a heterogeneous spectrum of mutations in Indian CF patients. Failure to detect mutations in 34% of alleles indicates the possible presence of gross deletions involving one or more exons or may indicate the location of the molecular defects in either the noncoding parts of the gene or in the promoter region, which warrants analysis of those regions. Additionally, we studied the mutations in the CFTR gene in CAVD patients. The spectrum and frequency of CFTR mutations in Indian males with congenital absence of vas deferens (CAVD) is unknown. We investigated 50 Indian males, diagnosed with unilateral or bilateral absence of vas deferens at the PGIMER, Chandigarh. This study led to the identification of 12 CFTR gene mutations on 48% of 100 Indian CAVD chromosomes. This study confirms the molecular heterogeneity of CFTR mutations in CAVD.

## 531/W/Poster Board #189

**Endothelial nitric oxide synthase gene VNTR polymorphism and Respiratory Distress in premature infants.** *H. Chen[1], J.G. Aryama[1], K. Yanamandra[1], D. Napper[1], S.A. Ursin[1], A. Pramanik[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Dept Pediatrics, Perinatal Gen, LSUHSC- Shreveport, Shreveport, LA; 2) Dpt Pediatrics, UT Health Science Center, Memphis, TN.

Premature infants frequently experience delayed cardiopulmonary transition from fetal to neonatal stage compared to full term and normal weight newborn infants, due to their immature vasculature, especially in the pulmonary system. This transition is mediated by endogenous nitric oxide (NO) from vascular endothelial milieu. As a result of this delayed transition, premature infants experience a great deal of respiratory distress. Pharmacological inhaled nitric oxide along with supplemental oxygen is instituted frequently to reduce the distress and to facilitate the improved vasculature in those infants. Endothelial nitric oxide (eNO) serves as a vasodilator, relaxes smooth muscle, prevents platelet aggregation, and facilitates improved blood flow, leading to vascular homeostasis. Reduced nitric oxide levels result in vasoconstriction and weak tone leading to decreased blood flow and hypoxia. Mutant eNO synthase (eNOS) genotypes result in reduced nitric oxide levels by decreasing the enzyme activity. Although several studies have been carried out with NO, polymorphic studies at gene level were limited at best. Our earlier studies have revealed a strong association of eNOS promoter polymorphism with delayed cardiopulmonary transition in premature infants. Presently we are studying the association of eNOS variable number of tandem repeats (VNTR) polymorphism and to address the role of eNOS genotypes during respiratory distress in premature infants. In the present investigation we have studied the association of eNOS VNTR genotypes of 27bp repeats in intron 4 region of the gene. We have collected peripheral blood specimens from a total of 281premature infants consecutively from our NICU facility and genotyped by PCR. Our earlier findings in the study of eNOS genotypes in the promoter region have shown an elevation of -786C mutant alleles resulting in lower nitric oxide levels in infants with respiratory distress as compared to controls. However, in the present study the frequency of rear allele *a* consisting of 4 repeats was elevated though not as much as promoter genotypes in patients as compared to controls (0.18 vs. 0.14, odds ratio 1.4). Thus we speculate that the mutant genotype in promoter region of eNOS gene may have a stronger role in the etiology of respiratory distress compared to the VNTR genotypes. Clinical data of patients, ethnic stratification, distribution of genotypes and their significance will be presented.

## 532/W/Poster Board #190

**The role of galectin-3 in the development of pulmonary fibrosis in Hermansky-Pudlak syndrome.** *C. Yeager[1,2], H. Dorward[1], T. Markello[1], B. Gomez[1], K. O'Brien[3], J. Salas[3], B.R. Gochuico[1], W.A. Gahl[1].* 1) Section on Human Biochemical Genetics, Medical Genetics Branch, NHGRI, Bethesda, MD; 2) HHMI-NIH Research Scholar, Howard Hughes Medical Institute, Bethesda, MD; 3) Intramural Program of the Office of Rare Diseases, OD, NIH, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is a rare autosomal recessive disorder characterized by abnormal biogenesis of lysosome-related organelles, such as melanosomes and platelet delta granules; defects in the biogenesis of these two organelles result in the oculocutaneous albinism and bleeding diathesis seen in HPS. There are 8 known HPS-causing genes, each encoding a protein that, in combination with other proteins, functions to form or traffic lysosome-related organelles. HPS-1 and HPS-4, subtypes of HPS with defective Biogenesis of Lysosome-related Organelles Complex-3 (BLOC-3), are notable for development of pulmonary fibrosis, which is the leading cause of mortality in HPS-1. All HPS-1 patients show evidence of pulmonary fibrosis by sixty years of age. Currently, the only treatments available for pulmonary fibrosis are investigational drugs and lung transplantation. The etiology of pulmonary fibrosis in HPS-1 and HPS-4 is unknown. Two pneumocytes of interest are the type II epithelial cell and the alveolar macrophage. In HPS-1 pulmonary fibrosis, type II cells are engorged with giant lamellar bodies, which are lysosome-related organelles that contain surfactant. In addition, alveolar macrophages in HPS-1 pulmonary fibrosis contain aggregates of ceroid lipofuscin and are activated. We hypothesized that galectin-3, an oncoprotein expressed by type II cells, contributes to the pathogenesis of HPS-1 pulmonary fibrosis. Our data demonstrate that galectin-3 immunostaining of type II cells and alveolar macrophages is more intense in HPS-1 pulmonary fibrosis lung tissue compared to that in idiopathic pulmonary fibrosis (IPF) or normal lung tissue. In addition, a cell surface predominance of galectin-3 is observed in alveolar macrophages in HPS-1 pulmonary fibrosis, but not IPF, lung tissue. Consistent with these data, bronchoalveolar lavage fluid concentrations of galectin-3 in HPS-1 pulmonary fibrosis are significantly higher than in IPF or normal volunteers (P=0.014 and =0.024, respectively). High alveolar concentrations of galectin-3 may be a consequence of aberrant trafficking of galectin-3 or its binding partners in HPS-1. Dysregulation of galectin-3 may contribute to abnormal modulation of inflammation and repair in the lung, which may lead to pulmonary fibrosis.

## 533/W/Poster Board #191

***COL1* C-propeptide Cleavage Site Mutations Cause OI with Increased Bone Mineralization.** *A.M. Barnes[1], K. Lindahl[2], M. Whyte[3], T. Hefferan[4], M.J. Yaszemski[4], C-J. Rubin[2], A. Kindmark[2], W. McAlister[3], S. Mumm[3], A. Boskey[5], O. Ljunggren[2], J.C. Marini[1].* 1) Bone and Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD, USA; 2) Department of Endocrinology, Medical Sciences, Uppsala University, Uppsala, Sweden; 3) Shriners Hospital for Children, St. Louis, MO, USA; 4) Department of Orthopedics, Mayo Clinic, Rochester, MN, USA; 5) Hospital for Special Surgery, Weill Medical College at Cornell University, New York, NY, USA.

Osteogenesis imperfecta (OI), or brittle bone disease, is most often caused by mutations in the type I collagen genes. Mutations in the type I procollagen C-propeptide cleavage site are of particular interest because they disrupt a unique processing step, but their clinical and biochemical consequences have not been reported. We investigated two children with mild OI who had cleavage site mutations in COL1A1 (P1: $\alpha$1(I)Asp1041Asn) or COL1A2 (P2: $\alpha$2(I)Ala1029Thr). P1 is an 11 yr old girl whose L1-L4 DEXA and pQCT vBMD z-scores were +3. Her elevated BMD contrasted with radiographs demonstrating osteopenia and os-in-os vertebrae. P2 is an 11 yr old boy with an L1-L4 DEXA z-score of 0 and pQCT vBMD of -1.8; his radiographs revealed gracile long bones with osteopenia. Both P1 and P2 are at the 75th percentile for height. Iliac crest histomorphometry was characteristic of mild OI: P1 had increased bone remodeling while P2 had decreased BV/TV; neither had a mineralization defect or signs of osteosclerosis. FTIR imaging analysis in both cortical and trabecular bone revealed elevated mineral/matrix in P1 and P2, compared to age-matched controls or classical OI. P1 and P2 have significantly increased collagen crosslinks in trabecular bone and slightly increased crosslinks in cortical bone. The dermal fibrils of P1 had a normal diameter with slight surface irregularities, while P2 had small fibrils with greater irregularities, including some with blebs. Steady-state collagen electrophoresis showed slight backstreaking of $\alpha$1(I) and $\alpha$2(I) in cell layers of both patients. Chain incorporation was normal in P1 and slightly delayed in P2. Pericellular processing of P1 and P2 was delayed, with increases in pC-$\alpha$1, pro-$\alpha$1 and pro-$\alpha$2, and less mature collagen formation. Pro-$\alpha$1(I) cleavage appears crucial to C-propeptide processing, while defective pro-$\alpha$2(I) specific or non-specific cleavage occurs after $\alpha$1(I) processing. Hence, these mutations define a novel phenotype among type I collagen defects which reveals the importance of the type I procollagen C-propeptide to bone mineralization. In combination with recently reported adult siblings with an $\alpha$1(I)Ala1040Thr substitution and high bone mass on radiographs and histomorphometry (Calcif Tissue Int 82S1: CC01), our cases suggest that defects in pro-$\alpha$1(I) processing lead to high BMD in childhood, with signs of osteopetrosis occurring subsequently.

## 534/W/Poster Board #192

**A specific interaction between a novel variant in the cis-acting sonic hedgehog regulatory sequence (ZRS) and transcription factor and its association with preaxial polydactyly with triphalangeal thumb.** *M. Farooq[1], L. Hansen[2], H. Eiberg[3], J.T. Troelsen[3], M. Boyd[3], M. Aslam[1], M.S. Hussain[1], M. Tariq[1], A. Ali[1], I. Ahmad[1], N. Tommerip[2], K.W. Kjaer[2], S.M. Baig[1].* 1) Human Molecular Genetics, National Inst for Biotech and Genet Eng (NIBGE), Faisalabad, Punjab, Pakistan; 2) Wilhelm Johannsen Centre for Functional Genome Research, Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark; 3) Department of Cellular and Molecular Medicne, University of Copenhagen, Copenhagen, Denmark.

Intact Sonic Hedgehog cis-regulatory sequence also known as 'ZRS' located in intron 5 of LMBR1 is important for proper spatiotemporal expression of Sonic hedgehog (SHH) in the developing limb bud. Many point mutations have been identified in ZRS leading to disruption of SHH expression during limb development leading to preaxial duplication in upper limbs. In this study, preaxial polydactyly and triphalangeal thumb in Pakistani family with autosomal dominant inheritance was analyzed molecularly. The phenotype was confirmed by radiographic examination of three affected members. Linkage analysis using microsatellite markers D7S550, D7S559 and D7S2423 was performed and maximum multipoint LOD score of 1.93 at an allele frequency of $\theta$= 0.1 was obtained. This region spans SHH and its cis-acting regulatory element (ZRS), which is well conserved among various species lying in intron 5 of LMBR1. Direct Sequencing of ZRS identified a novel point mutation (T>G) in ZRS element at base position 4976 in intron 5 of LMBR1. Restriction enzyme analysis confirmed that the mutation co-segregated with the phenotype. The mutation was absent in 280 unrelated normal chromosomes from the same ethnic group. We analyzed the effect on transcription factor binding affinity of identified point mutation. Electrophoretical mobility shift assay (EMSA) demonstrated a marked difference between wt and the mutant probe which uniquely bound a specific subset of nuclear transcription factors extracted from Caco-2 cells. We suggest that altered transcription factor affinity may be important for our understanding of how single nucleotide substitutions in long distance regulatory elements changes cis-regulation of its target gene.

## 535/W/Poster Board #193

**A distinct type II collagen phenotype: premature arthritis.** *P. Kannu[1,2,3], J. Bateman[2,3], S. Randle[5], S. Cowie[2], D. du Sart[2,3], S. McGrath[6], M. Edwards[4], R. Savarirayan[2,3].* 1) Medical Genetics Unit, Queen's University, Kingston, Ontario, Canada; 2) Murdoch Childrens Research Institute Flemington Road, Melbourne 3052 Australia; 3) University of Melbourne Parkville 3052 Australia; 4) Hunter Genetics, Hunter-New England Area Health Service, Newcastle, AUSTRALIA; 5) Glenroy Specialist Centre, 842 Pascoe Vale Rod, Melbourne, AUSTRALIA; 6) Princeton Medical Centre, 60 Lindsay Street, Hamilton 2303, AUSTRALIA.

Mutations in the gene encoding type II collagen (COL2A1) give rise to a spectrum of phenotypes predominantly affecting cartilage and bone. These chondrodysplasias are typically characterized by disproportionate short stature, eye abnormalities, cleft palate, and hearing loss. Less recognized is that mutations in COL2A1 can also present with degenerative joint disease in the absence of any other phenotypic clues. We report two Australian families presenting with an isolated arthritic phenotype, segregating as a dominant trait affecting both large and small joints, prior to age 30 years. Sequencing of the COL2A1 gene in the propositi revealed two novel sequence changes resulting in glycine substitutions in the triple helical domain of type II collagen. We review the increasing evidence implicating COL2A1 mutations in individuals presenting with isolated degenerative joint disease, aiming to alert physicians assessing these patients to this possibility. The importance of finding a COL2A1 mutation in such patients lies in the subsequent ability to accurately assess recurrence risks, offer early (including prenatal) diagnosis, and provide information regarding natural history of the condition. Most importantly, it enables at-risk individuals to be identified for implementation of preventative strategies (i.e. weight loss, joint-friendly exercise programs) and early ameliorative management of their condition.

## 536/W/Poster Board #194

**Brachydactyly Caused By a Frameshift Mutation in CHSY1.** *B. Merriman[1], H. Lee[1], B. O'connor[1], M. Shboul[2], C. Bonnard[2], J. Tian[2], A. Al-Hadidy[4], A. Masri[4], H. Hamamy[3], S. Nelson[1], B. Reversade[2].* 1) Dept Human Genetics, Univ of California, Los Angeles, Los Angeles, CA; 2) Institute of Medical Biology, A*Star, Singapore; 3) Geneva Foundation for Medical Education and Research, Geneva, Switzerland; 4) Department of Pediatrics and Radiology, Jordan University Hospital, Jordan.

We studied a consanguineous Jordanian family with two affected children exhibiting Brachydactyly Type A4 (OMIM 605282), and one unaffected child. A novel high-throughput strategy comprised of SNP-chip based homozygosity mapping, array-based genomic pulldown of exonic regions, and massively parallel resequencing on the Illumina GAII platform, was used to efficiently screen the coding regions of all 177 known genes in the 16.8 Mb candidate locus and identify a candidate causal mutation as a delG frameshift nonsense mutation at base 92 of exon 1 of CHSY1, which results in a severely truncated protein. CHSY1 is an enzyme involved in the synthesis of chondroitin sulfate, which is involved in extracellular matrix deposition and morphogenesis. This gene has not been previously been implicated in Brachydactyly or other Mendelian disorders, but gene co-expression analysis shows it is involved in NOTCH signaling, which has been linked to Brachydactyly via mouse knockout models of the Jagged2 and y-Secretase genes. We perform studies of protein expression in primary patient fibroblast cells to demonstrate greatly reduced CHSY1 levels and altered NOTCH signaling, thereby supporting the sequence-based evidence that this is the causal mutation in this family.

## 537/W/Poster Board #195

**Absence of FGF23 or DMP1 Mutations in 30 Patients Diagnosed Clinically/Biochemically With Sporadic X-Linked Hypophosphatemia.** *S. Mumm[1,2], D. Wenkert[2], M. Huskey[1], V.A. Wollberg[2], M.P. Whyte[1,2].* 1) Div Bone and Mineral Diseases, Washington University School of Medicine, St Louis, MO; 2) Ctr Metabolic Bone Disease, Shriners Hosp Children, St Louis, MO.

Heritable forms of hypophosphatemic rickets (HR) include: X-linked dominant HR (XLH, caused by de-activating mutations in the PHEX gene), autosomal recessive HR (ARHR, caused by de-activating mutations in the DMP1 gene), and autosomal dominant HR (ADHR, caused by activating mutations in the FGF23 gene). Over the past 26 years, we have cared for 259 pediatric HR patients from throughout the United States. After excluding 12 patients with HR from McCune-Albright syndrome, epidermal nevus syndrome, tumor-induced rickets, or cystinosis, etc., there were 73 sporadic cases diagnosed clinically/biochemically with XLH. Here, we investigated whether 30 of these 73 sporadic patients (those for whom DNA was available) have mutations in either the DMP1 or FGF23 genes. We noted that routine biochemical studies and pedigree review of our dominant HR cases have never shown male-to-male transmission indicating autosomal dominant inheritance. Genomic DNA was isolated from blood leukocytes. All five coding exons and adjacent mRNA splice sites of the DMP1 gene, and exon 3 (containing all known ADHR mutations) of the FGF23 gene, were amplified by PCR and sequenced in both directions. The patients' DNA sequences were analyzed by alignment to a control sequence using Vector NTI AlignX software, and by visually examining each DNA sequence electropherogram. No mutations in either the DMP1 or FGF23 genes that might cause either ARHR or ADHR, respectively, were identified among these 30 sporadic HR cases. Mutation studies of exons and mRNA splice sites of the larger and more complex PHEX gene should reveal specific defects that cause HR in most of this population. Accordingly, our cumulative experience with 259 hypophosphatemic rickets patients indicates that both ARHR and ADHR are exceedingly rare in the United States. Exclusion of defects in the DMP1 and FGF23 genes in our sporadic HR cases helps guide the care of these patients.

## 538/W/Poster Board #196

**MOdb, a new mutation database for the Multiple Osteochondromas causing genes EXT1 and EXT2.** *W. Wuyts[1], I. Jennes[1], E. Pedrini[2], M. Zuntini[2], M. Mordenti[2], S. Balkassmi[3], C. Asteggiano[4], B. Casey[5], E. Bakker[3], L. Sangiorgi[2].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Department of Medical Genetics, Rizzoli Orthopaedic Institute, Bologna, Italy; 3) Center for Human and Clinical Genetics, Leiden University Medical Centre, The Netherlands; 4) Center for the Study of Congenital Metabolophaties (CEMECO), Children's Hospital of Santísima Trinidad, National University of Cordoba, Argentina; 5) Molecular Genetics Laboratory, British Columbia Children's Hospital, Vancouver, BC, Canada.

Multiple osteochondromas (MO) is an autosomal dominant disease characterized by the formation of multiple cartilage-capped bone tumors growing outward from the metaphyses of the long bones. MO is genetically heterogeneous and is associated with mutations in Exostosin-1 (EXT1) or Exostosin-2 (EXT2), both tumor-suppressor genes of the EXT gene family. All members of this multigene family encode glycosyltransferases involved in the adhesion and/or polymerization of heparin sulphate (HS) chains at HS proteoglycans (HSPG's) with EXT1 and EXT2 implicated in the regulation of chondrocyte proliferation and differentiation. EXT1 is located at 8q24.11-q24.13 and comprises 11 exons, while EXT2 is located at 11p12-p11 and contains 16 exons. To date, an EXT1 or EXT2 mutation is detected in 70-95% of affected individuals. We have created the Multiple Osteochondromas Mutation Database (MOdb) based on the Leiden Open source Variation Database (LOVD) software system to provide an overview of known mutations and polymorphisms in both EXT genes. The variants currently described in the database were identified in 5 laboratories from MO reference centers in Europe, Canada and Argentina. Supplementary, data from published reports were included. If available, additional information, such as de novo origin, mode of inheritance, ethnic origin and functional consequences of mutations investigated, was included in the database. Furthermore, general information on the EXT1 and EXT2 genes is provided, accessible through links to other resources (Genbank, Entrez, OMIM). Currently, the MOdb lists over 900 variant entries of which more than 550 are unique. It provides a global overview of mutation distribution, frequency and nature of the identified mutations for both EXT genes. This database is a central resource of MO sequence variant data for investigators that will facilitate the interpretation of new mutations, variants and polymorphisms in patients. It is available online (http://medgen.ua.ac.be/LOVD/home.php) and open to future submissions.

## 539/W/Poster Board #197

**PCNT mutations discriminate MOPDII from SECKEL Syndrome.** *L. Chessa[1], M. Della Monica[2], M. Piane[1], G. Piatelli[3], P. Lulli[1], F. Lonardo[2], F. Ferrari[1], G. Scarano[2].* 1) II Faculty of Medicine, Sapienza University, Roma, Italy; 2) Medical Genetics Department, Gaetano Rummo General Hospital, Benevento, Italy; 3) Neurosurgery Unit, Istituto Giannina Gaslini, Genova, Italy.

A 3 years old boy with proportionate dwarfism and severe microcephaly, high forehead with high hairline, sparse scalp hair, beaked nose, mild retrognathia and hypotonia was diagnosed at birth as Seckel sindrome on the basis of reduced weight, length and cranial circumference, not taking into account the delivery at 33 weeks. At 3 years of age the patient showed all the measurements under the 3rd centile, dysmorphic face with beaked nose and small teeth, hypotonia and mild psychomotor delay, delayed bone age with metaphyseal widening, no appearance of the ossification nuclei in the femoral head, and irregular distal femoral epiphyses. Moreover, he suffered a paresis due to a cerebrovascular malformation. Western blot analysis of the patient's lymphoblastoid cell line lysate showed the absence of the protein pericentrin. Subsequent molecular analysis identified a novel homozygous single base insertion (c.1527_1528insA) in exon 10 of the PCNT gene, which leads to a frameshift (Treo510fs) and to premature protein truncation. Based on the clinical and radiological features as well on the molecular results a diagnosis of MOPD II syndrome was finally established. This case, together with the literature reports, confirms that PCNT mutations are diagnostic of MOPDII syndrome.

## 540/W/Poster Board #198

**A missense mutation in the aggrecan C-type lectin domain disrupts extracellular matrix interactions and causes dominant familial osteochondritis dissecans with short stature and early osteoarthritis.** *B.-A. Jonsson[1], E.-L. Stattin[1], F. Wiklund[2], K. Lindblom[3], P. Önnerfjord[3], Y. Tegner[4], T. Sasaki[5], A. Struglics[6], S. Lohmander[6], N. Dahl[7], D. Heinegård[3], A. Aspberg[8].* 1) Department of Medical Biosciences, Medical and Clinical Genetics, Umeå University Hospital, Umeå, Sweden; 2) Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 3) Department of Experimental Medical Sciences, Lund University, Lund, Sweden; 4) Department of Health Sciences, Technical University Luleå, Sweden; 5) Department of Experimental Medicin I, University of Erlangen-Nuernberg, Erlangen, Germany; 6) Department of Clinical Sciences, Lund University, Lund, Sweden; 7) Department of Genetics and Pathology, The Rudbeck Laboratory, Uppsala University, Uppsala, Sweden; 8) Department of Biology, University of Copenhagen, Copenhagen, Denmark.

Osteochondritis dissecans is a disorder where fragments of articular cartilage and subchondral bone dislodge from the joint surface. We analyzed a five generation family segregating autosomal dominant familial osteochondritis dissecans. Affected family members presented with OCD in knees, hips and elbows, short stature, and early osteoarthritis. A genome wide scan and a multipoint linkage analysis identified aggrecan (ACAN) as a prime candidate gene for the disorder. DNA sequence analysis of the ACAN-gene revealed heterozygosity for a missense mutation (c.6907G>A) in affected individuals, resulting in a p.V2303M amino acid substitution in the aggrecan G3 domain C-type lectin. This domain is important for the interaction with other proteins in the cartilage extracellular matrix. To determine the effect of the V2303M substitution on secretion and interaction, we performed binding studies with recombinant mutated and wild type G3 proteins. We found decreased affinity or complete loss of interaction between V2303M aggrecan and fibulin1, fibulin2 and tenacinR. Analysis of articular cartilage from an affected family member confirmed that V2303M aggrecan is produced and present. The results verified that V2303M results provide a molecular mechanism for the etiology of familial osteochondritis dissecans and confirm the importance of the aggrecan C-type lectin interaction for cartilage function in vivo.

## 541/W/Poster Board #199

**Screening the synemin gene for disease causative mutations in patients with myopathic and neurological diseases.** *Y. MIZUNO[1], J.R. GUYON[2], K. OKAMOTO[1], L.M. KUNKEL[2].* 1) Neurology, Gunma University Graduate School of Medicine, Maebashi, Gunma, Japan; 2) Howard Hughes Medical Institute/Division of Genetics, Children's Hospital Boston and Harvard Medical School, 300 Longwood Avenue, Boston, Massachusetts 02115, USA.

Purpose: Synemin is a novel intermediate filament protein that was originally identified as an $\alpha$-dystrobrevin-binding protein through a yeast two-hybrid screen. There are two isoforms and the smaller, $\beta$-synemin, is predominantly expressed in skeletal muscle whereas $\alpha$-synemin is expressed in both muscle and brain. The $\beta$-synemin gene consists of 5 exons and encodes a 1,253 amino acid protein. $\alpha$-Synemin is encoded by the same 5 exons, although exon 4 is not spliced away, resulting in C-terminus extended by an additional 312 amino acids. Based on its association with $\alpha$-dystrobrevin, synemin is thought to be a structural protein in muscle. Investigations are underway to understand the structural and genetic characteristics of synemin and its potential role in disease. Methods: The intracellular expression patterns of synemin were assayed using confocal microscopy in skeletal muscle and in situ hybridization and immunohistochemical analyses in brain. Its potential role in human disease was investigated by sequencing the genomic $\beta$-synemin sequence in 156 normal controls and 71 myopathic patients with unknown etiology. Summary of results: (1) Synemin expression was localized in skeletal muscle cells to the costamere and muscle Z-lines. (2) In the brain, synemin expression was localized in neurons between the midbrain and pons. (3) Sequencing results identified a potential heterozygous nonsense mutation (C598T: CAG to TAG) in exon 1 in three individuals including a myopathic patient, the patient's unaffected father, and one unaffected control. In other individuals, 12 amino acid altering single-nucleotide polymorphisms were also identified. (4) Histological analyses confirmed that synemin-expressing neurons also express tryptophan hydroxylase-1, a marker of serotoninergic nerve fibers. Conclusions: (1) Synemin is hypothesized to function in the stabilization of muscle by linking the myofibrillar Z-lines with the dystrophin-associated protein complex at the costameres. Its function in brain is still unknown. (2) The C598T mutation was found to be present in 0.44% (2/454) of the analyzed population suggesting that only a very small percentage of population (estimated 0.00002%) would be homozygous carriers. (3) Future studies of synemin-expressing neurons will be required to elucidate synemin's function in brain and continued sequence analyses will help ascertain whether mutations in synemin could contribute to muscle or psychiatric diseases.

**Decrease of Sarcolemmal nNOS as a Molecular Marker in Disorders Associated with Decreased Mobility and Muscle Atrophy.** *J.L. Simmers[1], E.F. Hedderick[3], E. Andres-Mateos[1], E.M. MacDonald[1], T.N. Burks[1], R. Marx[1], R.D. Cohn[1,2,3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD.

Muscle fatigue and atrophy are common clinical findings shared by a variety of hereditary and acquired conditions. Maintaining mobility and muscle integrity is crucial for the management and quality of life of these patients. Previous research connected neuronal nitric oxide synthase (nNOS) to essential roles in regulating muscle blood flow and muscle mass. In healthy muscle, nNOS is associated with the dystrophin-glycoprotein complex (DGC) at the sarcolemma. In dystrophin-deficient muscular dystrophies, such as Duchenne muscular dystrophy, a disruption of the DGC is accompanied by loss of sarcolemmal nNOS which in turn causes a decrease in muscle blood flow and the development of significant fatigue. This phenomenon is attenuated by administration of the PDE5 inhibitor, Sildenafil. To assess the expression pattern of nNOS in a variety of genetic disorders, human muscle biopsies were screened by immunofluorescence. We find that patients presenting with congenital hypotonia, including structural myopathies, mitochondrial disorders, and metabolic myopathies or with uncharacterized hypotonia syndromes exhibit loss or decrease of sarcolemmal nNOS. Moreover we find that patients with acquired forms of myopathy such as immobilization atrophy, denervation, and steroid-induced myopathy show decreased or loss of nNOS expression from the sacrolemma. Interestingly, all of these patients experience significant muscle fatigue associated with varying degrees of immobility. Similarly, in mouse models for steroid induced atrophy, we find a decrease in sarcolemmal nNOS accompanied by activation of well-characterized muscle atrophy pathways. Our results demonstrate that the decrease of sarcolemmal nNOS represents a molecular marker of muscle atrophy, often related to impaired mobility. These findings are of substantial clinical significance as the loss of sarcolemmal nNOS increases proteolysis and potentially causes a decrease in muscle blood flow in response to exertion in a variety of patients with inherited genetic disorders or acquired forms of muscle atrophy. Therefore, the physiological consequences of mislocalized nNOS may exacerbate any underlying muscle pathology. Given previous observations from muscular dystrophy mouse models, administration of Sildenafil may provide significant therapeutic benefit to a many of these patients.

### 543/W/Poster Board #201

**Evaluation of the JNK Signalling Cascade in Muscular Dystrophies.** *C. van Erp[1], R. Marx-Rattner[1], H. Dietz[1,2], R. Cohn[1].* 1) School of Medicine, Johns Hopkins Med Inst, Baltimore, MD; 2) Howard Hughes Medical Institute.

Muscular dystrophies are a heterogeneous group of disorders which are most often associated with significant skeletal muscle wasting and weakness. It has previously been demonstrated that levels of the cytokine TGFβ are significantly increased in skeletal muscle of both patients with Duchenne muscular dystrophy (DMD) and the dystrophin-negative mdx mouse. We have recently shown that antagonism of TGFβ via administration of TGFβ neutralizing antibody (TGFβNab) or the angiotensin II type 1 receptor blocker losartan attenuates the disease progression in mdx mice by improving steady-state muscle architecture, muscle regeneration and in vivo physiological function. TGFβ is known to activate the c-Jun N-terminal kinase pathways (JNK's), via crosstalk with the MAPK pathways. We therefore evaluated the expression pattern of JNK signalling in various animal models of muscular dystrophy. Interestingly, we find that JNK signalling is significantly increased in the skeletal muscle of mdx and laminin alpha2 deficient mice (a model for congenital muscular dystrophy type 1A) compared to wild-type mice, while levels of ERK and P38 remain unchanged. Preliminary results indicate that treatment of these mouse models with TGFβNab and/or losartan causes decrease of JNK signalling to a level comparable to wild-type mice supporting the notion of cross-talk between these pathways. Given the critical role that the JNK signalling pathway plays in the tissue homeostasis of various organs, we investigated whether administration of a JNK inhibitor would be able to alter activity of the JNK signalling cascade in skeletal muscle. Indeed, our data demonstrate that treatment with a JNK inhibitor can significantly decrease the activity of JNK in skeletal muscle of mdx mice to levels equal to and below the JNK levels in wild-type mice. We are currently exploring different pharmacological manipulations of JNK signaling in various mouse models of muscular dystrophies to investigate whether these treatments will result in therapeutic benefits for various forms of muscular dystrophies.

### 544/W/Poster Board #202

**Germline and somatic mosaicism for an *FGFR2* mutation in the mother of a child with Crouzon syndrome.** *J. Lim[1], A. Goriely[1], T. Lester[2], H. Lord[2], D. Johnson[3], H.V. Firth[4], A.O.M. Wilkie[1,3].* 1) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom; 2) Genetics Laboratory, Oxford, United Kingdom; 3) Craniofacial Unit, Oxford Radcliffe Hospitals NHS Trust, United Kingdom; 4) Clinical Genetics, Addenbrookes Hospital, Cambridge, United Kingdom.

Crouzon syndrome is a disorder characterised by craniosysnostosis and facial dysostosis involving over 50 different missense mutations in the Fibroblast Growth Factor Receptor-2 (*FGFR2*) gene. Although Crouzon syndrome is inherited as an autosomal dominant trait, most cases present as *de novo* mutations arising from unaffected parents. It was previously shown that, like other dominant disorders involving mutations in *FGFR2* or *FGFR3* (including Apert, Pfeiffer and Muenke syndromes and achondroplasia), Crouzon syndrome mutations show an exclusive paternal origin and a paternal age effect, meaning that the unaffected fathers tend to be older than the population average. Although the occurrence of germline mosaicism was previously suggested in Crouzon syndrome, these reports predated the identification of causative *FGFR2* mutations and none has been molecularly confirmed. The female proband presented at the age of 12 years with visual disturbance and was diagnosed clinically as having Crouzon syndrome. This was confirmed by identification of a heterozygous *FGFR2* c.1007A>G (p.D336G) mutation that locates in the IgIII domain mutation hotspot. There was no significant family history and both parents were clinically normal, but routine mutation analysis of DNA obtained from the peripheral blood of the mother (aged 28 years at the time of her daughter's birth) identified a low level of the *FGFR2* c.1007A>G mutation by direct sequencing. This finding was further confirmed by demonstrating mosaicism of the mutation in 3 different tissues (an independent blood sample, saliva and hair root) on direct sequencing. The mutation level was estimated in blood as 18% by *HhaI* restriction digest of a fluorescently labelled PCR product. The results of quantification using Pyrosequencing will be presented. To our knowledge, this is the first case of proven germinal and somatic mosaicism in the parent of a child with an apparently *de novo FGFR2* mutation. Whilst this is an unusual situation, it underlies the importance of always checking for parental mosaicism in apparent 'paternal age effect' *FGFR2* and *FGFR3* mutations, as its presence substantially increases the recurrence risk which is otherwise counselled as being less than 1%.

### 545/W/Poster Board #203

**Development and functional analysis of wildtype and R266Q GNE expression plasmids.** *Y. Valles-Ayoub[1,2], C. Saechao[1,4], A. Haghighatgoo[1,2], Z. Khokher[1,3], D. No[1,3], S.L. Martinez[1], I. Shah[1,4], S. Esfandiarifard[1], A.C. Riley-Portuges[1], C. Jay[5], M. Pietruszka[1], D. Darvish[1,2].* 1) HIBM Research Group (HRG), Inc., Encino, CA; 2) VA Greater Los Angeles (VA-GLA/UCLA), Los Angeles, CA; 3) Los Angeles Mission College, Sylmar, CA; 4) California State University, Northridge (CSUN), Northridge, CA; 5) Gradalis, Inc., Dallas, TX.

Hereditary Inclusion Body Myopathy (HIBM) is an adult onset progressive muscle wasting disorder affecting proximal and distal muscle, ultimately leading to severe disability. The etiology of HIBM is associated with mutations in the UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (GNE) gene, which encodes a bifunctional epimerase/kinase enzyme involved in the first two steps of sialic acid biosynthesis. Disruption of the sialic acid pathway leads to decreased sialylation of glycoproteins. Hyposialylation of alpha-dystroglycan, a muscle glycoprotein, jeopardizes the structural integrity of muscle and leads to myopathy. The functionality of a mutated UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase (GNE/MNK) enzyme, and thus sialic acid production, can be recovered by the introduction and expression of a wildtype GNE gene. In order to demonstrate this, we used the lectin-resistant Chinese hamster ovary (CHO) cell line, which lacks UDP-N-acetylglucosamine 2-epimerase activity. The CHO cells were transfected with a pUMVC3-GNE recombinant vector expressing either a wildtype GNE or an R266Q mutant insert. The R266Q mutation occurs in the allosteric domain of GNE/MNK and is associated with sialuria, a metabolic disorder in which feedback inhibition of the GNE gene is defective and sialic acid is overproduced. CHO cells transfected with wildtype or R266Q GNE expression vectors displayed approximately an 8.5-fold and 11.5-fold increase in sialic acid, respectively, in comparison to CHO cells transfected with the pUMVC3 bone vector. We intend to utilize this data to initiate a gene therapy model in mice and investigate its safety and effectiveness in the alleviation of muscle atrophy and dysfunction manifested by HIBM.

**Mutation analysis of limb enhancers in individuals with isolated limb malformations.** *J.E. VanderMeer[1,2], L.S.L. Clarke[3], G. Bejerano[4,5], N. Ahituv[1].* 1) Department of Bioengineering and Therapeutic Sciences and Institute for Human Genetics. University of California, San Francisco, San Francisco, CA; 2) Biomedical Sciences Graduate Program, UCSF; 3) Department of Genetics, Stanford University, Stanford CA; 4) Department of Developmental Biology, Stanford University; 5) Department of Computer Science, Stanford University.

The discovery of mutations leading to human disease in coding sequences has been extremely successful. However, the identification of mutations that lead to disease in the remaining 98% of the genome is challenging. Regulatory elements, such as enhancers, make prime candidates for harboring these disease-causing mutations due to their vital role in regulating gene promoters. The majority of characterized human enhancers show tissue-specific expression, suggesting that mutations within them will lead to an isolated disease phenotype. Previous studies have identified over 90 limb-specific enhancers where mutations could lead to isolated limb malformations. In addition, two recent examples in the literature illustrate cases where mutations or copy number variation of a limb enhancer leads to isolated limb malformations in humans. In order to identify additional mutations, we are currently collecting DNA from patients with isolated limb malformations and have enrolled over 100 patients as well as their immediate family members. Where large pedigrees are available, we are using linkage analysis to further pinpoint the genomic position where a potential deleterious mutation could reside. However, most isolated limb malformations occur as sporadic cases without useful pedigree information. For these patients, we use a candidate approach by sequencing limb enhancers in the vicinity of genes involved in specific limb patterning processes whose disruption could lead to the morphological characteristics observed in these patients. Sequence variants in these enhancers are screened for their prevalence in cases compared to controls, potential transcription factor binding changes, and the degree of evolutionary conservation at that site to determine which are more likely to be causative. Selected variants will be further characterized for differential enhancer activity compared to the reference allele using a transgenic mouse enhancer assay. Combined, these assays will result in an increased knowledge about the pathogenesis of human limb malformations and limb development and may lead to improved patient counseling and the development of molecular testing including prenatal genetic screens. In addition, this work will provide a model for studying the role of enhancers in other isolated disease phenotypes.

## 547/W/Poster Board #205

**MMP20 Hemopexin Domain Mutation in Amelogenesis Imperfecta.** *S.-K. Lee[1], F. Seymen[2], H.-Y. Kang[1], K.-E Lee[1], K. Gencay[2], B. Tuna[2], J.-W. Kim[1,3].* 1) Department of Cell and Developmental Biology, Dental Research Institute and BK21 Program, Seoul National University, Seoul, Korea; 2) Department of Pedodontics, Istanbul University, Istanbul, Turkey; 3) Department of Pediatric Dentistry, Dental Research Institute and BK21 Program, Seoul National University, Seoul, Korea.

Proteolytic enzymes serve important functions during dental enamel formation, and mutations in the kallikrein 4 (KLK4) and enamelysin (MMP20) genes cause autosomal recessive amelogenesis imperfecta (ARAI). So far only one KLK4 and three MMP20 mutations have been reported in ARAI kindreds. To determine whether ARAI in a family with a hypomaturation type enamel defect is caused by mutations in the genes encoding enamel proteolytic enzymes, we performed mutational analysis on candidate genes. Mutational and haplotype analyses revealed an ARAI-causing point mutation (c.910G>A, p.A304T) in exon 6 of MMP20 that results in a single amino acid substitution in the hemopexin domain. Western blot analysis showed decreased expression of the mutant protein, but zymogram analysis demonstrated this mutant was a functional protein. The proband and an affected brother are homozygous for the mutation, and both unaffected parents are carriers. The enamel of newly erupted teeth has normal thickness, but is chalky white and becomes darker with age. The study protocol and patient consents were independently reviewed and approved by the Institution Review Board at the Seoul National University Dental Hospital. Informed consent was obtained according to the Declaration of Helsinki. This work was supported by a grant from the Korea Health 21 R&D Project, Ministry of Health & Welfare, Republic of Korea (A060010), a grant from the Korea Science and Engineering Foundation (KOSEF) through the Biotechnology R&D Program (No. M10646010003-08N4601-00310), a grant from the KOSEF through the Bone Metabolism Research Center (No. R11-2008-023-02003-0), and an NIDCR/NIH grant DE12769.

## 548/W/Poster Board #206

**Molecular mechanisms in the TRPV4 disorders.** *S. Tompson[1], N. Camacho[2], P. Krejci[1], B. Boyce[3], P. Katzman[3], A. Janssens[4], D. Rimoin[1], R. Lachman[1], B. Nilius[4], D. Krakow[2], D. Cohn[1].* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Dept. of Orthopaedic Surgery, University of California at Los Angeles, Los Angeles, CA; 3) Dept. of Pathology and Laboratory Medicine, University of Rochester Medical Center, Rochester, NY; 4) Dept. of Molecular Cell Biology, Katholiek Universiteit, Leuven, Belgium.

Missense mutations in *TRPV4*, which encodes a $Ca^{2+}$-permeable ion channel, have been shown to cause a spectrum of dominantly inherited skeletal phenotypes ranging in increasing severity from autosomal-dominant brachyolmia, to spondylometaphyseal dysplasia Kozlowski type (SMDK) to nonlethal metatropic dysplasia (MD). Previous reports have suggested both autosomal recessive and dominant forms of MD. However, molecular analysis has demonstrated that the full spectrum of MD can result from heterozygosity for *TRPV4* mutations in 8/8 additional nonlethal MD and 3/3 lethal MD cases. Analysis of intracellular $Ca^{2+}$ levels in HEK cells expressing normal and mutant *TRPV4* demonstrated that the mutations activate the channel, increasing both the baseline and agonist-stimulated level of $Ca^{2+}$. This suggests the mutations exert their phenotypic effect by increasing intracellular $Ca^{2+}$. It has been shown in ATDC5 cells that overexpressing *Trpv4* or agonist activating endogenous protein causes upregulation of *Sox9* and its downstream targets. To determine whether mutant *TRPV4* produces a similar effect, dual luciferase reporter assays were performed with rat chondrosarcoma chondrocytes. *SOX9* reporter levels were increased when mutant *TRPV4*, but not wildtype, constructs were expressed. FACS analysis revealed that expression of mutant *TRPV4* reduced cell proliferation, without increasing apoptosis. Thus, activating mutations in *TRPV4* lead to increased *SOX9* transcription and decreased cell proliferation. Histology of long bone growth plates from 2 lethal MD cases revealed exuberant cartilage and extracellular matrix in the reserve zone with increased vascularity. Hypertrophic zones showed a reduced number of poorly aligned hypertrophic chondrocytes. Taken together, the data fit a model in which mutant TRPV4 in the reserve zone results in increased SOX9 and, consistent with published data, a consequent increase in extracellular matrix synthesis. Greater vascularity likely results from SOX9-dependent synthesis of VEGF, a key angiogenic regulator. As SOX9 is known to inhibit the differentiation of proliferating chondroctyes into hypertrophic cells, the decreased number and disorganization of hypertrophic chondrocytes seen in lethal MD would be predicted to result from increased *SOX9* expression in the growth plate.

## 549/W/Poster Board #207

**Loss of MMP13 or MMP9 function, or autocatalytic and transcatalytic inactivation result in impaired endochondral ossification and present as different forms of metaphyseal anadysplasia.** *B. Zabel[1,2], R. Keppler[1], K. Hilbert[1], V. Cormier-Daire[3], S. Nikkel[4], G. Nishimura[5], S. Unger[2], J. Spranger[1], A. Superti-Furga[1], E. Lausch[1].* 1) Centre for Pediatrics and Adolescent Medicine, Freiburg University Hospital, 79106 Freiburg, Germany;; 2) Institute of Human Genetics, Freiburg University Hospital, 79106 Freiburg, Germany;; 3) Department of Genetics and INSERM U781, Hôpital Necker Enfants Malades, Paris, France; 4) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Canada; 5) Department of Radiology, Tokyo Metropolitan Kiyose Children's Hospital, Kiyose, Tokyo, Japan.

Different families of proteases mediate extracellular matrix (ECM) turnover and cartilage remodelling in the growth plate, in particular the matrix metalloproteinases (MMPs). Many MMPs are presumed to play roles in bone formation and growth as they are able to cleave the most abundant proteoglycans and collagens of skeletal tissues. MMP9 and MMP13 catalyse the degradation of ECM components in the growth plate and at the same time cleave and release biologically active molecules stored in the ECM. Ablation of either Mmp9, Mmp13, or both, in mice causes severe distortion of the metaphyseal growth plate. We report that mutations in either MMP9 or MMP13 are responsible for the human disorder Metaphyseal Anadysplasia (MAD), for which a milder recessive variant and a more severe dominant variant are known. We found that recessive MAD is caused by homozygous loss of function of either MMP9 or MMP13, while dominant MAD is associated with missense mutations in the prodomain of MMP13 that determine autoactivation of MMP13 and intracellular degradation of both MMP13 and MMP9, resulting in a double enzymatic deficiency. A sequential action of MMP13 and MMP9 might explain the scarcely additive effect of the combined deficiency. Regarding possible downstream target(s) a large body of evidence supports that angiogenesis is a crucial step in bone formation. While ECM remodelling is essential for vascular invasion to occur, terminal chondrocyte differentiation and apoptosis depend on angiogenic factors. We suggest the existence of an activation cascade from MMP13 over MMP9 to VEGFA, and that this process is disturbed in MAD leading to impaired ossification.

## 550/W/Poster Board #208

**Mitochondrial mutation screening in Greek non-syndromic sensorineural childhood onset hearing impaired patients.** *H. Kokotas[1], M. Grigoriadou[1], G.S. Korres[1], E. Ferekidou[1], J. Economides[2], D. Kandiloros[3], A. Giannoulia-Karantana[4], S. Korres[3], M.B. Petersen[1].* 1) Department of Genetics, Institute of Child Health, 'Aghia Sophia' Children's Hospital, Athens, Greece; 2) Department of Audiology-Neurootology, 'Aghia Sophia' Children's Hospital, Athens, Greece; 3) Department of Otorhinolaryngology - Head and Neck Surgery, Athens University Medical School, Hippokration Hospital, Athens, Greece; 4) Department of Pediatrics, Athens University Medical School, 'Aghia Sophia' Children's Hospital, Athens, Greece.

Hearing impairment is one of the most common sensory handicaps with a frequency of at least 1/1,000, whereas at the age of 80 years more than 50% of the elderly have developed hearing loss severe enough to impair communication. Mitochondrial mutations are present in less than 1% of the children with prelingual deafness, but are more frequent at a later age. In the Caucasian population at least 5% of postlingual, non-syndromic hearing impairment is due to known mtDNA mutations, representing the most frequent cause of hearing loss after the 35delG mutation in the GJB2 gene encoding connexin 26. The use of aminoglycoside antibiotics can cause hearing loss in genetically susceptible individuals. Several mtDNA mutations leading to non-syndromic hearing impairment have been reported. Hot spot mutation regions are the MTRNR1 gene, encoding the 12S rRNA, and the MTTS1 gene, encoding the tRNA for Ser(UCN) . Some of these mutations could turn out to be polymorphisms without clinical significance, and most of them (including the frequent A1555G mutation) each have a low penetrance when they occur without other mutations. However, on the background of additional 12S rRNA mutations or nuclear mutations in genes involved in tRNA modification (TRMU-MTO2 and GTPBP3 genes) or rRNA modification (TFB1M gene), the penetrance is higher. To investigate the prevalence of the MTRNR1 A1555G mutation and the MTTS1 A7445G, 7472insC and T7510C mutations in the Greek population, we tested 600 unrelated cases of non-syndromic neurosensory childhood onset deafness. DNA extracted from whole blood was analyzed for the mtDNA mutations using PCR-RFLP protocols. The homoplasmic A1555G mutation was detected in two familial cases, one of which was found negative and the other heterozygous for the common GJB2 35delG mutation. Four cases had the A7445G mtDNA mutation; two of which were heterozygous for the 35delG mutation, one harbored the 35delG mutation in compound hetorozygosity with the GJB2 W24X mutation, and one case was homozygous for the 35delG mutation. None of the cases presented with the 7472insC or T7510C mutations. We conclude that the A7445G mutation might be a rather frequent cause of non-syndromic neurosensory deafness in the Greek population and should be screened in cases with non-syndromic childhood deafness (together with the A1555G mutation). It is noteworthy, that in 5 of the 6 cases with a mitochondrial mutation, at least one mutation of the GJB2 gene was also present.

## 551/W/Poster Board #209

**Novel mutations and loci are associated with limb girdle muscular dystrophy type 2.** *S.E. Boyden[1,2], M.A. Salih[4], E.A. Estrella[1], A.J. White[1], M.Z. Seidahmed[5], R.R. Bennett[1], L.M. Kunkel[1,2], P.B. Kang[1,3].* 1) Program in Genomics, Children's Hospital Boston, Boston, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA; 3) Department of Neurology, Children's Hospital Boston and Harvard Medical School, Boston, MA; 4) Department of Pediatrics, College of Medicine & KKUH, King Saud University, Riyadh, Kingdom of Saudi Arabia; 5) Department of Pediatrics, Security Forces Hospital, Riyadh, Kingdom of Saudi Arabia.

Limb girdle muscular dystrophy (LGMD) is a progressive muscle degeneration disorder resulting in profound weakness that affects primarily the shoulder and hip muscles. There are 14 genes known in which a variety of mutations cause autosomal recessive LGMD type 2 (LGMD2), but 30% of LGMD patients lack a molecular diagnosis. We hypothesized there may be additional undiscovered LGMD2 mutations and/or genes, and we ascertained eight consanguineous pedigrees in which patients had recessive LGMD. DNA samples for all affected family members and at least one unaffected sibling were genotyped at 10,204 SNP markers and linkage analysis was performed in MERLIN. Three families showed linkage to overlapping intervals on chromosome 19q13 containing the LGMD2 gene fukutin-related protein (FKRP). Sequence analysis of FKRP identified a novel missense mutation, T314M, in two of these families that shared a haplotype across a portion of the linkage peak containing FKRP, indicating they likely inherited a single founder mutation from a common ancestor. In the third family we discovered a second novel FKRP missense mutation, V338L. Two additional families showed linkage to chromosome 17q21, a region containing the LGMD2 gene alpha sarcoglycan/adhalin (SGCA). One family carried the previously-reported R34H mutation in SGCA, while in the other we found a novel 5' splice site mutation IVS5 +5G>A. The G base is highly preferred (75-85%) at the +5 position in the consensus 5' splice site sequence, and skipping of exon 5 would result in deletion of 66 amino acids and a frameshift, while inclusion of intron 5 would result in a premature stop codon. Efforts to confirm the presence of a mis-spliced mRNA in this family are ongoing. A sixth family produced a suggestive maximum LOD score of 2.5 at chromosome 5q33-34, a peak that includes the delta sarcoglycan (SGCD) gene, and mutation screening is underway. The final two families yielded several suggestive linkage peaks at loci throughout the genome, none of them corresponding to the location of a known LGMD gene. These data suggest the existence of at least 1-2 unreported LGMD2 loci and we are pursuing mutation identification in these regions. We have shown linkage mapping in consanguineous pedigrees to be a productive method for discovering novel mutations and novel loci for a genetically and mutationally heterogeneous disorder even when an abundance of genes and mutations have been previously identified.

## 552/W/Poster Board #210

**Exon-level analysis of Mendelian disorder genes by array CGH finds novel deletions and duplications.** *S. Aradhya, R. Busin, A. Stafford, K.S. Hruska, B. Boggs, G. Richard, S. Bale, J.G. Compton.* GeneDx, Gaithersburg, MD.

Intragenic deletions and duplications typically account for a small proportion of disease-related mutations in Mendelian disorders. Although the frequency of these mutations may be higher, the lack of a robust technology has prevented their discovery on a larger scale. Array CGH with high-resolution coverage within individual genes provides an opportunity to detect small deletions and duplications that may have been missed due to technical limitations of previous technologies or because the relevant genes have not been screened for these types of mutations. To identify such mutations, we have constructed an oligonucleotide microarray with probes concentrated in the exonic regions of approximately 450 genes associated with disorders caused by haploinsufficiency or with recessive disorders (in which the identification of only a single mutation may suggest the presence of a deletion on the other allele). When we used this microarray to analyze 700 clinical cases, many of which were negative by sequence analysis, we identified 28 novel intragenic or whole-gene deletions and one novel intragenic duplication. Intragenic deletions were identified in FLCN, STK11, PTCH1, CREBBP, VHL, MMACHC, VPS13B, MOCS2, USH2A, GPC3, and KCNQ1. We identified whole-gene deletions in TWIST1, PTEN, NDP, STK11, CREBBP, FOXC1, and PTCH1. An intragenic duplication was found in FLNA. These results demonstrate the utility of using exon-level array CGH for detecting clinically significant changes that may account for a larger proportion of mutations in Mendelian disorders than previously thought.

## 553/W/Poster Board #211

**High Throughput Genotyping Utilizing a Versatile Extraction Platform.** *T. Wayman[1], S. Mitchell[1,2], Y. Louie[1], C. Meadows[1], E. Lyon[1,3].* 1) ARUP Laboratories, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 3) Department of Pathology, University of Utah, Salt Lake City, UT.

Increased demand for molecular diagnostics testing has created the need to invest in higher throughput automation platforms. Due to increasing sample volumes, moving to a 96 sample extraction for high volume assays has been a priority of ARUP Laboratories. Without further automation, additional technologists will be required to extract, run, and analyze the increasing sample load. A 96 sample DNA extraction would ideally be able to increase efficiency and lower costs with existing personnel by allowing a larger batch size of multiple assays. In addition to increasing throughput we would expect any new extraction instrument to improve all possible aspects of the assay and be able to be used on multiple downstream analysis platforms. In investigating the SX-96GC (Precision System Science - Chiba, Japan) we have found a new platform and extraction reagent (MagDEA-HTS) to improve the efficiency of multiple endpoint detections through: increased quality of DNA, lower repeat rate, lower cost per test, and increased quality of result. DNA extracted on the SX-96GC was observed at an average yield of 47 ng/uL with a CV of 31%. This is an improvement from previous extraction platforms utilizing the MagNA Pure LC DNA Isolation Kit I (Roche Applied Science - Indianapolis, IN) like the Radius (Protedyne - Windsor, CT) (ave. yield 30 ng/uL, CV 50%) and the MagnaPure (Roche Applied Science - Indianapolis, IN) (ave. Yield 28 ng/uL, CV 35%). A260/280 ratios improved from 1.8 on the Radius and 1.9 on the MagnaPure to 2.1 on the SX-96GC. Assays used for endpoint evaluation were Factor V Leiden and Factor II 20210G>A mutations on the LC480 (Roche Applied Science - Indianapolis, IN) using an ARUP developed assay and the CFV30LA 23 mutation cystic fibrosis panel (Celera - Almeda, CA) on the ABI 3130 (ABI - Foster City, CA). Repeat rates of assays have been observed at 11.2% on the Radius and 10.6% on the MagnaPure with an improvement to 5% on the SX-96GC. The extraction cost using the PSS-SX96GC lowered by 10% compared to the MagnaPure and 8% from the Radius. The lower repeat rate is a product of improved results, which in turn lowers cost. In addition the SX-96GC has the ability to extract samples in horizontal and vertical half plates that allows easier migration to multiple endpoint detection platforms. Additional time and cost savings are realized when using the dual processing instrument to set up PCR reaction plates from the primary extraction plates.

## 554/W/Poster Board #212

**Mutation spectrum of the ABCA4 Gene in Greek patients with Stargardt disease: Identification of a novel mutation and evidence of three prevalent mutated alleles.** *S. Kamakari[1,2], P. Stamatiou[1,2], T. Panagiotoglou[3], C. Tsika[3], N.P. Anagnou[2], M. Tsilimbaris[3].* 1) Biogenomica Center for Genetic Research and Analysis, Athens, Halandri, Greece; 2) School of Medicine, University of Athens, Athens, Greece; 3) Department of Ophthalmology, School of Medicine University of Crete, Iraklion, Greece.

Purpose: Mutations in the ABCA4, photoreceptor-specific ATP-binding cassette transporter 4, gene have been associated with autosomal recessive Stargardt (STGD) disease, characterized by central vision impairment. This is the first systematic study investigating the frequency and pattern of disease-associated mutations among Greek STGD patients, never previously genetically characterized for sequence variations in the ABCA4 gene. Methods: 25 unrelated and 2 related STGD patients were analyzed by the ABCR400 microarray. Polymerase chain reaction (PCR) amplification and direct sequencing of 4 selected or all 50 exons of the ABCA4 gene was performed on 5 patients. Results: Disease-associated mutations, including the novel, likely pathogenic splice site mutation c.4352+1G>A in intron 29, were detected in 20/29 unrelated patients analyzed (69%). Both mutant alleles were found in 12 (41.4%) and only one was detected in 8 (27.6%). The major pathogenic allele IVS40+5G>A accounted for 30.3% (10/33) of the mutant alleles. Other frequently mutant alleles were p.L541P alone or as a complex p.L541P/p.A1038V allele and p.G1961E, each accounting for 24.2% (8/33) of the mutated alleles. Notably, a young patient with unaffected parents and his paternal affected aunt with different disease severity, were found respectively homozygous for the p.L541P/p.A1038V and compound heterozygous for the p.L541P/p.A1038V and p.G1961E alleles thus resolving the inheritance pattern. Direct sequencing of all 50 coding exons of the ABCA4 gene in 2 patients with one detected mutation revealed the second mutation in both patients: the novel, heterozygous c.4352+1G>A mutation in intron 29 in one patient and a known mutation, p.W1449X, in the second. The latter mutation had remained unidentified by the ABCR400 microarray although included on the chip. Finally, towards a cost-effective screening strategy, selective screening of the frequently mutated exons 12/21/40/42 successfully identified mutations in 2/3 unrelated patients. Conclusions: This first report of the ABCA4 mutation spectrum underlying STGD disease in Greece further elucidates the distribution of ABCA4 mutations in European populations. The detection rate by the combined methodology was 69%. We identified a novel potentially pathogenic ABCA4 splice mutation and 3 prevalent disease-causing alleles. Further evaluation of the genotype-phenotype correlations will advance our knowledge of STGD's etiology in Greek patients.

## 555/W/Poster Board #213

**Mutation analysis of the NEMO gene in patients with Incontinentia Pigmenti.** *W. Lissens, M. Bonduelle, S. Seneca, S. Van Dooren, I. Liebaers.* Ctr Med Gen, UZ Brussel, Brussels, Belgium.

Incontinentia pigmenti (IP) is a rare X-linked dominant genodermatosis that is lethal in males. Females can survive because of X-inactivation mosaicism. The most frequent mutation is a deletion of exons 4-10 of the gene, NEMO that causes IP. Molecular analysis was performed in 99 female patients referred for NEMO gene analysis. The patients were first studied for the presence or absence of the exon 4-10 deletion by PCR: 46 patients carried this deletion. Upon request of the referring physician, 10 of the 53 patients without a deletion were further sequenced, and in 7 a mutation (six resulting in nonsense codons and one in a missense codon) was found. From 30 patients with a proven mutation DNA samples from the mothers were available for testing and in 7 of them a mutation was found (7/30 or 23%). In the end, no mutation was found in 46/99 patients. Our results are in agreement with other studies that show that the exon 4-10 NEMO deletion is a major mutation causing IP, and that many mutations occur de novo. However, the deletion frequency in our patients is lower than has been described in literature (46% versus 70-90%). This can probably be attributed to the fact that we performed deletion screening for each request for IP mutation analysis without any selection. Clinical data are being collected to verify this hypothesis.

## 556/W/Poster Board #214

**An Interactive Database of Single Gene Disorders Among Plain People.** *H. Cross[1, 2], A.H. Crosby[2].* 1) Dept Ophthalmology & Vision, Univ Arizona Sch Med, Tucson, AZ; 2) Medical Genetics, Clinical Developmental Sciences, St. George's University London, London SW17 0RE, UK.

For a half century, endogamous isolates of plain people throughout the United States and Canada, including Amish, Mennonite and Hutterites, have been subjects of genetic studies. More than 120 disorders due to single gene mutations have been described in these populations. Some are unique to the Amish, others to Mennonites and Hutterites, while others are found throughout these populations. Published reports are widely scattered and no centralized resource useful to members of these groups and their medical providers has been available. We have compiled this information and published it as a searchable online database (www.wohproject.org). Each disorder contains a section with a general clinical description using plain non-medical language for individuals and families. Another section summarizes the clinical features in more detail to allow rapid consultation by busy medical practitioners in their daily practice. Known metabolic and biochemical pathways are graphically illustrated. Genomic information and inheritance patterns are summarized in a section on genetics, with additional information on treatment, prognosis, diagnostics and relevant specialists. Links to general information, support groups, and disease networks are provided. Literature references with PubMed links are included for each disorder as well as links to OMIM. We anticipate that this database, searchable via any combination of clinical, genetic, reference and population terms, will prove to be a useful resource for families affected by these conditions as well as healthcare workers and researchers involved in their study.

### 557/W/Poster Board #215

**Genetics of Congenital Stationary Night Blindness - Mutation Update and Clinical Variability.** *N.T. Bech-Hansen[1,2], R. Tobias[1], C. Kennedy[1], A. Jackson[1], N. Lodha[1], CSNB Consortium.* 1) Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Institute of Child and Maternal Health, Faculty of Medicine, University of Calgary.

Congenital stationary night blindness (CSNB) represents a group of low vision disorders (reduced visual acuity, impaired night vision, myopia, nystagmus, and strabismus) with abnormal retinal neurotransmission. Various analyses have shown mutations in *CACNA1F* in the patients with incomplete X-linked CSNB (CSNB2), in *NYX* in patients with complete X-linked CSNB (CSNB1) and in *GRM6* in patients with complete autosomal recessive CSNB (CSNB1B). In a total of 199 patients diagnosed with CSNB, 112 for X-linked iCSNB, 73 for X-linked cCSNB and 14 with ar-cCSNB, we have now identified a total of 101 unique mutations (57 unpublished) in 142 of these patients. Of the mutations, 65 were in *CACNA1F* (15 in splice sites), 29 in *NYX* (17 single-nucleotide substitutions or small in-frame deletions or insertions) and 7 in *GRM6*. No mutations were identified in *CAPB4*. *CACNA1F* mutations were distributed across the entire coding region, while *NYX* mutations predominated in conserved residues of the leucine-rich repeats. The *CACNA1F* mutations were identified among patients originally diagnosed with incomplete X-linked CSNB (iCSNB or CSNB2), Åland Island eye disease (AIED and AIED-like), and Åland eye disease (AED) suggesting that these conditions are essentially the same genetic condition. No mutations were identified in 53 of 199 CSNB patients (27 percent). We consistently observed the *CACNA1F* founder mutation (c.3166dupC, exon 27) among individuals with Dutch-German Mennonite ancestry. A 24-bp deletion mutation in *NYX*, which results in the loss of the RACPAACA amino acids in the N-terminal Cys-rich region of nyctalopin, was detected in 12 North American CSNB families. Of 164 CSNB mutations known worldwide, we note that 18 of 48 unique *NYX* mutations, 24 of 93 unique *CACNA1F* mutations and 7 of 17 unique *GRM6* mutations have been detected in more than one family. Preliminary analysis indicates that some of the clinical variability observed among CSNB patients can be accounted for by the type of CSNB mutation. The high success rate of detecting mutations in *NYX* and *CACNA1F* in our patient cohort supports the notion that X-linked CSNB is more common than the autosomal recessive form of CSNB, and that the proteins, Cav1.4 ($\alpha$1F) and nyctalopin, encoded by these two genes, together with the GluR6 receptor (encoded by *GRM6*) are evidently important for establishing and maintaining retinal neurotransmission function. Supported by FFB-Canada.

## 558/W/Poster Board #216

**Muscle Protein Polymorphism of Percids.** *A. Islam[1], M. Khasanova[2], V. Chernov[2].* 1) Dept Ophthalmology, Schepens Eye Res Inst, HMS, Boston, MA; 2) Kazan Institute of Biophysics and Biochemistry, Russian Academy of Sciences, Kazan, Russia 420111.

We compared the muscle protein polymorphism of two pikeperches (*Sander lucioperca* and *S. volgense*) through intra- and intermyomeric composition of white muscles. The protein expressions were investigated by using denaturing 10% sodium dodecylsulfate-polyacrylamide gel electrophoresis. The muscle proteins were studied through within- and between-species morphological development, sexual maturity and age of the species. Myosin, actin and troponin have a distinct role in the contraction and length tension of muscle fibers of these species. There were no obvious intramyomeric differences found in the myosin heavy chain of the species. Myosin light chains (15-38 kDa) have different expression in different age groups of the two *Sander* species. The muscle protein of the fingerlings and adults *S. lucioperca* had high molecular weight (50 kDa) myosin in contrast to the other Percid species. The molecular weight of actins increased comparatively in low-age-group fish. Troponin regulates the increasing concentration of light-chain myosin in both species. The muscle proteins of both species in different sexual maturity have polymorphism in various age groups but there is no difference in protein polymorphism of the same aged group. The white smooth muscle protein composition and contractile properties affect the power production during fast, unsteady movements and swimming of these species.

## 559/W/Poster Board #217

**Predicting Functionality of Missense Mutations with Varying Levels of Evolutionary Depth.** *S. Hicks[1], S.E. Plon[2,3], D.A. Wheeler[2], M. Kimmel[1].* 1) Department of Statistics, Rice University, Houston, Texas; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas; 3) Texas Children's Cancer Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas.

Several computational algorithms have been developed to predict the impact of missense mutations on protein structure and function. Informative classification of missense mutations is highly dependent on the parameters used in each algorithm. Past research has shown a high predictive value for methods that use evolutionary sequence conservation, surprisingly with or without protein structural information. Though the methods differ in parameters, they all agree that, in general, protein evolution is correlated with protein function: mutations at conserved residues are more likely to be pathogenic and affect protein function compared to more diverse residues. The goal of the study is to investigate the prediction accuracy of the functionality of missense mutations by using both curated and uncurated alignments of varying evolutionary depth. The three methods, SIFT, Polyphen and Align-GVGD were evaluated using a set of missense substitutions from the *BRCA1* and *BRCA2* mutation database (BIC), with sufficient evidence of clinical neutrality. We compared a) curated alignments with varying levels of evolutionary depth (http://agvgd.iarc.fr/) and b) uncurated alignments automatically generated in Uniprot using the built in ClustalW feature with sequences included based on a criteria of 90% or 50% identity. The results show SIFT dramatically overcalls neutral variants as deleterious as others have previously noted. The online version of Polyphen does not allow a rapid query of alignments of varying levels of depths, but has a comparable sensitivity to Align-GVGD. When considering curated versus uncurated alignments, Align-GVGD only miscalls as deleterious 1 of 17 *BRCA1* and 2 of 30 *BRCA2* neutral variants from the BIC database using a curated alignment compared to zero miscalls using an uncurated alignment that could only be obtained at a criteria of 50% identity. Simply considering evolutionary depth, Align-GVGD has a high sensitivity that increases with depth in curated alignments; the sensitivity also increases in uncurated alignments depending on the identity level of the sequences included in the alignment. Analysis of neutral variants in *MSH2* or *MLH1* yields a similar sensitivity with both types of alignments, but for the *TP53* gene a similar result is only obtained under 50% identity in the uncurated alignments. Thus appropriate alignment depth is dependent on the particular gene of interest and should be further explored.

## 560/W/Poster Board #218

**A nonsynonymous SNP in *EDAR* is associated with tooth shoveling.** *R. Kimura[1], Y. Yamaguchi[2], K. Maki[2], M. Takeda[3], O. Kondo[3], T. Hanihara[4], M. Osawa[5], H. Ishida[6], S. Kawamura[7], H. Oota[7].* 1) TRO-SIS, University of the Ryukyus, Okinawa, Japan; 2) School of Dentistry, Showa University, Tokyo, Japan; 3) Graduate School of Science, The University of Tokyo, Tokyo, Japan; 4) Saga Medical School, Saga, Japan; 5) Tokai University School of Medicine, Kanagawa, Japan; 6) Faculty of Medicene, University of the Ryukyus, Okinawa, Japan; 7) Graduate School of Frontier Sciences, The University of Tokyo, Chiba, Japan.

Teeth display variations among individuals in the size and the shape of cusps, ridges, grooves, and roots. In addition, there are certain dental characteristics which are predominant in certain human groups, such as tooth shoveling of upper incisors that is major in Asian populations but rare or absent in African and European populations. The common characteristics of dental morphology are thought to be determined mainly by genetic factors. However, genetic polymorphisms associated with dental morphology have not been elucidated yet. In humans, the *ectodysplasin A receptor* gene (*EDAR*) as well as the *ectodysplasin A* gene (*EDA*) is know to be responsible for hypohidrotic ectodermal dysplasia, a genetic disorder causing abnormal morphogenesis of teeth, hair, and eccrine sweat glands. Human genome diversity data have revealed that the derived allele of a nonsynonymous single nucleotide polymorphism (SNP), rs3827760 that is also called *EDAR* T1540C, is predominant in East Asian populations but absent in populations of African and European origins. It has recently been reported that the 1540C allele is associated with Asian-specific hair thickness. The aim of this study is to clarify whether the nonsynonymous polymorphism in *EDAR* is also associated with dental morphology in humans or not. For this purpose, we measured crown diameters and tooth shoveling grades, genotyped *EDAR* T1540C, and analyzed the correlations between them in Japanese populations. To comprehend individual patterns of dental morphology, we applied a principal component analysis (PCA) to individual-level metric data, the result of which implies that multiple types of factors affect the tooth size. This study clearly demonstrated that the number of the Asian-specific *EDAR* 1540C allele is strongly correlated with the tooth shoveling grade. The SNP significantly affected PC1 and PC2 in PCA, which denotes overall tooth size and the ratio of mesiodistal diameter to buccolingual diameter, respectively. Our study revealed a main genetic determinant of tooth shoveling that has classically received great attention from dental anthropologists. Further studies using powerful DNA technology will lead to clearer understanding about genetic factors for phenotypic variations in tooth morphology such as Carabelli's tubercle, the numbers of cusps and roots, and the size balances shown in metric measurements.

## 561/W/Poster Board #219

**Recombination and gene conversion in 17q21.31 inversion polymorphism region.** *W. Chen[1,2], X. Hao[1,2], L. Deng[1,3], C. Zeng[1].* 1) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) Graduate university of Chinese Academy of Sciences, Beijing, China; 3) Faculty of Basic Medical College, Nanchang University, Nanchang, China.

17q21.31 is a common inversion polymorphism region with relatively large size (0.9Mb), which is ideal for studying the effect of inversion on LD pattern and finding signals of conversion events. Using SNP data of Human Genome Diversity Project from 1043 individuals of 51 populations in 7 geographical regions (Africa, Mideast, Europe, South Asia, East Asia, Oceania, and America), we computed the recombination rates in 17q21.31. After haplotype phasing, principle component analysis resolved two distinct clades. As these corresponding to previously identified haplotype groups resolved by tag SNPs, we also use H1 and H2 (inverted) to represent the two opposite orientations. Accordingly a worldwide distribution map of 17q21.31 inversion polymorphism was constructed. In contrast to most populations whose frequencies of H2 haplotypes were lower than 10%, ethnic groups in Mideast and Europe showed significantly increases in both the frequency (20-25%) and the diversity of haplotypes in H2 clade, suggesting that H2 was perhaps historically under positive selection in these two areas. Consequently more H2 haplotypes were resulted after the pressure no longer existed. Computed by composite likelihood method in 29 HGDP populations (>19 individuals each), a low recombination rate was seen in 17q21.31 in comparison with a 1 Mb non-genic region in 22q12, indicating the inversion polymorphism suppressed crossover during meiosis. To discover possible conversion events, next we compared haplotypes in HapMap CEU samples with the method described by Betran. Totally 41 candidate domains with signals of gene conversion were found in 17q21.31. These domains were shown in two patterns. First, 26 were in the type of conversion as expected. For another 15 candidates, H1 and H2 appeared surprisingly to have parts of their specific haplotypes exchanged in H1/H2 heterozygous individuals. For detailed analysis, 5 CEU samples of each type were then selected for clone re-sequencing to separate each haplotype from diploid individuals on candidate regions. Finally, we verified that 5 regions from the group of 26 candidates were all experienced conversion events. However, the rest 5 showing the pattern of haplotype exchange were actually caused by phasing error of the HapMap. Moreover, 2 of the 5 verified regions experienced gene conversion events also displayed higher recombination rate, showing the conversion effect on the genetic information change in the human genome.

## 562/W/Poster Board #220

**HUMAN β-DEFENSIN 3: GENE COPY NUMBER VARIATIONS VARY GEOGRAPHICALLY.** *P. Fode[1], M. Theisen[2], D. Dodoo[3], M. Lenicek[4], L. Vitek[4], A. Viera[5], J. Freitas[5], I. Vind[6], P. Munkholm[6], N. Frimodt-Moller[1], P. Skytt Andersen[1].* 1) National Center for Antimicrobials and Infection Control, Statens Serum Institut, Copenhagen, Denmark; 2) Department of Clinical Biochemistry and Immunology, Statens Serum Institut, Copenhagen, Denmark; 3) Noguchi Memorial Institute for Medical Research, University of Ghana, Legon, Ghana; 4) Laboratory of Hepatology, Department of Clinical Biochemistry and Laboratory Diagnostics, Charles University, Prague, Czech Republic; 5) Department of Gastroenterology, Hospital Garcia de Orta, Almada, Portugal; 6) Digestive Disease Centre, Medical Section, Herlev Hospital, University of Copenhagen, Copenhagen, Denmark.

In recent years much interest has focused on variations in the genome among humans e.g. copy number variations (CNVs). The focus for the current study is to determine copy number variations for the human β-defensin 3 gene (DEFB103) in five different demographic populations. The nature and extent of CNVs in various populations are largely unknown, but differences are expected. Using a single tube duplex real-time PCR assay the copy number for DEFB103 was determined for 736 samples using RNaseP as reference gene. DEFB103 copy number varied in the five populations with copy number ranging from 2 to 17 per diploid genome. The mean copy number was found to be significantly higher in the Portuguese (X=7.2) and Ghanian (X=6.7) samples compared to the Danish (X=4.6), Czech (X= 5.1) and English (X=4.4) samples. In addition, a higher inter-population CNV was observed in the Ghanian and Portuguese populations (2-17 copies per diploid genome) compared to the Danish, English and Czech populations (2-12 copies per diploid genome). The DEFB103 copy number was found to vary significantly. Several studies indicate that the CNV polymorphism in the DEFB cluster may have impact on susceptibility to inflammatory diseases such as Crohn's Disease and Psoriasis. Others have linked the copy number for some defensin genes with the mRNA expression levels and CNVs might have important consequences for susceptibility to infectious diseases. The genetic variation in the DEFB cluster may explain the genetic predisposition to many biologic events and the polymorphism might reflect genomic drift in the human population.

## 563/W/Poster Board #221

**Study of genetic effects of atomic-bomb radiation using BAC-aCGH: *De novo* copy number mutants detected by aCGH in a Japanese population.** *N. Takahashi[1], Y. Satoh[1], M. Kodaira[1], K. Sasaki[1], Y. Kodama[1], Y. Shimoichi[1], J. Kaneko[1], A. Miura[1], M. Imanaka[1], E. Hiyama[2], I. Fukuba[2], H. Katayama[3], J. Cologne[4].* 1) Dept Gen, Radiation Effects Res Fdn, Hiroshima, Japan; 2) N-BARD, Hiroshima Univ, Hiroshima, Japan; 3) Dept Info Tech, Radiation Effects Res Fdn, Hiroshima, Japan; 4) Dept Stat, Radiation Effects Res Fdn, Hiroshima, Japan.

[Purpose] To study the effects of atomic-bomb radiation on human germline cells at the genome-wide level, we have introduced bacterial artificial chromosome (BAC) DNA micro-array based comparative genomic hybridization (BAC-aCGH). We report the results obtained from 305 individuals by BAC-aCGH analyses. [Experiment] We used an array with about 2,500 BAC-clones distributed across human autosomes at an interval of about 1.2 Mb. We examined 265 offspring who had at least one parent exposed to high-radiation doses (≥1.0 Gray) and 40 offspring from unexposed parents. [Results and Discussion] We found a total of 1,534 copy number variants (CNVs) in the genome; of these, 97 CNVs were termed "rare" CNVs whose frequencies were less than 1%, while the frequencies of the remaining 1,437 CNVs observed at 32 regions (termed "polymorphic" CNVs) were 1% or more. With respect to rare CNVs, DNA from the offspring and their parents were examined by quantitative polymerase chain reaction to confirm the inheritance. Three rare CNVs independently identified in three offspring were not identified in either their parents and these are defined as "putative *de novo* mutants." Two mutants were amplification types and remaining one was a deletion type. For the putative *de novo* mutants, we confirmed whether they are "true" mutants or ones generated as a consequence of Epstein-Barr virus transformation and/or extended cell culture. As a result, three were true mutants, not artificial. We determined the parental origin of the *de novo* mutants using single nucleotide polymorphisms (SNPs) proximal to the mutated regions in the offspring. For this purpose, Affymetrix SNP Array 6.0 was used. The results demonstrated that all three *de novo* mutants occurring on the gametes originated from exposed fathers. This number of *de novo* mutants (three) is too small to reach a firm conclusion as to whether the mutation rate of the exposed group is significantly higher than that in those from unexposed group. Therefore, we will continue the study using the high-density array system to increase the number of loci examined in order to increase the number of *de novo* mutants to be identified.

## 564/W/Poster Board #222

**A detailed phylogeography of mtDNA haplogroup C1d: another piece in the Native American puzzle.** *U.A. Perego[1,2], N. Angerhofer[1], M. Pala[2], J.E. Gomez-Palmieri[1], A. Olivieri[2], K.H. Ritchie[1], B. Hooshiar Kashani[2], V. Carossa[2], H. Lancioni[3], N. Myres[1], A. Gómez-Carballa[4], B. Zimmermann[5], G. Huber[5], M. Bodner[5], W. Parson[5], A. Salas[4], H.-J. Bandelt[6], S.R. Woodward[1], A. Torroni[2], A. Achilli[2,3].* 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 2) Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) Dipartimento di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 4) Facultad de Medicina, Universidad de Santiago de Compostela, Santiago de Compostela, Galicia, Spain; 5) Institute of Legal Medicine, Innsbruck Medical University, Innsbruck, Austria; 6) Department of Mathematics, University of Hamburg, Hamburg, Germany.

Recent studies based on complete mitochondrial DNA (mtDNA) sequences revealed that two almost concomitant paths of migration from Beringia led to the dispersal of the first Americans (Paleo-Indians) approximately 15-17 thousand years ago (kya). This first expansion was followed by later more restricted diffusion events from the same dynamically changing Beringian source. Thus, five pan-American (A2, B2, C1, D1, and D4h3a) and four geographically confined (D2, D3, X2a, and C4c) mtDNA haplogroups represent the current female legacy of the ancient migratory events that gave rise to the native populations of the double continent. Regarding haplogroup C1, all its members appear to belong to one of three branches: C1b (characterized by the control-region transition at np 493), C1c, and C1d (with the control-region transition at np 16051). These three sub-haplogroups are found throughout the Americas, thus supporting the scenario that they most likely differentiated at the early stages of the Paleo-Indian southward migration. If considered as three separate founders, C1b, C1c, and C1d would bring the currently known number of native pan-American lineages to seven. As a whole, the C1 haplogroup has an estimated age of 17.0-19.6 ky, while the three individual branches are dated 16.5-17.0 ky, 17.2-17.6 ky, and 7.6-9.7 ky, respectively. The extremely young age estimate of C1d has been attributed, at least for the moment, to a major under-representation of C1d mtDNAs (only nine complete sequences published to date) in the current Native American mtDNA phylogeny. We have addressed this issue in the current study by completely sequencing more than 60 novel mtDNAs belonging to haplogroup C1d, which were carefully selected on the basis of both control-region variation and geographic/ethnic origin. Phylogeographic analyses have provided not only an accurate evaluation of the expansion time of C1d in the Americas, but also a detailed picture of its current distribution in both general mixed and indigenous populations.

**Closely Spaced Multiple Mutations as Potential Signatures of Transient Hypermutability in Human Genes.** *J. Chen[1,2,3,4], C. Férec[1,2,3,4,5], D.N. Cooper[6].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U613, Brest, France; 2) Etablissement Français du Sang (EFS) - Bretagne, Brest, France; 3) Faculté de Médecine et des Sciences de la Santé, Université de Bretagne Occidentale (UBO), Brest, France; 4) Institut Fédératif de Recherche (IFR) 148, Brest, France; 5) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Universitaire (CHU) Brest, Hôpital Morvan, Brest, France; 6) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, United Kingdom.

Data from a diverse series of organisms suggested that transient hypermutability is a general mutational mechanism with the potential to generate multiple synchronous mutations, a phenomenon probably best exemplified by closely spaced multiple mutations (CSMMs). However, to date, its potential impact on the evolution of higher eukaryotes has not been widely appreciated. Here we attempted to extend the concept of transient hypermutability from somatic cells to the germline, using human disease-causing multiple mutations as a model system. Employing fairly stringent criteria for data inclusion, we have retrospectively identified numerous potential examples of CSMMs causing human inherited disease that exhibit marked similarities to the CSMMs reported in other systems. These examples include (i) eight multiple mutations, each comprising three or more components within a sequence tract of <100 bp, (ii) three possible instances of 'mutation showers' and (iii) numerous highly informative 'homocoordinate' mutations. Using the proportion of CpG substitution as a crude indicator of the relative likelihood of transient hypermutability, we also present evidence to suggest that CSMMs comprising at least one pair of mutations separated by ≤100 bp may constitute signatures of transient hypermutability in human genes. This analysis not only extends the generality of the concept of transient hypermutability but also provides new insights into what may be considered a novel mechanism of mutagenesis underlying human inherited disease. Finally, our findings raise serious concerns regarding current practices in mutation screening, which are likely to miss many potentially important secondary mutations linked in cis to the putative primary pathological lesion.

## 566/W/Poster Board #224

**Genetic variation in unsampled ancestral populations.** *R. Jiang[1], C. Eng[2], E.G. Burchard[1,2], J. Wall[1].* 1) Institute for Human Genetics, UCSF, San Francisco, CA; 2) Department of Medicine, UCSF, San Francisco, CA.

Analyses of genetic variation are important to the study of human populations, both for inferring population history and for understanding the genetic basis of complex traits. Here, we show how genetic variation in ancestral populations can be analyzed from sampling recently admixed individuals. This two-step process involves estimating local ancestry across chromosomes from genome-wide SNP data, followed by targeted resequencing of regions inferred to be inherited from a particular ancestral population. We apply the method to Mexican-American samples from the NIGMS panel, and analyze genetic variation in the Native American population(s) ancestral to the panel. To our knowledge, this is the first large-scale study of autosomal resequencing variation in any Native American group.

**Decrypting the mtDNA gene pool of modern Panamanians.** *A. Achilli[1,2], U.A. Perego[2,3], M. Tribaldos[4], N. Angerhofer[3], K.H. Ritchie[3], J. Robinson[3], L. Milani[5], M. Lari[5], D. Caramelli[5], N.M. Myres[3], R. Cooke[6], J.M. Pascale[4], J. Motta[4], A. Torroni[2], S.R. Woodward[3].* 1) Dipartimento di Biologia Cellulare e Ambientale, Università di Perugia, Italy; 2) Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia Italy; 3) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 4) Gorgas Memorial Institute for Health Studies, Panama City, Panama; 5) Dipartimento di Biologia Evoluzionistica, Università di Firenze, Firenze, Italy; 6) Smithsonian Tropical Research Institute, Panama City, Panama.

The Isthmus of Panama - the narrow neck of land connecting the northern and southern American landmasses - was a forced corridor for the Paleo-Indian expansion that originated from Beringia ~15-17,000 years ago. Archeological findings suggest that some descendants of the earliest migrants remained on the isthmus, while accounts from early European explorers witness the presence of two main indigenous groups (the Cueva and the Coclé) in pre-Columbian times - populations that have since disappeared due to disease, fights, and enslavement following the Spanish conquest. Today's indigenous groups total about 5.3% of the Panamanian population, mainly represented by the Ngöbé, Buglé, Kuna, Emberá, and Wounan tribes, which traditionally appear to have settled in Panama from surrounding regions after the autochthonous natives were decimated. However, there is no evidence that the ancestral indigenous gene pool was completely replaced. If this were the case, the populations of modern Panama should have retained at least a fraction of the native pre-Columbian gene pool, possibly at a variable extent, given the differential degree of geographical and genetic isolation of the different Panamanian communities during the past five centuries. To evaluate the nature and extent of the maternally inherited mitochondrial DNA (mtDNA) variation in modern Panamanians, DNA samples and historical records were collected from approximately 1500 volunteer participants living in the nine provinces and four indigenous territories of the Republic, and from a few pre-Columbian skeletal remains. Currently, mtDNAs for more than 500 subjects have been sequenced for the entire control region, thus including all three hypervariable segments (HVS-I, II, and III). Due to the recent gene flow from the Old World, we detected ~8% and ~13% of European and African mtDNAs, respectively, with a minor Asian component (~1%). However, the overwhelming majority (~78%) of Panamanian mtDNAs clustered into Native Pan-American haplogroups, mostly represented by A2 (49%), also identified in a pre-Columbian skeleton. In conclusion, despite the key location of the isthmus and the major construction efforts in the area (Panama Railroad and Panama Canal) that brought large numbers of slaves from Africa and immigrants from Asia, the analysis of mtDNA indicates an overall genetic continuity of female lineages between first and last inhabitants of Panama.

## 568/W/Poster Board #226

**hzAnalyzer: Analysis of contiguous homozygosity in eleven human sample populations using R and Java.** *T.A. Johnson[1,2], Y. Niimura[2], T. Tsunoda[1].* 1) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN Yokohama Institute, Yokohama, Japan; 2) Department of Bioinformatics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan.

Reports have shown that human genetic variation is often non-randomly organized into regions of restricted diversity in which a limited range of haplotypes can be observed. To examine such patterns, we have developed methods to analyze the genome-wide and localized extent of contiguous homozygosity, which represents one simple means for reducing high-density genotyping datasets into a form by which populations can be compared for their relative haplotype diversity. To apply these methods, we developed hzAnalyzer, a suite of programs using R and Java and analyzed the HapMap phase 3 rel. 2 dataset that includes approximately 1.5 million SNPs for 1,184 individuals from 11 sample populations representing founders from Africa, East Asia, India, and Europe. We detected and analyzed segments of contiguous homozygous genotypes and present as a summary the mean±SD (X$10^8$bp) of total homozygous segment length (≥131,367bp) on autosomes. Based on similarity between sample means, we grouped them into Low, Intermediate, and High groups. The Low group consisted of all populations with substantially African origins (ASW=1.6±0.1, n=83; LWK=1.7±0.2, n=90; MKK=1.7±0.2, n=171; YRI=1.9±0.1, n=167), while the Intermediate group had those with mainly European or Indian origins (CEU=4.5±0.3, n=165; GIH=4.4±0.2, n=88; MEX=4.4±0.6, n=77; TSI=4.5±0.2, n=88). East Asians possessed the highest levels of extended homozygosity (CHB=5.6±0.2, n=84; CHD=5.6±0.3, n=85; JPT=5.7±0.3,n=86). Based on recent reports on the intersection between migratory patterns during human history and haplotype diversity, these categories likely represent relative migration distances from humanity's origins in Africa. However, this data also highlights differences that might have occurred due to subsequent population admixture, since the ASW and MEX populations likely represent varying degrees of admixture between European, African, or Asian founders. Interestingly, of all groups, ASW showed the lowest levels of total homozygosity, suggesting that admixture between different African populations as well as Caucasians led to higher levels of haplotypic variation. Conversely, the MEX population showed the highest standard deviation, substantial overlap with the East Asian distributions, and a long lower tail indicating that some individuals had greater haplotype diversity. These results suggest that the impact of migration and admixture on haplotypic variation can be complex and bears further study.

**Haplogroup H of mitochondrial DNA, a far echo of the West in the heart of Central Asia.** *S.R. Woodward[1], U.A. Perego[1,2], J.E. Gomez-Palmieri[1], N. Angerhofer[1], D. Tumen[3], K.H. Ritchie[1], B. Hooshiar Kashani[2], M. Pala[2], A. Olivieri[2], V. Carossa[2], E. Myagmar[3], H. Lancioni[4], F. Panara[4], N. Babudri[4], D. Bayarlkhagva[3], M. Bayarlkhagva[3], A. Dyikanbaeva[5], A. Torroni[2], N.M. Myres[1], A. Achilli[2,4]*. 1) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA; 2) Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 3) National University of Mongolia, Ulan Bator, Mongolia; 4) Dipartimento di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 5) American University of Central Asia, Bishkek, Kyrgyz Republic.

Through the millennia, Inner Asia played a pivotal role in shaping the history that greatly added to the cultural, ethnic, and genetic diversity observed throughout present Eurasia. Perhaps the two most significant phenomena witnessed in this part of the world were the ambitious expansion strategy employed by Mongolia's most prominent personality, Genghis Khan and the complex network known as the Silk Road that for nearly 3,000 years contributed to the exchange of goods and the transmission of philosophy, art, and science that laid the foundation for the great civilizations of China, India, Egypt, Persia, Arabia, and Rome, and in several respects to the modern world. Over the last few years, through an international collaborative effort, researchers at the Sorenson Molecular Genealogy Foundation were able to collect 2,727 DNA samples, informed consents, and genealogical data in Mongolia, Kyrgyzstan, and Kazakhstan. All the samples were sequenced for the three hypervariable segments of the mitochondrial DNA (mtDNA) control region to assess the genetic composition of the modern population of these countries. We identified ~600 different haplotypes that could be ascribed to more than 30 haplogroups and sub-haplogroups. As expected, most haplogroups are typical of modern East Asian populations, but intriguingly, many different Western Eurasian clades were also identified, with a particular high incidence of H (~8.0%), the most common haplogroup in Europe. This feature cannot be attributed to genetic drift since different H sub-lineages have also been identified, each of them represented by several different haplotypes. The mtDNA distribution profile in the heart of Central Asia suggests a direct link between this area and Western Eurasia that could be explained by ancient migrations or by more recent historical events, such as Genghis Khan's conquering efforts and trade or cultural exchanges along the Silk Route. To discriminate between these two possible scenarios, we are now analyzing a subset of these samples at the highest possible level of resolution - that of complete mtDNA sequences - focusing particularly on those H mtDNAs that seem to be the most informative considering their control-region haplotypes. Our preliminary data seems to be in favor of rather ancient genetic inputs from the West in shaping the peculiar mtDNA gene pool of Inner Asia's present-day populations.

## 570/W/Poster Board #228

**Genetic Associations with Mountain Sickness for Chinese Residents at the Tibetan Plateau.** *N. Buroker[1,2], X-H. Ning[2], Z-N. Zhou[4], K. Li[3], W-J. Cen[3], X-F. Wu[4], M. Ge[5], L-P. Fan[2], W-Z. Zhu[4], M. Portman[1,2], S-H. Chen[1]*. 1) Dept Pediatrics, RR335 HSB, University of Washington, Seattle, WA; 2) Divisions of Cardiology, Seattle Children's Hospital. Institute. Foundation, Seattle, WA USA; 3) Lhasa People Hospital, Tibet; 4) Laboratory of Hypoxia Physiology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China; 5) Department of Molecular and Human Genetics, Baylor College of Medicine One Baylor Plaza, Houston, TX USA.

Acute (A) and chronic (C) mountain sickness (MS) are illnesses that occur among people visiting and inhabiting high altitude environments, respectively. Both diseases are influenced by genetics. Consequently, some individuals are genetically less fit than others when stressed by extreme high-altitude environment. We studied six polymorphisms in association with mountain illness among residents at the Tibetan plateau. The angiotensin-converting enzyme (ACE) insertion/deletion, angiotensinogen (AGT) M235T, angotensin II type 1 receptor (AT1R) A1166C and GNB3 promoter A(-350)G polymorphisms all associated with hypertension as well as two SNPs (apolipoprotein B, rs693 and tribbles homolog 1, rs17321515) associated with levels of LDL cholesterol and triglyceride, respectively, were studied with relation to AMS and CMS in normal Han and Tibetan populations. Among the hypertension polymorphisms, the ACE deletion (D) allele [OR= 1.71, CI = 1.04-2.8, p=0.036] and the AGT 235M allele [OR=2.71, CI=1.08, p=0.039] were associated with AMS and CMS, respectively, while the A allele of GNB3 was significantly (Fst, p=0.034) associated with AMS. Oxygen saturation (SO2a) was significantly lower for the AGTR-235MM genotype than for either the 235MT or 235TT genotypes. All polymorphisms were in Hardy-Weinberg equilibrium (HWE) for the Han and Tibetan controls. A departure from HWE was found for the apolipoprotein B SNP in the AMS study group. A significantly higher incidence of the TRIB1 SNP G allele was present in the CMS group compared to the normal Tibetan population. Pairwise linkage disequilibrium was found between the ACE and AGT M235T polymorphisms in the AMS study group.

**Statistical methods for estimating the rate of de novo mutation at FGFR3 in sperm samples from healthy men using high-throughput sequencing.** *S.P. Pfeifer[1], A. Goriely[2], G.A.T McVean[1], A.O.M. Wilkie[2]*. 1) Department of Statistics, University of Oxford, South Parks Road, Oxford OX1 3TG, UK; 2) Weatherall Institute of Molecular Medicine, University of Oxford, John Radcliffe Hospital, Oxford OX3 9DS, UK.

Some rare congenital disorders (such as Apert, Crouzon, Pfeiffer, Muenke, Costello and Noonan syndromes and achondroplasia) originate from spontaneous mutations in the germline of healthy fathers which are older than the average (paternal age effect). The prevalence of these specific mutations may reflect a protein-driven, positive selection of mutant cells according to the functional consequences of the encoded amino acid substitution. We aimed to use new sequencing technologies to quantify all possible point mutations at codon K650 (AAG) of the fibroblast growth factor receptor 3 (*FGFR3*) leading to achondroplasia. 78 sperm and 8 blood samples were sequenced using the Illumina sequencing technology. An attempt to use Illumina's inbuilt quality scores to estimate the rate of de novo mutations could not account for the underlying error structure. Therefore, a Bayesian approach was used to fit a model to the observed counts of each codon in the sequencing data to account for errors and bias derived from the rounds of PCR and digestion during the sample preparation, and the sequencing process. Titration data were analysed together with biological samples to validate our method down to the level of $10^{-5}$. Whilst mutation rates in blood were low, 73% of the total mutations quantified in the sperm samples were caused by a 1948A>G mutation. It reached high mutation levels (with a maximum of $2.1 \times 10^{-4}$) in sperm samples which were significantly correlated with donor age (Spearman rank r=0.34, P=0.002). Several other substitutions attained levels $>10^{-5}$ in a minority of sperm samples. These results show the utility of advanced statistical methods to estimate mutation rates in human sperm from high-throughput sequencing data down to the level of $10^{-5}$, whilst capturing subtle features of the machine and run dependent error structure.

## 572/W/Poster Board #230

**Analysis of mitochodrial DNA polymorphism in Chinese Han,Miao,and Tu populations.** *N. bin[1], z. hai yan[2], T. sai nan[3], y. zhao chu[4], Z. yong hua[5], C. yong[6]*. 1) medical genetics lab, Hunan family planning institute, Changsha, Hunan , China; 2) medical genetics lab,Hunan family institute,-Changsha,Hunan,China; 3) medical genetics lab,Hunan family planning institute,Changsha,Hunan,China; 4) medical genetics lab,Hunan family planning institute,Changsha,Hunan.China; 5) medical genetics lab, Hunan family planning institute,Changsha,Hunan,China; 6) medical genetics lab , Hunan family planning institute,Changsha,Hunan,China.

Analysis of mitochondrial DNA( mtDNA) is commonly performed in forensic investigations when the DNA in a sample is degreded or the amount is not sufficient for a STR analysis.However, mtDNA analysis has the draback of low discrimination power compared to what can be obtained by nuclear DNA analysis,owing to multiple individuals sharing identical mtDNA types in the HVI / HVII region.In this study,mtDNA sequences of the hypervariable regions HVI and HV IIand 15 SNP loci in mtDNA coding region were analyzed in 40 Chinese Han samples ,40 Miao minority ethnic group samples and 40 Tu minorityethni group samples from Hunan province,China as an initial effort to generate a database for forensic identification purposes.Comparing with Anderson sequence,98 polymorphic loci in HVI and 34 in HVII were found in total 120 individual samples, 90 and 65 haplotypes were then defined,respectively.Of 115 haplotypes,5 were shared by 2 individuals. When the HVI ,HVII and coding region were combined, only 1 haplotypes were shared by more than 1 individual.Thus,mitochondrial coding analysis can substantially increase the discriminatory power of mtDNA analysis.The random match probability and discrimination power in 120 individuls were 0.86% and 99.14%,respectively.

## 573/W/Poster Board #231

**Identification of rare variants for ulcerative colitis and celiac disease by high-throughput sequencing.** *A. Szperl[1], C.C. van Diemen[1], A. Zhernakova[2], E.A.M Festen[1,3], P. van der Vlies[1], R.K. Weersma[3], C. Wijmenga[1].* 1) Gen Dept, UMC Groningen, Groningen, The Netherlands; 2) Complex Genetics Section, DBG-Department of Medical Genetics, University Medical Center Utrecht, The Netherlands; 3) Department of Gastroenterology and Hepatology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Celiac disease (CD) and ulcerative colitis (UC) are chronic inflammatory diseases of the small intestine with a complex genetic origin. It has been shown that these disorders co-occur in patients and families. Recent genome wide association studies (GWAS) suggest a common genetic background for UC and CD with five loci already associated to both diseases. The loci identified by GWAS, due to the association to common variants, confer small risks with odds ratio between 1.2 and 1.5. We hypothesize that each of these loci may also contain rarer variants with higher risks that are causative for development of disease. The aim of this study was to identify rare causative variants in immune-related genes associated with CD or/and UC. We amplified the coding regions and 50-100 bp flanking intronic sequence of 19 immune-related genes in pools of DNA from 50 UC patients, 100 CD patients and 100 controls and analysed the samples by single-read sequencing on the Genome Analyzer II (Illumina). We have sequenced ~52 kb per DNA pool and identified 69 known SNPs and 110 unknown variants (65 non-synonymous and 114 synonymous). We selected 14 variants for follow-up that each fulfilled the following criteria: a) had a coverage of more than 700 reads per basepair; b) were observed in different reads in both the forward and reverse direction; c) were previously unknown; d) had a frequency <5%; e) were observed in CD and/or UC but not in controls; f) were non-synonymous. We were already able to confirm one stop codon variant in UC. We subsequently genotyped this variant in 900 UC, 900 CD patients and 900 controls by TaqMan genotyping and identified one other heterozygous UC individual for this stop codon. The variant is not found in CD cases nor in controls. Functional assays for the newly confirmed variant is currently ongoing as well as full sequence analysis of the entire gene in the entire cohort. Follow-up of other variants is also ongoing. Our study has shown that rare variants in a gene that also contains common variants may underlay the association to UC. This is very reminiscent to the study of common and rare variants in IFIH1 associated with type 1 diabetes.

## 574/W/Poster Board #232

**On the size distribution of private microsatellite alleles.** *Z.A. Szpiech[1], S.B. Reddy[1], N.A. Rosenberg[1,2].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Private microsatellite alleles tend to be found in the tails rather than in the interior of the allele size distribution. To characterize this phenomenon, we have investigated the size distribution of private alleles in a coalescent model of two populations, assuming the symmetric stepwise mutation model as the mode of microsatellite mutation. For the case in which four alleles are sampled, two from each population, we condition on the configuration in which three distinct allele sizes are present, one of which is common to both populations, one of which is private to one population, and the third of which is private to the other population. Conditional on this configuration, we calculate the probability that the two private alleles occupy the two tails of the size distribution. This probability is seen to be greater than the value that would be expected if there was no relationship between privacy and location in the allele size distribution. Results from our model can assist in interpreting the allele size properties observed for private microsatellite alleles in human populations.

## 575/W/Poster Board #233

**Direct estimation of the microsatellite mutation rate.** *J.X. Sun[1], A. Helgason[2], G. Masson[2], N. Patterson[4], D.E. Reich[3,4], K. Stefansson[2].* 1) Division of HST, Massachusetts Institute of Technology, Cambridge, MA, USA; 2) deCODE Genetics, 101 Reykjavik, Iceland; 3) Dept of Genetics, Harvard Medical School, Boston, MA, USA; 4) Broad Institute, Cambridge, MA, USA.

Characterizing the behavior of mutations is fundamental to our understanding of genetic variation. Attempts to directly observe DNA mutations arising from germline transmissions are confronted by two challenges: The large amount of DNA sequence that needs to be collected in order to observe a mutation (since the mutation rate in humans is estimated to be ~$2x10^{-8}$ per generation), and a poor signal-to-noise ratio, due to the fact that any modern genotyping technology has an error rate far exceeding the mutation rate. Using deCODE Genetics' database of over 95,000 Icelanders genotyped at over 3,000 microsatellite loci, we directly observed mutations in germline transmissions from pedigrees. Microsatellites are thought to have mutations rates as high as $10^{-3}$ per locus per generation. To overcome the genotyping error rate, which was estimated in this data set to be $\leq 10^{-2}$ per allele call after appropriate filtering, we carried out two independent analyses: (1) We restricted our analysis to mother-father-child trios, and required the mutated allele to be genotyped at least twice in both the child and in the transmitting parent to confirm mutant transmissions. This identified 2,124 mutant events from 5.62 million instances of parent-child transmissions, yielding a mutation rate estimate of $3.78x10^{-4}$ averaged across the markers that we analyzed. (2) We traced the haplotype affected by the mutation through local pedigrees, requiring that the mutant haplotype is observed in the affected proband's children, and simultaneously, that the wildtype haplotype is observed in the affected proband's siblings. This identified 788 mutant events from 1.59 million instances of parent-child transmissions, yielding a mutation rate of $4.96x10^{-4}$. Our collection of mutant events is significantly larger than previous studies. This allows for categorical analyses of microsatellite mutation rates partitioned based on the gender and age of the individual transmitting the allele, as well as the repeat type and cytogenetic position.

## 576/W/Poster Board #234

**Distribution of the CTG repeat polymorphism at the DMPK gene in a healthy Mexican population sample.** *J.J. Magaña[1], P. Cortés-Reynosa[1], R. Gómez[1], A. Miranda[1], N. Leyva[1], B. Cisneros[2].* 1) Genetics, National Rehabilitation Institute, Mexico City, D.F., Mexico; 2) Genetics and Molecular Biology Dept, CINVESTAV-IPN, Mexico City, D.F., Mexico.

Myotonic dystrophy type 1 (DM1) is the most common form of muscular dystrophy in adults, affecting 1/8000 individuals. DM1 is caused by expansion of the CTG trinucleotide repeats within the 3'-untranslated region (3'-UTR) of the DMPK gene. This repeat is polymorphic in normal individuals with alleles ranging from 5 to 37 repeats. Alleles exceeding a threshold of approximately 50 repeats and reaching up to a number of 4000 CTGs result in disease. The present study, analyze the variability at the DMPK gene polymorphism in 400 unrelated Mexican healthy subjects. CTG repeats were genotyped using capillary electrophoresis in an ABI PRISM 310 genetic analyzer. A total of twenty five alleles were found, ranging from 5 to 37 repeats. Distribution of alleles was bimodal, with peaks at 5 and 10-14 repeats. The most common allele had 13 repeats (38.8%) followed by the 11 and 5 repeats alleles (24.6% and 15% respectively). Alleles greater than 22 repeats had a frequency of 3.25%. As expected from such allelic distribution, the predominant genotypes were 11/13 and 13/13 repeats. Polymorphic distribution was compared with data from 8 different human populations (Caucasian European, Yugoslav, Japanese, Korean, Taiwan, African Negroids, African American and Chilean) and one Amerindian group (Cabecar, a tribal population of Costa Rica). We found that all populations were significantly different among them ($P < 0.01$). The 13 repeats allele was also the predominant allele in the Japanese population (27.35%), however its frequency is statistical different between the Japanese and our population. The frequency of the >22 repeats alleles in the Mexican population was similar than that of the others populations, with the exception of the African population, where these alleles exhibits low frequency. This fact may explain the low DM1 incidence in black populations. Generally, the 5 repeats allele is the most common allele in the analyzed populations; however, it showed lower frequency in the Mexican population. This particular distribution in the Mexican population could be attributable to our Native American Ancestry. We and others have evidenced the presence of a mixture of European, Native American and African ancestry in our population. Our findings confirmed the high variability of the CTG repeats at the 3'UTR of DMPK gene, which makes it a useful tool in forensic and ethnic admixture studies, and could explain also the different distribution of the disease in the world.

## 577/W/Poster Board #235

***MECP2* gene coding sequence variations in newborn infants.** *J. Yu[1], Z. Qi[1], Y. Zhang[2], C. Iyama[2,3], H. Zeng[2], G. Hoffman[4], D. Kurtycz[4,5].* 1) Lab Med, Univ California, San Francisco, San Francisco, CA; 2) Waisman Center, University of Wisconsin-Madison, Madison, WI; 3) Department of Pediatrics, University of Wisconsin-Madison, Madison, WI; 4) Wisconsin State Laboratory of Hygiene, University of Wisconsin-Madison, Madison, WI; 5) Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison, Madison, WI.

The *MECP2* gene codes for Methyl-CpG binding protein 2. Mutations in the gene are responsible for Rett syndrome (RTT) and other neurological disorders. Thus far more than 700 mutations/variations in the *MECP2* gene have been documented in affected individuals. However, the prevalence of the mutations/variations in general populations is unknown. We analyzed *MECP2* coding sequence changes in 1,000 randomly selected newborn infants and found that 35 infants (3.5%) carried 24 sequence variations, of which 14 were previously reported in patients and 10 were apparently new. This was the first observed distribution of *MECP2* mutations/variations in a general newborn population. The findings suggest that frequent coding sequence variations might be a genomic feature of the *MECP2* gene, which poses a potential challenge for clinical screening and testing of pathogenic mutations of the gene. The pathogenic significance of *MECP2* sequence variations without population studies needs to be carefully evaluated.

## 578/W/Poster Board #236

**Extensive population-based variation in drug metabolism is revealed by analyzing Hapmap DNA with the Affymetrix DMET Plus microarray.** *E. Mansfield[1], M. Sedova[2], C. Bruckner[1], R. Sapolsky[2], G. Mei[3], P. Dickinson[4], R. Wheeler[3], J. Burrill[1], C. Davies[3], S. Cawley[3], M. Shapero[2].* 1) Application Sciences Dept., Affymetrix, Santa Clara, CA; 2) Assay & Application Product Development Dept., Affymetrix, Santa Clara, CA; 3) Informatics Dept., Affymetrix, Santa Clara, CA; 4) Data Analysis Dept., Affymetrix, Santa Clara, CA.

**Background:** The DMET Plus assay is a comprehensive drug metabolism microarray capable of simultaneously genotyping ~2,000 common and complex functional variants in 225 drug-metabolizing enzymes, transcription regulators, and transporter genes. These genes have evolved as the major human hepatic detoxification system for processing environmental toxins and xenobiotics and show extensive genetic variation. Interpretation of the genetic profiles generated by the array is greatly aided by reports translating genotype data into well-recognized haplotype-based allele calls. **Methods:** Over 1,200 distinct DNA samples were analyzed, including 713 samples from the Hapmap extended-diversity panel. Genomic DNA extracted from blood samples or commercially available cell lines were used. Data was analyzed using Affymetrix' DMET Console software, followed by principal component analysis (PCA) and 2-class association analysis using HelixTree (Golden Helix, Bozeman, MT). **Results:** A 99.92% concordance between SNP6.0 and DMET Plus arrays was observed across the Hapmap samples at 219 overlapping SNPs. Analysis results and reports focused on the metabolic pathways of drugs of interest such as Tamoxifen, Warfarin, and Plavix will be used to illustrate the versatility of the array's analysis tools. The DMET Console software generates fully-annotated marker reports that include commonly recognized, haplotype-based allele names (e.g CYP2D6*7, NAT2*5F, GSTP1*C, etc.). Evidence-based reporting of variants with known phenotypic or structural alterations is documented in the translation summary. Star allele frequency distribution across the major populations in genes such as ABCG2, CYP2C19, CYP4F2, SLCO1B1, TPMT, and VKORC1 agree with published sources and are compiled in formats amenable to downstream genetic analysis. PCA reveals complete segregation of Asian, Caucasian and African samples by population of origin and stratification within these groups is evident when 7 Hapmap populations are compared. Among the ADME genes represented on the DMET Plus microarray, CYP3A4, PPARG, and VKORC1 show the greatest allele frequency differences worldwide. These 3 genes are the most abundantly expressed hepatic cytochrome P450, a transcription regulator, and the drug target for the blood thinner Warfarin respectively. **Conclusion:** The DMET Plus microarray and analysis tools facilitate highly-multiplexed genotyping of functional variants across full pharmacokinetic pathways.

## 579/W/Poster Board #237

**Medaka (*Oryzias latipes*) as a model to study human polymorphic functions.** *T. Katsumura, S. Oda, H. Mitani, S. Kawamura, H. Oota.* Dept Integrated Biosci, University of Tokyo, Kashiwa, Chiba, Japan.

Since the HapMap project, a lot of single nucleotide polymorphisms (SNPs) have been identified in human genome. Among the SNPs, we find highly differentiated non-synonymous SNPs among populations, which can be explained rarely by natural selection related to adaptation for each habitat. It is important to reveal a functional difference between distinct alleles. However, experiments using humans are almost impossible technically and ethically. We propose here the utility of the medaka fish (*Oryzias latipes*) as a model system for human polymorphisms. Medaka has a long time history of an experimental animal: inbred strains have been established, many lab-stocks from wild have been maintained, and molecular biological techniques are developed. Most importantly, genetic variations of medaka and its close relatives are known to be high.

To establish an efficient screening method, we first looked into genetic stratification of medaka. We examined the mitochondrial (mt) DNA diversity in the deme- and the grid-based sampling methods: the former was the sampling from local-wild schools in Kanto (the eastern part of Japan), while the later was the sampling from lab-stocks collected from various geographical regions. The population genetic statistics showed that the grid-based sampling provided larger polymorphisms than the deme-based one. Next, we focused on *cytochrome P450* (*CYP*) gene family because it is well known that each gene has highly polymorphic in humans and this gene family can be related in adaptation to circumstances. We found 20 *CYP* genes showing apparent orthology between medaka and human, and chose four *CYP* genes (*CYP1A*, *CYP1B1*, *CYP5A1*, and *CYP20A1*) harboring non-synonymous SNPs with different allele frequencies among human populations. We conducted SNP screenings for the medaka *CYP* genes and found non-synonymous SNPs at the same site or the vicinity in medaka genome where human *CYP* orthologs have SNPs. To assay functional difference among the *CYP* alleles, we made them express in a cell culture using the GAL4/UAS system and measured their enzymatic activities using a known substrate in human CYP.

This is first trial of comparative population genomics for CYP functions between medaka and humans, and opens up a new window to analyze the functional difference among human SNPs using medaka.

**Joint Haplotype Structure of the Tumor Necrosis Factor and HLA Class I Blocks in European Americans: Implications for Disease Association Studies.** *B. Aissani[1], K. Zhang[2], R. Malhotra[1], K.M. Ogwaro[11], J. Tang[3], S. Shrestha[1], O. Martinez-Maza[4,5], L.P. Jacobson[6], R. Detels[7], J.P. Phair[8], J.J. Martinson[9], J. Margolick[10], R.A. Kaslow[1,3].* 1) Department of Epidemiology, University of Alabama at Birmingham. Birmingham, AL; 2) Department of Biostatistics, University of Alabama at Birmingham. Birmingham, AL; 3) Department of Medicine, University of Alabama at Birmingham. Birmingham, AL; 4) Department of Obstetrics and Gynecology. University of California at Los Angeles. Los Angeles, CA; 5) Department of Microbiology, Immunology and Molecular Genetics, University of California at Los Angeles. Los Angeles, CA; 6) Department of Epidemiology, Johns Hopkins University. Baltimore, MD; 7) Department of Epidemiology, University of California at Los Angeles. Los Angeles, CA; 8) Division of Infectious Diseases, Northwestern University. Chicago, IL; 9) Department of Infectious Diseases and Microbiology, University of Pittsburgh. Pittsburgh, PA; 10) Department of Molecular Microbiology and Immunology, Johns Hopkins University. Baltimore, MD; 11) Department of Psychiatry, University of Alabama at Birmingham. Birmingham, AL.

Within the human major histocompatibility complex (MHC), the tumor necrosis factor (TNF) block including the LTA +252 (A>G) and TNF -308 (G>A) polymorphisms, henceforth G-A haplotype, has been implicated in the susceptibility to numerous immune conditions. However, the high gene density and the complex pattern of linkage disequilibrium (LD), independent of the intermarker distance, have hampered the precise identification of disease genes in this region. To better understand the haplotypic structure of central MHC, we have examined the association between *HLA-B* and the TNF block haplotypes. **Design & Methods:** We analyzed data on 656 non-Hispanic European American men from the Multicenter AIDS Cohort Study (MACS) and 92 unrelated subjects from the CEU population of the international HapMap project. A set of 47 single nucleotide polymorphisms (SNP) located in a 70 Kb-long region spanning the TNF gene cluster (*LTA*, *TNF* and *LTB*) and flanking genes (*MMCD1*, *BAT1*, *ATP6VIG2*, *NFKBIL1* and *LST1*) were typed in the MACS sample. HLA-B alleles were identified to four-digit resolution by reference-strand conformation polymorphism and DNA sequencing-based typing methods. The HAPLORE algorithm was used for the statistical inference of SNP-HLA-B haplotypes. **Results:** Of a total of 337 haplotypes inferred in the MACS sample, 23 unique haplotypes occurred at a frequency > 1% and accounted for approximately 61% of all haplotypes. As expected due to the high level of polymorphism at *HLA-B*, most of these common TNF block haplotypes were split into HLA-B-specific sub-haplotypes. The LTA-TNF G-A haplotype is carried on two major ancestral HLA-B haplotypes: the immune disease-prone HLA-B*08 (AH 8.1) and the less extensively conserved B*4402 (AH 44.2). Our haplotype data are consistent with the reconstructed haplotypes in the CEU reference population, although only 15 common haplotypes were found in this small population. **Conclusion:** Our study in the MACS is among the largest to examine the TNF block and HLA-B haplotypes jointly. Of relevance to disease association with central MHC genes, we identified a sub-haplotype of the B*4402 (AH 44.2) lineage carrying the LTA-TNF G-A haplotype. Because AH 44.2 shares only a limited portion of sequence with the more extended haplotype AH 8.1, if both haplotypes can be unequivocally associated with the diseases previously associated only with AH 8.1, it would greatly reduce the extent of the candidate region(s)requiring more intensive inquiry.

## 581/W/Poster Board #239

**Estimating Population Genetic Parameters and Comparing Model Goodness-of-fit Using DNA Sequences with Error.** *X. Liu, Y.-X. Fu, T.J. Maxwell, E. Boerwinkle.* Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX.

Sequencing error can bias estimation of evolutionary or population genetic parameters from deep re-sequencing studies. Sequencing errors are even more of a problem when using so-called next generation sequencing methods or when sequencing large sample sizes. To overcome this problem, we propose a new method based on the composite likelihood of SNP configurations to simultaneously infer the population mutation rate $\theta=4N_e\mu$, population exponential growth rate $R$ and error rate $\varepsilon$. Using simulation, we demonstrate the interactive effects of various parameters, such as $\theta$, $n$, $\varepsilon$ and $R$ on the accuracy of the estimators. We compared our maximum composite likelihood estimator (MCLE) of $\theta$ with other $\theta$ estimators that take account for error. The results show that the MCLE performs well when the sample size is large or the error rate is high. Using parametric bootstrap, composite likelihood can also be used as a statistic for testing the model goodness-of-fit of the observed DNA sequences.

We applied our method to published exon data from ANGPTL4 in 1,832 African American and 1,045 European American individuals. Previous analysis showed a significant excess of rare alleles assuming a constant population size and no sequencing error. To test the robustness of this conclusion under an error model, we estimated that per base-pair MCLE($\theta$)=0.0017 and MCLE($\varepsilon$)=$3\times10^{-6}$ for African Americans, and MCLE($\theta$)=0.0011 and MCLE($\varepsilon$)=$4\times10^{-6}$ for European Americans. Using the estimated $\theta$ and $\varepsilon$, we simulated the null distribution of two neutrality test statistics (Achaz's Y and Y*). By comparing the results of the two tests using the original sequence data, we confirmed the conclusion of a significant excess of rare alleles in both African Americans and European Americans. Using the fact that the rare nonsynonymous changes were verified experimentally in these data, singletons should have a lower error rate than other SNPs. Because this information is not incorporated in our model, our MCLE($\varepsilon$) should be an upper limit of $\varepsilon$. Even with an error model with overestimated $\varepsilon$, Y and Y* rejected the null hypothesis of no excess rare alleles, which suggests that sequencing error cannot explain the excess of rare alleles. This leaves us alternative explanations that include purifying selection, population expansion, or mixed effects of multiple acting factors mentioned above.

## 582/W/Poster Board #240

**THE PREVALENCES OF INHERITED THROMBOPHILIC RISK FACTORS IN TURKISH PATIENTS EXPERIENCING RECURRENT MISCARRIAGE, INFERTILITY AND VENOUS THROMBOSIS : FACTOR V LEIDEN, PROTHROMBIN G20210A, AND METHYLENETETRAHYDRO FOLATE REDUCTASE C677T.** *B. Ozturk[1], H. Comert[2], B. Yazar[2], O. Ilbay[2], L. Erkan[2], N. Ercelen[2].* 1) Clinical Genetics/Pediatrics, ECU Brody Sch Med, Greenville, NC; 2) Genetics & Genomic Sciences Center, American Hospital, Istanbul, TURKEY.

Introduction: Inherited thrombophilia has has been associated with recurrent pregnancy loss, infertility and venous thrombosis. The aim of this retrospective study is to evaluate the prevelance of inherited thrombophilic risk factors in Turkish patients experiencing recurrent miscarriage, infertility and venous thrombosis. Materials and Methods: A total of 596 patients who referred to American Hospital, Genetics and Genomic Sciences center were included in this study. All of the patient group subjects had a history of recurrent miscarriage, infertility and/or venous thrombosis. Informed consent was obtained from all subjects. DNA samples were isolated from peripheric blood samples drawn from all the participants. 596 patients were analyzed for Factor V Leiden, 567 patients were analyzed for Prothrombin G20210A and 558 patients were analyzed for Methylenetetrahydro-folate Reductase C677T. Results: The prevalence of FVL, Prothrombin G2010A and MTHFR C677T mutations were detected for Turkish recurrent miscarriage, infertility and venous thrombosis patients. The prevalences of inherited thrombophilic risk factors were found for our patient group: FVL (26.84%), prothrombin G20210A (7.93%) and MTHFR C677T (55.55%). Conclusions: In the litearature prevelances of FVL1, Prothrombin G20210A2 and MTHFR C677T2 were reported as 7.9%, 2.74% and 40.56% respectively in healthy Turkish population. As a conclusion high prevalences of FVL, prothrombin G20210A and MTHFR C677T mutations in our patient group suggest that these inherited thrombophilic risk factors should be considered in patients with a history of recurrent miscarriage, infertility and/or venous thrombosis. ## 583/W/Poster Board #241

**ASSOCIATION Helicobacter pylori and mtDNA-A IN A SAMPLE OF MEXICAN NAHUA POPULATION.** *R. Penaloza[1], P. Negrete[1], U. Galicia[1], G. Gonzalez[2], J. Torres[2], L. Buentello[3], K. Sandoval[4], D. Comas[4], F. Salamanca[1].* 1) UIM Gen Humana, Inst Mexicano del Seguro Soc, Mexico City, Mexico; 2) UIM Enfermedades Infecciosas, Inst Mex Seg Social, Mexico City, Mexico; 3) Inst. Inv. Antropologicas, UNAM Mexico City. Mexico; 4) Depto. Biol. Molecular, Univ. Pompeu Fabra, Barcelona, Spain.

Background: Helicobacter pylori (Hp) infects more than 50% of the world's population, infection can persist in the human stomach and induce chronic gastritis for the lifetime, increasing the risk for developing peptic ulceration, noncardia gastric adenocarcinoma and gastric lymphoma; it is considered by WHO as a carcinogenic type I and there are some reports showing relatedness with susceptibility and some markers including mutations in mitochondrial DNA (mtDNA). Aim: To assess a possible association of mtDNA haplotypes and Hp infection in a sample of Mexican Nahua population. Material and Methods: .Twenty two Mexican Nahua individuals from Atocpan, Milpa Alta with previous informed consent were studied. The urea breathe test (UBT) and the string test were applied for diagnosis and isolation of H pylori. The string was inoculated immediately in blood agar plates with antimicrobials, packed in Jars with campy pack CO2 generators (Beckton Dikinson Co. USA). DNA was extracted of four ml of peripheral blood by standard method. HVI from D-loop was amplified by PCR and sequenced directly with product previously labeled by BigDye kit (Applied Biosystems, USA). Results were compared with Andrews et al. (1999) sequence corrected. Results and Conclusions: H pylori CagA was isolated from thirteen samples. Eight samples have mtDNA haplogroup A2, two haplogroup C1 and three D1, suggesting an association between H. pylori and mtDNA-A, haplogroup highly frequent in some Mexican Indigenous and Noth Amerindian populations.

**What should we call a microsatellite: A case study of human dinucleotides.** *K. Makova[1], Y. Kelkar[1], N. Candiello[2], S. Hile[2], F. Chiaromonte[1], K. Eckert[2].* 1) Center for Comparative Genomics and Bioinformatics, Penn State University, University Park, PA; 2) Department of Pathology, Gittlen Cancer Research Foundation, Penn State University College of Medicine, Hershey, PA.

Microsatellite sequences are abundant in the human genome and have mutation rates orders of magnitude higher than any other genomic sequences. Microsatellite mutations cause over 40 neurological diseases, implicated in several types of cancer, and allele-length polymorphisms at microsatellites are implicated as genetic risk factors in several other diseases. Microsatellites are also frequently used as markers in forensics and population genetics. However, there is a disagreement about what we should call a microsatellite. In this interdisciplinary project, to determine the threshold value at which a repetitive motif becomes a microsatellite, we utilized two approaches - a biochemical one and a computational (population genomic) one. The threshold was defined as the number of repeats for which the insertion-deletion (indel) frequency is higher than the average indel frequency in genomic DNA. In the biochemical approach, we analyzed the in vitro replication slippage error rates of DNA polymerase (Pol Beta) at repetitive sequences of different repeat numbers as well as at control sites. We discovered that GT repeats with 5-7 units acquire rates higher than these of control sites. In the computational approach, we studied microsatellite indel polymorphism in ten ENCODE regions, using the HapMap-II resequencing data for 48 humans. To find the minimal size of a microsatellite, we investigated the relationship between the proportion of polymorphic repetitive loci, and the size of the smallest repetitive allele. Similar procedure was followed for control sites. We found that repetitive loci with the smallest allele size of 4-5 repeats were rarely polymorphic. In contrast, ~20% of loci with 6-7 units were polymorphic, this proportion was higher than at control sites. Therefore, the results of the two approaches are in remarkable agreement and point towards the threshold of 5-7 units for GT microsatellites in humans. Thus, measuring the proportion of polymorphic loci depending on repeat number is an appropriate method to study the dynamic microsatellite mutational activity. In this context, we also characterized the mutational processes responsible for pushing a DNA sequence beyond the microsatellite size threshold. Additionally, we found that the microsatellite threshold size depends on a repeated motif.

## 585/W/Poster Board #243

**The heritability of endometriosis in a Utah population.** *P. Farrington, K. Ward, H. Albertsen, G. Frech, T. Maness, S. Dintelman, L. Wong.* Juneau Biosciences, LLC, Salt Lake City, UT.

Purpose: Endometriosis is a complex condition of uncertain etiology in which endometrial glands, stroma, and/or tissue normally confined to the inner lining of the uterus is found outside the uterus, most often in the pelvic area. Endometriosis is also characterized by inflammation, cysts, and scarring at affected sites, as well as by pelvic pain, dysmenorrhea, and infertility. Endometriosis affects up to 10% of reproductive-age women. The present study utilizes a population-based genealogical database and a list of women diagnosed with endometriosis to estimate its heritability. The present study seeks to extend the heritability study of the Icelandic population by Stefansson et al. (Hum Reprod 17, 555-9, 2002), with a different and more diverse population from the U.S. Intermountain West. Methods: Women who had endometriosis surgically confirmed by laparoscopy or laparotomy were ascertained for this study. All participants had their endometriosis-related medical records reviewed by a research Ob-Gyn physician to confirm the diagnosis. An extensive genealogy database (GenDB) was constructed using more than 15,000 genealogy sources in the public domain (birth, death, and marriage records from prior to 1930). This database was searched for the names, birth dates, and birthplaces of the four grandparents of the probands. Heritability-related parameters were determined for the probands' grandparents and compared to randomly chosen sets of control groups whose birth years and connectivity in GenDB closely matched the patient group. Summary of Results: Results indicate that in our population of mostly Utah individuals, in agreement with a previous study from the Icelandic population, patients with endometriosis are more closely related than matched controls, close family members have an increased relative risk for the disease, and the minimum number of founders required to account for the cases is smaller than for the controls. A preliminary analysis using 165 cases, excluding contributions from affected first-degree relatives and allowing for up to six generations of ancestors, revealed a significantly higher ($p<0.001$) average kinship coefficient (KC) of $2.07 \times 10^{-4}$ compared to matched control sets ($0.58 \pm 0.07 \times 10^{-4}$). When contributions from affected first- and second-degree relatives were omitted, the average KC was $1.04 \times 10^{-4}$ (155 cases) versus $0.49 \pm 0.07 \times 10^{-4}$ ($p<0.001$). Conclusion: A genetic component contributes to endometriosis.

## 586/W/Poster Board #244

**Fast and Accurate Inference of Long-Range Haplotypes for Large Cohorts of Unrelated Individuals.** *P.F. Palamara, A. Gusev, I. Pe'er.* Columbia University, New York, NY.

Current technologies allow the sampling of large cohorts of individuals using high-density SNP arrays. Unfortunately, genotype data obfuscates the phase of the sampled individuals, which is relevant in several applications such as disease-gene association studies and genealogy reconstruction. This technological deficiency is currently remedied by either trio data or computational phasing methods, that can be unreliable over long regions where recombination events are likely to occur. A recently introduced implementation relying on remote genetic relatives as surrogate parents has shown the great benefits of long-range phasing, although it has only been demonstrated for localized regions and would be computationally infeasible on a genomewide, population-wide scale. In this work we report methodology and software for haplotype inference in large cohorts of unrelated individuals genomewide. The method relies on GERMLINE, our recent efficient algorithm for the detection of segments identical-by-descent (IBD) between purported unrelateds. Compared to the currently used methods for the detection of IBD segments, GERMLINE allows a dramatic increase in speed and sensitivity, traded for limited false positives. We use shared segments identified in pairs of individuals to resolve ambiguous phase. We utilize information beyond IBD pairs, identifying subsets of haplotype carriers, thus propagating phase information within these sets. The proposed methodology is evaluated on real datasets for two large populations that present different levels of IBD sharing. Through results obtained on a variety of large sets of synthetic data we outline the dependency of our method's performance on two main parameters, namely the sample size and the expected chance of IBD sharing in the studied population. We finally show how long-range haplotype inference can be used to decrease the false-positive rate of the GERMLINE algorithm, exploiting the interdependency between phasing accuracy and specificity. Propagating the information derived from incorrect IBD segments, in fact, leads to detection of inconsistencies, which can be used to improve the detection of IBD.

**The perfect phylogeny map of human genome and its applications.** *G. Zhang[1,2], R. Chakarborty[2], S. Xu[3], L. Jin[2,3].* 1) Department of Family Medicine, University of Cincinnati, OH; 2) Center for Genome Information, Department of Environmental Health, University of Cincinnati, OH; 3) 3. CAS-MPG Partner Institute of Computational Biology, SIBS, CAS, Shanghai.

Genealogies of human genetic variations will assist the understanding of how various forces (i.e. mutation, selection, recombination and demographic history) have shaped the extant patterns of our current genome. However, reconstructing the full history of a set of genetic variants is close to impossible due to the complexities introduced by recombination events. To overcome this difficulty, we introduced the concept of perfect phylogeny block of SNP markers. In contrast to commonly used block definitions based on linkage disequilibrium or haplotype block deversity, the proposed perfect phylogeny blocks can be physically overlapped and the mutation history of each variant within the block is well represented by a perfect phylogenic tree. Following this definition we have developed an efficient computational algorithm to find all perfect phylogeny blocks by using genotype data of high-density SNP markers. By applying our method to the recent released HapMap III data set, we constructed a high resolution perfect phylogeny map of human genome (http://tgx.uc.edu/ppb) and reconstructed the genealogy of each individual block. This map has two direct practical applications. First, the perfect phylogeny structure is more informative in identifying targets of natural selection than the traditional methods based on summary statistics on individual loci or haplotype diversity. Second, the perfect phylogeny block structure can facilitate robust inference of local recombination rates. Accordingly, we developed several methods that can interrogate the genealogy information of perfect phylogeny blocks for detecting signals of positive selection and estimation of local recombination rate. By comparing with other methods, we demonstrated that by integrating the genealogy information and by summarizing evidences from multiple overlapped blocks, these perfect phylogeny block based methods are able to detect positive selection signals with higher confidence and can accurately quantify fine-scale recombination rate.

## 588/W/Poster Board #246

**The architecture of long-range haplotypes shared across populations.** *A. Gusev[1], P.F. Palamara[1], A. Darvasi[2], P. Gregersen[3], I. Pe'er[1,4].* 1) Computer Sci, Columbia Univ, New York, NY; 2) Department of Genetics, Hebrew University, Jerusalem, Israel; 3) Long Island Jewish Medical Center, North Shore, NY; 4) Center for Computational Biology and Bioinformatics, New York, NY.

The availability of cost-effective, high throughput technologies to genotype common alleles has yielded an unprecedented wealth of genomewide data on human variation, deeply sampled within and across populations. Examining thousands of individuals now facilitates extensive evaluation of shared genetic segments across millions of sample-pairs. Analysis of such sharing has the potential of revealing recent genetic history of samples, both genomewide as well as for specific loci. In this work, we extend a method for efficiently identifying co-inherited shared segments in a large population of unphased genotype data. We apply this method to data from multiple populations and demonstrate the surprisingly pervasive amount of sharing within and between populations. The bulk of this sharing yields insights into population history and substructure. In particular, we use this sharing in a bottom-up clustering approach to differentiate between the varying populations of the International HapMap Project. Exploring the distribution of segment sharing in a more dense population of Ashkenazi Jews, we are able to make inferences into the effective population size and structure near the present. Looking at long inter-population sharing, likely indicative of positive selection, we expose hotspots of commonly shared haplotypes and report their unique functional and structural significance. Specifically, we found 16 commonly shared regions that span only 0.92% of the genome and account for 18% of sharing between continents. We establish significant overlap between these regions and long structural variants (p=0.00052 in long variants), suggesting functional importance. Our results have implications in both population genetics and genome structure; illuminating the history of heritable variation from a fresh angle focused on modern times; and discovering functional connections between the patterns of long range haplotype sharing and structural variants, an unexpected result pointing to haplotype-sensitive recombination rates.

## 589/W/Poster Board #247

**Variable gene copy number determination of *CCL3L1* related gene family cluster.** *M. Nyaku, S. Shrestha.* Department of Epidemiology, School of Public Health, University of Alabama at Birmingham, Birmingham, Alabama.

Copy number variations (CNVs) of the gene CC chemokine ligand 3-like1 (*CCL3L1*) have been implicated in several disease outcomes, specifically HIV-1 susceptibility. *CCL3L1* is a nonallelic isoform of CC chemokine ligand (*CCL3*) and a potent ligand for CC chemokine receptor 5 (CCR5), the major coreceptor for HIV. In comparison to other CCR5 chemokine ligands, *CCL3L1* exhibits the most superior suppressive characteristics against HIV-1. Studies have shown that individuals with *CCL3L1* copies greater than their ethnic population medians are less susceptible to HIV-1 infection and progression to AIDS. Several CNV assays have been developed for the *CCL3L1* gene. *CCL3L1* however, shares very significant homology with a cluster of genes localized to chromosome 17q12, namely chemokine (C-C motif) ligand 3 (*CCL3*), CC chemokine ligand 3-like 2 (*CCL3L2*), and CC chemokine ligand 3-like 3 (*CCL3L3*) Through pairwise and multiple alignments of these genes, we have shown that the homology between these genes ranges from 50% to 99% in complete gene sequences and above 70% in the exonic regions with *CCL3L1* and CCL3L3 being very identical. We have developed an algorithm that shows that previously utilized RT-PCR based CNV assays for *CCL3L1* are indeed not specific to *CCL3L1*. We aligned sense primers, anti-sense primers and probes used in seven previously described assays against pre-multiple alignments of all 4 chemokine genes. Each set of probe and primers aligned without a nucleotide mismatch with at least 2 out of the 4 genes. We have now developed gene specific CNV assays after carefully accounting for the high homology regions between these regions. Some of the inconsistencies in the association studies could be due to heterogeneity in these assays that are not specific for a single *CCL3L1* gene but rather non-specific combinations of the 4 genes in this genomic cluster. The applications of these new assays can be extended to ongoing *CCL3L1* CNV association studies in other human disease pathogenesis including psoriasis, Crohn's disease, rheumatoid arthritis, systemic lupus, type 1 diabetes and Kawasaki disease.

## 590/W/Poster Board #248

**Admixture between Ashkenazi Jews and Central Europeans.** *W. Klitz[1,2], L. Gragert[3], M. Maiers[3], M. Fernandez-Viña[4], Y. Ben-Naeh[5], G. Benedek[6], C. Brautbar[6,7], S. Israel[7].* 1) Pub Hlth, Univ California, Berkeley, CA; 2) Public Health Institute, Oakland, CA; 3) National Marrow Donor Program, Minneapolis, MN; 4) University of Texas, MD Anderson Cancer Center, Houston, TX; 5) Hebrew University, Jerusalem, Israel; 6) Hebrew University - Hadassah Medical School, Jerusalem, Israel; 7) Hadassah University Hospital, Jerusalem, Israel.

When distinct populations inhabit the same geographic space, culture often acts to restrict random mating in our species, while at the same preventing complete genetic privacy. The residency across Central Europe by the Ashkenazi Jews over the last thousand years is such a case. HLA typing from bone marrow donor registries in Israel, Poland and Germany were utilized to measure admixture between central European host populations and Ashkenazim. Inferred high resolution HLA A-B-DRB1 haplotype frequencies were generated from each population. A total of 1,676 Polish-origin-Ashkenazim and 13,556 Polish haplotypes were analyzed, along with a similar sample of ~5 million German haplotypes. The informativeness of HLA haplotypes is shown by the A-B-DRB1 haplotype 0101-0801-0301, the most common haplotype found in northern Europe. HLA B*0801 bearing haplotypes are present in the Near East, but those B*0801 haplotypes carry the HLA C allele Cw*0702 instead of the Cw*0701 found in 0101-0801-0301. The 100 most common haplotypes constituted 53% of the total Ashkenazi, and 45% of the Polish, and 43% of the German samples, reflecting the sizeable total fraction of very rare haplotypes familiar in population samples of the diverse HLA system. The most common Ashkenazi haplotype had a frequency of 6.14% (n = 102.9) and the 100th haplotype was present at 0.29% (n = 4.86). Comparable values for the Polish sample were 5.83% (n = 790.3) and 0.13% (n = 17.6), respectively. Haplotypes from one population compared to those haplotypes in a second could be classified into three categories: less frequent, statistically identical or more frequent. In the graph of the ordered 100 Polish haplotypes, the less frequent Ashkenazi haplotypes supply a possible signature of admixture from the Poles into the Polish Ashkenazim, while the haplotypes more frequent in Ashkenazim than Poles are candidates for movement of genes from the Ashkenazim to the Poles. The averaged frequency differences between these categories give an indication of population admixture. The analysis showed that 1.8% of Polish haplotypes may be of Ashkenazi origin and 0.6% of Ashkenazi of Polish origin. The sample from Germany, in which the initial generations of Polish-Ashkenazi history was spent, was useful in demonstrating consistency of haplotype frequencies by rank order. The results show clear evidence of admixture occurring in both directions between two largely HLA-distinct populations.

**An Effective and Cost-Efficient Approach to High Throughput Analysis of Population Stratification.** *E.R. Londin[1], L.A. Mamounas[2], R. Zhang[2], L. Gutmann[2], R.A. Corriveau[1].* 1) Coriell Institute Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke, Bethesda, MD.

The NINDS Repository was established in 2002 to accelerate discovery of genetic risk factors for neurological disorders by providing a centralized and open resource of biomaterials, genotype and phenotype data, and collaborative support to researchers. Genetic ancestry is an important variable that impacts discovery of genetic risk for heritable disease, as well as susceptibility to disease itself. Self-reported ancestry has been tracked for individual subjects since inception of the Repository. However, considerable evidence indicates that self-reported ancestry and genetic ancestry are not equivalent for populations with admixture, as is the case in the United States and Canada, where most of the 26,000 NINDS Repository samples were collected. Moreover, self-reported indications of Hispanic and non-Hispanic generally reflect social constructs rather than genetic ancestry. Therefore, we have set out to develop a systematic approach for efficient and cost-effective determination of genetic ancestry applicable to high throughput collections such as the NINDS Repository. This will help ensure that genetic ancestry and population stratification does not confound the mission of genetic discovery. For preliminary studies we have used two sources of samples and data: (i) publicly available microsatellite (MSAT) data for HGDP-CEPH ancestry standards consisting of 1064 samples from 51 worldwide populations genotyped with 431 MSATs. (ii) Coriell-generated data representing a panel of 19 MSAT markers (ABI Identifiler panel plus four additional MSAT markers) genotyped on 8000 NINDS samples. Preliminary results obtained using both STUCTURE and principle component analysis (PCA) suggest that while a relatively small number of MSATs can provide adequate data for ancestry analyses, the panel of 19 MSATs currently used for NINDS Repository samples needs to be modified. We plan to test additional MSAT markers, chosen based on F-statistic (Fst) values, together with our original panel of 19 markers, on both NINDS samples and HGDP-CEPH standards to optimize the approach.

## 592/W/Poster Board #250

**The genetic structure of Native Americans: inferences from SNPs in genes involved in carcinogenesis, immunity and pharmacogenetics.** *E. Tarazona-Santos[1,2], G.B. Soares-Souza[1], J. Chevitarese[1], R.H. Gilman[4,5], M. Yeager[6], S.J. Chanock[2,3].* 1) Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Brazil; 2) Section of Genomic Variation. Pediatric Oncology Branch. National Cancer Institute. National Institutes of Health. MD. US; 3) Laboratory of Translational Genomics. National Cancer Institute. National Institutes of Health. MD. US; 4) Asociación Benéfica PRISMA. Lima, Peru; 5) Bloomberg School of Public Health, Johns Hopkins University, MD, US; 6) Core Genotyping Facility. National Cancer Institute. National Institutes of Health. MD. US.

We have studied the genetic structure of South Amerindian populations in the context of worldwide diversity. We genotyped 1442 SNPs located on 400 genes involved in cancer, immunity and pharmacogenetics in the following 67 Western South Amerindians: (a) 22 Quechua highlanders from the Peruvian Andes; (b) 17 Quechua from San Martin, (c) 21 Matsiguengas from the Monte Carmelo community and (d) 7 Cayapas from Ecuador. Samples b-d are settled in the geographic region located between the Andean mountains (West) and the Amazon region (East). We also genotyped the Human Genome Diversity Project panel that include the following South Amerindians: 24 Karitiana, 21 Surui, 13 Piapoco-Curripaco, 25 Pima and 25 Maya. The following results emerged from SNPs and haplotype analyses: (1) Most of the loci fit the Hardy-Weinberg equilibrium in most populations. With the exception of the San Martin population (Fis = 0.06), none of the Western South Amerindian populations studied by us evidenced high levels of inbreeding or Wahlund effect. (2) Consistently with previous studies, South Amerindians and Oceanian populations show the lowest intra-population diversity when compared with autochthonous populations from other continents. (3) Within South America, Western South Amerindian populations show the highest intra-population diversity, consistently with an evolutionary model previously proposed by us, which suggest a higher long term effective population size and levels of gene flow among them. (4) Comparing the different continents, the between-population diversity is clearly the highest for South Amerindians (Fst = 0.19). This value is almost twice the level of differentiation observed for the worldwide population (Fst = 0.11). (5) We identified genes (such as COMT and CYPA1A, important in pharmacogenetics), with a high level of differentiation in Native Americans respect to other continents. Identifying SNPs with these characteristics is important because markers with large differences in allele frequencies among continental groups may produce false positive results in epidemiological studies involving complex traits with different incidences among continental groups. Our results provide important information about the genomic structure of South Amerindians, an underrepresented group in population genetic studies, in particular for genes involved in carcinogenesis, immunity and pharmacogenetics. Financial Support: NCI/NIH, Brazilian agencies CAPES and CNPq.

## 593/W/Poster Board #251

**Deep population structure in sub-Saharan African populations.** *J. Wall[1], M.P. Cox[2], F.L. Mendez[3], A.E. Woerner[2], M.F. Hammer[2,3].* 1) Institute for Human Genetics and Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 2) ARL Division of Biotechnology, University of Arizona, Tucson, AZ; 3) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ.

We analyzed ~500 Kb of resequencing data from 91 different intergenic regions in samples from three sub-Saharan African populations: Mandenka from Senegal, Biaka pygmies from the Central African Republic and San from Namibia. We employed novel methodology to estimate the split times and migration rates between populations. We found strong evidence for split times that predate the exodus of modern humans out of Africa (e.g., > 100 Kya). In addition, we also found evidence of ancient admixture (with unknown 'archaic' human groups) in the recent history of both the Biaka and the San.

## 594/W/Poster Board #252

**Gorillas out of the mist: Unravelling the fog surrounding another genome.** *B. Yngvadottir, A. Scally, J. Simpson, Y. Gu, W. Whitener, A. Rogers, Z. Ning, J. Burton, M.A. Quail, H. Swerdlow, R. Durbin, C. Tyler-Smith, Gorilla Genome Consortium.* [The first two authors contributed equally to this work] Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Gorillas are divided into two species based on their morphology and geographical location within Africa, eastern gorillas (*Gorilla beringei*) and western gorillas (*Gorilla gorilla*), each of which has two subspecies. Most field studies have been carried out on eastern gorillas, while genetic studies have been largely confined to western gorillas. The gorilla and human lineages diverged around eight million years ago and although humans are genetically more similar to chimpanzees over most of their genome, some regions are more similar to gorillas. A fuller picture of the gorilla genome is therefore expected to provide us with a better understanding of the differences between humans and chimpanzees by identifying which traits are uniquely human and which ones are unique to the chimpanzee as well as contributing to our understanding of gorilla biology. The genome of Kamilah, a female western lowland gorilla, has been sequenced with a coverage depth of 2x capillary and 35x Illumina, and an initial assembly has been created. While previous studies of the gorilla genome have relied on a limited number of loci, this assembly will enable us to perform a genomewide analysis at the inter-specific level and will be a useful resource for further biological and medical studies. In addition, we have sequenced to ~5x the genome of Mukisi, an eastern lowland gorilla, which will give us more information on genetic variation at the intra-specific level, within and between eastern and western gorillas. To this end, we are identifying different classes of variants including: 1) those shared by both gorilla species but no other closely related species 2) those that are not variable in Kamilah but are heterozygous in Mukisi and 3) vice versa. We intend to genotype these variants in a larger set of individuals from both species to get further insights into the genetic variation and evolutionary history of the species. This project will help us understand what makes gorillas unique as well providing us with a further understanding of our own species. For example, how different are humans and gorillas and what similarities do they share that exclude their chimpanzee cousin, how distinct are eastern and western gorillas, when did they differentiate, how much genetic variation is present within populations of each, how much gene flow has there been between these populations? We hope to answer these questions and begin unravelling the fog enveloping the gorilla genome.

## 595/W/Poster Board #253

**Super Y-chromosomes in Eurasia and the impact of social selection and Neolithic transition.** *P.L. BALARESQUE[1,2], E. HEYER[2], M.A. JOBLING[1].* 1) Department of genetics, University of Leicester, Adrian Building, Leicester LE2 1WL, Leicestershire, United Kingdom; 2) Muséum National d'Histoire Naturelle - Centre National de la Recherche Scientifique-P7 Unité Mixte de Recherche 5145, Eco-Anthropologie, Musée de l'Homme, 75016 Paris, France.

Some Y-chromosomal haplotypes have been found at unusually high frequencies in Asian and European human populations. The massive spread of these lineages has been explained by the impact of social selection i.e. the high reproductive success of some males and their relative/descendants due to their high social status. The most well-known examples are the "Khan haplotype" and the "Manchou haplotype" in Asia, and the U'Neill haplotype in Ireland. But are these frequent haplotypes always associated with recent events of social selection, or could they be linked to much older processes? To address this question, we have surveyed ~ 3500 males in 97 populations from Turkey to Japan. We have focused on the 12 most frequently represented haplotypes in Eurasia and tested whether their expansions are linked to a specific factor such as language or subsistence methods. Our results show that both recent and ancient processes are responsible for the expansions of these lineages. The recent expansions (2000-3000 years) likely to be linked to social selection are prevalent in Altaic-speaking and pastoral populations. This might indicate a recent cultural change in the social organization of these populations. The ancient expansions (8000-10000 years) are over-represented in Indo-European speaking and sedentary farmer populations, and are likely to be the result of the Neolithic transition.

## 596/W/Poster Board #254

**Discovering Distant Relatives within a Diverse Set of Populations Using DNA Segments Identical by Descent.** *L. Hon, B.M. Henn, J.M. Macpherson, N. Eriksson, A. Wojcicki, L. Avey, S. Saxonov, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

Close familial relationships, such a parent-offspring relationships, are inferred readily from genotype and allele frequency data for a limited number of single nucleotide polymorphisms (SNPs) or short tandem repeat (STR) polymorphisms. However, researchers have not focused on accurately inferring the degree of relationship between individuals who share a common ancestor 3-10 generations ago; such inference requires high density genome-wide information not available until recently. In order to characterize relatively distant relationships for a sample, we analyzed the sharing of DNA identical by descent (IBD) in a large database of self-selected individuals of European ancestry, including a subset identified as Ashkenazim. Individuals from more endogamous ethnic populations, such as the Ashkenazim, share on average more DNA identically by descent than do individuals of Asian ancestry or of European ancestry broadly defined. Extensive population-level sharing of identical genomic segments complicates the prediction of relationship level for a pair of individuals since identical segments may reflect common ancestry older than the most recent ancestor for a pair of individuals in a pedigree. In order to understand the pattern of the observed population-level sharing, we simulated extended pedigrees using different populations to calculate the expected amounts of sharing for 1st through 10th cousins. Specifically we assessed the relationship between the length of the longest segment and the most recent common ancestor. From the simulations, we also determined bounds for predicted cousinships given a specific amount of segmental sharing. Using these bounds as a guide, we detected at least one distant relative, between 2nd-8th degree cousin, for 90% of individuals in our dataset of more than 5000 individuals with European ancestry. An even higher fraction of our Ashkenazi sample, 99%, had at least one distant relative between 2nd-7th degree cousinship in our dataset.

## 597/W/Poster Board #255

**Comparing spatial maps of population-genetic variation using Procrustes analysis.** *C. Wang[1], Z.A. Szpiech[1], N.A. Rosenberg[1,2].* 1) CCMB, University of Michigan , Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Multivariate analysis techniques such as principal components analysis (PCA) and multidimensional scaling (MDS) are often used with population-genetic data used to produce "statistical maps" of sampled individuals or populations. With these techniques, each individual or population is represented as a point in a spatial coordinate system in such a manner that nearby placement of two points carries information about the similarity of the genotypes in the underlying individuals or populations. To quantitatively evaluate the relationship between pairs of maps generated in different ways from the same individuals, we have borrowed another multivariate analysis technique, namely Procrustes analysis. This approach separately transforms the maps, preserving relative distances among points within each map, to maximize a measure of the similarity of the placement of the points in one transformed map to the placement of the corresponding points in the other transformed map. We consider the Procrustes approach applied to two scenarios with human population-genetic data. In the first scenario, we compare positions on an MDS map constructed from individual SNP genotypes to a map of the geographic sampling locations of the individuals. In the second scenario, we compare positions on MDS maps constructed from different types of genetic markers studied in the same individuals. As statistical maps have become increasingly common as a tool for summarizing population relationships, our examples illustrate the potential of Procrustes-based quantitative comparisons for interpreting the results in these maps.

**European Population Genetic Substructure: Refining Ancestry Informative Markers for Distinguishing Among Diverse European Ethnic Groups.** *R. Kosoy[1], C. Tian[1], R. Nassir[1], A. Lee[2], P. Villoslada[3], L. Klareskog[4], L. Hammarstrom[5], H. Garchon[6], A.E. Pulver[7], M. Ransom[1], P.K. Gregersen[2], M.F. Seldin[1].* 1) Dept Biological Chemistry, Univ California, Davis, Davis, CA; 2) The Robert S. Boas Center for Genomics and Human Genetics, Feinstein Institute for Medical Research, North Shore LIJ Health System, Manhasset, NY; 3) Center for Applied Medical Research, University of Navarra, Pamplona, Spain; 4) Karolinska University Hospital, Stockholm, Sweden; 5) Karolinska Institutet at KUS Huddinge, Stockholm, Sweden; 6) Institut Cochin, Inserm U567, University Paris Descartes, Paris France; 7) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD.

The definition of European population genetic substructure and its application to understanding complex phenotypes is becoming increasingly important. In the current study using over 4000 subjects genotyped for 300 thousand SNPs we provide further insight into relationships among European population groups and identify sets of SNP ancestry informative markers (AIMs) that can be used in a variety of genetic studies. In general, the graphical description of these principal components analyses (PCA) of these diverse European subjects showed a strong correspondence to the geographical relationships of specific countries or regions of origin. Clearer separation of different ethnic and regional populations was observed using PCA when northern and southern European groups were considered separately and PCA results were influenced by the inclusion or exclusion of different self-identified population groups including Ashkenazi Jewish, Sardinian and Orcadian ethnic groups. SNP AIM sets were identified that could distinguish the regional and ethnic population groups. Moreover, the studies demonstrated that most allele frequency differences between different European groups (defined by PCA) could be effectively controlled by analyses using these AIM sets. These European substructure AIMs should be widely applicable to ongoing studies to confirm and delineate specific disease susceptibility candidate regions without the necessity to perform additional genome-wide SNP studies in additional subject sets.

**Genome-wide patterns of homozygosity in worldwide human populations.** *T.J. Pemberton[1], D. Absher[2], M. Flickinger[3], M. Feldman[4], R.M. Myers[2], N.A. Rosenberg[1], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) Department of Biological Sciences, Stanford University, Palo Alto, CA.

Genome-wide patterns of runs of homozygosity and their variation across individuals can provide a rich source of data for uncovering patterns of diversity, population structure, and history of human populations, and for facilitating the identification of genes underlying recessive traits via homozygosity mapping. We identified runs of homozygous genotypes in 53 populations of the Human Genome Diversity Project and 11 populations of the International HapMap Project by using a likelihood-based approach and data from >640K common SNPs. We observed considerable variation across populations in the number and length of runs of homozygosity. For a given individual, the per-individual count and total length of homozygous segments between 0.5 and 5 Mb are predicted extremely well by the geographic origin of the individual, with Africans having the lowest values and Native Americans having the highest values. However, the per-individual count and total length of homozygous segments larger than 5 Mb showed a different pattern, with more inter-individual variation and larger values in populations where isolation and consanguinity are more common. This difference reflects the distinct forces generating unusually long homozygosity runs compared to runs of intermediate length. Additionally, genomic regions containing homozygosity runs in many individuals and those with runs in unusually few individuals are both present in the human genome, and not all of these regions are explained by local recombination rate estimates. This pattern suggests that many forces, including inbreeding, recombination, selection, and random drift, have played a role in shaping genome-wide patterns of homozygosity in the human genome, and they provide important clues to the genomic background and population diversity that must be taken into account in homozygosity mapping of disease genes.

### 600/W/Poster Board #258

**The distribution of sex-specific human genetic variation in Ethiopia.** *C.A. Plaster[1], A. Tarekegn[2], E. Bekele[2], N. Bradman[1], M.G. Thomas[1].* 1) Genetics, Evolution, Environment, University College London, London, United Kingdom; 2) Department of Biology, University of Addis Ababa, Addis Ababa, Ethiopia.

Ethiopia has been proposed as a candidate location for the emergence of anatomically modern humans, and the source region for the expansion out of Africa. It is also a region of substantial cultural diversity as expressed in languages (Nilo-Saharan, Cushitic, Semitic, and Omotic language families), religions (Christians, Jews, Moslems and Animists), ethnic identities (over 80 groups) as well as many marginalised groups socially excluded on grounds of caste-like occupation, supposed origin, or both. The demographic history of Ethiopia over the past several thousand years has involved both sustained migration of Semitic speakers from the Arabian Peninsula as well as internal conquests of lands in the south. To investigate the demographic histories of ethnic groups we analysed a battery of SNPs and microsatellites on the non-recombining portion of the Y chromosome (NRY) and sequence variation in the Hypervariable Segment 1 (HVS1) of mtDNA (5756 samples from 45 ethnic groups). Commonly used summary statistics (gene diversity h, genetic distance Fst) were analysed within the context of non Ethiopian data e.g. West Africa (Igbo, Nigeria) and Europeans. We present preliminary results reporting a wide range of genetic diversity values within ethnic groups (h: NRY = 0.743 - 0.972, HVS1 = 0.962 - 0.996) and pairwise genetic distance values between groups (Fst: NRY = 0.000 - 0.294, HVS1 = 0.000 - 0.035). A clustering of Ethiopian groups was observed when using principal coordinate analyses with genetic distances, appearing midway between a West African Niger-Congo speaking group (Igbo of Nigeria) and an Indo-European speaking group (Greek Cypriots). Some south-western groups (e.g. Anuak) showed greater similarity to West-Africans while the culturally influential Amhara were more similar to Europeans. Gene flow between dominant Dawuro agriculturalists and excluded members of the Manja was sex-biased, with many more NRY haplotypes common to the two groups than mtDNA haplotypes, relative to the distribution of the two systems across all the ethnic groups. The marginalised group had a particularly low level of mtDNA HVS1 diversity (h = 0.705). Of particular interest is the extensive sharing of discriminating NRY and mtDNA haplotypes across many ethnic groups, suggesting either a) the creation or preservation of cultural diversity despite substantial inter-group gene flow or b) recent ethnogenesis of the currently extant groups.

### 601/W/Poster Board #259

**Genetic Diversity of the Ancient People in Mesoamerica.** *L. Wang[1], K. Kurosaki[2], N. Saitou[3], S. Sugiyama[4], S. Ueda[5].* 1) Medical & Animal Gen, Inst Gen, Chinese Academy Sci, Beijing, China; 2) Department of Legal Medicine, School of Medicine, Toho University, Tokyo, Japan; 3) Division of Population Genetics, National Institute of Genetics, Mishima, Japan; 4) Graduate School of International Cultural Studies, Cultural Symbiosis Research Institute, Aichi Prefectural University, Aichi, Japan; 5) Department of Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan.

DNAs were extracted from the human remains buried in the Moon Pyramid at archaeological Teotihuacan site in Mexico. Nucleotide sequences of their mitochondrial D-loop and SNP sites were determined by the PCR-direct sequencing. To reveal the genealogy of mitochondrial DNA sequences of the individuals buried in the Moon Pyramid and assess their positions among Native Americans, we first constructed a network of the mitochondrial DNA from the contemporary Native Americans; the northern Native Americans (Haida, Bella Coola, and Nuu Chah Nulth), the central Native Americans (Huetar, Kuna, and Ngöbé), and the southern Native Americans (Yanomami, Zoro, Gavião, and Xavante), and compared them with those of the individuals from the Moon Pyramid. All of the mitochondrial DNA types from the Moon Pyramid individuals were unique, and clear genetic affinities were not observed between the Moon Pyramid individuals and any of the 10 Native American populations. To investigate genetic diversity among the contemporary central Native American populations, we constructed a phylogenetic tree of their mitochondrial DNA sequences using the neighbor-joining method. There was a major mitochondrial DNA sequence common to these three central Native American populations. However, there were a relatively small number of mitochondrial DNA types in each population, most of which were, moreover, unique to each Native American population. Next we compared the mitochondrial DNA sequences of the Moon Pyramid individuals with those of the ancient Mesoamerican people, ancient Maya people from the classic Copán site. We also used Huetar people as a reference for the contemporary central Native Americans. The distribution of the mitochondrial DNA types found in the ancient Native Americans is greatly different from that found in the contemporary Native Americans. These results show that genetic diversity in the ancient Native Americans was not as low as that in the contemporary Native Americans, suggesting an occurrence of bottleneck in the past.

### 602/W/Poster Board #260

**Genomic runs of homozygosity: population history and disease.** *J. Wilson, M. Kirin, C.S. Franklin, H. Campbell, R. McQuillan.* Pub Hlth Sci, Univ Edinburgh, Edinburgh, United Kingdom.

Runs of homozygosity (ROH), resulting from the inheritance from both parents of identical haplotypes, are abundant in the human genome. ROH length is determined partly by the number of generations since the common ancestor: offspring of cousin matings have long ROH, while the numerous shorter ROH reflect shared ancestry tens and hundreds of generations ago. We have previously shown in studies of European populations, that Froh, a multipoint estimate of individual autozygosity derived from genomic ROH, distinguishes clearly between subpopulations classified in terms of demographic history and correlates strongly with pedigree-derived inbreeding coefficients. Now in a global population dataset, our analysis of ROH allows categorisation of individuals into four major groups, inferred to have (a) parental relatedness in the 150 years (many south and west Asians), (b) shared parental ancestry arising hundreds to thousands of years ago through population isolation and restricted effective population size (Ne), but little recent inbreeding (Oceanians, African hunter-gatherers, some European and south Asian isolates), (c) both ancient and recent parental relatedness (Native Americans), and (d) only the background level of shared ancestry relating to continental Ne (east Asians, urban Europeans; African agriculturalists). Long runs of homozygosity are therefore a widespread and underappreciated characteristic of our genomes which record past consanguinity and population isolation and provide a unique record of individual demographic history. Individual ROH measures also allow quantification of the disease risk arising from polygenic recessive effects. We present preliminary data from a survey of the effects of ROH on quantitative disease-related traits and disease risk.

## 603/W/Poster Board #261

**Patterns of gene flow in South Amerindians: inferences and reanalysis based on mitochondrial DNA data.** *L.W. Zuccherato[1], M.C.F. Silva[1,2], S. Fuselli[3], R.H. Gilman[4], E. Tarazona-Santos[1].* 1) Departamento de Biologia Geral, Universidade Federal de Minas Gerais, Brazil; 2) Fundação Hemominas, Minas Gerais, Brazil; 3) Università di Ferrara, Italy; 4) Asociación Benéfica PRISMA, Lima, Peru.

Between 2001 and 2003, we proposed the following scenario to explain the pattern of genetic diversity of South Amerindian populations: Western populations of South America, settled in the Andean area, showed higher long-term effective sizes and gene flow than Eastern populations (settled in Brazil and Paraguay). This scenario has caused a homogenization of the gene pool in the former but a divergence of populations in the latter. During the last five years, a considerable amount of data about the mitochondrial DNA diversity in South Amerindians have been generated, and we have studied three new Peruvian native populations presenting the following autochthonous Pan-American A-D haplogroup frequencies: Shimaa (n=37, A:3%, B:89%, C:8%, D:0%) and Monte Carmelo (n=28, A:31%, B:61%, C:8%, D:0%) from the Matsiguenga ethnic group; and the population of Rio Tambo (n=60, A:40%, B:55%, C:0%, D:5%) from the Ashaninka ethnic group. Interestingly, these populations are located in a geographic and environmental area of transition between the Andes and the Amazon that is underrepresented in human population genetics studies. Admixture analysis using 16 Ancestry Informative Markers confirms a very low (<10%) level of European admixture for these populations. An updated database of mtDNA data for South Amerindians has been implemented, containing 1758 individuals from 46 populations. By using the Isolation by Distance (IBD) model as null hypothesis, we confirmed that there is no correlation between geographic distance and genetic variability when populations from all South America were analyzed together, as well as when Eastern South Amerindian populations are considered, differently from our previous finding and suggesting that complex evolutionary scenarios have conceal the effect of geography on the genetic structure of these populations. On the other hand, Andean populations from Colombia to Chile do fit the IBD model, also when non-Andean populations settled in the area between the Andes and the Peruvian Amazon (Matsiguenga and Ashaninkas) are included in the analysis. In particular, the Ashaninka (Rio Tambo) and Monte Carmelo populations also present high level of intrapopulation diversity, which is suggestive of gene flow or a recent split from populations from the Andean region. Financial Support: Brazilian agencies CAPES-Ministry of Education, FAPEMIG and CNPq.

## 604/W/Poster Board #262

**Considerations on the use of shared controls in genome-wide association studies.** *G.K. Chen, D. Stram.* University of Southern California Los Angeles, CA.

Thanks to the large number of samples that have been collected for modern genome wide association (GWA) studies, researchers have been able to detect many genetic risk factors in common diseases with modest effect sizes (e.g., odds ratios~1.5). However, these variants alone usually account for only a small fraction of the population attributable risk for a disease and it is likely that much larger sample sizes are needed to elucidate the variants with even smaller effect sizes. To address this issue, we consider the strategy of sharing a set of common controls across different studies with the primary goal of cost efficiency. While this strategy can improve power to detect variants, it can increase the false positive rate when controls are not genetically matched to cases and the relative risk of disease is higher in one ethnicity than others. To quantify the effect of the inflation in type 1 errors, we compare false positive rates across various relative risks by simulating disease status in a set of 1,500 African-Americans spanning a wide range of admixture levels. Finally, we consider the merits and potential pitfalls of applying two well known methods that are designed to address this problem, genomic control and principal components analysis, as well as an extension of a method originally described by Bourgain et al (AJHG, 2003) which shares several properties of the former two methods.

## 605/W/Poster Board #263

**A comprehensive partitioning of associations of all orders among genome-wide SNPs.** *M.K. Uyenoyama[1], D. Fusco[2], Y.-J. Li[3].* 1) Biology, Duke Univ, Durham, NC; 2) Computational Biology and Bioinformatics, Duke Univ, Durham, NC; 3) Center for Human Genetics, Duke Univ, Durham, NC.

We introduce a full partitioning of genomic SNP variation, including analogues of linkage disequilibrium (LD) and all higher-order disequilibria. Even in the absence of population structure, 2n(2n+1)/2-1 independent forms of genetic associations can exist among n biallelic SNP loci. In contrast, most genome-wide studies describe only two kinds of genetic association, homozygosity and LD. Classical population genetics theory suggests that the analysis of higher-order associations may provide a basis for inferences about population structure. For example, partial inbreeding generates identity disequilibrium (correlation in heterozygosity) across the entire genome, even between unlinked loci. Our partitioning of genotypic associations simplifies schemes previously proposed for inbred populations. All of our measures of association constitute functions of Bernoulli random variables, a structure particularly well-suited for analytical explorations using coalescence arguments. Because classical measures of multilocus association are generally estimated as covariances, they represent properties of samples, not of individuals or haplotypes. In contrast, each zygote or haplotype can be scored under our definition, with sample-wide associations obtained by summing the individual scores. This property opens the analysis of genome-wide associations to a large corpus of dimension reduction procedures, including principal components analysis (PCA). We describe an exploration of pairwise associations in simulated data. Our analogue of identity disequilibrium is a major contributor to the first principal component (PC1) over both long and short recombinational distances (correlation = -0.67). Our analogue of LD tends to be negatively correlated with identity disequilibrium over short scales and is a major contributor to PC2 over longer scales. Regular systems of inbreeding and population subdivision generate entire ensembles of associations. We present analytical distributions for measures of association in the absence of crossing-over. For example, the distribution of our analogue of LD becomes more concentrated near zero as the rate of substitution increases, but has a pronounced negative skew and a negative expectation. Lastly, we describe pairwise and higher-order associations in human genomes using HapMap data.

## 606/W/Poster Board #264

**Homozygosity scan: a valuable addition to the clinical geneticist's armamentarium.** *F. Alkuraya[1,2,3].* 1) Dept Gen, KFSH & RC, Riyadh, Riyadh, Saudi Arabia; 2) Department of Pediatrics, King Khalid University Hospital and College of Medicine, King Saud University, Riyadh, Saudi Arabia; 3) Department of Anatomy and Cell Biology, College of Medicine, Alfaisal University, Riyadh, Saudi Arabia.

Consanguinity (union between related individuals) is an ancient practice that is still common in multiple cultures. Coefficient of inbreeding (percentage of genome that is identical by descent) of the progeny of consanguineous union ranges from <1% (third cousin parents) to 12.5% (double first cousins). The consequence of increased coefficient of inbreeding on the frequency of autosomal recessive conditions is well established. On the other hand, this same phenomenon increases the probability of disease causing mutations to reside in blocks of autozygosity. This has made it possible for researchers to identify disease causing mutations by pursuing hypothesis-free genomewide search for blocks of autozygosity. This has been particularly helpful in the setting of very rare disorders that are much more likely to present in a homozygous (really autozygous) state than combined heterozygous state. Our group has similarly utilized this phenomenon to identify novel disease causing genes. Increasingly, we have also realized that consanguineous populations lend themselves to “shortcuts” that make the practice of clinical genetics easier in a number of ways, again in the setting of autosomal recessive disorders. Genetically heterogeneous conditions, for example, represent a major challenge in outbred populations where prioritization scheme for mutation analysis usually follows published frequencies of the involved genes.In the setting of consanguineous parents, however, a much more efficient prioritization scheme is homozygosity scan which is becoming increasingly easier and cheaper to perform thanks to the advent of SNP chip-based genotyping platforms. This scan can easily eliminate genes and often identifies one or very few genes for downstream mutation analysis.In our experience, this has brought about significant reduction in cost, impressively boosted the yield of mutation analysis and dramatically enhanced patient care. This approach has allowed us to revisit genes that have been excluded by major referral centers on the basis of lack of identifiable mutation, only to leave us uncover deep intronic mutations that we could only pursue because those were the only genes highlighted by the homozygosity scan. In summary, we have shown that consanguinity can be taken advantage of not only in the research arena but, as importantly, in the practice of clinical genetics. We show that homozygosity scan is a valuable addition to the clinical geneticist's armamentarium.

## 607/W/Poster Board #265

**An African village in Colombia.** *N. Ansari Pour[1], Y. Monino[2], C. Duque[3], N. Gallego[3], G. Bedoya[3], A. Ruiz-Linares[1,3], M.G. Thomas[1], N. Bradman[1].* 1) Dept of Genetics, Environment and Evolution, University College London, United Kingdom; 2) Dept of Linguistics, CNRS, France; 3) Institute of Molecular Genetics, University of Antioquia, Colombia.

The Palenque, who live in Palenque de san Basilio some 70km from Cartagena in Colombia and speak a Spanish Creole (Palenquero), have an oral history of the community's formation that includes, early in the seventeenth century, an initial founding group of escaped slaves establishing a village and subsequently maintaining their independence in the face of Spanish military presence in the region. They developed a thriving community that has continued to the present day. Interestingly linguists have identified some 200 words in regular usage that originate in a Kikongo language that is still spoken in the Republic of Congo. The most likely source of this vocabulary has been identified as the Yombe who live mainly in Pointe-Noire on the west coast of the Republic of Congo. In this study we investigated whether similarity in the distribution of the paternally inherited non-recombining portion of the Y chromosome (NRY) in the Palenque and in 42 sub-Saharan ethnic groups supported linguistic data that Yombe individuals were the most likely principal male members of the founding group. All the sub-Saharan groups in the dataset, which included representatives of the Yombe and seven other Congolese groups, could have contributed individuals to the Atlantic slave trade (n = 2870) and no group contributed less than 26 samples (median = 54), all of which were unrelated at the paternal grandfather level. On analysing 15 SNP and six microsatellite markers on the NRY using pairwise Fst and applying a sign test to the distribution of NRY haplotypes among groups with low pairwise Fst values we established that Yombe were the most similar to the Palenque (Fst = 0.015, Sign Test p-value = 0.001) thereby supporting the prior hypothesis based on linguistic analysis. Analyses of mtDNA to elucidate the likely maternal origins of the Palenque are in progress.

## 608/W/Poster Board #266

**Improved resolution of the human Y-chromosomal phylogeny using targeted next-generation sequencing.** *Q. Ayub, Y. Xue, C. Tyler-Smith.* Human Evolution, The Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, CB10 1SA, United Kingdom.

The non-recombining part of the Y chromosome provides unique insights into male-specific aspects of human genetics and history. We are using next-generation Illumina sequencing to fully re-sequence targeted regions of the Y and resolve the Y-chromosomal phylogeny by characterization of additional single nucleotide polymorphisms (SNPs) on lineages of interest. Initially ~6 Mb of Y sequence (NCBI36:Y-chromosome: 12,308,579-18,230,132) is being generated for an African haplogroup A male. The strategy involves sequence enrichment by long template PCR of genomic DNA (10-20 ng/reaction) using overlapping fragments of 5.5 - 6.5 kbp. Currently ~70% of primer pairs work using a standard touchdown PCR protocol. Fragments obtained from a single individual are pooled and used for library preparation and Illumina sequencing. Re-sequencing generates accurate high coverage data; SNP calling and their subsequent validation will be presented. Most SNPs are expected to be rare but some are likely to resolve deep divisions within African populations. Subsequently, we aim to (1) determine the time depth of the human Y phylogeny, (2) resolve multifurcations in the major lineages by discovering additional SNPs on the relevant and (3) discover SNPs that mark any lineage of particular interest. In addition, we will be able to provide a subset of all primers that work well with this protocol to investigators who are interested in Y-chromosomal phylogenies so that comparable standard datasets can be generated for use by the community.

## 609/W/Poster Board #267

**Identifying ancestry of genomic regions in admixed individuals.** *A. Brisbin[1], K. Bryc[2], J. Degenhardt[2], A. Reynolds[2], A. Auton[3], J.G. Mezey[2], H. Ostrer[4], C.D. Bustamante[2].* 1) Center for Applied Mathematics, Cornell University, Ithaca, NY; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, United Kingdom; 4) Departments of Medicine, Pediatrics (Genetics) and Pathology, New York University School of Medicine, New York, NY.

Identifying ancestry along each chromosome in admixed individuals is of great interest for admixture mapping, removing confounding in association mapping, and identifying recent targets of selection. We present a Principal Components-based forward-backward algorithm for determining ancestry along each chromosome from a high-density, genomewide set of SNP genotypes of admixed individuals. We compare our method as applied to genotype and phased haplotype data, and find that the phased haplotype data allows confident assignment of ancestry to a larger proportion of the genome, in diverged populations where admixture is difficult to assess. We apply our method to a dataset of Hispanic/Latino populations and identify regions of excessive ancestry that may be recent targets of selection and could serve as candidate regions for admixture-based association mapping. Additionally, application of the method to the CEPH Human Genome Diversity Panel finds surprising signatures of admixture within and among isolated and anthroplogically defined populations.

## 610/W/Poster Board #268

**Genetic Differences of the Northern and Southern Han Chinese.** *C.H. Chen, M.H. Su, T.H. Lu, J.Y. Wu, Y.T. Chen.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

**BACKGROUND** Genetics evidences suggested that the Han people could be genetically differentiated into northern and southern Hans, separated by the Yangtze River. Two recently available data sets of Hans, the Chinese Han in Beijing (CHB) and the Chinese Han in Denver (CHD) of the HapMap Project Phase III, were widely-referred but not yet fully examined accordingly. This study was aimed (1) to conduct a norm that could more accurately summarize the genome-wide genetic profiles of northern and southern Hans; (2) to genetically localize the two Han groups of the HapMap Project.

**METHODS** Self-reported language/location group data and genotype data (Illumina Hap550duov3 chip) of 2,400 Hans were obtained from the National Clinical Core and the National Genotyping Center at Academia Sinica, Taipei, Taiwan. Data of three Asian samples, CHB, CHD and Japanese in Tokyo (JPT), were obtained from the HapMap project. Multidimensional scaling analysis on genome-wide identity-by-state (IBS) pairwise distances was performed to extract genetic information. Discriminant functions were then derived based on subsets of subjects having four grandparents with a same origin. Predict rate was estimated for the language/location groups.

**RESULTS** Minnan and Hakka, two major Han groups in Taiwan, were correctly predicted as southern Hans (99.3% and 98.3%). Hans with origins in more northern or southern locations were also correctly predicted (> 95%). However, subjects from the places along the Yangtze River were difficult to predict. The overall predict rate was greater than 90%. For the HapMap Asian groups, the JPT group was completely separated from the Hans but showed a close relationship to the northern Hans; 64.6% of the 82 CHB subjects were categorized as northern Hans while only 24.3% for the 70 CHD subjects.

**SUMMARY** Our algorithm was able to differentiate between the northern and southern Hans while the genetics differences between the two HapMap Han samples demand further analysis.

## 611/W/Poster Board #269

**The origin of the population on Ontong Java, a Polynesian Outlier in the Solomon Islands, based on the genetic diversity of mtDNA.** *M. Christiansen[1], R. Kuschel[2], A.E. Christensen[3], P.L. Hedley[1,4], C.M. Hagen[1], D. Schmidt[1], F.H. Aidt[1], D.V. Møller[1].* 1) Dept Clinical Biochemistry and Immunology, Statens Serum Inst, Copenhagen, Denmark; 2) Institute of Psychology, University of Copenhagen, Copenhagen, Denmark; 3) Department of Geography and Geology, University of Copenhagen, Denmark; 4) Department of Biomedical Sciences, University of Stellenbosch, Cape Town, South Africa.

Ontong Java (also known as Lord Howe Atoll) is a large atoll in the South West Pacific consisting of 120 islands located 220 km north of Santa Isabel in the Solomon Islands. The total population comprises 3,000 persons, of which 1,850 reside on the island. The remaining population live elsewhere in the Solomon Islands or abroad. Ontong Java is one of numerous Polynesian Outliers in Melanesia; there is also an apparent Micronesian cultural influence and little is known about the origin of the population. In order to establish the origin of the maternal gene pool we collected cheek swabs from 36 persons, representing all unrelated "ramages" (where the members are unrelated at least beyond first cousins) on Ontong Java. Mitochondrial DNA was extracted from 32 samples and the control region was sequenced. The presence of the COII/tRNA$^{Lys}$ 9 bp deletion was also ascertained and 24 persons (75%) were carriers. In total 10 different haplotypes were identified. Eight haplotypes, comprising 24 persons, belonged to the B4a haplogroup, occuring with a near 100% prevalence in central Polynesia, and two haplotypes, identified in eight persons, belonged to the M7c1 haplogroup, previously found in Micronesia and South East Asia. Twenty-one individuals (66%) had the full Polynesian motif. The B4a cluster comprised a star-like subcluster in an MJ network and three more distant haplotypes. The greater diversity in the B4a haplotypes compared to the M7c1 haplotypes suggests the the Polynesian-derived population may be older than the likely Micronesian-derived population element. An alternative and supplementary explanation is the extensive inter-island contact among the Central Polynesian Outlier atolls. The present population of Ontong Java most likely has a mixed Polynesian and Micronesian origin on the maternal side. The genetic diversity in the B4a haplogroup is compatible with a single expanding Polynesian-derived population in combination with additions from other Polynesian Outliers.

## 612/W/Poster Board #270

**Incompatibility of current Finnish mitochondrial diversity with simulations of assumed settlement history.** *M. Heger[1], J. Palo[2], T. Sundell[1,3], A. Sajantila[2], P. Onkamo[1].* 1) Department of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland; 2) Department of Forensic Medicine, University of Helsinki, Helsinki, Finland; 3) Institute for Cultural Research, Department of Archaeology, University of Helsinki, Helsinki, Finland.

Traditionally, geneticists studying Finnish population history have assumed a model where Northern and Eastern Finland were mostly uninhabited until the 16$^{th}$ Century A.D. and were then settled by small family groups from South-Western Finland. The reduced genetic diversity and the distinct Finnish disease heritage are seen as consequences of these founder effects. Y-chromosomal diversity is indeed reduced in the present population, especially in the eastern parts of the country. However, mitochondrial diversity is not heavily reduced compared to South-Western Finnish or other European populations. This discrepancy has been explained with the higher mitochondrial mutation rate having restored mitochondrial diversity in these populations since the founder effects.

In our view it seems unlikely that even with high mitochondrial mutation rates mtDNA diversity could be restored over a mere 17 generations after the alleged tight bottlenecks. Archaeological evidence also suggests a different settlement history, e.g. settlement beginning in South-Eastern instead of South-Western Finland.

In this study we use simuPOP, a state-of-the-art forward simulation tool, to simulate datasets corresponding to Finnish mitochondrial diversity under the traditional model and compare them with actual present-day Finnish data. We show that current mitochondrial variation is unlikely under this model, increasing the credibility of alternative hypotheses.

## 613/W/Poster Board #271

**Phylogeographic characterisation of mtDNA lineages from Northern Thailand.** *J. Horst[1], B. Zimmermann[2], M. Bodner[2], S. Amory[2, 3, 4], L. Fendt[2], A. Röck[5], D. Horst[6], B. Horst[7], T. Sanguansermsri[8], W. Parson[2], A. Brandstätter[9].* 1) Institut für Humangenetik, Universität Münster, Münster, Germany; 2) Institute of Legal Medicine, Innsbruck Medical University, Innsbruck, Austria; 3) Laboratory of Molecular Anthropobiology, Institute of Legal Medicine, Strasbourg, France; 4) International Commission on Missing Persons, Sarajevo, Bosnia and Herzegovina; 5) Institute of Mathematics, University of Innsbruck, Innsbruck, Austria; 6) Pathologisches Institut der Ludwig-Maximilians-Universität München, Germany; 7) Department of Surgical Pathology, Columbia University, New York, USA; 8) Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand; 9) Division of Genetic Epidemiology, Innsbruck Medical University, Innsbruck, Austria.

Footprints in the genetic composition of Thai mitochondrial DNA (mtDNA) lineages have been left by the immigration of ethnical minorities from surrounding countries into Thailand. The entire mtDNA control region (1122 bp) was typed in 190 unrelated male volunteers from the Northern Thailand province of Chiang Mai following highest quality standards. For a more precise haplogroup classification, selected SNPs from the mtDNA coding region were genotyped. Quasi-median networks were constructed for visualization of character conflicts. The data were put into population-genetic relationships with other Southeast Asian populations. We found several new, so far undescribed mtDNA lineages. Although the frequencies of the Thai haplogroups were characteristic for Southeast Asia in terms of haplotype composition and genetic structure the Thai population was significantly different from other Southeast Asian populations.

## 614/W/Poster Board #272

**Mobile elements reveal small population sizes in the ancient ancestors of Homo sapiens.** *C.D. Huff[1], J. Xing[1], A.R. Rogers[2], L.B. Jorde[1].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Anthropology, University of Utah, Salt Lake City, UT.

Because the insertion of a new mobile element in any small genomic region is a rare event, the genealogy of a region that contains such an insertion is older than that of the rest of the genome. Remarkably, the analysis of polymorphic mobile insertions in the complete genomes of just two humans provides substantial information about ancient human population size. In a simple model with a sample size of two and a constant population size, the expected time to most recent common ancestor (TMRCA) is doubled if a rare insertion is present in one of the samples. We test this model by examining single nucleotide polymorphisms (SNPs) around polymorphic Alu insertions from two human genomes: the NCBI reference genome (hg18) and the genome of Craig Venter (HuRef). We find that genealogies of genomic regions that contain polymorphic mobile elements are insensitive to the effects of recent bottlenecks and expansions but instead are shaped largely by the forces of ancient population history. The estimated TMRCA for regions containing a polymorphic insertion between HuRef and hg18 is 1.99x the genomic average ($p < 10\text{-}300$), as predicted. We employ coalescence simulations conditioned on the presence of a rare insertion under different demographic models. By comparing the likelihood of these models, we estimate that the effective population size of human ancestors living prior to one million years ago is between 10,000 and 20,000, and we can reject all models where the ancient effective population size is larger than 25,000. This result implies an unusually small population size for a species spread across the entire Old World, particularly in light of the estimated effective population sizes of chimpanzees (21,000) and gorillas (25,000), which together inhabit only one small part of a single continent.

## 615/W/Poster Board #273

**On the borderline between the east and the west: the maternal genetic background of Karelians.** *S. Koivumäki[1], T. Lappalainen[2], P. Lahermo[2].* 1) Medical Genetics, University of Turku, Turku, Finland; 2) 2 Finnish Genome Center, University of Helsinki, Helsinki, Finland.

Introduction: The frontier between Finland and Russia represents one of the most conspicuous socioeconomic gaps in the world. Based on the mean gross national product, there is a ten-fold difference between Russian Karelian Republic and Finnish Karelia. Otherwise these populations share the same geophysical environment. For these reasons, Karelia has been a very interesting field of research for multifactorial disease studies. However, this area has undergone many demographic incidents, such as wars and famine, which may cause local differences in the gene pool. In this study, we wanted to elucidate the maternal genetic background of Karelians. Materials: Blood samples were collected from healthy unrelated individuals without known foreign background from four Karelian districts; Aunus(n=218), Viena(n=87), Tver(n=61) and Finnish Karelia (n=70), The sample collection was performed according to the Basic Principles of the Declaration of Helsinki. Methods: The entire mitochondrial DNA was sequenced in 32 reactions per sample with the BigDye® Terminator v3.1 Cycle Sequencing Kit in the Applied Biosystem's 3730 Genetic Analyzer sequencing machine. Sequence alignments were made by the SeqScape® Software, Version 2.5 (Applied Biosystem). Results: Haplogroup H was very common in all populations. However, H1a is almost absent in Finnish Karelia. Also U and its subhaplogroups were common. Specially U5b1b1 reached over 16% in Viena Karelians. U4 was most common among Tver Karelians. Conclusions: The maternal genetic background seem to be complex in this area. There is clear regional differences. Also there is solid evidence of gene flow from various sources. Representation of the clearly Asian haplogroups is strikingly low.

## 616/W/Poster Board #274

**Female to male breeding ratio in the history of modern humans.** *D. Labuda[1,2], J-F. Lefebvre[2], P. Nadeau[2], M-H. Roy-Gagnon[2, 3].* 1) Département de pédiatrie, Université de Montréal, Montreal, PQ, Canada; 2) Centre de Recherche CHU Sainte-Justine, Université de Montréal, Montreal, PQ, Canada; 3) Département de médecine sociale et préventive, Université de Montréal, Montreal, PQ, Canada.

Was the genetic contribution of men and women to successive generations the same? As a population, did we have fewer fathers than mothers? Was polygyny present among hominid lineages to influence relative divergence rates of autosomes and sex chromosomes? Students of genetic variation of the uniparentally inherited mitochondrial and Y-chromosome DNA confronted these questions, fewer addressed it by looking at the DNA diversity of autosomes and sex chromosomes (Hammer et al. 2009, Keinan et al. 2009) with equivocal results. Our approach is different: we analyzed the ratio of the population recombination rate, $\rho$, between autosomes and the X chromosome. The chromosome X recombines only in the female meiosis whereas autosomes undergo cross-overs in both male and female germ lines such that their relative $\rho$ reflects changes in the breeding ratio, $\beta$. The estimate of $\beta$ is calculated from the observed chromosomal $\rho$'s, obtained by InfRec (Lefebvre and Labuda 2008), after their calibration with the average chromosomal recombination rates known from pedigree data. We have tested our approach using coalescent simulations under different input parameters' values and various demographic scenarios. For the HapMap populations we obtained $\beta$ of 1.4 in Yoruba from West Africa, 1.2 in European and 1.0 in East Asian samples. This suggests that in the history of modern humans the reproductive variance between men and women did not drastically differ, thus consistent with the prevalence of monogamy or mild polygyny in the human lineage. Known incidences of polygyny may be of recent origin, related to raise of agriculture and shift from hunter-gathering to food producing economies, and therefore not sufficiently common to leave a strong genetic signature in the recombinational record. (*Supported by* GenomeQuebec/Genome Canada and Canadian Institutes of Health Research).

## 617/W/Poster Board #275

**Testing models of sex-biased demography using patterns of linkage disequilibrium.** *K.E. Lohmueller[1,2], C.D. Bustamante[1], A.G. Clark[2].* 1) Dept Biol Stat & Comp Biol, Cornell Univ, Ithaca, NY; 2) Dept Molec Biol & Gen, Cornell Univ, Ithaca, NY.

The X-chromosome is an important tool for studying differences in demographic history between males and females. Since males have only one X-chromosome, the ratio of the effective population size ($N_e$) of the X chromosome is expected to be ¾ that of the autosomes (i.e. $N_X/N_{Auto} = 0.75$) when assuming an equal number of males and females and a constant population size. Departures from this ratio are indicative of sex-biased demographic processes. Recently, a study by Hammer et al. (Plos Genetics 2008; 4: e1000202) found that $N_X/N_{Auto} > 0.75$. Conversely, a different study by Keinan et al. (Nat Genet 2008; 41:66-70) found no departure from the ¾ ratio in an African population, and $N_X/N_{Auto} < 0.75$ in non-African populations. By focusing on patterns of sequence diversity and SNP frequencies, both of these studies are dependent on having an accurate estimate of the mutation rate from divergence data as well as accurate calling and genotyping of low frequency SNPs. As an alternative measure that is not dependent on the mutation rate and low frequency SNPs, we estimated $N_X/N_{Auto}$ from patterns of linkage disequilibrium (LD) summarized by an estimate of the population scaled recombination rate, $\rho$. In particular, using data from the CEU (individuals having Northwestern European ancestry) and YRI (individuals from Ibadan, Nigeria) populations in HapMap project, we estimated $\rho$ on chromosome 7 and chromosome X using Hudson's composite likelihood estimator. Under the standard neutral model for autosomal data, $\rho = 4N_e r$, where $r$ is the per region recombination rate per generation. We obtained an estimate of $r$ from the deCODE genetic map and converted our estimates of $\rho$ into estimates of $N_e$. We find $N_X/N_{Auto} \approx 0.75$ in YRI and $\approx$ 0.64-0.69 in CEU. We are using coalescent simulations to investigate the consistency of these estimated ratios with various models of sex-biased demography. In particular, we are testing whether simple models with equal numbers of males and females can explain these patterns, or whether we need to invoke sex-biased demographic events. Since patterns of LD are calibrated by a genetic map, rather the mutation rate as inferred from an outgroup, our analysis provides an independent method to verify the conclusions of Hammer et al. or Keinan et al.

## 618/W/Poster Board #276

**Isolation and gene flow among 10 Polynesian Outliers and their geographic neighbors within Melanesia and Micronesia: A mtDNA perspective.** *J.K. Lum[1,2,3], R.M. Garruto[1,2], A. Kaneko[4], M.G. Vilar[1,3].* 1) Department of Anthropology, Binghamton University, Binghamton, NY; 2) Department of Biological Sciences, Binghamton University, Binghamton, NY; 3) Laboratory of Evolutionary Anthropology and Health, Binghamton University, Binghamton, NY; 4) Unit of Infectious Disease, Karolinska Institute, Stockholm, Sweden.

Polynesians are descendants of the first settlers of Remote Oceania, characterized archaeologically by the Lapita Cultural Complex that coalesced in the Bismark Archipelago 3,400 years ago. Within a few centuries of its formation, evidence of the Lapita Cultural Complex is found extending through the Solomon Islands, Vanuatu, New Caledonia, and Fiji into the Western Polynesian archipelagoes of Tonga and Samoa in a range expansion so rapid it has been referred to as archaeologically instantaneous. After a substantial pause the remaining archipelagoes of Eastern Polynesia and the peripheries of the Polynesian triangle (Hawai'i, Easter Island, and New Zealand) were settled within the past 2,000 years. At about the same time that Western Polynesians first began to colonize islands farther East, they also began to voyage back West into Melanesia and Micronesia to settle islands that were often remote and ecologically marginal, but occasionally included villages on high island otherwise settled by Melanesians (e.g. Fila on Efate). These culturally and linguistically Polynesian populations located geographically within Melanesia and Micronesia, are collectively known as the Polynesian Outliers. All previously examined Polynesian populations are nearly fixed for mtDNA haplogroup B sequences. Although thought to be derived from this relatively restricted Western Polynesian mtDNA gene pool, over the past 1,500 years, the different Polynesian Outliers have interacted to varying degrees with their neighboring Melanesian and Micronesian populations reflecting a range of physical and cultural isolation resulting in the potentially diverse populations observed today. In order to characterize the extent of gene flow between Polynesian Outlier populations and their geographic neighbors we compared mtDNA HVS1 sequences from 253 individuals representing ten Polynesian Outlier populations and 481 individuals from 17 geographically adjacent populations from Melanesia, Micronesia, and Polynesia. These comparisons revealed substantial variation (0% to 90%) in inferred maternal lineage replacement within Polynesian Outlier populations. Populations with minimal inferred maternal gene flow tended to be small, remote islands in Micronesia, the Solomon Islands, and northern Vanuatu, while populations in central and southern Vanuatu and on high islands surrounded by Melanesian populations were substantially admixed.

## 619/W/Poster Board #277

**Accurate inference of individual ancestry geographic coordinates within Europe using small panels of genetic markers.** *P. Paschou[1], J. Lewis[2], P. Drineas[2].* 1) Dept of Molecular Biology & Genetics, Democritus University of Thrace, Alexandroupoli, Greece; 2) Rensselaer Polytechnic Institute, Troy, NY, USA.

The study of genomewide datasets of thousands of individuals of European ancestry supports the close correspondence between genetic distances and geographic coordinates within Europe, especially when information from hundreds of thousands of genetic markers is used. In fact, Principal Components Analysis (PCA), summarizing genetic variation over the top two principal components (PCs), results in plots that are surprisingly reminiscent of geographic maps of Europe. We set out to discover those markers that are most closely correlated with geographic origin, seeking to predict individual ancestry at a fine level, and even for closely spaced populations. To this end we analyzed a previously described subset of the Population Reference Sample (POPRES). We focused on 12 populations and 1224 individuals for which geographic coordinates (longitude and latitude) of individual origin are given for at least 20 individuals per population. First, we performed a complete leave-one-out crossvalidation experiment using 447,212 SNPs, and a simple nearest neighbors approach to infer geographic coordinates. This resulted in extremely high accuracy, placing individuals within an average longitudinal error of 2.2 degrees, and an average latitudinal error of 0.88 degrees. Next, we applied an algorithm that we have previously described to select the top 5,000 SNPs that correlate well with population structure as captured by PCA. We then filtered highly correlated SNPs using standard linear algebraic algorithms for the column subset selection problem. We thus selected 500 maximally uncorrelated markers, which have a Pearson correlation coefficient of 0.92 with PC 1, and 0.83 with PC 2. We extensively validated the effectiveness of such SNP panels for genetic ancestry testing by once more performing a complete leave-one-out crossvalidation experiment on the 1224 studied individuals (approx. two weeks of CPU time in commodity hardware). Using 500 carefully selected SNPs we can place individuals within a few hundred kilometers of their reported origin (average longitudinal and latitudinal error of 4.7 and 1.9 degrees respectively). Finally, we crossvalidated our best panel of 500 SNPs on the HapMap CEPH European individuals, placing them accurately on the Northwestern corner of Europe. Not surprisingly, our SNP panel includes markers that are either within genes reported to be under selective pressure in Europeans, or in high LD with such genes.

## 620/W/Poster Board #278

**Limited distribution of a common cardiomyopathy-associated variant in India.** *T.S. Simonson[1], Y. Zhang[1], C.D. Huff[1], J. Xing[1], W.S. Watkins[1], D.J. Witherspoon[1], S.R. Woodward[2], L.B. Jorde[1].* 1) Department of Human Genetics, University Utah, Salt Lake City, Utah; 2) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah.

Cardiomyopathy is a leading cause of heart failure in South Asia. Myosin binding protein C (MYBPC3) is expressed in the heart muscle, where it regulates the cardiac response to adrenergic stimulation and is important for the structural integrity of the sarcomere. Mutations in the *MYBPC3* gene are associated with hypertrophic or dilated cardiomyopathies. A 25-base-pair deletion in intron 32 causes skipping of the downstream exon and is associated with familial cardiomyopathy. The deletion is found only in South Asian individuals. In order to better characterize the distribution of this variant among South Asians, we determined its frequency in 660 individuals from 24 populations, including neighboring populations from Pakistan and Nepal. Consistent with previous reports (Dhandapany *et al.* 2009, *Nature Genetics*), the heterozygote frequency is as high as 19% in some of our Indian samples, although it is not present in any of the populations we sampled outside of India. The limited geographic distribution of this mutation is surprising considering its estimated age of 30,000 years before present. The differences in the deletion frequencies among populations in India are consistent with patterns of variation we observe among Indian populations based on high-density SNP chip data (Xing *et al.* 2009, *Genome Research*). For example, genome-wide SNP data indicate that caste populations are relatively homogeneous, whereas tribal Indian populations are more distinct from caste populations and each other, reflecting the effects of genetic drift. The South Indian Khonda Dora tribal population, who exhibit genetic similarity to Southeast Asians, has the highest frequency of the deletion (19% of individuals are heterozygotes), whereas the mutation is completely absent in our Irula sample, another South Indian tribal group. More than 15% of the Mala and Yadava (lower and middles castes, respectively) are heterozygotes; all other Indian populations sampled, including upper-caste Brahmins, exhibit heterozygote frequencies less than 10%. Our results indicate the *MYBPC3* deletion is primarily found among Indian populations and that its distribution is consistent with genome-wide patterns of variation in this region.

## 621/W/Poster Board #279

**Evidence for Population Bottleneck in Stone Age Finland from archaeological and genetic perspective.** *T. Sundell[1,2], M. Heger[1], J. Palo[3], A. Sajantila[3], P. Onkamo[1].* 1) Department of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland; 2) Institute for Cultural Research, Department of Archaeology, University of Helsinki, Helsinki, Finland; 3) Department of Forensic Medicine, University of Helsinki, Helsinki, Finland.

Investigation of population continuation has been a confounding issue in Finnish archaeology. Around 6,000 years ago Finland seems to have undergone a powerful and rapid development shown by the appearance of new cultural manifestations. This can be clearly seen in archaeological material. Furthermore the amount of dwelling sites increases threefold from the previous era only to plummet after 3,750 calBC. Thus, archaeologically there is emerging evidence for a population bottleneck. Genetically, it has long been assumed that the reduced genetic diversity of the Finns and the specific 'Finnish Disease Heritage' could be explained by founder effects and bottlenecks.

Since archaeological specimen, in the form of crop remains and bones i.e. aDNA, is scarcely found and almost non-existing from the Stone Age due to the poor preservation of bone material caused by the acidic soil in Finland, direct measurement of past population densities has been somewhat arbitrary. However, through the application of Bayesian archaeology and population genetic simulations it has become possible to estimate prehistoric population demography, framed by present day population diversity. The first estimations of ancient population densities show that based on radiocarbon datings (N=937), consisting of all independent findings in Finland, the demographic fluctuations have been more significant in the eastern part of Finland with the population size reaching its peak approx. 3750 calBC in the typical Comb Ceramic Culture, only to rapidly decline in few centuries.

In this multidisciplinary study we will shed new light on the prehistory of the Finns by integrating evidence from genetic and archaeological data. Bringing together apparently completely different types of information: rich archaeological data existing from the Finnish prehistory spanning from 10,000 years ago together with coalescence histories of mtDNA and Y chromosomal haplotypes in our country, equals to more profound conclusions. The questions to be answered are: when exactly did the archaeologically justified and genetically often assumed population bottlenecks take place in our past and how deep were they? How can the possible bottlenecks be seen in our gene pool and thus present genetic variation?

**Genetic relationships among the ancient Chinese populations viewed from discrete cranial traits.** *J. Tan[1,4], W.Q. Fu[1,4], Y.G. He[2], L.M. Li[1], Y. Wang[1], Z. Xu[1], B.S. Li[1], X.D. Chen[1], K.X. Han[3], H. Li[1], L. Jin[1,2].* 1) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China; 2) Chinese Academy of Sciences and Max Planck Society Partner Institute for Computational Biology, SIBS, CAS, Shanghai 200031, China; 3) Institute of Archaeology, Chinese Academy of Social Sciences, Beijing 100710, China; 4) Equally contributed. This study was supported by National Natural Science Foundation of China (3057101), Chinese National Science Fund For Distinguished Young Scholars (30625016), and Key Project of CMOST Natural Science Foundation (30890034).

The discrete cranial traits are informative in revealing the genetic relationship of human populations. Given little available knowledge on these traits, especially their underlying genetic determinants, the primary aim of this study is to select a small number of traits that are sufficiently informative to represent genetic differentiation among East Asian populations. We studied overall 51 traits for 1,578 skulls from 19 necropolises, and found that 5 traits could capture the largest variation in East Asian populations studied. They are accessory mandibular foramen, palatine torus, mandibular torus, mastoid foramen extra-sutural, and infraorbital suture. The analysis on these 5 traits resulted in similar population relationships to that using all 51 traits. The study on discrete cranial traits could not only facilitate exploration of the genetic relationship of populations, and could also allow identification of the genes underlying these anthropological traits.

## 623/W/Poster Board #281

**Ancestry reflects history: genetic implications for epidemiologic studies in admixed populations.** *M. Via[1,2], C.R. Gignoux[2,3], L. Fejerman[2,4], G. Toro Labrador[5], J. Viera Vera[6], K. Beckman[7], E.G. Burchard[1,2,8], J.C. Martínez Cruzado[5].* 1) Dept Medicine, University of California, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, CA; 3) Program in Pharmaceutical Sciences and Pharmacogenomics, University of California, San Francisco, CA; 4) Helen Diller Family Comprehensive Cancer Center, University of California, San Francisco, CA; 5) Dept. Biology, University of Puerto Rico, Mayagüez, PR; 6) Dept. Biology, University of Puerto Rico, Río Piedras, PR; 7) Dept. Genetics, Cell Biology and Developmental Biology, University of Minnesota, Minneapolis, MN; 8) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA.

Admixture among human populations is not a random process. However, the effect that historical and geographical factors have exerted on the distribution of admixture and its potential impact on epidemiological studies within a population or geographic region has not been analyzed. We modeled the geographical variation of admixture in the island of Puerto Rico using spatial analysis tools. A population-based sample of 642 Puerto Rican individuals collected throughout the island was genotyped for 106 ancestry informative markers (AIMs). Individual ancestry estimates (IAE) were calculated through a Bayesian approach and location at the census block level was determined for each sample. The place of birth for the grandparents was used to compare the distribution of admixture across different generations. Average ancestry values for the Puerto Rican population were 25.05%, 22.77%, and 52.18% for the African, Native American, and European contributions, respectively. There were significant differences in the ancestry proportions between municipalities and between main geographic regions in the island (Kruskal-Wallis $p < 10^{-4}$). African ancestry clustered in the eastern part of the island (Moran's I $p < 10^{-9}$), reaching a maximum of 51.3% in the municipality of Loíza. Native American ancestry was significantly clustered in the northern part of the island (Moran's I $p < 10^{-9}$) even though regional variation in this ancestral component was smaller. Similar results were obtained when samples were relocated according to the grandparents' place of birth (Moran's I $p < 10^{-9}$, both for African and Native American ancestry). The locations of historical sites from the colonial period (i.e. sea ports associated with the slave trade and the sugar mills) were associated with the geographical distribution of African ancestry, but the influence of these factors showed regional variation according to the results of geographically weighted regressions. These results suggest that the design of genetic studies in Puerto Rico must take into account regional differences in ancestry. Sampling in different regions of the island results in significant differences in statistical power for admixture mapping studies. These results have important implications for genetic association studies of complex traits and drug response.

## 624/W/Poster Board #282

**Analysis of Genomic Admixture in Costa Rica Population.** *Z. Wang[1,2], K. Yu[1], G. Thomas[1], L. Burdette[1,2], A. Hutchinson[1,2], R. Herrero[3], S. Wang[1], A. Hildesheim[1], S. Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland, United States of America; 2) Core Genotyping Facility, Advanced Technology Program, SAIC Frederick, Inc. National Cancer Institute - Frederick, Frederick, Maryland, United States of America; 3) Proyecto Epidemiologico Guanacaste, San Jose, Costa Rica.

Costa Rica (CR) population is a unique population representing a typical admixture of major continental ancestral populations. 1,301 samples collected from participants in a population-based study conducted in the Guanacaste region of CR were genotyped on a custom Illumina iSelect chip harboring 27,635 SNPs. The SNPs on the chip were selected based on multi-ethnic tagging strategy for three HapMap populations: CEU, YRI and JPT+CHB and cover 1,000 candidate genes/regions for a range of cancers. This data set was sufficiently large for the investigation of population substructure in our CR study and the examination of linkage disequilibrium (LD) patterns. Three HapMap major continental populations and a Native American population from the Illumina iControl DB were used as the reference populations for these analyses. Our preliminary results indicate that the Guanacaste CR population was formed mainly by a three-way admixture with 42.5%, 38.3% and 15.2% Native Indian, European, and African respectively. In addition, 4.0% residual genetic component derived from Asians was observed in our CR samples. Both model based STRUCTURE program and Principal Component Analysis (PCA) revealed consistent substructure pattern for the CR population. The magnitude of LD in the CR population seems to be smaller than all the reference populations except YRI. A more detailed knowledge of the underlying genetic structure of the CR population would be informative to assess its population genetic history and to assist in the interpretation of investigations of complex diseases in the CR or a comparably admixed population. Funded by NCI Contract No. HHSN261200800001E.

## 625/W/Poster Board #283

**Admixed ancestry and stratification of regional gene pools of Quebec.** *C. Bherer[1,2,3], D. Labuda[1,4], L. Houde[2,5], M. Tremblay[2,6], H. Vézina[2,6].* 1) CHU Sainte-Justine Research Center, Montréal, Québec, Canada; 2) Département de Biologie Moléculaire, Université de Montréal, Montréal, Québec, Canada; 3) Interdisciplinary Research Group in Demography and Genetic Epidemiology, Université du Québec à Chicoutimi, Chicoutimi, Québec, Canada; 4) Département de Pédiatrie, Université de Montréal, Montréal, Québec, Canada; 5) Département de Mathématiques et d'Informatique, Université du Québec à Trois-Rivières, Trois-Rivières, Québec, Canada; 6) Département des Sciences Humaines, Université du Québec à Chicoutimi, Chicoutimi, Québec, Canada.

In Quebec, studies of different molecular polymorphisms have shown that the French Canadian gene pool is as diverse as its source European populations and, contrary to what was previously anticipated, does not display more homogeneity. To better understand the genetic structure of the contemporary population, we analyzed the origins and contribution of 7,798 immigrant founders identified in the genealogical ascendance of a sample of 2,221 subjects representative of the French Canadian population of Quebec. As expected, French founders are the most important in number (n=5,326) in all Quebec regions. They contribute for about 90% of the regional gene pools, except for regions located in the easternmost part of the province (76%), which are characterized by more diverse origins. Although this study supports the French founders' importance, it also puts in the balance arguments in favor of the heterogeneity of the founding pool. The majority of immigrants landed as single member of their family, originating from all the regions of France. In addition, nearly all subjects have mixed origins, including French and non-French. Taken together, these results put into perspective the idea of the homogeneity of the origins of the French Canadians and of a pan-Quebec founder effect. The differential descent and genetic contribution of immigrant founders across regions points to the stratification of the French Canadian population of Quebec, showing a east-west gradient of diversity. These results will contribute to optimize study design in gene mapping studies relying on the founder effect in the French Canadian population of Quebec.

## †626/W/Poster Board #284

**Genome-wide patterns of population structure and admixture among Hispanic/Latino populations.** *K. Bryc[1], C. Velez[2], M. Hammer[3], R. Hernandez[4], A. Reynolds[1], A. Auton[5], T. Karafet[3], H. Ostrer[6], C.D. Bustamante[1].* 1) Dept Biol Statistics/Comp Biol, Cornell Univ, Ithaca, NY; 2) Human Genetics Program, Department of Pediatrics, New York University School of Medicine, New York, NY; 3) ARL Division of Biotechnology and Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 4) Department of Human Genetics, University of Chicago, Chicago, IL; 5) Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, United KingdomDepartments of Medicine, Pediatrics (Genetics) and Pathology, New York University School of Medicine, New York, NY; 6) Departments of Medicine, Pediatrics (Genetics) and Pathology, New York University School of Medicine, New York, NY.

In order to document genome-wide patterns of variation in Hispanics/Latinos (HL's) we genotyped individuals from five distinct populations recruited in the US: Mexico, Colombia, Ecuador, Dominican Republic and Puerto Rico. We present population structure results from an extensive genome-wide SNP dataset compiled by merging Affymetrix 500K and Illumina 650K data from these populations together with the Human Genome Diversity Panel, HapMap, Mao et al (2005), and POPRES studies. We apply Principal Component Analysis (PCA) and a clustering method, frappe, to infer admixture and genetic relationships of 262 HL individuals with 467 Africans, 715 Europeans, and 210 Native Americans comprising a total of 88 populations. We observe substructure within Native Americans, and, as expected, find that the admixed HL populations show Native American ancestry derived from local Native American populations. We find striking differences in estimated population-wide mean African, European and Native American ancestry proportions which are consistent with historical admixture and proximity to slave trade routes. The Dominican Republic and Puerto Rico, located on islands along slave trade routes, show high levels of African Ancestry (means 41.7% and 23.6% respectively) with less Native American Ancestry (11.5% and 18.9%). Colombians show a wide range of both African and Native American ancestry, though they have an overall mean of slightly higher Native American ancestry (36.3%) and lower African ancestry (11.7%) than the highly-African Dominicans and Puerto Ricans. Ecuadorians show the highest Native American mean ancestry (54.0%) with low estimated mean African Ancestry (7.3%). Mexico shows the largest range of Native American ancestry (11.0% - 79.0%) with an overall mean of 50.1% Native American ancestry and the lowest African ancestry (5.6%). Our study shows a broad range in admixture proportions across different HL individuals as well as different admixture patterns across populations. We also compare this genotype data with mtDNA and Y chromosome genotypes and use simulations to estimate ancient male and female sex ratios in each HL population. Lastly, we discuss implications of population structure for genome-wide association studies in admixed populations such as HL's, especially when recruited in the United States.

## 627/W/Poster Board #285

**Population Structure in Brazilian and other Worldwide Human Populations Revealed by SNP arrays.** *S.R. Giolo[1,2], J.M.P. Soler[3], M. de Andrade[4], J.E. Krieger[2], A.C. Pereira[2].* 1) Department of Statistics, Federal University of Parana, Curitiba, PR, Brazil; 2) Laboratoty of Genetics and Molecular Cardiology, Heart Institute, University of Sao Paulo, SP, Brazil; 3) Department of Statistics, University of Sao Paulo, SP, Brazil; 4) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN, USA.

Brazilians are one of the most admixture populations in the world, formed by extensive interethnic crosses between Amerindians, Europeans, Africans and Asians. Although there are several studies that have investigated the genetic structure of several populations, the worldwide coverage remains incomplete with, for instance, populations from South America being under-represented in databases of human genetic variation. Only in such continent, almost 200 millions of people live in Brazil, which represents around 52% of the South America population and 3% of the world's inhabitants. An investigation of the genetic structure of this population is therefore of interest since it can provide complementary insights to other large studies of genetic variation. To this end, we have analyzed patterns of genetic variation across 365,116 single nucleotide polymorphisms (SNPs) genotyped using Affymetrix SNP array 6.0 and/or Illumina Human 1M in 1,129 unrelated individuals from twelve worldwide populations: one Brazilian and eleven of the International HapMap Project, Phase III, which include Amerindian, European, African, and Asian ancestry. In our analysis we have considered only the SNPs that all these populations had in common, excluding those with more than 5% missing entries, not in Hardy-Weinberg equilibrium and with minor allele frequency smaller than 1%. Principal components analysis applied to this data revealed discernible genetic differentiation among these populations and also that the large degrees of racial miscegenation experienced by the Brazilian population over centuries play an important role in its pattern of genetic variation. In this work, we have also analyzed whether small panels of markers could effectively capture the genetic variation revealed by all 365,116 markers. In this regard, we found that around 500 SNPs could efficiently reproduce the revealed population structure.

## 628/W/Poster Board #286

**Spatial autocorrelation in Asia using Principal Components of HLA Haplotype Frequencies.** *L. Gragert[1], M. Maiers[1], W. Klitz[2].* 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) Public Health Institute, Oakland, CA.

Geographic patterns of genetic diversity have corroborated the isolation-by-distance model of human migration. Visualizing genetic differences between humans using principal component analysis (PCA) has been accomplished using SNP data from multiple markers across the genome to compare individuals. Previous work using thousands of SNPs has shown that principal component values can be used to map the locations of individuals in Europe with a high degree of accuracy. We were able to accomplish a similar feat using a set of 3 linked HLA loci, the most polymorphic gene system in humans. The high dimensionality of full haplotype frequency distributions can be reduced to a few dimensions that capture the majority of the population variation. Visualizing haplotype frequency differences between populations is valuable for examining population history and barriers to gene flow. PCA maps were generated from 2-digit HLA A-B-DR haplotype frequencies of 7 different Asian populations (18,620 Chinese, 11,076 Filipino, 1,242 Hawaiian, 33,970 Indian, 8,753 Japanese, 20,605 Korean, and 13,507 Southeast Asian). We performed Mantel correlation tests between matrices of great circle distance between the population centers and Euclidean distance between PCA coordinates for the first 5 PCA dimensions. We detected correlation between PCs 3 and 4 and geographic distance with a correlation coefficient of 0.725 and a P-value of 0.028. The PCA chart for PCs 3 and 4 showed large separation of Indian and Hawaiian populations from the others in a way that closely mirrors the map of Asia. This work demonstrates the utility of the HLA system for population studies and provides new genetic evidence for examining human population relationships and the colonization of the Asian continent.

## 629/W/Poster Board #287

**A new statistical method to infer population admixture events using genetic variation data.** *G. Hellenthal[1], D. Falush[2], S. Myers[1].* 1) Dept Statistics, Univ Oxford, Oxford, United Kingdom; 2) Department of Microbiology, Environmental Research Institute, University College Cork, Cork, Ireland.

We present a novel statistical method that uses densely-spaced Single-Nucleotide-Polymorphism (SNP) data to identify the major admixture events occurring throughout a population's history. The model has several advantages over leading available analytical approaches in this area, such as principal-components-analysis and STRUCTURE. In particular it can simultaneously (i) take advantage of the information inherent in patterns of linkage disequilibrium, i.e. non-random associations amongst neighbouring SNPs along a chromosome, (ii) efficiently analyse hundreds of individuals at hundreds of thousands of SNPs genome-wide, and (iii) allow for relatively straight-forward interpretation and direct inference of key historical parameters, such as the proportions and times of major admixture events. Using simulated data matched to currently available human datasets, we show that our model can identify and accurately date admixture events that have occurred between 7 and 150 generations ago. As our technique exploits the rich information in genetic data to infer details of a population's admixture history, it marks a powerful complement to anthropological research and can help to resolve a number of existing controversies. We present results from applications of our model to two datasets: (1) SNP data from 22 distinct genetic regions for individuals from three chimpanzee populations in Africa; (2) genome-wide 650K SNP data for individuals from 53 world-wide populations of the Human Genome Diversity Panel (Science 319, 1100-1104). We highlight a number of intriguing new insights from these analyses. For example, the chimpanzee analysis showcases the model's ability to infer the relative divergence among populations. The human analysis identifies several important admixture events, some of which are historically well-established (e.g. identification of recent European genetic influx into the Maya Native American population), others that can be placed into a clear historical context (e.g. an East Asian genetic influx into several Central and South Asian populations dated precisely to the era of the Mongol empire), and some that are to our knowledge novel (e.g. admixture in the Cambodian population between a Central/South Asian source and an East Asian source dated to around the period of the Cambodian Empire).

## 630/W/Poster Board #288

**Analysis of Assortative Mating Patterns in Humans.** *S. Kim[1], R. Jiang[1], E. Jorgenson[2], J. Wall[1], J. Witte[1].* 1) Inst Human Gen, Univ California, San Francisco, San Francisco, CA; 2) Ernest Gallo Clinic and Research Center, Emeryville, CA.

Assortative mating patterns in plants are well document, but among mammalsin particular humanssuch mating patterns remain unclear. Understanding assortative mating in humans can provide insight to genomic regions involved with positive or negative selection. To help clarify mating patterns in humans we have developed two methods to detect genetic signatures of assortative mating. The first method is a likelihood-based approach which measures overall genetic similarity at a given locus compared to a panmictic population. The second method is a variance components approach that includes an over-all genetic similarity matrix to adjust for potential confounding due to population stratification. We apply both of our methods to the HapMap data to identify genomic regions that are potentially involved with assortative mating (e.g., MHC). In addition, we provide a simulation-based approach to identify the degree of positive assortative mating required to generate the genetic variation observed in the current human population.

### 631/W/Poster Board #289

**World-wide patterns of genomic inbreeding estimates in unrelated individuals from the HGDP-CEPH diversity panel.** *A.L. Leutenegger[1,2], M. Sahbatou[3], H. Cann[3], E. Génin[1,2].* 1) INSERM, U946, Paris, France; 2) Univ Paris-Diderot, UMR-S 946, Paris, France; 3) Fondation Jean Dausset, CEPH, Paris, France.

We present inbreeding coefficients estimated from genotypes at 642,914 autosomal SNPs (Illumina650Y) for 940 unrelated HGDP-CEPH individuals from 51 populations (Li et al., Science, 319:1100-4, 2008).

FEstim (Leutenegger et al., AJHG, 73:516-23, 2003) was used to estimate the inbreeding coefficients from these individuals' genomic information. It is a maximum likelihood method that uses a hidden Markov chain to model the dependencies along the genome between the (observed) marker genotypes and the (unobserved) homozygosity-by-descent status. This estimation requires a marker map without linkage disequilibrium (LD); this is not the case for very dense SNP maps. We developed a procedure to generate multiple LD free sub-maps and to combine their information. 75% of the original map could be captured using 1,000 sub-maps.

Inbreeding levels were highest in the Americas, the Middle East and Central South Asia. In some populations of these regions, they reach values above 0.1 (similar to what is expected from double-first cousin or uncle-niece marriages). The lowest levels of inbreeding were found in Europe, East Asia and sub-Saharan Africa. For the Mbuti Pygmy and San samples, results were not always consistent between the different random maps. This may be related to the fact that these populations are known to have allele frequencies different from the other sub-Saharan populations. Indeed, inbreeding coefficient estimates depend on allele frequencies, and because of limited population sample sizes, these frequencies were estimated at the regional level. An allele frequency sensitivity analysis of these populations is underway.

### 632/W/Poster Board #290

**Genetic Landscape of Eurasia Viewed from Large Allele Frequency Differences.** *H. Li, K. Cho, J.R. Kidd, K.K. Kidd.* Department of Genetics, School of Medicine, Yale University, New Haven, CT 06520.

The diversification leading to modern human populations in Eurasia is one of the most important topics in the study of human expansions after leaving Africa. Most studies of Eurasia populations have used either limited markers or involved insufficient population coverage. We chose 68 markers based on large allele frequency differences among a few Eurasian populations and then typed them on 1766 individuals from 34 populations representing all subdivisions of Eurasia. Analyses using the STRUCTURE program showed a clinal east-west division when K=2, with a median border dividing Central Asia along the Ob River, the Kazakh highland, the western side of Pamir Mountains, and the southwestern side of the Himalayas. We fit curves to the STRUCTURE loadings using distances of the population coordinates from the median border. The genetic structure changed dramatically only within 2000km on each side of the border. At higher values of K the western populations of East Asia are the first to be distinguished (at K=3): Mongols, Tibetans, Qiang, and Baima, are most distinct from the more eastern populations. At K=4 Southwest and South Asians are distinguished from the Europeans; At K=5 Southeast Asians and at K=6 Central Asians are successively distinguished from eastern East Asians. Several more isolated populations such as Samaritans, Atayals, or Micronesians were distinguished in different independent runs when K=7 providing no clear anthropological information. South Asians were always clustered with Southwest Asians with pronounced similarity to Central Asians. The failure to distinguish South Asians maybe due to the selection of the markers with large allele frequency differences specifically between Europeans and East Asians. We also tested for statistical differences in the allele frequencies for all pairs of clusters when K=6. The results showed significant borders (P<0.0001) including those between western East Asians and eastern East Asians or Central Asians; however, insignificant borders were observed between Southwest Asians and Southeast Asians or western East Asians, neither was between Central Asians and eastern East Asians. This indicates substantial gene flow in North Asia between eastern East Asians and Central Asians, and in South Asia between South Asians and Southeast Asians. Using increased population and marker coverage, this study helps to understand the details of genetic diversity and landscape of Eurasians.

### 633/W/Poster Board #291

**Characterizing the history of sub-Saharan African gene flow into southern Europe.** *P. Moorjani[1], N. Patterson[2], J. Hirschhorn[1,3], D. Reich[1,2].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Divisions of Endocrinology and Genetics and Program in Genomics, Children's Hospital, Boston, MA.

Recent analyses of whole-genome SNP data sets have suggested a history of sub-Saharan African ancestral contribution into southern Europe but not in northern Europe, consistent with previous analyses based on the Y-chromosome and mitochondrial DNA. However, there has been no characterization of the proportion of African admixture in southern Europe, or of its date. Here we analyze data from ~450,000 autosomal SNPs in the Population Reference Sample, ~650,000 SNPs from the Human Genome Diversity Panel, and ~1.5 million SNPs from the HapMap Phase 3 Project, and studied patterns of correlation in allele frequencies across populations to confirm the evidence of African ancestry in many southern European populations but not in northern Europeans. Using methods that can infer admixture proportions in the absence of accurate ancestral populations, we estimated that the proportion of sub-Saharan African ancestry in Spain is 2.4 +/- 0.3%, in Tuscany 1.5 +/- 0.3%, and in Greece 1.9 +/- 0.7% (1 standard error). We also studied the decay of admixture linkage disequilibrium with genetic distance, which provided a preliminary estimate of the date of African gene flow into Spain of roughly 60 generations ago, or about 1,700 years ago assuming 28 years per generation. This date is consistent with the historically known movement of individuals of North African ancestry into Spain, although it is possible that this estimate also reflects a wider range of mixture times.

### 634/W/Poster Board #292

**Recovering mitochondrial DNA lineages of extinct Amerindian nations in extant homopatric Brazilian populations.** *V.F.G. Oliveira[1], F.C. Parra[1], H. Gonçalves-Dornelas[1], C. Rodrigues-Carvalho[2], H.P. Silva[2], S.D.J. Pena[1].* 1) Biochemistry, UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Museu Nacional do Rio de Janeiro, Rio de Janeiro, Brazil.

Brazilian Amerindians suffered a drastic population decrease in the past 500 years. Most autochthonous groups which existed in the early 16th century, especially those in the eastern seashore have vanished. Their mitochondrial haplotypes, however, still persist among Brazilians. Our studies show that in Brazil circa 50 million people carry mitochondrial lineages of Amerindian origin. Such reservoir is a rich potential information source about extinct Amerindian nations. Our objective was to test if through the study of the present-day rural populations that inhabit the region anciently occupied by Botocudo Indians, we could identify and rescue the mitochondrial lineages from this largely extinct Amerindian group. We have called this methodology "Homopatric Targeting". We studied 174 individuals living in a small village in the northeast part of the state of Minas Gerais, a territory previously occupied by Botocudos. Pedigree analysis revealed 74 persons without matrilineal relationship, from which DNA samples were obtained. One hundred individuals from surrounding cities were used as control group. The screening of A, B, C and D mtDNA lineages was done by RFLP. We identified 20 Amerindian lineages, which had their HVRI and HVRII sequenced. We finally obtained 13 Amerindian haplotypes, of which 7 appeared to be novel, since they were not present in available databanks. Among the 13 haplotypes we observed a significant excess of haplogroup C (70%) and absence of haplogroup A, the most common in the control group. The novelty of the haplotypes and the excess of the C haplogroup suggested that we indeed might have identified Botocudo lineages, although genetic drift might also explain some of these differences. In order to validate our strategy, we studied teeth extracted from 12 ancient skulls of Botocudo Indians (approximately 200 years ago) from the anthropological collection of the National Museum of Rio de Janeiro. We recovered mtDNA sequences from all the teeth, identifying only 4 different haplotypes (a very low haplotypic diversity of 0.78), two of which were present among the lineages observed in the extant individuals. This validates "Homopatric Targeting" as a useful new strategy to study the peopling and colonization of the New World, especially when direct analysis of the genetic material is not possible.

## 635/W/Poster Board #293

**Two major post-glacial genetic sources for the peopling of Sardinia.** *M. Pala[1], A. Achilli[1,2], A. Olivieri[1], U.A. Perego[1,3], B. Hooshiar Kashani[1], V. Carossa[1], S.R. Woodward[3], A. Torroni[1].* 1) Dipartimento di Genetica e Microbiologia, Università di Pavia, Pavia, Italy; 2) Dipartimento di Biologia Cellulare e Ambientale, Università di Perugia, Perugia, Italy; 3) Sorenson Molecular Genealogy Foundation, Salt Lake City, Utah, USA.

Sardinia remained unconnected with the mainland even when the sea level was lowest during the Last Glacial Maximum and was probably the last of the large Mediterranean islands to be colonized by modern humans. Due to its geography and history, the island has been characterized by a rather strong isolation that allowed its population to preserve specific genetic and cultural traits. Indeed molecular analyses from both classical and uniparental markers often placed present day Sardinians as “outliers” within the European genetic landscape. In order to clarify timing and dynamics of the peopling of the island, we analyzed the mitochondrial DNA (mtDNA) variation of 922 Sardinian subjects. By sequencing the control region and surveying diagnostic coding region markers we were able to describe in detail the pattern of haplogroup distribution on the island. Three haplogroups - U5b3, H1, and H3 - were found to encompass approximately 35% of the Sardinian population and their frequency distribution was specifically evaluated. These three haplogroups were also analyzed at the highest level of molecular resolution - that of complete mtDNA sequences. The analysis of U5b3, which involved the complete sequencing of 52 mitochondrial genomes, revealed that the ancestral homeland for U5b3 was the Italian Peninsula. According to our reconstruction, in contrast to mtDNA haplogroups that expanded from other refugia, the Holocene expansion of haplogroup U5b3 towards the North was restricted by the Alps and occurred only along the Mediterranean coasts, mainly towards nearby Provence (southern France). From there (about 7-9,000 years ago), a sub-clade of this haplogroup moved to Sardinia, possibly as a result of the obsidian trade that linked the two regions, leaving a distinctive signature in about 4% of today’s islanders. The sequence data obtained from 22 Sardinian mitochondrial genomes belonging to haplogroups H1 and H3 instead highlighted the role played by another European glacial refuge area - Iberia - as major source of founder lineages for the Sardinian gene pool. In conclusion our study reveals that concomitant post-glacial population re-expansions from two distinct geographic sources, the Franco-Cantabrian and the Italian refuge areas, have largely determined the present-day Sardinian genetic landscape. These initial major founding genetic inputs were then extensively shaped through the millennia by both founder effect and genetic drift.

**Genetic diversity of European population isolates in the context of their geographic neighbors.** *J. Novembre[1], K. Lohmueller[2], K. Veeramah[1], A.R. Boyko[2], A. Tonjes[3], P. Kovacs[3], I. Klimes[4], M. Stumvoll[3], C.D. Bustamante[2].* 1) Dept Eco & Evo Biol, Interdepartmental Program in Bioinformatics, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Department of Medicine, University of Leipzig, Leipzig, Germany; 4) Institute of Experimental Endocrinology, Slovak Academy of Sciences, Bratislava, Slovak Republic.

Mapping traits in population isolates provides an opportunity to simplify the challenges of complex trait mapping because such populations likely have enhanced levels of linkage disequilibrium and reduced genetic heterogeneity for the underlying traits. Here we analyze high-throughput SNP genotyping data to compare genomic-scale patterns of variation in several European population isolates (Adygei, Basque, Orcadian, Roma from Slovakia, Sardinians, and Sorbs) and contrast their patterns of variation to geographical proximal populations. Our results reveal insights for the demographic history of each of these unique populations, suggest substantial variation among these population isolates in patterns of diversity, and highlight the importance of population selection in genome-wide association mapping.

## 637/W/Poster Board #295

**The population frequency of alleles that cause cystinosis, cystic fibrosis, congenital glaucoma and galactosemia in an isolated Old Order Amish community.** *T. Rupar, V. Siu.* Departments of Pediatrics, Biochemistry, and the Children’s Health Research Institute University of Western Ontario, London, Ontario, Canada.

An Old Order Amish community in Ontario, Canada is a very conservative Anabaptist group that originated from the Alsace-Lorraine district bordering Switzerland and France in Europe. There has been little influx of new genes into the community since the founding members arrived in Ontario in 1825. The population of the community is about 900 and includes 220 married couples within 10 church districts. All marriages are consanguineous and about 25% of marriages are isonymous. Several genetic disorders that are rare in the general population are present in increased frequency in this population. There are eight surnames in the population with 37% of the community having the most common surname and the two most frequent surnames accounting for 55% of the community. With support from the community, a program was established in 2002 to screen all newborn and some older children and adults for nephropathic cystinosis, congenital glaucoma, cystic fibrosis and galactosemia. These disorders were selected for newborn screening because clinical experience indicated a relatively high incidence in the population and early diagnosis and intervention improves outcomes for affected children. Mutations known to be present in the community are cystinosis (CTNS G339R), cystic fibrosis (CFTR Δ F 508 and c3905insT), congenital glaucoma (CYP1B1 c1410 del 13 and E387K), and galactosemia (GALT Q199R). Since 2002, DNA has been isolated from umbilical cord blood for newborn and buccal swabs from older children and some adults. Genotypes for the six tested alleles were obtained for about 390 individuals when data from the newborn and older individuals are combined. **Results**: The carrier frequencies in the combined newborn and older population are cystinosis 16%, cystic fibrosis 16% with c3905insT the more common allele, galactosemia 11%, and congenital glaucoma 11% with the E387K the more common allele. A total of 6 alleles were tested with a maximum possible of 12 mutations in one individual. The frequency of mutations in individuals with no mutations was 59%, one mutation 32%, two mutations 8%, and three or more mutations 1%. The maximum number of mutations identified in one individual was 5. Haplotype analysis of normal and mutant alleles was performed for both of the mutations that cause cystic fibrosis and congenital glaucoma and the results indicate that for both diseases the two mutations are present on different haplotypes.

## 638/W/Poster Board #296

**Genetics of celiac disease in the Saharawi population.** *J. Romanos[1], C.C van Diemen[1], G. Trynka[1], L. Franke[1], A. Zhernakova[2], S. Teresi[3], G. Iacono[4], R. Francavilla[5], S. Castellaneta[5], A. Ravelli[6], M.D Cantarero[7], C. Catassi[8], C. Wijmenga[1].* 1) Dept Genetics, UMCG, Groningen, Groningen, Netherlands; 2) Dept of Medical Genetics, University Medical Center Utrecht, the Netherlands; 3) Dept of Clinical Chemistry, Children's Hospital "G. Di Cristina", Palermo, Italy; 4) Dept of Pediatric Gastrienterology, Children's Hospital, Palermo, Italy; 5) Dept of Pediatrics, University of Bari, Italy; 6) Dept of Pediatrics, University of Brescia, Italy; 7) Pediatrician of Health Center of Illescas, Toledo, Spain; 8) Dept of Pediatrics, Università Politecnica delle Marche, Ancona, Italy.

Celiac disease is an autoimmune disorder of the small intestine caused by a reaction to gluten, a protein present in wheat, barley and rye. Celiac disease occurs in genetically predisposed individuals of all ages and it is estimated to affect approximately 1% of the European population. Symptoms include diarrhea, failure to thrive and abdominal distention. The only treatment is a life-long gluten free diet. Celiac disease is a complex disorder with a strong genetic component: 95% of the patients carry at least one of the risk alleles HLA-DQ2 and HLA-DQ8, which contribute to 40% of celiac disease heretability. This means that having HLA risk variants is necessary but not sufficient to develop the disease. The first genome-wide association study (GWAS) in celiac disease and its follow-up have identified 10 new genetic loci that contribute significantly towards celiac disease risk. Seven of these contain genes controlling adaptive immune responses, including IL2/IL21 (4q27), RGS1 (1q31), IL18RAP (2q11-2q12), CCR3 (3p21), IL12A (3q25-3q26), TAGAP (6q25), TNFAIP3 (6q23.3) and REL (2p16.1) and SH2B3 (12q24). The highest prevalence of celiac disease in the world (5.6%) has been described in the Saharawi, an African population living in Western Sahara and of Arab-Berber origin. It is yet unknown whether this results from a higher frequency of celiac disease risk alleles or that other genes are contributing to increased risk in this population compared to other populations. Our aim is to study the genetics of celiac disease and the involvement of susceptibility celiac genes in the genetically isolated population of Saharawi. We conducted a GWAS in 166 individuals, including 38 perfect trios, using the Illumina Infinium 610K HD beadchips. Analysis of the data revealed the linkage disequilibrium (LD) structure in this population to be different to that of Caucasians. Moreover, we were able to replicate the association of the HLA region to celiac disease. We investigated in detail the previously described IL12A/SCHIP region and showed association to two SNPs from this region to celiac disease in the Saharawi population. In order to increase the power of the study, we are currently genotyping 192 additional individuals. Moreover, the LD structure will help in narrowing down the associated regions initially identified in Caucasian populations. This information should assist us in identifying the causal celiac genes.

## 639/W/Poster Board #297

**DISCERNING KIR HAPLOTYPES.** *M. Maiers[1], S. Spellman[1], C. Vierra-Green[1], H. Noreen[2], M. Stewart[2], N. Yu[3], T. Lebeveda[3], E. Reed[4], R. Rajalingam[4], C. Hurley[5].* 1) Bioinformatics, National Marrow Donor Program, Minneapolis, MN; 2) University of Minnesota, Minneapolis, MN, USA; 3) American Red Cross, Dedham, MA; 4) UCLA, Los Angeles, CA; 5) Georgetown University.

KIR (Killer Immunoglobulin-like Receptors) whaplotype frequency analysis has been hampered by a lack of solid reference data with as many as 42 haplotypes described in the literature from a variety of sources determined using indirect and sometimes incompatible methods. We describe an analysis utilizing only reference haplotypes confirmed by genomic sequencing. A total of 509 European American samples were typed for 14 KIR loci (2DL1-5, 3DL1-3, 2DS1-5 and 3DS1). All samples have complete high resolution HLA data (HLA-A, B, C, DRB1/3/4/5, DQA1, DQB1, DPA1 and DPB1) and ~85% have cell lines available. Each sample was typed in duplicate by two of three different contracted laboratories. The typing was completed using a two-tiered approach: KIR gene presence/absence was determined by low-resolution methods followed by high resolution allelic typing using a combination of SSO, SSP and SBT. We developed software to interpret our data in light of the 7 gene-content haplotypes. We found that over 97% of the observed presence/absence genotypes could be described as combinations of 6 of these reference haplotypes. Furthermore, KIR genes that are located in different positions on the reference haplotypes (e.g. KIR2DL5, KIR2DS3/5) and framework KIR genes (e.g. KIR3DL2, KIR3DL3) exhibited allele-specific variation that correlated with gene-content haplotype. This analysis suggests a simpler picture of KIR haplotype and allele variation than described in earlier studies.

## 640/W/Poster Board #298

**Pedigree and kinship analysis of a large founder population in rural mid-Michigan.** *B.C. Schutte[1,2,3,4], R.A. Fisher[2], J.D. Bonner[3], C. Wei[5], Q. Lu[5], K.H. Friderici[1,2,4], J.L. Elfenbein[6], E. Wilch[4], D.L. Schutte[7].* 1) Microbiol and Molec Gen, Michigan State Univ, East Lansing, MI; 2) Pediatrics and Human Development, Michigan State Univ, East Lansing, MI; 3) Comparative Medicine and Integrative Biology, Michigan State Univ, East Lansing, MI; 4) Genetics PhD Program, Michigan State Univ, East Lansing, MI; 5) Epidemiology, Michigan State Univ, East Lansing, MI; 6) Communicative Sciences and Disorders, Michigan State Univ, East Lansing, MI; 7) College of Nursing, Michigan State Univ, East Lansing, MI.

Previously, we identified a cluster of individuals with an autosomal recessive form of deafness from a small region of mid-Michigan. Eleven cases are homozygous for the 35delG mutation of GJB2, and four cases are heterozygous for 35delG and a novel deletion located upstream of GJB2. We hypothesized that affected individuals descend from a founder population and the population has a high degree of kinship. Using public records and personal interviews, we constructed a genealogical database that included the extended families and ancestors of individuals who are deaf from this rural Mid-Michigan region. We used a novel algorithm similar to the connected components algorithm to cluster individuals into extended pedigrees and used the methods of Crow and Mange to calculate the degree of kinship based on isonymy. The genealogical database contains 27,726 records and includes 1681 surnames and 6328 marriages from ancestors and descendents of the founders. Although our analysis grouped the individuals into 336 pedigrees, 25,899 individuals (93%) were assigned to a single, exceptionally large, pedigree. The coefficient of isonymy indicates that, on average, matings from the founder population share a common ancestor 8 generations past. A 2001 analysis of isonymy in 247 US cities (including 10 Michigan cities) showed that matings within these cities share a common ancestor 9 to 12 generations past. We conclude that most individuals within the genealogical database, including the 15 individuals who are deaf from the previous study, belong to a common founder population, and the individuals in this population are highly related. Future studies will directly measure the kinship coefficient using pedigree-based methods of Wright. Given the high degree of relatedness/isolation of this immigrant founder population, their participatory history and their proximity to our institution, we developed a partnership with this community to 1) identify genetic and environmental factors involved in common health-related conditions and 2) to translate those discoveries.

## 641/W/Poster Board #299

**Genome-wide SNP analysis of Ashkenazi Jews reveals unique population substructure.** *S.M. Bray[1], J.G. Mulle[1], A.F. Dodd[1], A.E. Pulver[2], S.T. Warren[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, Maryland.

The Ashkenazi Jews (AJ) are a genetic isolate that has been widely utilized in genetic studies of both mendelian and complex disorders. However, the genetic variation and population structure of the AJ have been previously investigated with relatively few individuals and few genetic markers. We have now genotyped a large AJ cohort with the Affymetrix 6.0 genome-wide SNP array. After strict quality control filters, genotype data at 775K SNPs in 466 unrelated AJ individuals were available for analysis. To investigate the genetic structure of the AJ relative to other populations we used principle components analysis (PCA) as well as the *frappe* clustering algorithm. When merged with the worldwide Human Genome Diversity Project dataset, PCA shows the AJ are distinct from all other groups, including both European and Middle-Eastern populations. Further PCA using AJ genotypes combined with a large European dataset again validates the separation of AJ from European populations. Interestingly, principle component one seems to largely separate European and Middle-Eastern populations geographically according to latitude with the AJ fitting South of Europe and North of the Middle-East. Additional analysis using the *frappe* population clustering algorithm is consistent with a unique population signature for the AJ. Limiting the *frappe* clustering to only two population groups, specifying k=2, reveals that AJ cluster more closely to Europeans than Middle-Eastern populations but when allowing three populations, k=3, AJ form a group distinct from both the Middle-East and Europe. Compared to European populations, AJ also show an increase in genome-wide linkage disequilibrium, consistent with possible founder effects. These findings will aid in the design and use of AJ in case-control and association studies and clearly demonstrate the genetic separation of AJ from other populations.

**Fine-scale Population Structure in Worldwide Ethnic Populations as Revealed by Identical by Descent Segments.** *B.M. Henn, L. Hon, J.M. Macpherson, N. Eriksson, A. Wojcicki, L. Avey, S. Saxonov, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

It is well established that human population genetic diversity reflects continental-level geographic divisions, and that within-continental geographic and linguistic differences contribute to population structure between regions. The continental and regional differences reflect ancient demographic events, such as early migrations Out of Africa into Eurasia. However, it is not clear how recent demographic processes occurring on the order of hundreds, rather than thousands, of years affect patterns of genomic diversity. We analyzed the sharing of DNA identical by descent (IBD) inferred from 580,000 SNPs using a large database of individuals with European ancestry, including a subset identifying as Ashkenazim. We also explored the pairwise distributions of identical by descent segments in populations from the Human Genome Diversity Panel (HGDP-CEPH), a diverse set of ethnic groups from across the world. We observed that the average number and sizes of shared genomic segments differ substantially across the ~55 populations. The different patterns are likely attributable to differences in population histories such as recent bottlenecks and sub-structure. In particular, populations that are highly structured will contain individuals that share elevated amounts of IBD, indicative of recent common ancestry through multiple ancestors. In order to understand the pattern of the observed population-level sharing, we simulated extended pedigrees using empirical data from several populations and calculated the expected amounts of sharing for 1st through 10th cousins. We assumed random mating within each population for the simulations. Interestingly, the average sharing in the simulated distant cousins was consistently less than the observed average sharing in each population sample. This finding indicates the presence of fine-scale population structure for many ethnic groups, such as the Ashkenazim, within the last 10 generations (200-300 years).

## 643/W/Poster Board #301

**Scale Effects and Recent Brain Evolution: Theory and Preliminary Evidence.** *G. Jones.* Dept Economics, George Mason Univ, Fairfax, VA.

What forces have driven human evolution since the grand human diaspora? In this paper, I argue that the scale effects so central to endogenous growth theory in the field of economics (e.g., Kremer's widely-cited "Population Growth and Technological Change: 1,000,000 B.C. to 1990," Quarterly Journal of Economics, 1993) have been important drivers of human brain development since the diaspora. Scale effects have made prominent appearances in recent explanations of continent-level outcomes. For instance, in Kremer's model, big continents create larger, denser, faster-growing populations. In Diamond's Guns, Germs, and Steel model, wide continents raise the chance that an innovation will arise at a given latitude, an innovation which can then disperse across that latitude, enriching those who live on wider continents. In both models, the Malthusian nature of pre-Industrial Revolution existence imposes strong conditions on the general equilibrium outcome. My model takes those channels as given, and works out the theoretical implications for the divergent evolution of human brains on these continents. Brains are biologically costly, so evolution will only select for larger brains if there is a substantial payoff. And since larger brains tend to have higher levels of intelligence [corr(Brain Size, IQ)= 0.4 in recent in brain-scan studies], larger brains tend to have more processing and memory power. Under certain parameter values, Kremer's and Diamond's models both imply that the payoff to a big braina brain that can better adopt someone else's ideaswill be higher on wider, larger continents. Thus, we would expect human populations living on larger, wider continents to develop larger, more powerful brains. I model this relationship formally. This result should only hold on average: intra-group diversity is central to evolutionary theory, and massive intra-group diversity is an important fact of quantitative human genetics. The main purpose of the paper is to set forth the model, but I include some tests of its implications. I discuss whether, as the model predicts, human brain size and average IQ correlate positively with continent size and continent width. Indeed, evidence generally supports this hypothesis. Further empirical testing of the model's predictions will occur as future researchers employ genetic diversity databases. I plan to present the results in a manner intelligible to non-economists.

## 644/W/Poster Board #302

**Natural selection -a and the pattern of Identity by Descent in the human genome.** *R. Nielsen, A. Albrechtsen, I. Moltke.* Depts. of Integrative Biol. and Statistics, Univ California, Berkeley, Berkeley, CA.

Most forms of natural selection will tend to increase the degree of Identity By Descent (IBD) in the population. Individuals in a population will in average be closer related to each other in a region that has been targeted by selection than in regions that have evolved neutrally. We show mathematically that even when selection is acting on standing variation the amount of IBD in a region can be increased dramatically. We have also developed a fast method based on Hidden Markov models for identifying pairwise IBD, and a somewhat slower but more precise method based on Markov Chain Monte Carlo (MCMC) for identifying all sets of IBD sharing among multiple individuals. We apply these methods to large scale human SNP data sets and identify a number of extreme IBD patterns, the most extreme of which is located in the Major Histocompatibility Complex (MHC) region - a known target of selection. We do extensive work to verify that the patterns observed are not caused by genotyping errors, variation in recombination rates, or by random genetic drift. The new IBD based method for detecting selection has the advantage over other haplotype based methods that it maintains high power when selection is acting on standing variation.

## 645/W/Poster Board #303

**Copy number variation among rhesus macaques: evolutionary and phenotypic implications.** *O. Gokcumen[1,2], R.S. Smith[1,2], E.J. Vallender[3], M.E. Blake-Kinnin[2], R.E. Mills[1,2], W.E. Johnson[2,3], C. Lee[1,2].* 1) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) New England Primate Research Center, Southborough, MA.

A substantial amount of genomic variation is now known to exist in humans and other primate species. Recent studies have shown copy number variants (CNVs), which are segments of DNA that can range in size from hundreds to millions of base pairs in length and have different number of copies between individuals, constitute a significant portion of the genetic diversity within primate genomes. CNVs in humans have already been associated with susceptibility to certain complex diseases, dietary adaptation, and several neurological conditions. However, despite these exciting developments, the important role of CNVs in primate evolution and genetic diversity is still largely unknown. To explore the evolution and distribution of CNVs in non-human primates, we have sampled from rhesus macaques (Macaca mulatta), which have been the preferred model animals for biomedical and evolutionary research. For this study, we have designed a custom, array-based comparative genomic hybridization (aCGH) platform with 1,000,000 species-specific oligonucleotide probes. This platform allowed us to identify more than 500 CNVs (more than 25% of these CNVs observed in multiple individuals) with a median size of approximately 30,000 base pairs, among 10 unrelated macaque individuals. The average number of CNVs observed in a single individual was approximately 75, which is more than a threefold increase from the previous studies. This improvement is due to the substantial increase in the resolution of the platform used in this study, which enabled us to detect CNVs as small as 4,000 base pairs. Using the same platform, we also conducted cross-species experiments, hybridizing macaque samples to a human reference. We confirmed the previous observations that segmental duplications were significantly enriched at macaque CNV loci. Furthermore, we have correlated the macaque and human CNVs to identify hot-spots of CNV genesis. We also revealed CNVs in several loci that are conserved, genic or previously associated with expression of phenotypic variation. Interestingly, we found that most of the annotated genes that are copy number variable in macaques are immune system related, suggesting evolutionary pressures (or lack thereof) that induce or tolerate variation in these loci.

## 646/W/Poster Board #304

**Extreme Evolutionary Disparities Seen in Positive Selection Across Seven Complex Diseases.** *E. Corona[1,2,3], J. Dudley[1,2,3], A. Butte[1,2,3].* 1) Biomedical Informatics, Stanford Univ, Stanford, CA; 2) Department of Pediatrics, Stanford University School of Medicine, Stanford, CA; 3) Lucile Packard Children's Hospital, Palo Alto, CA.

Genome-wide association studies (GWASs) have successfully illuminated disease-associated variation. But whether human evolution is heading towards or away from disease susceptibility remains an open question. We analyzed the seven diseases studied by the Wellcome Trust Control Case Consortium (WTCCC), to calculate the relative selective pressure at every significant loci. Results reveal striking differences between the seven studied diseases. We find evidence of recent positive selection in favor of alleles increasing the risk of Type 1 Diabetes (T1D), Crohn's Disease (CD), Hypertension (HT), Rheumatoid Arthritis (RA), and Bipolar Disorder (BD). Risk-associated alleles (defined as the allele most strongly associated with disease among associated SNPs) for Type 2 Diabetes (T2D) fall largely within the random neutral region, and Coronary Artery Disease (CAD) shows less positive selection than expected by random. When only protective alleles are considered (defined as the allele least strongly associated with disease among associated SNPs), we find that SNPs only associated with T1D, CD, and RA appear to exhibit significant signatures of positive selection. There is significant asymmetry in the 96 SNPs strongly associated with T1D (p-value ≤ 0.005) showing strong signs of positive selection, with 79 SNPs selecting for the risky allele, and only 17 SNPs selecting for the protective allele. Furthermore, selection patterns of Coronary Artery Disease (CAD) fall far below the expected levels of random, implying stable allele frequencies. Results reveal the evolutionary trajectories of T1D and CD favor risk alleles, possibly due to their simultaneous role in protection from infectious diseases. These results inform on current understanding of disease etiology, thus aiding efforts to discover novel approaches to disease treatment and prevention.

## 647/W/Poster Board #305

**Timing of selective pressures on geographically-restricted selected alleles.** *J.L. Kelley[1], J.K. Pickrell[1], R.R. Hudson[2], M. Przeworski[1,2].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Ecology and Evolution, University of Chicago, Chicago, IL.

Genome scans for selection have identified a number of loci at which an allele appears to have reached intermediate frequency due to positive directional selection. Interestingly, the geographic distribution of these putatively selected alleles vary markedly: in particular, some putatively selected alleles are at high frequency only in Europe or Asia (such as SLC24A5, TYRP1, and EDAR), while others are at high frequency throughout Eurasia (e.g., KITLG and ENAM). One interpretation of these geographic patterns is that the selected alleles currently at high frequency across non-African populations arose when humans first colonized these environments and were subsequently selected for in all populations, whereas locally selected alleles arose more recently and have not had the time to spread to other regions. An alternative is that geographically-restricted alleles are not on average younger but instead that their variable frequencies across populations reflect local differences in selective pressures. To distinguish between these possibilities, we estimated the time to the most common ancestor (tMRCA) for two sets of putatively selected alleles: those at high frequency only in Europe or only in Asia, and those at high frequency throughout Eurasia. If locally restricted alleles are simply too young to have spread, we would expect them to have a more recent tMRCA, on average. Alternatively, if their distribution reflects geographic differences in selective pressures, the ages should not differ systematically. Preliminary analyses reveal no significant difference in the onset of selection on the two sets of alleles, with most selected pressures estimated to predate the Neolithic. We evaluate this hypothesis using forward simulations of demography and selection. Our findings suggest that the distribution of selected allele frequencies reflects geographically varying selective pressures rather than differences in the timing of selection.

## 648/W/Poster Board #306

**Homing in on signals of positive selection in the human genome by large-scale re-sequencing.** *M. Hu[1], Q. Ayub[1], A. Assuncao[2], N. Huang[1], Q. Long[1], M. Quail[1], H. Swerdlow[1], J. Burton[1], C. Tyler-Smith[1], Y. Xue[1].* 1) Sanger Inst, Cambridge, United Kingdom; 2) The European Bioinformatics Inst, Cambridge, United Kingdom.

The detection of positive natural selection in the human lineage is of great interest for studying human adaptations to specific environmental conditions and understanding human history. Sabeti et al. reported 22 regions in the human genome that showed the strongest signals of recent positive selection based on their analyses of HapMap phase II data [Nature 449, 913-918, 2007]. However, most of these regions were hundreds of kb in length, and the biologically functional elements that had undergone selection could not be identified. We have amplified two of them, both about 300 kb long, in 27 HapMap individuals from the selected population using overlapping long PCR, and re-sequenced to high depth using Solexa/Illumina technology. The reads were mapped to the reference human genome sequence and SNPs were called using SSAHA [Ning et al. Genome Res. 11, 1725-1729, 2001]. We filtered out calls that are likely to be false positives, including SNPs with low read depth, within the PCR primers, near indels, within PCR failure gaps as well as heterozygous calls with significant differences between the read depths of the two alleles, and obtained high-quality sequence data. Haplotypes were then inferred using PHASE [Stephens et al. Am J Hum Genet 68, 978-989, 2001; Am J Hum Genet 73, 1162-1169, 2003]. Diversity was calculated and neutrality tests (Tajima's D, Fay and Wu's H) were performed using custom perl scripts. We successfully narrowed down the positively selected targets to ~10 kb for each region. One target contains a predicted miRNA gene [Assunção et al., unpublished] with sequence variants specific to the putatively selected haplotype. The other contains a small mRNA expressed in hippocampus, and is a possible protein coding gene. This target also lies ~10 kb downstream from a sperm antigen protein gene, SPAG6, which plays important roles in sperm motility. Our study indicates that using re-sequencing data in multiple individuals, we can identify positive selection targets in the human genome with a high resolution, so the biological elements that have undergone positive selection can be followed up.

## 649/W/Poster Board #307

**Lactase Persistence; Multiple causal mutations in sub-Saharan pastoralists.** *B.L. Jones, C.J.E Ingram, M.G Thomas, N. Bradman, D.M Swallow.* University College London, London, United Kingdom.

*Background* Milk is the primary source of nutrition for newborn mammals, including humans. The majority of human adults, estimated at approximately 65%, are unable to digest lactose (the main carbohydrate in milk) effectively since lactase expression is down-regulated after weaning, as it is in other mammals. In some humans however, lactase expression persists into adulthood (lactase persistence, LP) allowing adult consumption of milk from other species, and the frequencies of this trait vary throughout the world. A C-T SNP -13910 bases upstream from the lactase gene (*LCT*) is associated with LP in Europe. The *-13910*T* is rare in milk drinking groups in Africa although two other variants (*-13915*G, -14010*C*) have been shown previously to be significantly associated with LP and in an accompanying abstract (Ingram *et al*) we confirm a third locus (*-13907*G*) and present a fourth candidate SNP. However some LP individuals have also been identified who carry none of these alleles. *Aims* To examine the distribution across Africa of these and other allelic variants; to examine other regulatory regions in population groups in which enhancer alleles are lacking. *Results* The geographic and ethnic distribution of *-13907*G, -13910*T, -13915*G, -14009*G*, and *-14010*C* in 10 different countries and 15 distinct ethnic groups across Africa (n=1221 individuals) is presented here. Several other variants in this enhancer region are also described here for the first time. These tightly clustered enhancer variants are more frequent in pastoralist milk drinking groups than agriculturalist populations and are associated with several different *LCT* core haplotypes. Two further candidate regulatory regions have been sequenced in the same populations including a 1000bp region immediately upstream from *LCT* where novel variants have been found. *Conclusions* The data support the notion that many different mutations do have a functional role in LP, and that the trait has arisen independently several times, being subject to the positive selection conferred by the increased ability to digest milk lactose by people in pastoralist societies.

## 650/W/Poster Board #308

**Evolutionary insights into a common genetic variant for dyslipidemia, Gln241His variant of *MLXIPL*.** *K. Nakayama[1], L. Munkhtulga[2], Y. Yanagisawa[1], T. Gotoh[1], K. Yamanaka[1], T. Ishida[3], Y. Koda[4], Y. Kagawa[5], S. Iwamoto[1].* 1) Division of Human Genetics, Jichi Medical University, Shimotsuke, Japan; 2) Health Science University of Mongolia, Ulaanbaatar, Mongolia; 3) Department of Biological Sciences, Graduate School of Science, the University of Tokyo, Tokyo, Japan; 4) Division of Forensic Medicine and Human Genetics, Kurume University, Kurume, Japan; 5) Kagawa Nutrition University, Sakado, Japan.

*MLXIPL* is recently identified as a novel gene that influences plasma concentrations of triglycerides in humans. The gene product of *MLXIPL* is a transcriptional factor that is mainly expressed in the liver and upregulates the expression of lipogenic genes in response to glucose influx into hepatocytes. In addition to its importance in the genetic predisposition to dyslipidemia, *MLXIPL* has been of interest for a presumptive role in adaptation to famine in modern human evolution. We investigated phenotypic effects, distribution and evolution of *MLXIPL* gene variants in a total of 3,667 individuals of 20 worldwide populations. A nonsynonymous SNP of *MLXIPL*, Gln241His variant (rs3812316), was strongly associated with plasma concentrations of triglycerides in the tested populations ($P$ = 5.8E-6, 11mg/dl decrease per minor His allele). The tested populations generally showed low frequencies of His allele (0.02 0.12) with the notable exception of three Central Asian populations including Mongolians (0.23), Tibetans (0.26) and Uygur (0.21). The glutamate residue was evolutionarily highly conserved and an in silico analysis demonstrated a possible damaging effect of the replacement with histidine residue. Characterizations of SNPs surrounding Gln241His exhibited strong linkage disequilibrium in the genomic region spanning 200kb. Haplotypes carrying His allele formed a distinctive cluster that was separated from haplotypes carrying Gln allele by many mutational steps. In the Mongolians, moreover, a significant deviation of Tajima's $D$ statistics ($D$ = 3.38: $P$<0.001) and "twin-peak" observed mismatch distribution were detected in the 200kb region. Such an allele frequency skew was not detected in HapMap JTP and CHB panels. The global high prevalence of Gln allele, which predisposes to higher triglyceride levels, is consistent with a hypothesis that *MLXIPL* was a "thrifty gene" that permits more efficient conversions of excess carbohydrates to fat at the times of food abundance. On the other hand, the high frequency of His allele and the non-neutral pattern of the surrounding SNPs in the Mongolians suggest that the His allele, which reduces glucose utilization and lipogenesis in the liver, likely had an metabolic advantage in nomadic ancestors of the Central Asians, whom relied on fatty acids for their dietary carbon source.

**Exploring the Genetic Basis of Human Uniqueness.** *J.P. Noonan[1], S. Sholtis[1], H. Breslawski[1], L. DeMare[1], C. Pease[2], J.M. McGrath[2], P. Zumbo[3], S. Mane[3], A. Ayoub[4], P. Rakic[4].* 1) Department of Genetics, Yale University School of Medicine, New Haven, CT; 2) Department of Comparative Medicine,Yale University School of Medicine, New Haven, CT; 3) W.M. Keck Foundation Biotechnology Resource Laboratory, Yale University School of Medicine, New Haven, CT; 4) Department of Neurobiology, Yale University School of Medicine, New Haven, CT.

The evolution of biological differences that distinguish humans from other species - such as increased brain size, bipedalism, and the dexterity of the human hand - likely required genome sequence changes that altered development. Although it has long been thought that gene regulatory changes have been a major driver of human evolution, evidence for human-specific developmental regulatory functions has remained elusive. We are investigating this fundamental question from two perspectives: through the identification of developmental regulatory sequences with human-specific functions, and by comparative analysis of gene expression of human, rhesus macaque and mouse at the earliest embryonic stages when biological differences emerge. Using mouse transgenic reporter assays, we have identified a set of developmental enhancers that are highly conserved across non-human vertebrate species but show extreme human-specific sequence divergence (HACNSs). These elements are located near genes that encode developmental transcription factors such as EN1, GLI2, and RUNX1T1 and act as enhancers in the developing brain, limb, and other structures. As a paradigmatic case we are focusing on the detailed functional characterization of the most rapidly evolving enhancer, HACNS1, in vivo. HACNS1 is located downstream of GBX2, an essential developmental transcription factor, and drives human-specific gene expression in the developing mouse limb, most notably in the mouse equivalent of the primordial thumb at embryonic day 13.5. To test the hypothesis that HACNS1 has influenced the evolution of human-specific limb development by altering the expression of nearby genes, we are characterizing transgenic mice that express a Gbx2 cDNA under the control of the HACNS1 enhancer. We are combining these cis-regulatory studies with global transcriptome sequencing of developing cortex and limb in human, rhesus and mouse. We are using laser capture microdissection to recover cortical stem cells and cortical plate neurons and have obtained robust, biologically meaningful transcriptome profiles from these samples using RNA-sequencing on the Illumina Genome Analyzer. These studies provide the foundation for an integrated understanding of how changes in developmental regulatory programs contributed to human evolution.

## 652/W/Poster Board #310

**Adaptive events in the evolution of innate immunity.** *D.J. Wilson[1], H. Quach[2], E. Patin[2], J. Manry[2], L. Barreiro[1,2], L. Quintana-Murci[2], M.F. Przeworski[1].* 1) Dept Human Gen, Univ Chicago, Chicago, IL; 2) Department of Genomes and Genetics, Institut Pasteur, Paris, France.

A major goal of human population genetics has been to detect adaptive change in the ancestry of modern humans and their hominid relatives. To date, practical considerations have focused this inquiry towards whole gene approaches, in which selection coefficients are estimated assuming that an entire coding region experiences selection uniformly, with no heterogeneity in selective pressure across sites. Consequently, the genes in which positive selection is detected are enriched for multiple amino acid substitutions, and adaptive changes that occur against a background of selective constraint tend to be missed.

As a first step towards developing a method to detect changes in selection pressure acting on specific sites over time, we present a new approach that jointly analyzes patterns of polymorphism and divergence from multiple species. Our intention is to employ both the flexibility of phylogenetic models of molecular evolution and the signal provided by polymorphism within populations. We motivate our work by a study of polymorphism and divergence between humans and other hominids (chimpanzee, bonobo, gorilla, orangutan and gibbon) in a family of ten toll-like receptor genes involved in the innate immune response.

**Positive selection of common variants associated with celiac disease.**
*A. Zhernakova[1], C.C. Elbers[1], J. Romanos[2], G. Trynka[2], C.G.F. de Kovel[1], D. Barisani[3], M.T. Bardella[4,5], P. Saavalainen[6], D.A. van Heel[7], C. Catassi[8], C. Wijmenga[2].* 1) Department of Biomedical Genetics, UMC Utrecht, Utrecht, Netherlands; 2) Genetics Department, University Medical Centre Groningen and University of Groningen, The Netherlands; 3) Department of Experimental Medicine, Faculty of Medicine, University of Milano-Bicocca, Monza, Italy; 4) Fondazione IRCCS Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena, Milan, Italy; 5) Department of Medical Sciences, University of Milan, Italy; 6) Department of Medical Genetics, University of Helsinki, Finland; 7) Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, London, UK; 8) Department of Pediatrics, Università Politecnica delle Marche, Ancona, Italy.

Celiac disease (CD) is a common (1-2% of Westerns population) food intolerance to dietary proteins of wheat, barley and rye. At present, the genetic background of CD is one of the best elucidated complex diseases as approximately 50% of genetic susceptibility can already be explained by association to both common HLA and non-HLA genetic variants. It is puzzling however why common variants associated with CD are frequent in modern populations, and were not selected out during the evolution. The domestication of wheat, barley and rye started around 10,000 years ago, and since then gluten became the major dietary protein in most populations. Classical CD should have been lethal in the past in grain-consuming societies, whereas latent CD - which is associated with infertility - should have reduced fitness and subsequently led to negative selection of CD. Hence, we hypothesized that some of the common alleles associated with CD are located in the blocks of linkage disequilibrium (LD) which also include genes that have been under positive selection. To test this hypothesis we took advantage of our genome-wide association study in CD comprising 2300 cases and 3000 controls from 4 Caucasian and one North-African Saharawi population. In this study we investigated the HLA locus and the 10 known non-HLA CD loci for the signs of positive selection, using the Extended Haplotype Homozygosity (EHH) and Integrated Haplotype Score (iHS) methods. Apart from the HLA region, we observed strong and consistent signs of positive selection of the CD-associated allele in the SH2B3 loci. Interestingly, this associated variant is predisposing to several autoimmune diseases, as well as to other common diseases including myocardial infarction and hypertension, and is located in an extended block of strong LD. The associated block harbors several good candidates for positive selection during evolution, including immune-related and metabolic genes. Above that, we observed signs of positive selection of the CD-associated variants in the IL12A/SCHIP genes locus. These particular alleles might have been beneficial during the times of infections - the major cause of mortality in the past. We are currently extending our cases and control cohorts and are also including other common variants of several complex traits. The analysis of associated variants in the evolutionary perspective might enhance our understanding of why common diseases are caused by common variants.

## 654/W/Poster Board #312

**Multiple rare variants as a cause of a common phenotype: increased diversity may signal selection.**
*C.J.E. Ingram[1], T. Oljira Raga[2], A. Tarekegn[1, 2], S.L. Browning[1], M.F. Elamin[3], E. Bekele[2], M.G. Thomas[1], M.E. Weale[4], N. Bradman[1], D.M. Swallow[1].* 1) Department of Genetics, Evolution & Environment, University College London, UK; 2) Addis Ababa University, Ethiopia; 3) Elrazi College of Medical Sciences, Sudan; 4) Department of Medical & Molecular Genetics, King's College London, UK.

**Background:** Persistence of intestinal lactase into adulthood allows humans to use milk from other mammals as a source of food and water. It has previously been shown that this genetic trait has been subject to convergent evolution and the derived alleles of at least three different single nucleotide polymorphisms (*-13910C>T*, *-13915T>G*, *-14010G>C*) are significantly associated with and probably causal of lactase persistence in different populations. Each of these alleles are present on different extended haplotypes consistent with positive directional selection. The SNPs occur in an intron of a neighbouring gene (*MCM6*) within an 'enhancer' sequence, and modulate lactase transcription *in vitro*. However, in all previous studies, a number of lactase persistent individuals were identified who carry none of the above alleles, and other low frequency single nucleotide polymorphisms have been observed within the enhancer sequence. **Aim:** We investigated a cohort of 107 milk-drinking Somali camel-herders from Ethiopia to establish the frequency of lactase persistence and to characterise patterns of association of *MCM6* intron 13 alleles with the trait. **Results:** The frequency of lactase persistence was found to be 0.24. Milk-drinking was far more common than lactase persistence, providing evidence that the cultural trait can precede the genetic adaptation. Eight polymorphic sites were identified in the enhancer region. Two of these, *-13915*G* and *-13907*G* (a previously reported candidate), were significantly associated with lactase persistence after correction for multiple testing ($p = < 1x10^{-4}$). A new allele, *-14009*G* was also shown to have a borderline association with lactase persistence ($p = 0.056$). However, of greatest note is the novel finding that sequence diversity of the enhancer region is significantly higher in the lactase persistent members of the cohort compared with the non-persistent members of the group ($p = 7.6 \times 10^{-9}$). This contrasts with the widely expected observation of positive selection decreasing diversity by driving up the frequency of a single advantageous allele. By examining diversity of the Y-chromosome, the hypervariable region of the mtDNA, and the allele distributions of 15 autosomal microsatellites, we show that this difference is not due to population substructure, and that increased diversity can be a signal of selection.

## 655/W/Poster Board #313

**Use of 96-plex indexing and Illumina sequencing to analyse the worldwide population genetics of a polymorphism associated with human muscle function.**
*D.G. MacArthur[1,3,4], I. Kozarewa[2], Q. Ayub[1], Y. Xue[1], K.N. North[3,4], D.J. Turner[2], C. Tyler-Smith[1].* 1) Human Evolution Team, Wellcome Trust Sanger Institute, Hinxton, UK; 2) Sequencing R&D Team, Wellcome Trust Sanger Institute, Hinxton, UK; 3) Institute for Neuromuscular Research, Children's Hospital at Westmead, Sydney, Australia; 4) Discipline of Paediatrics and Child Health, University of Sydney, Sydney, Australia.

Massively parallel sequencing technologies provide extremely high sequence output, but are challenging to apply to the resequencing of small candidate regions (<1 Mb) in large numbers of samples. Here we describe an index-based approach that permits the pooling of 96 samples in a single Illumina lane, and its application to population genetic analysis of a human gene associated with variation in muscle function.

The human *ACTN3* gene encodes the protein $\alpha$-actinin-3, which is expressed in fast muscle fibres. Remarkably, a common nonsense polymorphism (R577X) in *ACTN3* results in complete deficiency of $\alpha$-actinin-3 in more than one billion humans worldwide. Analysis of human and mouse data suggest that $\alpha$-actinin-3 deficiency decreases muscle size and strength while increasing metabolic efficiency and endurance. These changes appear to have been advantageous during human evolution: 577X displays a genetic signature of recent positive selection in Europeans and East Asians (MacArthur et al. *Nat Genet* **39:**1261-1265).

To further characterise the recent evolutionary history of *ACTN3* we amplified and sequenced 25 kb of genomic DNA around this gene in 1,457 individuals from 57 worldwide populations with Illumina short-read technology. Using enrichment PCR primers that contain unique 8bp indexing tags we are able to load 96 different samples per lane, along with 6 cloned control sequences. All individuals were then sequenced using paired-end 50bp reads. We have developed a custom pipeline for assigning reads to individual samples, mapping reads to the reference genome, calling SNPs, short indels and structural variants and performing basic population genetic analyses.

Here we show that adding several methodological improvements to the standard Illumina pipeline results in very high (>200X per lane) and uniform coverage across pooled samples. We also present detailed analysis of variation within *ACTN3*, including estimates of the age, geographical origin and selection intensity acting on the 577X null allele in a variety of human populations, and integrate functional and population genetic evidence to constrain scenarios for its recent evolutionary history.

## 656/W/Poster Board #314

**Human-specific insertions and deletions: simply neutral or not?** *C.H. Chen[1], T.J. Chuang[2], B.Y. Liao[1], F.C. Chen[1,3,4].* 1) National health research institutes, Zhunan Town, Taiwan; 2) Genomics Research Center, Academia Sinica, Taipei, 115 Taiwan; 3) Department of Life Science, National Chiao-Tung University, Hsinchu, 300 Taiwan; 4) Department of Dentistry, Chinese Medical University, Taichung, 404 Taiwan.

The number of human-specific insertions and deletions ("HS indels"; with length <100 Bp) is surprisingly large in the human genome, affecting more than 7,000 genes and many noncoding regions. However, the selection pressures that work on HS indels remain unclear. In coding sequences, the indel rate (the length of indels divided by the length of the aligned sequence) is significantly lower than that in pseudogenes, suggesting negative selection on HS indels. Nevertheless, HS indels are most abundant in intergenic and intronic regions. Are all of these indels selectively neutral? Or they actually contribute to human-specific traits? To search for the signatures of positive selection on HS indels, we employ a modified McDonald-Kreitman test, with human-specific substitutions as the neutral reference, to test whether the ratio of fixed-to-polymorphic HS indels significantly exceeds the neutral expectation in sliding windows through the human genome. Although most of the HS indels are selectively neural, we conservatively estimate that ~12MB of the human genome to be potentially positively selected. Moreover, these regions tend to be located in the vicinity of genes. Since the fixed-to-polymorphic indel ratio is significantly higher in noncoding regions than in coding sequences in these positively selection regions, the indel-associated positive selection may have affected the transcriptional or translational regulation, rather than the protein sequences *per se*.

## 657/W/Poster Board #315

**Detecting Natural Selection in the Human Genome from Pilot1 Data in the 1000 Genomes Project.** *P. Hu[1,2], H. Siu[1,2], Z. Hou[1,2], F. Yu[4], Y. Fu[3], J. Jin[1,2], M. Xiong[1,3].* 1) Laboratory of Theoretical Systems Biology and Center for Evolutionary Biology, School of Life Science and Institute for Biomedical Sciences, Fudan University, Shanghai 200433, China; 2) State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, 200433, China; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225; 4) Human Genome Sequencing Center, Molecular and Human Genetics Department, Baylor College of Medicine, Houston, TX 77030.

Identifying signatures of natural selection in the human genome is of fundamental implication for the study of population evolution and for the biomedical research. The distribution of selection in genome will provide important functional information. Natural selection modify the level of variability within and between populations and shapes the pattern of genetic variations in the genome. Genetic variation in genome is the raw data for detection of natural selection. The 1000 Genomes Project produces whole genome sequencing data and offers a unique and great opportunity to scan the genome for signature of natural selection. Five statistics: Tajima'D, Fu and Li's F, Achaz's Y, Fay and Wu's H and Zeng et al.'s E (based on comparing the site frequency spectrum within population) and Fst statistic (based on the measure of population subdivision) were applied to Pilot 1 data in 1,000 genome project to scan the entire genome for detection of selection, where 344 chromosomes from ASI, CEU and YRI were sequenced. A total of more than 20 million of variant sites, 4.8 millions common in three populations were identified. We calculated seven statistics in 10 kb and 100 kb windows across the genome for each population and obtained their empirical distributions. Results show that two kinds of windows analyses lead to the similar distributions. The proportional rank of the test statistic in a particular window compared with the overall empirical genomic distribution was taken as empirical P-value for that window. We identified 3,046 candidate selection regions in ASI population, 2,015 selection regions in CEU, and 2,204 selection regions in YRI at 5% empirical significance level in 10 kb by five statistics based on differences in frequency spectrum. Among 457 candidate genes of selection reported from PubMed, we detected 102 selection genes in ASI, 53 selection genes in CEU, and 101 selection genes in YRI and 11 selection genes common in three populations by familiar Tajima D test. By comparison we obtained 3.9 million SNPs and the whole genome's fixation index about 0.10~0.11. By compared with the empirical genome-wide distribution of FST, we identified 5, 278 candidate selection regions at an empirical significance level of 2.5% from each of the 22 autosomal chromosomes. Among 581 identified selection regions by FST which were reported from literatures, we found that 294 selection regions overlap our results.

## 658/W/Poster Board #316

**Genomic Landscape of Positive Natural Selection in North European Populations.** *T. Lappalainen[1,2], E. Salmela[1,2], P.M. Andersen[3], K. Dahlman-Wright[4], P. Sistonen[5], M.-L. Savontaus[6], S. Schreiber[7], P. Lahermo[1], J. Kere[2,4,8].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, and Folkhälsan Institute of Genetics, Biomedicum Helsinki, Helsinki, Finland; 3) Department of Neurology, Umeå University Hospital, University of Umeå, Umeå, Sweden; 4) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 5) Finnish Red Cross Blood Transfusion Center, Helsinki, Finland; 6) Department of Medical Genetics, University of Turku, Finland; 7) Department of General Internal Medicine, Institute for Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 8) Clinical Research Centre, Karolinska University Hospital, Huddinge, Sweden.

Analysing genetic variation of human populations to detect loci that have been affected by positive natural selection is important for understanding adaptive history and phenotypic variation in humans. In this study, we analysed recent positive selection in Northern Europe from genome-wide datasets of 250 000 and 500 000 single nucleotide polymorphisms in a total of over 1000 individuals from Great Britain, Northern Germany, Eastern and Western Finland, and Sweden. Coalescent simulations were used to demonstrate that the integrated haplotype score (iHS) and long-range haplotype (LRH) statistics have sufficient power in genome-wide datasets of different sample sizes and SNP densities. Furthermore, the behavior of the FST statistic in closely related populations was characterized by allele frequency simulations. In the analysis of the North European dataset, dozens of regions in the genome showed strong signs of recent positive selection. Most of these regions have not been discovered in previous scans, and many contain genes with interesting functions (e.g. RAB38, INFG, NOS1AP, and APOE). In the putatively selected regions, we observed a statistically significant overrepresentation of genetic association to complex disease, which emphasizes the importance of the analysis of positive selection in understanding the evolution of human disease. Altogether, this study demonstrates the potential of genome-wide datasets to discover loci that lie behind evolutionary adaptation in different human populations.

## 659/W/Poster Board #317

**Signatures of balancing selection at the HLA-G promoter region in Native-American populations.** *M.R. Pincerati[1], E.J.M. Santos[2], D. Labuda[3], A. Ruiz-Linares[4], D. Meyer[1].* 1) Departamento de Genética e Evolução, Universidade de São Paulo, São Paulo, Brazil; 2) Laboratório de Genética Humana e Médica, Departamento de Patologia, Universidade Federal do Pará, Belém, Pará, Brazil; 3) CHU Sainte-Justine, Département de Pédiatrie, Université de Montréal, Montréal, PQ, Canada; 4) The Galton Laboratory, Department of Biology, University College London, London, United Kingdom.

HLA-G is a class Ib HLA gene initially described as being selectively expressed at the maternal-fetal interface. Since it was first described, in cytotrophoblasts, this molecule has attracted attention due to its immunotolerogenic properties. Recent advances show the relevance of HLA-G in physiological and pathological contexts, such as transplantation, autoimmunity, cancer and haematological malignancies. The fact that HLA-G exerts several immunomodulatory effects suggests that its expression is under tight regulation. The singular organization of its promoter region also reflects the unique expression pattern of HLA-G. Evidence of balancing selection at the HLA-G promoter region have previously been found in the African American, European American and Chinese populations. These observations demonstrated the importance of the functions of the HLA-G gene and suggest that its expression may be under strong selective pressures. The aim of the present study was to describe the sequence variation and haplotype structure of the HLA-G promoter region in Native-American populations. We sequenced the 1320 bp region immediately upstream of the HLA-G translation start site in 21 individuals distributed throughout the American continent. We observed high levels of nucleotide variation. In this survey we identified 24 SNPs and 22 different haplotypes, most of them shared with the three major human populations already studied. Nucleotide diversity in the samples was 0.00641, which is about eight times as high as the human genome average. Indeed, a significant departure from the expectation of evolutionary neutrality was observed. A significant positive Tajimas'D value was found, which is consistent with action of balancing selection in this locus. Altogether these features represent evidence that natural selection is influencing polymorphism of the HLA-G promoter region. The fact that we found retention of a substantial amount of allelic diversity, even in populations that have undergone loss of heterozygosity, as is the case of Native-Americans, reinforces the importance of the promoter region of this gene in the human evolutionary history.

## 660/W/Poster Board #318

**Evidence of Indigenous American specific selection in skin pigmentation genes.** *E. Quillen[1], A.W. Bigham[2], R. Mei[3], M.D. Shriver[1].* 1) Dept Anthropology, Pennsylvania State Univ, University Park, PA; 2) Dept. of Pediatrics, University of Washington, Seattle, WA; 3) Affymetrix, Inc., Santa Clara, CA.

Recent studies of selection in human pigmentation genes have focused on Old World populations, neglecting the evolutionary changes that have occurred in Indigenous American populations since their migration into the Americas. Previous research shows correlations between Indigenous American ancestry and skin pigmentation variation, suggesting a genetic role in the determination of skin pigmentation among these populations. However, few genes contributing to these differences have been described. To identify genes that may have undergone Indigenous American specific changes, this work examines signatures of selection in 82 pigmentation candidate genes by genotyping 88 indigenous individuals from Central and South America using the Affymetrix Genomewide Human SNP Array 6.0. The resulting 906,600 single nucleotide polymorphisms (SNPs) were surveyed for signatures of selection in the Indigenous American populations compared to the HapMap Phase I populations. Evidence of selection was identified using four measures selected for the complementarity of their approaches, including the reduction in heterozygosity (ln*RH*), Locus-Specific Branch Length (LSBL), Tajima's D, and by examination of the haplotype block structure. When computing ln*RH* and LSBL as well as when examining changes in haplotype frequency, the East Asian and European HapMap populations were included because they are the most closely related populations available. These analyses differentiate the selective changes that appear to be shared among East Asian and Indigenous American populations from those that are unique to the Indigenous American populations. For each test, the top 5% of the empirical distribution of results was examined and pigmentation genes falling in this tail of the distribution were considered to show statistically significant evidence of selection. Based on these analyses, 12 genes - *ADAM17, POMC, AP3B1,OPRM1, SILV, OCA2/HERC, PLDN, MYO5A, RAB27A, CYP1A2, ATRN*, and *ASIP* - show evidence of selection unique to the Indigenous American populations. Many of these genes have known functional roles in melanogenesis and suggest potential pathways responsible for the observed differences in skin pigmentation between Indigenous American and Old World populations.

## 661/W/Poster Board #319

**Molecular evolutionary study of the ionotropic glutamate-receptor gene family as schizophrenia susceptibility genes: human-specific non-neutral pattern observed in *GRIN2B* upstream region.** *H. Shibata[1], K. Watanabe[1], K. Tanaka[1], H. Goto[2], S. Mano[3], O. Takenaka[4], Y. Fukumaki[1].* 1) Medical Inst Bioregulation, Kyushu University, Fukuoka, Japan; 2) Center for Comparative Genomics and Bioinformatics, Pennsylvania State University, State College, PA, USA; 3) Graduate School of Natural Science, Nagoya City University, Aichi, Japan; 4) Primate Research Institute, Kyoto University, Aichi, Japan.

Schizophrenia is a common psychiatric disease with relatively strong genetic background ($\lambda_s$ = 10). Typical adolescent onset characterized by loss of sociality suggests severe reduction of fitness. However, the disease prevalence is highly stable to be ~1% in any human populations. We hypothesized that the schizophrenia susceptibility alleles are maintained by non-neutral process such as balancing selection. To test this hypothesis, we resequenced the upstream region (3-5 kb) of fourteen ionotropic glutamate receptor genes: *GRIN1*, *GRIN2A*, *GRIN2B*, *GRIN2C*, *GRIN2D*, *GRIA1*, *GRIA2*, *GRIA3*, *GRIA4*, *GRIK1*, *GRIK2*, *GRIK3*, *GRIK4* and *GRIK5* using 50-72 unrelated humans and 24-50 unrelated chimpanzees as non-human controls. From the neutrality tests for the overall regions, we identified significant negative values of Tajima's *D* in *GRIA2* (-2.14) and *GRIK5* (-1.94) in humans suggesting human-specific positive selection. By window plot analyses, we identified a significant positive value of Tajima's *D* (+2.19) only in humans at the 1.5 kb upstream region of *GRIN2B*. Since population contraction is unlikely for humans, this positive Tajima's *D* is a signature of balancing selection specific to human lineage. The region harbors a common SNP, rs1019385 of which the most significant association with schizophrenia has been shown by meta-analysis (Allen et al 2008). By coalescent simulation we dated the divergence of two common haplogroups in the region to be 1.3 MYA that is much older than the genome average TMRCA, 0.8 MYA. Therefore, we conclude that the *GRIN2B* upstream region has been subject to balancing selection associated with schizophrenia as well as human brain function.

## 662/W/Poster Board #320

**Genotype and allele of the rs1799983 (Glu298Asp) polymorphism in the endothelial nitric oxide synthase gene are associated with high altitude adaptation in Quechua population.** *P. Wang[1], A. Ha[2], KK. Kidd[3], MS. Koehle[1], JL. Rupert[1].* 1) School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Biochemistry and Molecular Biology, University of British Columbia, Vancouver, BC, Canada; 3) Department of Genetics, the Yale University School of Medicine, New Haven, CT, USA.

PURPOSE: Human high altitude adaptation involves a number of physiological and anatomical changes that serve to maximize the uptake, transport and delivery of oxygen. There is substantial evidence that Andean populations are genetically adapted to life at high altitude. Nitric oxide (NO)-dependent endothelial function plays an important role in vascular homeostasis and the exhaled NO level of highlanders has been reported to be 25% - 200% greater than that of lowlanders prompting the postulation that changes in NO mediated hypoxia responses play in evolutionary adaptation to high altitude. Endothelial-derived nitric oxide synthase (eNOS) is the main source of NO in blood vessels. Several polymorphisms in eNOS have been shown to affect the expression, enzyme activity, and concentration of exhaled NO. Our study investigated possible associations between variants of the rs1799983 (Glu298Asp) polymorphism of eNOS and high altitude adaptation. METHODS: Seventy-eight highlanders (Quechua) and fourty-nine lowlanders (Maya) were recruited. DNA was collected from buccal cells. The genotype and allele frequencies were compared between highlander and lowlander groups by Chi-Square analysis. RESULTS: Positive associations were found between variants and genotypes of the rs1799983 (Glu298Asp) polymorphism in eNOS and high altitude adaptation. Both the G allele and GG genotype of the polymorphism were over-represented in Quechua highlanders ($p = 0.01$ for allele frequency; $p = 0.03$ for genotype frequency). CONCLUSIONS: Our data suggest that the G allele and GG genotype may have played a role in high altitude adaptation in the Quechua population.

**Ancestry variation along the genome in Latin American populations and implications for recent natural selection.** *S. Wang[1], M. Burley[2], P. Sabeti[1], A. Ruiz-Linares[2].* 1) FAS Center for Systems Biology, Harvard University, Cambridge, MA; 2) Department of Genetics, Evolution and Environment, University College London, London.

Latin American populations stem from the admixture starting about 500 years ago of Europeans, Africans and Native Americans. Extreme deviation in ancestry estimates at certain genome locations (relative to the genome-wide average) could reflect the action of recent natural selection. We evaluated the distribution of ancestry estimates along the genome using 678 microsatellite markers in 249 individuals sampled from 13 admixed populations across Latin America. We found a significant deviation in ancestry at two genomic locations with more than four times standard deviations from the genome-wide mean: an excess of European ancestry at 14q32 (Z-score = 4.14), and an excess of African ancestry at 6p22 (Z-score = 4.71). These deviations in ancestry were observed in the analysis of the combined dataset as well as in most of the individual populations examined. We showed that our findings are robust to the Native American ancestry populations used. We discussed the implications for recent natural selection in the context of the unique history of the New World, as well as the possibility of artifacts.

**A powerful extended homozygosity score test to detect positive selection in genome-wide scans.** *M. ZHONG[1], K. LANGE[2], J. PAPP[2], R. Fan[1,3].* 1) Department of Statistics, Texas A&M University, College Station, TX; 2) Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 3) Department of Epidemiology, MD Anderson Cancer Center, University of Texas, Houston, TX.

Extended stretches of homozygosity serve as a surrogate indicator of recent positive selection. We developed, evaluated and applied three new tests, extended genotype-based homozygosity test (EGHT), hidden Markov model test (HMMT) and extended haplotype-based homozygosity test (EHHT) to detect excess homozygosity in genome-wide scans. All three assume random mating and Hardy-Weinberg equilibrium but different level of linkage disequilibrium (LD) under null hypothesis. The EGHT postulates linkage equilibrium, the HMMT allows pair-wise LD but no higher order interactions, and the EHHT allows arbitrary LD. In essence, we started from a measure of extent of homozygosity, calculated its mean and variance via different routes under the corresponding null hypotheses and formulated test statistic based on central limit theorem. Comparing to other haplotype-based methods which lack of clear distribution, the test statistic is asymptotically normal and that makes analysis and application more straightforward. The assumption of multi-locus LD endows the EHHT with a conservative nature and it is confirmed by our preliminary simulation study. Therefore, we focused our consequent study on the EHHT. By running coalescent simulations, we were able to demonstrate that the EHHT leads to appropriate false positive rates under various demographic models in population genetics. We also showed that the EHHT has higher or similar power comparing with the existing popular methods. We applied the EHHT method to HapMap phase II data and replicated previous findings of candidate regions under positive selection. Moreover, by applying multiple filtering criteria including high EHHT scores and population differentiations, we identified 15 new candidate regions which may undergo recent selection and deserve further investigation.

## 665/W/Poster Board #323

**A genome-wide scan for highly polymorphic loci suggests that balancing selection has acted on reproductive and metabolic processes.** *A. Fujimoto[1,2], M. Kato[1,3], N. Hosono[1], M. Kubo[1], Y. Nakamura[1], T. Tsunoda[1].* 1) Ctr Genomic Med, Riken, Japan; 2) Data Analysis Fusion Team, Computational Science Research Program, RIKEN, Japan; 3) Cold Spring Harbor Laboratory, USA.

Besides positive selection, balancing selection is one of the central interests of evolutionary genetics. To identify loci that have been influenced by balancing selection, we scanned for highly variable loci using resequencing data from exonic and promoter regions of 24 Japanese individuals released by the JSNP project. To normalize the mutation rate, we utilized the ratio of number of SNPs per individual to divergence between human and macaca as a measure of polymorphism of each locus. We found the *OVCH1* gene, which is expressed on the egg surface, to have high polymorphism. We also resequenced the *OVCH1* region using HapMap-CHB+JPT individuals and observed an excess of intermediate allele frequencies. We also observed that genes with GO (gene ontology) terms of "heat generation", "negative regulation of blood pressure", and "thymic T cell selection" tend to have high polymorphism. These results suggest that several genes with metabolic and reproductive functions evolved by balancing selection.

## 666/W/Poster Board #324

**Identifying genes under selection using generalized linear mixed models.** *K.E. Eilertson[1], J. Booth[2], C.D. Bustamante[2].* 1) Statistics, Cornell University, Ithaca, NY; 2) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Of significant interest to geneticists is identifying genes under selection and quantifying the selection force. We present an approach for identifying genes under selection using polymorphism and divergence data from synonymous and nonsynonymous sites within genes. Generalized linear mixed models are used to identify the effect of the relationship between polymorphic/fixed mutations and synonymous/nonsynonymous sites on the expected number of mutations. The estimated effects can then be used not only to estimate the selection coefficient, $\gamma$, but also the mutation rate, $\theta$, the proportion of non-lethal mutations, *f*, and the time to the most recent common ancestor, $\tau$, both genome-wide and gene by gene. The model is fit in both the Bayesian and frequentist settings using Markov Chain Monte Carlo Methods in WinBUGS and the lme4 package in R. The proposed methodology was designed to analyze several thousand genes between two species. Using simulated data we compare our method to existing methods for detecting genes under selection, the MK statistic, MKprf and MKprfk. The simulations showed our method to be a significant improvement in both power and false positive rates. We then apply these methods to human v chimp data as well as D. simulans v D. melanogaster . Our method found many human genes under selection that are involved in neurological and cardiological functions, along with DNA replication and repair, and development.

## 667/W/Poster Board #325

**Involvement of the Modifier Gene of a Human Mendelian Disorder in a Negative Selection Process.** *I. Jéru[1], H. Hayrapetyan[2], P. Duquesnoy[1], E. Cochet[1], J.L. Serre[3], J. Feingold[1], G. Grateau[1], T. Sarkisian[2], M. Jeanpierre[4], S. Amselem[1].* 1) INSERM U.933, Université Paris 6 Pierre et Marie Curie, Hôpital Armand-Trousseau, Paris, France; 2) Center of Medical Genetics and Primary Health Care, National Academy of Sciences, Yerevan, Armenia; 3) Equipe Structure-Fonction, EA 2493, Université de Versailles-Saint Quentin en Yvelines, Versailles, France; 4) INSERM U.567, Faculté de médecine, site Cochin, Paris, France.

Identification of modifier genes and characterization of their effects represent major challenges in human genetics. SAA1 is one of the few modifiers identified in humans. This gene is known to influence the risk of renal amyloidosis (RA) in patients with familial Mediterranean fever (FMF), a Mendelian autoinflammatory disorder associated with mutations in MEFV. Indeed, the SAA1 alpha homozygous genotype and the p.Met694Val homozygous genotype at the MEFV locus are two main risk factors for RA. Here, we investigated Armenian FMF patients and controls from two neighboring countries: Armenia, where RA is frequent (24%), and Karabakh, where RA is rare (2.5%). Sequencing of MEFV revealed similar frequencies of p.Met694Val homozygotes in the two groups of patients. However, a major deficit of SAA1 alpha homozygotes was found among Karabakhian patients (4%) as compared to Armenian patients (24%) (p=5.10-5). Most importantly, we observed deviations from Hardy-Weinberg equilibrium (HWE) in the two groups of patients, and unexpectedly, in opposite directions, whereas, in the two control populations, genotype distributions at this locus were similar and complied with (HWE). The excess of SAA1 alpha homozygotes among Armenian patients is readily explained by the recruitment of patients with severe phenotypes. In contrast, a population-based study revealed that the deficit of alpha/alpha among Karabakhian patients results from a negative selection against carriers of this genotype. This study, which provides new insights into the role of SAA1 in the pathophysiology of FMF, represents the first example of deviations from HWE and selection involving the modifier gene of a Mendelian disorder.

## 668/W/Poster Board #326

**Patterns of correlation between genetic ancestry and facial features suggest selection on females is driving differentiation.** *D.K. Liberton[1], K.A. Matthes[1], R. Pereira[2], T. Frudakis[3], D.A. Puts[1], M.D. Shriver[1].* 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) Catholic University of Brazil, Brasilia, Brazil; 3) DNAPrint Genomics, Sarasota, FL.

Human facial features show extensive variation within and among populations. By investigating the relationship between dimorphism in facial features and genetic ancestry in different populations, we can explore the roles of sexual and natural selection on the human face. We measured sexual dimorphism in facial traits while controlling for the effects of overall size differences and then tested for interactions between sex and genetic ancestry. The study sample consists of 254 subjects (n=170 females, n=84 males), ages 18-35, showing West African and European genetic ancestry sampled in the United States and Brazil. Maximum likelihood genetic ancestry estimates were determined from 176 ancestry informative markers (AIMs), which allowed for the proportional estimation of genetic ancestry from four parental populations (West African, European, East Asian, and Native American). Three-dimensional photographs of faces were acquired using the 3dMDface imaging system (Atlanta, GA). 22 standard anthropometric landmarks were placed on each image and XYZ coordinates were collected. All 231 possible pairwise inter-landmark distances were calculated and then log transformed. Using the pairwise distances, we tested whether some distances were larger in one sex than the other, having taken size into account, in a) African Americans sampled in the United States, b) Brazilians sampled in Brazil, and c) the combined African American and Brazilian sample. We found that several pairwise distances differed between the sexes. For example, the distance from the brow to nasal bridge was found to be more than 5% larger in females than males. We then tested for an interaction between sex and genetic ancestry by testing for differences in the slopes of the ancestry association between males and females. Although the pattern differed slightly between samples, after Bonferroni correction many correlations were the found to be same in both sexes. However, females in all three samples had many additional significant correlations that were not seen in males, while males had very few correlations that were not found in females. The results of these analyses suggest that selection on females is driving the differentiation in facial features among populations.

**Selection Mapping to Identify West Nile Virus Susceptibility Loci.** *A.W. Bigham, M.J. Bamshad.* Department of Pediatrics, University of Washington, Seattle, WA.

The most common strategy for identifying disease susceptibility alleles is association mapping. This strategy relies on choosing candidate genes based on a priori information about disease pathogenesis, effects in animal models, etc. When such information is unavailable or too many candidate genes exist to screen cost-effectively, this approach is problematic. Consequently, there is keen interest in developing more efficient strategies to find and prioritize candidate alleles. Alleles that influence phenotypic change in a particular population must be functionally different than wild-type alleles, and thus they are likely to have been the target of natural selection. Here, we applied and evaluated the selection mapping approach to identify West Nile Virus (WNV) susceptibility candidate loci in a panel of immune response genes using 31 African, 31 European, and 31 East Asian individuals. Twenty-nine innate and adaptive immune genes were sequenced in the three population samples to detect evidence of local adaptation. We applied three tests that detect departures from neutrality including Tajima's *D*, Fu and Li's *D**, and *F** to assess population specific patterns of variation. Next, in order to prioritize alleles to be tested for association with WNV disease, single nucleotide polymorphism (SNP) - specific $F_{ST}$ values were computed for each allele. At a majority of the loci analyzed, Africans showed evidence of putative balancing selection. For the East Asians and Europeans, evidence of both balancing selection and directional selection was detected. We were especially interested in identifying candidate loci in Europeans because this population will make up the majority of both cases and controls in future association studies. Evidence of positive selection was found for a group of related genes, *OAS1*, *OAS2*, and *OAS3* in Europeans. Moreover, SNPs in *OAS1* and *OAS3* exhibit SNP-specific $F_{ST}$ values falling in the top 5% of the empirical distribution generated from this dataset. Interestingly, significant associations between WNV pathogenesis and SNPs in *OAS1* have been found previously. In summary, we have identified selection nominated candidate genes for WNV susceptibility studies. The results of this study indicate that using the selection mapping approach to identify susceptibility loci can be a powerful tool to rank and prioritize candidate gene lists, but that it may miss important susceptibility loci.

## 670/W/Poster Board #328

**Birth of New Exons in Primates.** *L. Lin[1], S. Shen[2], J. Peng[1], S. Sato[1], A. Tye[1], J. Cai[3], B. Davidson[1,4,5], Y. Xing[1,6].* 1) Internal Medicine, University of Iowa, Iowa City, IA; 2) Department of Biostatistics, University of Iowa, Iowa City, IA; 3) Department of Biology, Stanford University, Stanford, CA; 4) Department of Molecular Physiology and Biophysics, University of Iowa, Iowa City, IA; 5) Department of Neurology, University of Iowa, Iowa City, IA; 6) Department of Biomedical Engineering, University of Iowa, Iowa City, IA.

Transposable elements (TEs) are major sources of new exons in higher eukaryotes. Almost half of the human genome is derived from transposable elements, and many types of transposable elements have the potential to exonize. We conducted a large-scale analysis of human exons derived from two classes of TEs - the primate-specific Alu retrotransposons, and mammalian-wide interspersed repeats (MIRs). Using exon array data of 330 Alu-derived exons and 328 MIR-derived exons, as well as RT-PCR analysis of 77 exons in 10 tissues, we identified numerous Alu and MIR exons with constitutive or tissue-specific splicing patterns. Interestingly, exon array data suggest substantially higher splicing activities of MIR exons as compared to Alu exons. This appears to be a universal difference between exons derived from young and old transposable elements, as it is also observed when comparing Alu exons to exons derived from LINE1 and LINE2, two other groups of old transposable elements. In several human genes (e.g. SEPN1, TTLL6), the tissue-specific splicing of TE-derived exons results from a human-specific splicing change after the divergence of humans and chimpanzees. Together, this study significantly expands current knowledge about functions and evolution of new exons. Our data imply that with sufficient evolutionary time, numerous new exons could evolve beyond the evolutionary intermediate state and contribute functional novelties to modern mammalian genomes.

## 671/W/Poster Board #329

**The Utility of Information Content Analysis in combination with Evolutionary Analysis in Genomic Applications.** *G. Wyckoff[1], M. Yang[1], A. Solidar[2].* 1) Div Molec Biol & Biochemistry, Univ Missouri, Kansas City, Kansas City, MO; 2) Bioinformatica, LLC Oakland, CA.

A common problem in molecular comparative genomics is the identification of genes that are under positive, adaptive selection. Such genes are likely to be crucial for speciation, species differentiation, and functional specialization. We propose a novel approach to help distinguish between different evolutionary trajectories in comparative molecular genomic studies. Information theory allows measurement of the gain or loss of entropy within a sequence when married to evolutionary methodologies, and combined with evolutionary approaches may allow us to distinguish between genes and genetic elements that are under positive selection from those that are evolving neutrally or under constraint. We here show the results from three different analyses performed using the VaSSA software from Bioinformatica, LLC. First, we examined the difference in information content between 500 coding genes and carefully aligned pseudogene homologs of recent derivation. Secondly, we examined single nucleotide polymorphism (SNP) data from humans and rodents. Lastly, we examined several known rapidly-evolving genes and show their information content profile and how it differs from several genes with more constrained functions. The methodology presented here has utility for the analysis not only of coding region data, but also non-coding regions and other genomic segments. We are able to show that we can successfully identify many known genes and SNPs that are clinically relevant, and present an integrated method for testing for SNP function in large, poorly annotated genomic regions. We'd like to acknowledge Bioinformatica, LLC and the NIH for funding of this work.

## 672/W/Poster Board #330

**Evolution of MCPH1 in catarrhine and platyrrhine primates.** *M. Raveendran[1], J. Rogers[1,2].* 1) HGSC, Baylor College of Medicine, Houston, TX; 2) Southwest National Primate Research Center, San Antonio, TX.

Primary microcephaly (MCPH) is a neurodevelopmental disorder characterized by smaller-than-normal brain size with architecturally normal brain and nonprogressive mental retardation in humans. MCPH is genetically heterogeneous. Mutations in seven different loci (MCPH1-MCPH7) can lead to microcephaly. Cross-species comparisons of one gene (microcephalin, MCPH1) have shown that this locus exhibits adaptive sequence changes that may be involved in the significant brain enlargement from lesser apes to great apes and humans. We sequenced 6379 bp covering exons 2-14 (2507 bp, 834 amino acid) and the flanking intron segments of the MCPH1 gene from 48 individuals from five species of Old World (catarrhine) and New World (platyrrhine) monkeys (40 Papio hamadryas from three subspecies, and two animals each from Macaca nemestrina, M. fascicularis, Callithrix jacchus and Saimiri boliviensis). Our analysis identified 24 amino acid changes that distinguish the two New World monkeys from all Old World monkeys and apes, and 81 amino acid changes differing between the two New World monkeys. We found 22 amino acid changes that distinguish baboons from all macaques and various changes that are unique to each Old World monkey species and subspecies. These results indicate that the rapid rate of MCPH1 evolution observed across the human, great ape and lesser ape lineages is also true for Old World and New World monkeys. This gene shows rapid amino acid evolution in primate lineages that have not exhibited the rapid expansion of brain size observed in human evolution.

## 673/W/Poster Board #331

**Cruciform-forming Inverted Repeats Appear to have Mediated Many of the Microinversions that Distinguish the Human and Chimpanzee Genomes.** *H. Kehrer-Sawatzki[1], J. Kolb[1], N.A. Chuzhanova[2], J. Högel[1], K.M. Vasquez[3], D.N. Cooper[4], A. Bacolla[3].* 1) Human Genetics, University of Ulm, Ulm, Germany; 2) School of Computing, Engineering and Physical Sciences, University of Central Lancashire, Preston UK,; 3) Department of Carcinogenesis, University of Texas M.D. Anderson Cancer Center, Smithville, Texas, USA; 4) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, UK.

Submicroscopic inversions have contributed significantly to the genomic divergence between humans and chimpanzees over evolutionary time. Those microinversions which are flanked by segmental duplications (SDs) are presumed to have originated via non-allelic homologous recombination between SDs arranged in inverted orientation. However, the nature of the mechanisms underlying those inversions which are not flanked by SDs remains unclear. We have investigated 35 such inversions, ranging in size from 51-nt to 22056-nt, with a view to characterizing the DNA sequences in the breakpoint-flanking regions. Using the macaque genome as an outgroup, we determined the lineage specificity of these inversions and noted that the majority (N=31; 89%) were associated with deletions (of between 1-nt and 6754-nt) immediately adjacent to one or both inversion breakpoints. Overrepresentations of both direct and inverted repeats, ≥6-nt in length and capable of non-B DNA structure formation, were noted in the vicinity of breakpoint junctions suggesting that these repeats could have contributed to double strand breakage. Inverted repeats capable of cruciform structure formation were also found to be a common feature of the inversion breakpoint-flanking regions, consistent with these inversions having originated through the resolution of Holliday junction-like cruciforms. Sequences capable of non-B DNA structure formation have previously been implicated in promoting gross deletions and translocations causing human genetic disease. We conclude that non-B DNA forming sequences may also have promoted the occurrence of mutations in an evolutionary context, giving rise to at least some of the inversion/deletions which now serve to distinguish the human and chimpanzee genomes.

## 674/W/Poster Board #332

**Empirical measurement of gene conversion rate in primates.** *R. Assis, A.S. Kondrashov.* Bioinformatics, Univ Michigan, Ann Arbor, MI.

Gene conversion prevents divergence of duplicate genes via recombination. Here, we examine the properties of gene conversion by using a comparative genomics approach on noncoding sequences of human, chimpanzee, and orangutan. We explore the minimum and maximum lengths of and distances between gene conversion tracts. For the first time, we are able to measure the rate of gene conversion in noncoding sequences.

## 675/W/Poster Board #333

**Ferritin L RNA Sequences on Pairs of Human Chromosome Pairs Reflect Genome Duplication.** *R. Lebo[1], K. Bosnick[2].* 1) Dept Pathology, Akron Children's Hosp, Akron, OH; 2) Hathaway Brown, Cleveland, OH.

The 6,000,000,000 basepair human genome and the other similar size mammalian genomes are hypothesized to be the product of two genome duplications between primitive fish and mammals. Given that the genome duplicated twice at different times in ancestoral organisms predicts that pairs of similar size chromosomes arose during the most recent genome duplication after prior changes made the first pair of duplicated chromosomes different in size. The most recent duplication of the human genome was proposed to be reflected in the current 46 human chromosomes by the similar size and banding patterns of human chromosome pairs of similar shaped pairs of "homeologous" chromosomes (Comings, Nature, 1972). This hypothesis was further tested by studying the sequences and distribution of the shorter ferritin L RNA that inserted into multiple locations throughout the genome at different times. Typically these nonfunctional sequences would have escaped selective pressure while serving as a means to determine how long ago these sequences inserted and whether duplication occurred when similar size chromosomes doubled in number. The previously published relationship, function, and expression of the human aldolase A, B, C, and pseudogene supports two genome duplications in human homeologous chromosome pair 9 and 10 and chromosome pair 16 and 17 (Tolan et al, 1987). Studies of similar ferritin L (ferritin L; OMIM #134790) gene messages inserted into multiple other chromosome locations further supports genome duplication. The ferritin L gene had been mapped with the most similar sequences onto three chromosomes (Lebo et al, 1985), but only the gene on chromosome 19 is active (Worwood et al, 1985). The most identical inserted messages from this active gene have been found on chromosomes 19, 20, and X, confirming the chromosome sorting results. This study found a ferritin L mRNA most likely inserted into the short arm of an ancestral chromosome 19/20 that replicated and resulted in the current duplicated copies on homeologous chromosome pair 19 and 20 to suggest the similar size chromosomes 19 and 20 share a common ancestral chromosome. Furthermore, ferritin L messages that previously inserted at additional genomic sites with no negative functional consequences now serve as additional markers. The results of analyzing all these sequence homologies support the ancestral replication of other similar size human chromosomes.

## 676/W/Poster Board #334

**Rickettsia prowazekii shares homology with human sequences that have implications in pathogenesis and vaccine development.** *J. Dong.* Molec Diagnostics/Pathology, Univ Texas Med Branch, Galveston, TX.

Rickettsiae are obligately intracellular gram-negative, arthropod-transmitted bacteria that cause life-threatening rickettsioses such as Rocky Mountain spotted fever, typhus fever, Mediterranean spotted fever, and murine typhus. Rickettsiae are classified into two groups; typhus group (TG), which includes R. prowazekii and R. typhi, and the spotted fever group (SFG), which includes R. rickettsii, R. conorii, and R. sibirica. Rickettsiae grow initially in undetermined cell type(s) in the bite site and spread to regional lymph nodes where they multiply prior to spreading to the blood stream. The main pathology is widespread endothelial injury resulting in increased vascular permeability and microvascular leakage. Despite the availability of effective antibiotic therapy, rickettsial infection has a high mortality rate. Purpose: It is known that during evolution, nucleotide and protein sequences that have essential cellular functions are conserved. The significance of homologous sequences in disease pathogenesis and vaccine safety has not been firmly determined. The purpose of the study is to identify homology between R. prowazekii and human sequences that may be important in the pathogenesis and vaccine development of R. prowazekii. Methods: The genome of R. prowazekii contains 834 protein-coding genes. We performed sequence comparison of Rickettsia prowazekii (strain Madrid E, locus NC_000963) with human sequences using NCBI BLAST search. Summary of Results: We identified regions of matching sequences in several human proteins, supporting the notion that the genome sequence of R. prowazekii has a mitochondrial connection. The chief culprit antigens of circulating antimitochondrial antibodies (AMA) identified in primary biliary cirrhosis patients share homology with R. prowazekii. Some of the proteins identified are predicted to harbor strong cytotoxic T lymphocyte (CTL) epitopes.

### 677/W/Poster Board #335

**Coevolution causes allelic association between physically unlinked gamete receptor genes.** *R.V. Rohlfs[1], W.J. Swanson[1], B.S. Weir[2].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Biostatistics, University of Washington, Seattle, WA.

Coevolving interacting genes undergo complementary mutations to maintain their interaction. If coevolving genes are polymorphic, different allele combinations may interact differently, conferring varying degrees of fitness. This differential fitness would result in selection for allele matching. In a population, excess matched alleles in a gene pair could be observed as linkage disequilibrium (LD)-like allelic association. Allelic association is usually thought to be a result of physical linkage or population structure however, intense selection for allele matching may also maintain allelic association.

If coevolving genes are physically unlinked, traditional gametic LD is not an appropriate measure of allelic association. We propose both standard composite linkage disequilibrium (CLD) and novel genotype association (GA), as measures for allelic association. Using a simple selective model, we calculated the power of these tests. Our results indicate the tests can feasibly detect allelic association when there is intense selective pressure. We apply CLD and GA tests to the putatively coevolving gamete recognition genes ZP3 and ZP3R. There is evidence that these unlinked polymorphic genes interact and are under positive selection, making them candidates for coevolution-induced allelic association.

We observe unusual allelic association between ZP3 and ZP3R as compared to random unlinked gene pairs. Since we compare ZP3-ZP3R to other gene pairs in the same individuals, the ZP3-ZP3R association can not be attributed to population structure. Our results support a biological instance of selection for allele matching between unlinked loci causing allelic association in a population. The observation of this selection is surprising since it requires an unusually intense selective coefficient, but that is reasonable in fertilization. This study shows that selection for allele matching can drive allelic association in a modern human population and that selection can be detected using CLD and GA tests. We are currently applying the CLD and GA tests genome-wide to estimate the number of loci associated due to selection for allele matching and to identify classes of coevolving genes.

### 678/W/Poster Board #336

**The presence of a purine rich 6-mer is likely correlated with the occurrence of recombination events.** *H.R. Johnston[1], D.J. Cutler[2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322.

We have previously demonstrated that apparent recombination hotspots could be plausibly explained not by elevated rates of recombination, but relatively uniform recombination rates combined with bottlenecks in human demographic history. Under this model recombination "hotspots" are not generally regions of increased recombination "rate", but are instead regions of the genome that are unusually old, and have therefore had more time to accumulate recombination events in their history. Here we identify a purine rich 6-mer likely associated with the occurrence of recombination in humans.

To do this, we analyze two complimentary datasets: the apparent recombination "hotspots" identified by McVean et al, from population data, and the regions of known recombination identified by Coop et al. from large pedigrees. We analyze each dataset independently, and find the same pattern in both data sets. Recombination "hotspots" and regions of known recombination event both show an excess of purine rich 6-mers, and especially G-rich 6-mers over randomly chosen regions, matched to overall GC content. This pattern is highly statistically significant, representing an approximately 10-20% excess of G-rich 6-mers over random regions. When the top 25 motifs are analyzed by MEME, a motif finding tool, a very strong and simple motif is found: (A/G)GG(A/G)AG.

To differentiate whether or not this motif is a merely a statistical artifact of regions of high recombination, or a motif associated with the initiation of recombination, we ask for the location of motif within the "hotspots" and windows of known recombination. We show that the 10-20% excess of this motif is strongly associated with center of the regions, consistent with the motif being a recombination initiation signal.

The implication of this work is that the large-scale differences in recombination rate between regions of the genome could well be due to increased or decreased levels of the motif on a macro scale. Apparent "hotspots" themselves, however, seldom have more than a 10-20% increase in this motif above random sequence. Notably, alpha-satellite DNA, associated with centromeric regions with virtually no recombination, is completely free of this motif.

### 679/W/Poster Board #337

**Effect of natural selection on North Asian mitochondrial haplogroup variation.** *M. Derenko[1], B. Malyarchuk[1], T. Grzybowski[2], G. Denisova[1], U. Rogalla[2], M. Perkova[1], I. Dambueva[3], I. Zakharov[4].* 1) Genetics Laboratory, Institute of Biological Problems of the North, Russian Academy of Sciences, Magadan, Russian Federation; 2) Forensic Medicine Institute, the Ludwik Rydygier Medical College, the Nicolaus Copernicus University in Torun, Bydgoszcz, Poland; 3) Institute of General and Experimental Biology, Russian Academy of Sciences, Ulan-Ude, Russian Federation; 4) Animal Comparative Genetics Laboratory, Vavilov Institute of General Genetics, Russian Academy of Sciences, Moscow, Russian Federation.

The human mtDNA exhibits striking, region-specific sequence variation. The regional distribution of mtDNA haplogroups have attributed either to genetic drift assisted by purifying selection (Elson et al., 2004; Kivisild et al., 2006; Ingman, Gyllensten, 2007) or to an adaptation to different climates (Mishmar et al., 2003; Ruiz-Pesini et al., 2004). In an attempt to study the mode of selection in mtDNA variation in human populations we sequenced and analyzed 211 complete mtDNA sequences belonging to haplogroups A, C and D accounting in total for 49.3% of mtDNA lineages in North Asia. The North Asian haplogroups A, C and D showed a highly significant deviation from the standard neutral model as well as a bell-shaped distribution of pairwise differences consistent with rapid population expansion. To determine the overall importance of selection in shaping human mtDNA variation we calculated Ka/Ks ratio both for aggregated mtDNAs and for 13 protein-encoding genes within particular haplogroups (A, C and D). We have found a prevalence of Ks over Ka within haplogroups A, C and D indicating the influence of negative selection on mtDNA during evolution. Consistent with some previous reports we have found the Ka/Ks ratio for the ATP6 gene to be the highest among the North Asian sequences suggesting thereby that this gene has been subject to positive selection. We have also observed a set of genes with a somewhat higher Ka/Ks ratio relative to other mitochondrial genes - CO2 for haplogroup A, ND3 and ND4 for haplogroup C. Meanwhile the other approach taking into account the difference in NS/S ratios between the haplogroup-associated and private substitutions (Elson et al., 2004) shows the significant departures from neutrality only for haplogroup D and its subhaplogroup D4. Furthermore single gene analysis reveals the relatively strong influence of negative selection only in CYTb gene within haplogroup D (p=0.011, NI=14.1). In general, our results indicate that there is an evidence for both gene-specific and lineage-specific variation in selection acting on North Asian mtDNAs. This study was supported by Russian Foundation for Basic Research grant 07-04-00445 and by Far-East Branch of the Russian Academy of Sciences grants 09-III-A-06-220 and 09-I-P-23-10.

### 680/W/Poster Board #338

**Constructing the initial map of transmission distortion based on high resolution haplotype data.** *L. Deng[1,2], D. Zhang[2,3], E. Richards[4], Y. Wang[5], J. Fang[5], F. Long[5], X. Tang[1].* 1) Faculty of Basic Medical College, Nanchang University, Nanchang, China; 2) Beijing Inst Genomics, Beijing, China; 3) Graduate School of the Chinese Academy of Sciences, Beijing, China; 4) Department of Biology, College of Life Sciences, Brigham Young University, Provo UT 84602, USA; 5) The laboratory center of Medicine, Nanchang University, Nanchang, China.

Transmission distortion (TD) is defined as a significant departure from Mendelian predictions of genes or chromosomes to offspring. While many biological processes have been implicated, there is still much to be understood about TD in humans. Here we present our findings from a genome-wide scan for evidences of TD using haplotype data of 60 trio families from the International HapMap Project. Fisher's exact test was applied to assess the extent of TD in 629,958 SNPs across the autosomes. Based on the empirical distribution of PFisher and further permutation tests, we identified 1,205 outlier loci and 224 candidate genes with TD (137 in Africa and 90 in Europe samples). Most of candidate genes (221/224) were observed in only one of the two populations, indicating an ethnicity-related property of TD. Using the PANTHER gene ontology database, we found 19 categories of biological processes with an enrichment of candidate genes. In particular, the "protein phosphorylation" category contained the largest number of candidates in both HapMap samples. Further analysis uncovered an intriguing non-synonymous change in PPP1R12B, a gene related to protein phosphorylation that appears to influence the allele transmission from male parents in the Africa population. Our findings also indicate enrichment for selective signals in genes with TD relative to genomic background and provide new clues for our understanding of TD in humans.

**DIVERGENOME: a bioinformatics tool to assist the analysis of genetic variation.** *W.C.S. Magalhães[1], M. Rodrigues[1], B. Araujo[1], M.L. Iannini[1], A.A. Faria-Campos[2], E. Tarazona-Santos[1].* 1) Departamentos de Biologia Geral e Bioquímica, Instituto de Ciências Biológicas, Universidade Federal de Minas Gerais, Brazil; 2) Departamento de Ciências da Computação, Instituto de Ciências Exatas, Universidade Federal de Minas Gerais, Brazil.

We developed a bioinformatic tool (DIVERGENOME) to assist investigators in data storage and analysis for population genetics and genetic epidemiology studies. The platform contains two components. The first component, DIVERGENOMEdb, is a relational database developed using the open source database management system MySQL. It allows to safely storage individual genotypes for three different types of data: contigs (resulted from re-sequencing projects), SNPs/INDELs and microsatellites. Genotypes may be linked to a description of protocols used to generate these data. Individuals may be linked to populations, as well as to individual phenotypic information that may be collected in genetic epidemiology studies, using different kinds of variables: binary, numerical or categorical. The access to DIVERGENOMEdb is controlled by a hierarchical system of passwords that include different privileges for administrators, principal investigators (PIs) and researchers linked to a specific PI. The second component of the platform, DIVERGENOMEtools, is a set of informatics tools (developed in PERL) that allow an easy preparation of input files for commonly used population genetics and genetic epidemiology software, departing from output files obtained from previous analyses. These programs include: PHASE, Structure, Arlequin, Haploview, DNAsp, Haplostats, as well as tools developed for R environment. Moreover, a web interface allows investigators to interact with DIVERGENOMEdb and DIVERGENOMEtools. Currently, DIVERGENOME is being used to assist studies of candidate genes studies about genetic susceptibility to gastric cancer in Latin American populations; population genetics studies from admixed populations of the Minas Gerais State (Brazil), and public data from the HapMap, SNP500Cancer and the HGDP projects (which have been used in ours projects for comparative purposes). We also use DIVERGENOME to storage and facilitate analyses of simulated databases generated under different evolutionary scenarios using coalescent simulations. Financial Support: Brazilian agencies CAPES-Ministry of Education, FAPEMIG and CNPq.

## 682/W/Poster Board #340

**CD4 INTRAGENIC SNPS ASSOCIATE WITH HIV-2 PLASMA VIRAL LOAD AND CD4 COUNTS IN A COHORT FROM GUINEA-BISSAU, WEST AFRICA.** *G. Sirugo[1,2,3], D.R. Velez[4,2], M.F. Schim van der Loeff[6], S.M. Williams[5], T.L. Edwards[4], W.K. Scott[4], C. Bisseye[1], A. Tacconelli[2], E. Brunetti[2], G. Novelli[2,3], P. Aaby[7], S. Kaye[8], A. Jaye[1], H.C. Whittle[1], A.V. Hill[8], B.J. Hennig[9].* 1) MRC, The Gambia; 2) Unita' di Genetica Medica, Ospedale S. Pietro FBF, Rome, I; 3) Dipartimento di Biopatologia e Diagnostica per Immagini, Tor Vergata University School of Medicine, Rome, I; 4) University of Miami, Miller School of Medicine, USA; 5) Center for Human Genetic Research, Vanderbilt University, USA; 6) Academic Medical Center, Amsterdam, NL; 7) Bandim Health Project, INDEPTH Network, Guinea-Bissau; 8) UCL, London, UK; 9) LSHTM, London, UK.

**Background**: HIV infection rates are variable across Africa with the highest prevalence of HIV-1 in Eastern and Southern Africa and the highest prevalence of HIV-2 in West Africa, particularly in Guinea-Bissau where it exceeds 5% in the adult population vs. 1-2% in other West African countries. We investigated single nucleotide polymorphisms (SNPs) in two genes encoding molecules critical in HIV pathogenesis and disease progression: CD4 and DC-SIGN (encoded by CD209). **Methods**: The study comprised of 29 HIV-1, 143 HIV-2, 30 dually infected individuals and 194 HIV-uninfected controls recruited from a rural area in Guinea-Bissau. We genotyped fourteen CD4 and four DC-SIGN intragenic SNPs. HIV infection, viral load, and CD4 count (for HIV-2), were the outcome measures. Genomic variation was analyzed for single markers and haplotypes by logistic regression and multi-marker analysis by multifactor dimensionality reduction (MDR) for dichotomous outcomes (comparing HIV groups (1, 2, and dual infection) to the control group), and with parametric and nonparametric linear and haplotype type trend regression for continuous outcomes (CD4 count). **Results**: HIV-1 infected subjects were younger than other comparison groups, but no other demographic variable showed differences between groups. Our analyses showed associations of four CD4 single SNPs with 'HIV infection', with the most significant observed for CD4 SNP rs2255301with the model TT v CC&CT (OR=2.50 CI 1.34-4.69, p=0.004). We also saw a haplotype association in DC-SIGN (CD209) (rs8105483- rs2287886-rs4804803, global p=0.03). Within the HIV-2 group we observed single marker (rs11575097 p=0.02) and haplotype (rs8105483-rs2287886, global p=0.02) associations of DC-SIGN SNPs with CD4 counts and a more significant association of plasma viral load with CD4 variants (rs11575097-rs10849523, global p=0.004). **Conclusions**: These results suggest that CD4 gene variation has an effect on HIV-2 infection dynamics. Replication studies in well characterized HIV-1 African cohorts will be warranted to confirm the biological relevance of this finding in HIV-1 infection and progression to AIDS.

## 683/W/Poster Board #341

**The spectrum and frequency of MEFV mutations in newborns from Tbilisi, Georgia.** *C. Oberkanins[1], B. Rauscher[1], I. Korinteli[2], M. Korinteli[2], G. Kriegshaeuser[1], K. Pagava[2].* 1) ViennaLab Diagnostics, Vienna, Austria; 2) Department of Pediatrics and Adolescent Medicine, Tbilisi State Medical University, Georgia.

Familial Mediterranean Fever (FMF) is a hereditary inflammatory disorder caused by mutations in the MEFV gene. Carrier rates are known to be particularly high among Sephardic Jews, Turks, Armenians and Arab populations. The spectrum and frequency of MEFV mutations in Georgia has not at all been investigated so far. Multiplex PCR and reverse-hybridization teststrips (FMF StripAssay) were applied to simultaneously analyze twelve common MEFV mutations in DNA samples from dried blood on filter cards, which had been obtained from 202 unselected newborns at various hospitals in Tbilisi, Georgia. We found 30 samples to be heterozygous and 1 to be compound heterozygous or complex (two mutations in cis). The carrier rate of MEFV mutations (15.3%) was remarkable, although lower than data reported from neighbouring Turkey and Armenia (approx. 20%). The most frequently observed variants were E148Q (15x), M680I G/C (5x) and M694V (4x). Five other MEFV mutations were found at lower incidence (V726A, A744S, R761H: 2x each; P369S, F479L: 1x each). Although low in number, newborns of parents with Armenian roots had a substantially higher carrier rate of MEFV mutations compared to the Georgian population overall. Our data indicate that MEFV mutations, including severe ones such as M680I and M694V, are not uncommon in the Georgian population. Based on these new findings, the awareness for FMF and the availability of appropriate testing should be further promoted in Georgia. (oberkanins@viennalab.-co.at).

## 684/W/Poster Board #342

**Detecting epistatic interactions between human alleles through non-monotonic LD decay.** *A.A. Shpunt[1,2], G.V Kryukov[1], S.R. Sunyaev[1].* 1) Division of Genetics, BWH, Harvard Medical School, Boston, MA; 2) Massachusetts Institute of Technology, Boston, MA.

Importance of epistasis for the evolutionary dynamics of alleles in the human population and for genetics of complex phenotypes remains a controversy. We developed a statistical strategy to search for epistatic selection. Our method is based on detecting non-monotonic decay of linkage disequilibrium (LD). Lewontin and Kojima (1960) demonstrated that epistatic selection can maintain LD if the strength of selection is comparable with recombination rate between the two polymorphic sites. Computer simulations suggest that this effect leads to a non-monotonic LD decay. We designed a statistic to detect non-monotonic LD decay and applied it to SNPs from the HapMap dataset. We compared functionally pre-selected pairs of SNPs such as SNPs in the same gene, SNPs in neighboring co-expressed or co-functioning genes, putative regulatory SNP paired with a coding SNP. We used random SNP pairs separated by the same distance as control. Our analysis suggests potential importance of epistatic interactions in the human genome. We further investigated robustness of our analysis to parameters and to various evolutionary and demographic scenarios using forward simulations.

## 685/W/Poster Board #343

**Evaluation of population-specific reference haplotypes for imputing untyped genotypes.** *K.-K. Kim[1], H.-H. Won[2,3], M.-J. Kim[2], S. Kim[2], K.-A. Lee[4], J.-W. Kim[1].* 1) Department of Laboratory Medicine and Genetics, Sungkyunkwan University School of Medicine, Samsung Medical Center, Seoul, Korea; 2) Samsung Biomedical Research Institute, Seoul, Korea; 3) Department of Bio and Brain Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea; 4) Department of Laboratory Medicine, Yonsei University College of Medicine, Seoul, Korea.

Genome-wide association studies using high density SNP data have reported a number of significant risk alleles affecting disease susceptibilities. However, low genotype relative risk requires a large number of samples to detect association with the disease. Conventional meta analysis of data from different studies is one way to apply the association test more effectively. Another efficient strategy is to genotype a larger number of samples with SNP chips that include fewer SNPs and to impute untyped SNPs or missing genotypes. Recent several association studies showed that imputation could successfully estimate untyped SNPs based on the international haplotype data. Because haplotype structures of a particular population differ greatly from those of other populations, the evaluation of population-specific haplotype references is necessary. We constructed Korean haplotypes based on 90 Korean normal subjects selected from cohort samples of the Korean HapMap using fastPHASE. For comparison of imputation accuracy, we used reference haplotypes of East Asian (CHB+JPT), Caucasian (CEU), and African (YRI) populations from the International HapMap. For a genotype data set, 498 samples were randomly selected from Korean cohort data (KARE, Korean Association Research). To evaluate the accuracy of imputation, we randomly selected a part of the genotype data set for untyped SNPs, used the IMPUTE program to impute the untyped SNPs, and compared imputed genotypes of the SNPs with their real genotypes. We performed imputation on untyped SNPs using reference haplotypes from the four populations. Imputation performance using the CHB+JPT (ethnically close population) haplotypes for imputing the Korean genotype data was superior to those using other ethnic reference haplotypes (CEU and YRI). Moreover, imputation based on the Korean haplotypes was more accurate than that of the CHB+JPT haplotypes. The comparison of the Korean and CHB+JPT haplotypes also showed that minor allele frequency, heterozygosity, and linkage disequilibrium partially influenced the difference in imputation accuracy. These results suggest the need for constructing specific sub-population haplotypes for imputing untyped genotypes of the corresponding population.

**Metabonome Quantitative Trait Linkage Mapping in Organ Extracts using Nuclear Magnetic Resonance Profiling.** *J.-B. CAZIER[1], M.E. DUMAS[2], S. WILDER[3], T. TSANG[4], Y. WANG[4,5], J. NICHOLSON[4], D. GAUGUIER[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OxfordShire, United Kingdom; 2) Centre de RMN à Très Hauts Champs, Ecole Normale Supérieure de Lyon, Villeurbanne, France; 3) European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, United Kingdom; 4) Department of Biomolecular Medicine, Imperial College London, South Kensington Campus, London, United Kingdom; 5) State Key Laboratory of Magnetic Resonance and Atomic and Molecular Physics, Wuhan Centre for Magnetic Resonance, Wuhan Institute of Physics and Mathematics, The Chinese Academy of Sciences, Wuhan, PR China.

Linkage analysis has long been the key method to localize genomic regions associated with a disease phenotype using pedigree information. Lately this method has seen some revival with the integration of a large quantity of newly available molecular phenotypes derived from gene transcription or metabolic profiling. We describe here our method to perform metabonomic Quantitative Trait Linkage (mQTL) in model organism using the 1H Nuclear Magnetic Resonance (NMR) profile of organic sample as a trait. The complexity of the observed signal requires a careful tuning of the analysis to allow true signals to be revealed. Although NMR spectra are very stable, they can vary greatly between tissues. In a previous study of plasma tissue in F2-cross between diabetic and control rats we successfully identified, and validated, the association of benzoate, a gut microbial metabolite, with the deletion of a uridine disphosphate glucuronosyltransferase. We have extended this method in the same rat F2-cross to the analysis of other tissues, such as the aqueous and lipid extracts of adipose tissue. We identified a new locus (LOD>9) on chromosome 4 linked to a specific shift of 2.65ppm in the NMR spectra, which corresponds to candidate metabolites that we can now attempt to validate. In conclusion mQTL analysis of organ extracts provides a very powerful tool to identify new loci and pathways associated with a disease variable, but it requires extra careful care to minimize the noise in the large amount of data. Furthermore this method can help to pinpoint the pathway associated with the locus by identification of the affected metabolite.

## 687/W/Poster Board #345

**The role of CRISPLD2 during Zebrafish Development.** *B. Chiquet[1,2], E. Swindell[1], L. DeVault[1], M. Warman[3], Y. Nakamura[4], J. Hecht[1].* 1) Dept Pediatrics, Univ Texas Med Sch, Houston, Houston, TX; 2) Univ Texas Dental Branch, Houston TX; 3) Dept Genetics, Howard Hughes Medical Institute, Boston, MA; 4) Institute of Medical Science, Univ of Tokyo, Tokyo, Japan.

Craniofacial development is a highly regulated process that involves the complex orchestration of genetic and environmental stimuli, including interaction of cell growth, growth factors and receptors, the convergence and fusion of the facial and palatal processes, apoptosis, and adequate nutrient supply. Disruption of any of these factors can predispose birth anomalies, such as non-syndromic cleft lip with or without cleft palate (NSCLP). NSCLP affects 1 out of 700 live births, or 4000 newborns each year in the United States. Treatment of NSCLP includes surgical, dental and speech therapies, creating a significant healthcare burden on families of affected children. Therefore, research has focused on identifying etiological factors of NSCLP and understanding how these factors contribute to the clefting phenotype. Recently we identified a novel gene, cysteine-rich secretory protein LCCL domain containing 2 (CRISPLD2), which is associated with NSCLP and expressed during murine craniofacial development. However, the in vivo biological function is unknown. To help understand how CRISPLD2 might function during normal development, a zebrafish model was used. In situ hybridizations show that CRISPLD2 is present at all stages of zebrafish embryogenesis and that CRISPLD2 localizes in the head of developing zebrafish. Knockdown of CRISPLD2 using CRISPLD2-specific anti-sense oligonucleotide morpholinos caused a dose-dependent lethality. Morpholino concentrations that allow development to progress past the blastula stage cause abnormal development by one-day post fertilization. Our data shows that embryos with a knockdown of CRISPLD2 have both a lower survival rate and higher percentage of abnormal phenotypes, such as delayed differentiation and head/tail truncation, compared to uninjected and control morpholino injected embryos. On-going studies are determining whether the expression pattern of other genes that regulate craniofacial development (i.e., Dlx2 and Sox9) are altered in CRISPLD2 zebrafish morphants. Together, these results show that CRISPLD2 plays a critical role during zebrafish craniofacial development and will provide information about how perturbation of CRISPLD2 contributes to NSCLP etiology.

## 688/W/Poster Board #346

**A novel mouse model reveals a critical role for *SOX7* in the formation of diaphragmatic hernias and cardiovascular malformations associated with recurrent 8p23.1 deletions.** *M. Wat[1], Y. Chen[1, 3], M. Garcia[2], M. Dickinson[2], B. Lee[1, 3], D.A. Scott[1].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Molecular Physiology & Biophysics, Baylor College of Medicine, Houston, TX; 3) Howard Hughes Medical Institute.

Recurrent interstitial deletions of a region of 8p23.1 flanked by low copy repeats are associated with a spectrum of anomalies that can include congenital diaphragmatic hernia (CDH) and cardiovascular malformations (CVMs). Haploinsufficiency of *GATA4*, a retinoid responsive transcription factor, has been hypothesized to be responsible for these birth defects based, in part, on the fact that *Gata4*$^{+/-}$ mice have anterior CDH and heart defects. However, no clearly causative *GATA4* mutations have been identified in patients with CDH, and the spectrum of heart defects associated with 8p23.1 deletions is more severe than that associated with *GATA4* mutations. This led us to hypothesize that haploinsufficiency of another gene may also contribute to this phenotype. *SOX7* is another, retinoid responsive, transcription factor which lies adjacent to *GATA4* in the CDH/CVM critical region on 8p23.1. *SOX7* was a particularly interesting candidate gene for CDH and CVM development since it was known to upregulate *Gata4* expression in retinoic acid-treated F9 cells and human embryonic stem cells. In situ hybridization studies in mice at E13.5 and E16.5 confirmed that *Sox7* was expressed in the developing diaphragm and heart. To further explore the role of *Sox7* in diaphragm and heart development, we created *Sox7*$^{+/-}$ mice. Approximately 15% of these mice have retrosternal CDH in which a portion of the liver and gallbladder have herniated into the thoracic cavity and are encased in a thin membrane. This type of retrosternal sac hernia is identical to that seen in *Gata4*$^{+/-}$ mice and in some patients with 8p23.1 deletions. Although cardiovascular anomalies were not identified in *Sox7*$^{+/-}$ mice, *Sox7*$^{-/-}$ mice die in utero around E10.5, a time period critical for heart development. *Sox7*$^{-/-}$ mutants have enlarged pericardial sacs and are smaller and developmentally delayed suggesting that heterozygosity of *SOX7* likely contributes to the CVMs seen in patients with 8p23.1 deletions. This work clearly demonstrates how a careful analysis of human phenotypes combined with animal modeling can be an effectively means to identify genes that contribute to the complex phenotypes associated with recurrent genomic disorders.

## 689/W/Poster Board #347

**FAF1 in Cleft Lip and Palate Development.** *M. Ghassibe[1], L. Desmyter[1], T. Langenberg[2,3], F. Claes[2,3], O. Boute[4], B. Bayet[5], Ph. Pellerin[6], P. Brouillard[1], N. Revencu[1], R. Vanwijck[5], P. Carmeliet[2,3], M. Vikkula[1].* 1) Laboratory of Human Genetics (GEHU), de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Department for Transgene Technology and Gene Therapy, VIB, Leuven, Belgium; 3) Center for Transgene Technology and Gene Therapy (CTG), K.U.Leuven, Leuven, Belgium; 4) Centre de Génétique, CHU de Lille, Lille, France; 5) Centre Labiopalatin, Service de Chirurgie Plastique, Cliniques universitaires Saint-Luc, Brussels, Belgium; 6) Service de Chirurgie Plastique et Reconstructive, CHU de Lille, Lille, France.

Cleft lip and palate is a congenital anomaly of complex etiology. Predisposition is governed by numerous genetic loci, in combination with environmental factors. Clefts have an incidence of 1/700 births. We recently identified a translocation in a cleft palate only (CPO) and Pierre Robin sequence (PRS) family. The translocation disrupts the FAF1 gene, which has not been implicated in clefts before. We also showed that FAF1 is associated with CPO and PRS in a cohort of 1500 individuals. In order to replicate the association, we have conducted transmission disequilibrium test in five independent cohorts of different ethnic backgrounds. The same FAF1 variant as in our first study was genotyped. Overall, replications yielded positive results in the CPO/PRS subgroup. In parallel, we showed that zFaf1 is expressed in the pharyngeal cartilages of the zebrafish larvae, where its knock-down results in orofacial defects. Proliferation coupled to apoptosis assays, as well as in situ hybridization of different craniofacial markers have shown that whereas early proliferation and migration of neural crest cells towards the cranial region is normal, later morphogenic processes are altered. We have also generated a mouse line defective for Faf1. Although the heterozygous mice are viable, a more detailed study of their facial features, bone structures, as well as the generation of null mice will help us to better characterize the molecular function and role of Faf1 in cleft development. (miikka.vikkula@uclouvain.be).

## 690/W/Poster Board #348

**Tackling the complexity of the genotype-phenotype relationship in the Down syndrome with the mouse AnEUploidy Zoo: a resource of new models to study aneuplodies involving human chromosome 21.** *Y. Herault[1,6], P. Lopes Pereira[1], L. Magnol[1], I. Sahun[2], A. Duchon[1,6], P. Prandini[3], E. Dalloneau[1], M. Raveau[1,6], V. Nalesso[1,6], J.-C. Bizot[4], B. Chadefaux-Vekemans[5], S. Deutsch[3], C. Borel[3], F. Trovero[5], V. Brault[1,6], S.E. Antonarakis[3], M. Dierssen[2], The AnEUploidy consortium (www.aneuploidy.eu).* 1) MORPHEM, CNRS INTRAGENE, Orleans, France; 2) Genes and Disease Program, Center for Genomic Regulation, Barcelona, Spain; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Key-Obs S.A, Orléans, France; 5) Service de Biochimie Métabolique, Hôpital Necker-Enfants Malades, Faculté de Médecine, Université Paris Descartes, France; 6) ICS/IGBMC, Illlkirch, France.

50 Years after the discovery of the Trisomy 21, the underlying genetic basic of the Down syndrome (DS), the study of the complex genotypes - phenotypes relationship in DS is still a challenge. Currently it is accepted that interactions between “dosage sensitive” genes along the HSA21 are responsible for the complex feature of the pathology. Orthologues of genes on HSA21 exist in the same order separated on mouse chromosomes (MMU) 16, 17 and 10. Most of the exisiting mouse models for DS are trisomic for part of the MMU16 homologous region. These models exhibit many of the characteristics of DS, but not all the mechanisms have been described up to now. In order to complement these models and to decipher the gene interactions generating the DS phenotype, we created new partial trisomies and monosomies for different regions on MMU10, 16 and 17 that are homologous to HSA21 by using chromosomal engineering technic. Now we succeeded in getting a complete series of mouse trisomic models and monosomic models covering the region of the mouse genome homologous to HSA21. These models are listed below: New segmental trisomy, Chr., Modification (interval); Ts1Yah, MMU17, Dup(Abcg1-U2af1); Ts2Yah, MMU16, Dup(Stch-App); Ts3Yah, MMU10, Dup(Cstb-Prmt2); New Segmental Monosomy, Chr., Modification (interval); Ms1Yah, MMU10, Del(Col6a1-Prmt2); Ms2Yah, MMU17, Del(Abcg1-U2af1); Ms3Yah, MMU16, Del(Stch-App); Ms4Yah, MMU10, Del(Cstb-Prmt2); Ms5Yah, MMU16, Del(App-Runx1); Ms6Yah, MMU16, Del(Stch-Runx1); Using such a series we are now oriented toward deciphering the role of each region in the induction of DS phenotypes, their interactions and at term the signal pathways that are affected, with the hope that this would lead to development of new therapeutical approaches. We will report here the phenotypic analysis of the new models and the results obtained on cognition, learning and memory and gene expression in brain of such models. Then we will propose hypothesis to explain the physiopathology of the disease showing that genetic interactions can balance both negative and positive contributions, highlighting the complexity of the genetic codes in DS.

## 691/W/Poster Board #349

**A genome-wide association study identifies two novel loci that regulate canine body size.** *J.J. Schoenebeck[1], N.B. Sutter[2,4], B.M. vonHoldt[3], P. Quignon[1], J. Allen[2,4], A.R. Boyko[4], L. Li[4], R.K. Wayne[3], C.D. Bustamante[4], E.A. Ostrander[1].* 1) Cancer Genetics Branch, National Human Genome Research Institute, Bethesda, MD; 2) College of Veterinary Medicine, Cornell University, Ithaca, NY; 3) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA; 4) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Purebred dogs display phenotypic diversity that is unparalleled by any other terrestrial species: size, shape, posture, coat color and texture, as well as behavior can vary profoundly breed to breed. CanMap is an ongoing effort to identify genes important in controlling fixed traits in domestic dogs. To date we have genotyped 1000 domestic dogs from 80 breeds and 400 wild canids using the Affymetrix V2 SNP chip, generating a data set of 50,000 SNPs per dog. This body of data lays the foundation for many mapping studies, including investigations into domestication, population structure, and mapping breed-defining traits such as leg length and width, skull shape, and fur patterning. One of the most striking examples of intraspecies morphological diversity is dog body size, which can vary greater than 40-fold across animals of distinct breeds. We showed previously that variation at the *IGF1* locus plays an important role in determining the body size of small and toy breed dogs. Association testing of CanMap data using breed mass averages and principal components analysis reveals numerous, highly significant quantitative trait loci (QTLs), including associations to *STC2*, a secreted glycoprotein known to inhibit postnatal growth ($P$ = 4.42x10-26) and *SMAD2*, a transcription factor critical for TGF-beta signaling ($P$ = 5.48x10-25). Fine mapping of the *STC2* and *SMAD2* loci (chromosomes 4 and 7, respectively) validated the original associations produced from CanMap analysis. Interbreed haplotype comparisons suggest that small and toy breeds experienced selective sweeps at both loci, implying strong, artificial selection of genetic variants that restrict growth. To identify causal mutations, we are currently fine mapping both *STC2* and *SMAD2* loci. Intriguingly, within the *SMAD2* locus we identified a 10 kb deletion that segregates with small and toy breed dogs. The deletion spans a multispecies conserved sequence (MCS) located downstream of *SMAD2*, raising the possibility that in the absence of this MCS, *SMAD2* transcription is downregulated. Characterization of the functional significance of this deletion, as well as other polymorphisms within the critical intervals of *SMAD2* and *STC2* are planned.

## 692/W/Poster Board #350

**Imputation of Ancestry in Inbred Strain Crosses.** *J.J. Zhou[1], J.S. Sinsheimer[1,2,3], K. Lange[1,2].* 1) Department of Biomathematics, University of California, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, CA; 3) Department of Biostatistics, University of California, Los Angeles, CA.

Association studies with inbred strains can assist in mapping quantitative trait loci (QTL) for human traits. A major confounding factor with inbred crosses is polygenic background, but recent theory makes it possible to accurately capture this complication as a random effect in a mixed effects statistical model (Bauman *et al* 2008). Another potential difficulty with inbred crosses is their reduced genetic diversity compared to natural animal populations. Multiple crosses, for example, the eight-way cross announced by Complex Trait Consortium (Churchill *et al* 2004, Chesler *et al* 2008), circumvent these difficulties. In our latest expansion of theory for QTL association mapping with inbred strains, we directly impute local strain origins by choosing the most probable strain. Strain origins can then serve as mean effects in a multivariate normal model for testing association between trait levels and strain origin along the genome. Imputation is a combinatorial process that locally assigns the maternal and paternal strain origin of each animal using prior pedigree information. Without some kind of smoothing, imputation is likely to be ill defined or jump erratically from one strain to another as we travel along the genome of an animal. In practice, we expect to see long stretches where strain origin is constant. This can be arranged by penalizing strain changes from one marker to the next. A dynamic programming algorithm solves the strain imputation process in one quick pass through the genome of an animal.

Simulation was performed by mimicking the 8 way Complex Trait Consortium. Eight inbred strains of mice were chosen as founders. The mating design is rigid for the first 3 generations and random mating for by siblings' mating. By using more than 1000 markers we recover strain origins with 99% accuracy. We also compared our results with the software HAPPY (Mott *et al* 2000) on their published data for 1016 markers. Our method gave more accurate results than HAPPY.

**Developmental elevation of neutrophils is associated with increased Serpina-1 expression in a rat model of innate airway hyperresponsiveness.** *N. Carpe[1,2], I. Mandeville[2], T. Bao[2,3], J. Chu[4], B.A. Raby[4], S.T. Weiss[4], F. Kaplan[1,2,3,4,5].* 1) Dept of Human Genetics, McGill University; 2) Montreal Children's Hospital Research Institute; 3) Dept of Biology, McGill University; 4) Channing Laboratory, Brigham and Womens Hospital, Harvard Medical School; 5) Dept of Pediatrics, McGill University.

Rationale: An growing body of evidence suggests that a significant proportion of asthma in both children and adults, including mild to moderate asthma, is associated with neutrophilic airway inflammation. Yet the role of neutrophil mediated inflammation in asthma pathophysiology remains unclear. We are exploring the origins of innate airway hyperresponsiveness (AHR) in developing lung of the Fisher rat. Atopic (Brown Norway) and normoresponsive (Lewis) rats serve as controls. We hypothesized that neutrophil-mediated inflammation may contribute to the Fisher respiratory phenotype. Methods: We assessed bronchoalveolar lavage (BAL) cell differentials in postnatal lungs of naïve Fisher, BN and Lewis rats from postnatal day (PN)1-14. Pregnant dams and adult rats were sensitized and challenged with ovalbumin (OVA) using the inExpose aerosol inhalation system. BAL fluid was collected from pups of sensitized dams and adult rats to analyze inflammatory cell profiles. Illumina genome wide profiling was used to compare global gene expression patterns in naïve PN rat lung. Lung mRNA levels of Serpina-1(alpha-1-antitrypsin), were validated by real-time [RT]-PCR. Results: Fisher rats displayed a significantly greater number of neutrophils in BAL fluid than BN and Lewis rats from PN1-14 ($P<0.05$). Following a 3 day acute OVA exposure, adult Fisher rats had significantly elevated neutrophils in BAL fluid relative to Lewis rats. Increased BAL neutrophils were also observed in lungs of Fisher rat pups compared to Lewis pups born to dams challenged with OVA or saline during pregnancy. OVA exposure enhanced this effect. Serpina-1expression was elevated in adult Fisher rat and in PN7 rat pups of naïve and OVA challenged mothers. Linear regression analysis of Illumina expression profiles (n=4 per strain per time point, with interaction terms age x strain) identified 4 additional genes displaying significantly different expression trajectories over time that were unique to Fisher rats. Two of these (Defb3, FCN) are expressed in neutrophils and produce proteins previously reported to have a role in innate immunity. Conclusions: The Fisher rat exhibits innate neutrophilic airway inflammation that is enhanced by OVA challenge *in utero* and in adulthood. These findings suggest that the Fisher rat can serve as a useful model to elucidate developmental mechanisms involved in neutrophil mediated inflammation in asthma.

## 694/W/Poster Board #352

**Investigating the role of Fragile X related proteins in mammalian circadian behaviors.** *J.G. Lumaban, D.L. Nelson.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Fragile X syndrome, the most common form of inherited mental retardation, results from the absence of the fragile X mental retardation 1 (FMR1) gene product FMRP. FMR1 has two paralogs in vertebrates: fragile X related gene 1 and 2 (FXR1 and FXR2); it has been postulated that the presence of FXR1P and FXR2P could partially compensate for the loss of FMRP in Fragile X syndrome. One of the behavioral symptoms observed in Fragile X patients is the increased occurrence of sleep disorders. Studies on animal models revealed that Fmr1/Fxr2 double knockout (KO) and Fmr1 KO/Fxr2 heterozygote mice exhibit a complete loss of rhythmic activity in a light:dark (LD) cycle, and that Fmr1 or Fxr2 KO mice display a shorter free-running period of locomotor activity in total darkness (DD). Furthermore, the cyclical patterns of abundance of several core clock component messenger RNAs are altered in the livers - which contain a major peripheral clock - of Fmr1/Fxr2 double KO mice, while the overall clock gene expression in the central clock appears unchanged between animals of different genotypes. These findings suggest that Fmrp and Fxr2p are acting downstream of the central clock to control rhythm in mice. Current efforts are aimed at determining the relevance of this role to sleep and other behavioral alterations observed in fragile X patients. Locomotor assays after restricted feeding are being employed to test whether the Fmr1/Fxr2 double KO mice are able to entrain to food, even when they cannot entrain to light. Electroencephalography studies are also in progress to analyze brain electrical activity of Fmr1/Fxr2 double KO mice and determine whether their sleep/wake cycles are significantly altered compared to the WT mice. Results of these assays will help to determine the nature of circadian defect. The close association between the circadian system and the timing of sleep and wakefulness together with the typical disturbances of circadian behavior and sleep in Fragile X syndrome opens up a new perspective for the investigation and treatment of patients suffering from this disorder.

**Modifier Genes Buffer Cardiac Developmental Pathways From The Effects of Nkx2-5 Mutation.** *J. Winston, J. Erlich, C. Green, A. Aluko, P. Jay.* Dept of Pediatrics, Washington Univ, St Louis, MO.

Mutations of the transcription factor NKX2-5 cause pleiotropic heart defects with incomplete penetrance. In this study we assess the role of cryptic genetic variants to phenotypic variability. *Nkx2-5*$^{+/-}$ mice in the inbred strain background C57Bl/6 frequently have atrial and ventricular septal defects (ASD, VSD). Outcrosses were performed to FVB/N and A/J to assess the effect of genetic background variation on phenotype. Our analysis of >3000 *Nkx2-5*$^{+/-}$ hearts from five F2 crosses reveals the profound influence of genetic modifiers on disease presentation and possibly human epidemiologic patterns. All three strains carry susceptibility alleles for ASD and VSD. Relative to the other two strains, C57Bl/6 carries polymorphisms that confer greater susceptibility to muscular VSD, and A/J for ASD and atrioventricular septal defects. Genome-wide linkage analysis on 200 *Nkx2-5*$^{+/-}$ mice each with VSD+ or normal hearts from the C57Bl/6 X FVB/N intercross yielded main effect and interacting loci throughout the mouse genome that correlate with risk. Significant main effect loci (LOD > 3.0) were mapped to chromosomes 4, 8, 10 and 19. A second linkage analysis on 100 cases and controls from the C57Bl/6 X A/J intercross yielded shared and unique modifiers with the previous scan. Similar analyses for ASD yielded loci shared with VSD on chromosomes 8 and 10, which indicates that some polymorphisms may affect the development of multiple cardiac structures. Interestingly, the loci generally contain no known cardiac developmental genes. Alleles of modifier genes can either buffer perturbations on cardiac development or direct the manifestation of a defect in response to an insult such as *Nkx2-5* haploinsufficiency. Our unbiased genetic analysis of modifiers of the *Nkx2-5* mutant phenotype elucidates the genetic architecture of cardiac developmental pathways.

## 696/W/Poster Board #354

**Fine-mapping and genetic architecture underlying obesity-related phenotypes.** *G.L. Fawcett[1,5], J.P. Jarvis[2], C.C. Roseman[3], B. Wang[5], J.B. Wolf[4], J.M. Cheverud[5].* 1) Dept of Mol. & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 3) Department of Anthropology, University of Illionois at Urbana-Champaign, Urbana-Champaign, IL; 4) Faculty of Life Sciences, The University of Manchester, Manchester, UK; 5) Department of Anatomy and Neurobiology, Washington University in St. Louis, St. Louis, MO.

Obesity is one of the most prevalent diseases in developed countries with heritability estimated between 30-90%. While some causes of obesity are monogenic (melanocortin-4 receptor, leptin, leptin receptor), these are rare and most obesity in human populations is caused by many genes of relatively small (less than 10% of heritable variance explained) effect. Current focus in genome-wide association studies is on identifying loci, but most of these studies either lack the statistical power or the computational wherewithal to effectively study the genetic architecture of the heritable variation underlying obesity. Understanding epistatic effects and pleiotropy will be critical to effective drug therapy design. We present the fine-mapping ($F_{9/10}$ combined generations) of previously identified obesity-related loci in the LG,SM murine model of obesity. In comparison to the $F_2$ and $F_{2/3}$ populations, we observed narrowed QTL confidence regions (~5-fold). More interestingly, most of the $F_2$ and $F_{2/3}$ QTL peaks resolved into very narrow multiple $F_{9/10}$ QTL peaks and revealed new QTLs that may have been previously masked due to opposite gene effects at closely linked loci. Pleiotropic effects may be important in species evolutionary history and in considering side-effects for drug design. We observed significantly less pleiotropy in the $F_{9/10}$ population than had been reported previously with this model. This drop in pleiotropy is likely due to increased resolution of effects, which presents a more accurate depiction of the architecture. Epistatic interactions were primarily novel, although several strong epistatic interactions were observed to replicate from the $F_2$ population. We propose that increased consideration of the genetic architecture underlying complex traits in human studies will facilitate translational applications to human health.

## 697/W/Poster Board #355

**A novel glaucoma locus identified in Dandie Dinmont Terrier dog breed.** *S.J. Ahonen[1,2,3], L. Hansen[4], G. Johnson[4], H. Lohi[1,2,3].* 1) Department of Medical Genetics, University of Helsinki, Finland; 2) Department of Molecular Genetics, the Folkhälsan Institute of Genetics, Finland; 3) Department of Basic Veterinary Sciences, University of Helsinki, Finland; 4) Department of Veterinary Pathobiology, College of Veterinary Medicine, University of Missouri, US.

Hereditary glaucoma is a common eye disease both in dogs and in humans. In both species glaucoma is the second leading cause of blindness after cataracts. Unlike in many cataracts, the blindness in glaucoma is irreversible and cannot be restored. In humans, glaucoma is considered a complex disease with multiple susceptibility genes combined with environmental factors. Glaucoma is a disease where the intraocular pressure has raised, damaging the optic nerve and causing loss of retinal ganglion cells. In primary glaucoma there is no obvious reason for glaucoma development and it is considered to be hereditary. Glaucoma can also be secondary occurring as a result of some other cause, for example, diabetic retinopathy, uveitis, lens luxation, cancer and trauma. Although several genes and loci have been found in human there are no known glaucoma genes in dogs. Glaucoma has been described in several dog breeds including Dandie Dinmont Terrier (DDT), Basset Hound, Beagle and Chow Chow. In DDT primary glaucoma seems to develop slowly affecting middle-aged and elderly dogs and there are several abnormalities associated with the drainage or iridocorneal angle. We have established a large pedigree including 26 affected DDTs. To map the glaucoma locus 21 affected and 21 controls were genotyped with Illumina canine 22K SNP array. The average onset of glaucoma in affected dogs was 7.07 years. Control dogs selected for the analysis were over 10 years and confirmed healthy at older age by veterinary ophthalmologists. Analysis of the genotyping results by PLINK software revealed a single locus with a genome-widely significant association ($P_{raw}$= $1.6*10^{-7}$, $P_{genome}$ =0.00116) at CFA8. As expected for a small breed, the associated gene-rich region spans several mega bases and ongoing fine-mapping of the region with additional samples and markers aim to narrow down the region. The most prominent candidate genes are being sequenced in parallel. The identified locus maps to a syntenic region in human that has been associated with human glaucoma but there are no known glaucoma genes in the region in either species. Further studies are likely to reveal a novel glaucoma mutation in this breed and will facilitate the identification of the corresponding human gene. This study will also establish an important new glaucoma model for therapeutic studies while the breed will benefit from the upcoming genetic test.

## 698/W/Poster Board #356

**Genome-wide linkage and association mapping of hip dysplasia using dog as a model organism.** *K. Zhao[1], Z. Zhang[2], L. Zhu[3], L. Corey[4], G. Lust[4], C.D. Bustamante[1], S. Harris[5], R. Todhunter[6].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY, 14853; 2) Institute for Genomic Diversity, Cornell University, Ithaca, NY, 14853; 3) Dept of Statistics, Oklahoma State University, Stillwater OK,74078; 4) Baker Institute for Animal Health, College of Veterinary Medicine, Cornell University, 14853; 5) Waltham PetCare, Waltham-on-the-Wold, Leicestershire LE14 4RT, UK; 6) Department of Clinical Sciences, College of Veterinary Medicine, Cornell University, Ithaca NY, 14853.

Canine hip dysplasia (CHD) is a heritable complex disease characterized by hip instability that results in secondary osteoarthritis, lameness, and physical disability. Human Hip Dysplasia (HD) and CHD share common phenotypic characteristics, thus the study in dogs would also shed light on the genes and pathways involved in humans. The unique genetic structure of long haplotype within breeds and short haplotype across breeds and ability to manipulate the pedigrees make dog an idea model organism for studying the genetic basis of this disease. Platforms used to date for canine complex disease mapping have mainly used microsatellite markers and linkage or sib pair analysis. Here, we present the first genome-wide linkage and association mapping analysis by means of a 22K Illumina SNP platform. The sample of 366 dogs consisted of a crossbred pedigree formed by crossing and backcrossing dysplastic Labrador retriever/greyhounds, and six other pure breeds (Labrador Retriever, Bernese Mountain Dog, German Shepherd, Newfoundland, Golden Retriever, Rottweiler). We confirmed and narrowed many QTL for CHD and hip osteoarthritis identified by traditional microsatellite linkage mapping and identified additional QTL. This study demonstrated both the feasibility and the challenges of utilizing genome-wide SNP data for the identification of the genetic contribution to complex diseases using dog as a model organism. Power simulation studies also showed the importance of controlling genetic relatedness in association mapping when combining pedigree and unrelated samples.

## 699/W/Poster Board #357

**Transgenic rescue of neurobehavior in Ube3a KO mice.** *T. Kishino[1], L. Rayburn[2], J. Wagstaff[3].* 1) Center for Frontier Life Science, Nagasaki University, Nagasaki, Japan; 2) Department of Pediatrics, James G. Cannon Research Center, Carolinas Medical Center, Charlotte, N.C; 3) Genetics Division, Department of Pediatrics, Levine Children's Hospital at Carolinas Medical Center, Charlotte, N.C. deceased 4/08.

Angelman syndrome is a neurodevelopmental disorder caused by a defect of the maternally expressed imprinted gene, *UBE3A*. The mouse models of AS with targeted disruption of *Ube3a* reveal that *Ube3a* is imprinted only in neurons and the UBE3A protein may function in synaptic morphology and/or plasticity. Maternal chromosomal duplications of 15q11-13, where *UBE3A* is located, are the most frequent cytogenetic abnormalities found in autism, suggesting that dup(15) phenotypes result from over-expression of the contiguous loci including maternally expressed *UBE3A*. To address the role of UBE3A in neurons, we generated transgenic *UBE3A* mice expressing a full length UBE3A cDNA under control of the rat enolase 2, gamma, neuronal (*Eno2*) promoter. Transgene expression in neurons was clearly demonstrated by RT-PCR and Western Blot. *UBE3A*-overexpressing transgenic mice showed normal phenotype. Neurobehavioral phenotypes of AS model mice with maternal *Ube3a* deletion were partially rescued by transgene expression in neurons. We present detailed phenotypic data of the transgenic mice and rescued phenotypes.

**Identification of Novel Loci for Canine Steroid Responsive Meningitis-Arteritis.** *P.J. Jokinen[1], M. Wilbe[2], K. Truvé[2], E.H. Seppälä[1], E. Karlsson[3,4], T. Biagi[3], A. Hughes[5], D. Bannasch[5], K. Ahlgren[6], O. Kämpe[6], G. Andersson[2], H. Hansson-Hamlin[2], K. Lindblad-Toh[3,7], H. Lohi[1].* 1) Department of Basic Veterinary Sciences, Department of Medical Genetics, Program in Molecular Medicine, University of Helsinki and Folkhälsan Institute of Genetics, Helsinki, Finland; 2) Swedish University of Agricultural Sciences, Uppsala, Sweden; 3) Broad Institute of Harvard and Massachusetts Institute of Technology (MIT), Cambridge, USA; 4) FAS Center for Systems Biology, Harvard University, Cambridge, USA; 5) School of Veterinary Medicine, University of California, Davis, USA; 6) Department of medical sciences, Uppsala University, University hospital, Uppsala, Sweden Uppsala; 7) Department of Medical Biochemistry and Microbiology, University, Uppsala, Sweden.

Dog breeds form homogeneous genetic isolates that originate from few ancestors and provide therefore feasible models to map genes in complex phenotypes. We have established a large sample collection of Nordic and North American Nova Scotia Duck Tolling Retrievers (NSDTRs) that have genetic predisposition for different type of autoimmune disorders including immune-mediated rheumatic disease (IMRD), steroid-responsive meningitis-arteritis (SRMA) and hypoadrenocorticism (Addison's disease). To identify the genetic risk factors for SRMA we performed a genome wide association (GWA) study with 44 SRMA cases and 57 healthy controls from Finland and Sweden. We identified a region with multiple associated SNPs on CFA32 (praw=7.10 x 10-6 and pgenome=0.04). By examining Finnish and Swedish SRMA dogs separately associations were found for a single SNP on CFA30 (praw=6.7 x 10-6 and pgenome=0.03) and again on CFA32 (praw=2.1 x 10-4 and pgenome=0.69), respectively. To narrow down and validate the loci we used additional NSDTRs and also SRMA cases from other breeds such as Boxers and Petite Basset Griffon Vendeen in fine-mapping. Our results further supported the association on CFA32 for a protective haplotype (praw=2.4*10-7, OR=0.3) while the association on the Finnish cases weakened on CFA30 (praw=1.2*10-4, OR=0.2). However, this locus has a 69 kb-haplotype consisting of three SNP's that contains a strong candidate gene (RORA) and the association is also supported by a shared haplotype with the other breeds. Combining GWA data from IMRD and Addison's disease in a parallel study with SRMA we found shared loci on CFA32 (praw=4.4*10-6 and OR=3.0), CFA8 (praw=3.2*10-7 and OR=2.6) and CFA3 (praw=4.4*10-6 and OR=3.0). In summary, we have successfully discovered four candidate loci for canine SRMA in a small case-control material, three of which are shared with other complex autoimmune diseases. Meningitis is also known to be a symptom in human systemic autoimmune conditions such as SLE. Re-sequencing of the associated regions is likely to unravel causative variants that may have important implications for the understanding of the immune-mediated diseases in both species.

## 701/W/Poster Board #359

**Genome-wide association mapping identifies multiple loci for a canine SLE-related disease complex.** *M. Wilbe[1], P. Jokinen[2], K. Truvé[1], E. Seppala[2], E. Karlsson[3,4], T. Biagi[3], A. Hughes[5], D. Bannasch[5], K. Ahlgren[6], O. Kämpe[6], G. Andersson[1], H. Hansson-Hamlin[7], H. Lohi[2], K. Lindblad-Toh[3,8].* 1) Department of Animal Breeding and Gentics, Swedish University of Agricultural Sciences, Uppsala, Sweden; 2) Department of Basic Veterinary Sciences, Department of Medical Genetics, Program in Molecular Medicine, University of Helsinki and Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Broad Institute of Harvard and Massachusetts Institute of Technology (MIT), Cambridge, USA; 4) FAS Center for Systems Biology, Harvard University, Cambridge, USA; 5) School of Veterinary Medicine, University of California, Davis, USA; 6) Department of medical sciences, Uppsala University, University hospital, Uppsala, Sweden; 7) Department of Clinical Sciences, Swedish University of Agricultural Science, Uppsala, Sweden; 8) Department of Medical Biochemistry and Microbiology, University, Uppsala, Sweden.

The dog is an outstanding model for human disease based on the many similar disease phenotypes, a similar gene set and shared environment with humans. The unique canine breed structure also makes the mapping of both monogenic and complex genetic diseases more efficient. The dog has gone through two major bottlenecks that affect their haplotype structure; the domestication from the wolf population (resulting in short haplotypes) and the breed creation (resulting in long haplotypes within breeds). We take advantage of the long haplotypes within a breed for genome-wide association (GWA) mapping and the short haplotypes shared across breeds in for fine-mapping. In this proof-of-principle study we mapped the first canine complex trait, a systemic lupus erythematosus (SLE)-related disease complex in the canine breed Nova Scotia duck tolling retriever. These dogs share many symptoms with human SLE patients. All affected dogs show polyarthritis of a non-erosive character, 70 % display antinuclear antibodies (ANA). Additional symptoms occurring are muscle pain, skin, liver and kidney problems and fever. MHC class II is also a risk factor for SLE in both dogs and humans. GWA of 81 cases and 57 controls revealed six highly associated loci, and fine-mapping in twice as many dogs validated the results with twice as strong p-values. The ANA-positive disease was validated particularly strongly as a complex trait with three loci, on chromosomes 3, 11 and 24, showing p-values of $10^{-11}$ to $10^{-13}$ and odds ratios of 4.5-8. All associated regions contain strong candidate genes based on biological function. Interestingly, four of these genes (*PTPN3*, *HOMER2*, *DAPP1* and *PPP3CA*) have all been defined to influence nuclear factor of activated T-cells (NFAT) activities, which might be a major novel SLE-related pathway. Re-sequencing of associated regions and expression studies of candidate genes in the dog are ongoing to identify causative mutations. The corresponding regions in human populations affected by SLE are currently being examined, both by data mining of human GWA data and by additional genotyping, to detect genetic risk factors that are common to canine and human disease. We conclude that the dog is a highly efficient model for comparative complex trait mapping.

## 702/W/Poster Board #360

**Activin signaling: effects on body composition and mitochondrial energy metabolism.** *C.W. Brown[1,2], J.J. Shen[3], J.C. Bournat[1], L. Huang[1], A. Chattopadhyay[1], Z. Li[1], C. Shaw[1], B.H. Graham[1], L. Li[4].* 1) Dept Molec/Human Gen, Baylor Col Medicine, Houston, TX; 2) Dept Pediatrics, Baylor Col Medicine, Houston, TX; 3) Children's Hospital Central California, Madera, CA; 4) Dept of Pediatrics, M.D. Anderson Cancer Center, Houston, TX.

Activin beta A and activin beta B (encoded by *Inhba* and *Inhbb* genes, respectively) are closely related TGF beta superfamily members that participate in a variety of biological processes. These include maintaining body composition, adiposity, and energy metabolism. We previously generated mice with an insertion allele at the *Inhba* locus, *Inhba*$^{BK}$. The *Inhba*$^{BK}$ allele results in the misexpression of activin beta B in locations where activin beta A is normally produced and does not adversely affect the expression level or processing of the protein, yet renders the gene product functionally hypomorphic in this context. Homozygous (*Inhba*$^{BK/BK}$) and hemizygous (*Inhba*$^{BK/-}$) mice are smaller and leaner than their wild-type littermates in an allele dose-dependent fashion, and many tissues (liver, spleen, white adipose) are disproportionately small relative to total body weight. To determine the mechanisms that contribute to these phenomena, we have investigated the metabolic consequences of the mutation. Although the growth of *Inhba*$^{BK}$ mice is improved by providing a calorie-rich diet, diet-induced obesity, fatty liver, and insulin resistance (hallmarks of chronic caloric excess) do not develop, despite greater caloric intake than wild-type controls. Physiologic, molecular, and biochemical analyses all revealed characteristics that are commonly associated with increased mitochondrial energy metabolism, with a corresponding up-regulation of several genes in metabolically active tissues that reflect enhanced mitochondrial biogenesis and function. Oxygen consumption, an indirect measure of the metabolic rate, was markedly increased in *Inhba*$^{BK/BK}$ mice, and polarographic analysis of liver mitochondria revealed an increase in ADP independent oxygen consumption, consistent with constitutive uncoupling of the inner mitochondrial membrane. Preliminary expression microarray data from the livers of these mice suggest prominent roles for a variety of biological processes and pathways in the hypermetabolic phenotype. These findings establish a functional relationship between activin signaling and mitochondrial energy metabolism, provide clues as to how these processes are linked, and further support the rationale to target this signaling pathway for the medical treatment of cachexia, obesity, and diabetes.

## 703/W/Poster Board #361

**Genetic Regulation of Chronic Pain Responses After Sciatic Nerve Injury.** *R. Levitt[1], E. Fu[1], Y. Zhang[1], Q. Li[1], R. Morris[2].* 1) Department of Anesthesiology, The University of Miami, Miami, FL 33136; 2) Department of Human Genetics, The University of Miami, Miami, FL 331336.

Neuropathic pain (NP) is a complex heritable disorder. We utilized the well described chronic constriction injury of the sciatic nerve (CCI) model to evaluate NP behaviors using inbred mice (C57BL6/J, DBA2/J, A/J, NZW/LacJ, SJL/J, AKR/J, 129X1/SvJ, CAST/EiJ, n=8 each). Thresholds for withdrawal to mechanical pain (von Frey filaments applied to the affected hindpaw) were measured on day 7 and 14 after CCI. Thresholds after CCI as compared with baseline indicates A/J and NZW/LacJ are the two least sensitive strains and AKR/J is most sensitive (see Table 1). Based on these data, our estimates of heritability exceed 0.5 with an estimated 2.5 effective factors underlying the measured strain differences (assuming independent equal and additive gene effects). We report here for the first time that mechanical hypersensitivity after CCI is heritable and strain differences are likely to be determined by a small number of genes. These data establish the feasibility of mapping susceptibility genes underlying NP in the CCI model. Mapping neuropathic pain susceptibility genes may facilitate an understanding of mechanism and better diagnostic and therapeutic approaches.

| Day After CCI | | Strain Pairs | | P Value |
|---|---|---|---|---|
| Day 7 | | A/J vs. AKR/J | | 0.00186 |
| Day 7 | | NZW/LacJ vs. AKR/J | | 0.00016 |
| Day 14 | | A/J vs. AKR/J | | 0.00016 |
| Day 14 | | NZW/LacJ vs. AKR/J | | 0.00016 |

**LOXL1 null mouse phenotype suggests that loss of lysyl oxidase like 1 function contributes to exfoliation glaucoma.** *J.L. Wiggs[1], L.R. Pasquale[1], B. Pawlyk[1], X. Xu[1], E. Connolly[1], I. Kim[1], J.W. Miller[1], D. Rhee[1], R. Haddadin[1], C. Grosskreutz[1], T. Chen[1], B.J. Fan[1], J.L. Haines[2], T. Li[1].* 1) Dept Ophthalmology, Harvard Med Sch, MEEI, Boston, MA; 2) Center for Human Genetics Rearch, Vanderbilt University Medical Center, Nashville, TN.

Exfoliation syndrome is a common condition that is a major risk factor for open angle glaucoma. The condition is characterized clinically by the deposition of fibrillar material systemically and throughout the eye, compromise of the blood aqueous barrier in the ocular anterior segment and changes in the ocular lens. Approximately 50% of individuals with this condition develop a high intraocular pressure form of glaucoma causing blindness due to permanent damage to the optic nerve. Exofoliation glaucoma is inherited as a complex trait, and three SNPs in the LOXL1 gene coding for lysyl oxidase like 1 have been shown to be significantly associated with exfoliation syndrome in human populations throughout the world. Two of the associated SNPs are missense changes which could contribute to disease through a gain of function mechanism or could be associated with a loss of function of the LOXL1 protein. The purpose of this study is to evaluate the phenotype of a LOXL1 knockout (null) mouse to help define the pathogenic disease mechanism. Twenty LOXL1 null mice (ages 3-8 months) and 20 control mice (DBA/2J) were characterized for the following phenotypic traits: ocular histology, intraocular pressure (rebound tonometer), and iris fluorescein angiography. Compared with controls null mice demonstrated a pronounced vesiculation of the anterior lens, and also a compromise of the blood aqueous barrier in the ocular anterior segment (shown by iris angiography). Other phenotypic measures were normal including intraocular pressure. These results show that the LOXL1 null mouse replicates the lens and blood aqueous barrier abnormalities observed in human exfoliation syndrome, suggseting that a loss of LOXL1 protein function is the underlying genetic mechanism responsible for the condition. Certain aspects of the human phenotype, including increased intraocular pressure, are not apparent in the LOXL1 null mouse suggesting that other factors may also contribute to this disease. Supported by NEI grants: R21EY019161 (Li); R01EY013882 (Wiggs); P30EY014104 (Wiggs).

## 705/W/Poster Board #363

**Detection of Bax and Bak proapoptotic determinants polymorphisms in Iranian Ataxia -Telangiectasia patients.** *M. Sanati[1], A. Isaian[2], T. Dork -Bousset[3], N. Bogdanova[3], M. Houshmand[1], M. Movahadi[2].* 1) Medical Genetics department, National Institute for Genetic Engineering and Bio, Tehran, Tehran, Iran; 2) Tehran Medical science University , Medical School Dept.of Immunology and Allergy Tehran- Iran; 3) Medical School of Hannover, Molecular Gynaecology Research Group ,Hannover Germany.

AT is an autosomal recessive disorder That is characterized by early onset progressive cerebellar ataxia,oculocutaneous telangiectasia bronchopulmonary disease and lymphoid tumors,immunodeficiency and chromosomal instability. The defective gene is ATM (AT mutated) was localized to chromosome 11q22-23.AT patients are in the risk of cancer. and it is the second cause of death in this syndrome.40% of cancers are non-Hogkin's lymphoma,25% are leukemia.25% are associated with solid tumors and 10% are Hogkin's lymphoma.The risk for malignancy in AT is 38%. In addition apoptosis is critical not only for tissue homoestasis but also in the pathogenesis of a variety of disease including cancer . The major goal of this study was to determine the role and alternations of Bax ,Bak proapoptotic determinants and in general ,mitochondrial apoptotic pathway in developing of cancer in AT patients.Bax mutation are commonly formed in lymphoma and leukemia ,and Bak gene mutations in different types of cancer are detected . For the first time we studied 50 AT patients and 50 healthy control for Bax and Bak genes alternations.We performed sequencing analysis of entire coding region of Bak gene (exons 2-6) and bax gene( exons 1-7).Our observation suggest that Bak gene polymorphisms were detected in region of c342C to T in exon 2 and Intronic site of exon6 IVS6-35T to C in Bak gene .In Bax gene we detected polymorphism in exon 3 IVS3+14A to G as homozygote and heterozygote. In conclusion we suggest that in AT patients in addition of ATM gene mutation ,the loss or mutation of Bax and Bak genes are associated with shorter overall survival or developing and acceralation of lymphoma.

## 706/W/Poster Board #364

**Candidate genes for presbycusis from mouse to man.** *D.L. Newman[1], L.A. Birdsall[1], D. Cunningham[1], C.A. Hu[2], R.D. Frisina[3].* 1) Department of Biological Sciences, Rochester Institute of Technology, Rochester, NY; 2) Department of Biochemistry & Molecular Biology, Univeristy of New Mexico School of Medicine, Albuquerque, NM; 3) Department of Otolaryngology, University of Rochester School of Medicine, Rochester, NY.

Presbycusis is a major public health problem in the U.S. People with this disorder suffer from gradual hearing loss, beginning at high frequencies in middle age and progressing to lower frequencies in old age, and compounded by a loss of the ability to understand speech in the presence of background noise. Glutamate is the primary excitatory neurotransmitter, and serotonin is a modulatory neurotransmitter in the central/peripheral auditory system. The CBA mouse is a model for human presbycusis that has been used to search for genes that are up- or down-regulated in the auditory system as it ages. Glutamate-related genes and serotonin-related genes were examined specifically. Glutamate pathway gene *Pycs* mRNA level decreased with age in the auditory midbrain (inferior colliculus, IC), while Serotonin 2B receptor mRNA was upregulated with both age and hearing ability in the IC. We examined the human homologues of these two genes in a population of ~600 aged Caucasians from the Rochester, NY area. Nine nonsynonymous SNPs in *PYCS* and six noncoding tagging SNPs in *HTR2B* were genotyped in this population. Little or no association was observed with any SNP or haplotype. We conclude that although these genes may play a role in hearing ability, there is no evidence for our population carrying polymorphisms in these genes that contribute to presbycusis susceptibility.

## 707/W/Poster Board #365

**IL-6, IL-10, IFN-$\gamma$, TGF-$\beta$1 and TNF$\alpha$ Gene Polymorphisms as Risk Factors for Aggressive Periodontitis: A Brief report.** *K. Erciyas[1], S. Pehlivan[2], T. Sever[2], M. Igci[2], A. Arslan[2], R. Orbak[3].* 1) Gaziantep University, Faculty of Dentistry, Department of Periodontology, Gaziantep, Turkey, DDs, PhD; 2) Gaziantep University, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey, PhD; 3) Ataturk University, Faculty of Dentistry, Department of Periodontology, Erzurum, Turkey, DDs, PhD.

The aim of this study was to investigate links between cytokine genetic variants and aggressive periodontitis. Twelve aggressive periodontitis patients and 30 healthy controls without periodontitis were included in the study. We studied the polymorphisms of IL-6, IL-10, IFN-$\gamma$, TGF-$\beta$1 and TNF$\alpha$ genes, using the PCR-SSP method. Significant differences were not determined for IL-6, IL-10, IFN-$\gamma$, TGF-$\beta$1(C25/G25) and TNF$\alpha$ cytokine polymorphism from the genotype distribution and allele frequency between aggressive periodontitis and healthy control groups. In contrast, significant differences were determined for TGF-$\beta$1(T10/C10) polymorphism from the genotype distribution (TC) between aggressive periodontitis and healthy control groups (p:0.032).

## 708/W/Poster Board #366

**In silico analysis of genes in the genome regions covered by quantitative trait loci for essential hypertension in rat model.** *W. Gu[1], J. Zhu[2], Q. Xiong[1,3], A. Postlethwaite[4], Y. Wang[5].* 1) Dept Orthopedic Surgery, Univ Tennessee-HSC, Memphis, 38163, TN; 2) Rust College, Holly Spring, Mississippi, 38635, USA; 3) Department of Computer Science and Technology, Southwest University, Chongqing 400715, P.R.China; 4) Department of Medicine, University of Tennessee Health Science Center, Memphis, TN 38163, USA; 5) Beijing Tiantan Hospital, Capital University of Medical Sciences, Beijing, 100050 PR China.

Introduction: Hypertension in humans is a quantitative trait and controlled by many genes. Currently, more than 300 hundred Quantitative trait loci (QTL) for blood pressure and hypertension have been reported in Rat genome. In this study, we used our recently developed software named PGMapper (http://www.genediscovery.org/pgmapper/index.jsp) to systematically examine the genes of essential hypertension in the genomic regions for QTL across whole rat genome. Materials and Methods: We first selected blood pressure as a trait to pick up all possible QTL from Rat Genome Database (RGD, http://rgd.mcw.edu/). We then selected all QTL that have a LOD score >2.8. If two QTL are overlap and connected, we analyze them independently. If one QTL is located in the other, we just use the QTL with the larger gnome size. We used flanking markers to search genes for QTL that are fine-mapped and well-defined. We next used PGmapper software to search candidate genes. The key words are “hypertension, hypertensive, and blood pressure”. At least one abstract of the report was read to determine the candidacy of a gene. In most of the cases, more than one abstracts was read to confirm the importance of a gene. A gene is considered to be a hypotension-associated gene if it was associated with hypotension in at least one of the following studies: 1) functional studies such as knockouts, transgenics, mutagenesis, RNA interference, etc.; 2) association studies; 3) clinical studies. Results: A total of 62 hypotension QTL cover 2,015,062,129 base pairs (bp) of genomic sequence, which is roughly 73% of the total rat genome. Every autosome and the X chromosome, except chromosome 19 and Y, contains at least one hypotension QTL. The genomic size of those QTL ranges from 5873857 bps to 167769667 bps. Within the 2,015,062,129 bp genomic sequences, a total of 20,266 genes have been located. The number of genes in a QTL region is from 79 to 1398. The average gene density throughout the whole rat genome except ChrY is about one gene per 99,918 bp. Within the total of 2,015,062,129 bp genomic sequences representing hypotension QTL, there is about one gene per 99,430 bp, similar to the whole genome. Among total of 20266 genes, 160 was selected as candidate genes for hypotension, about 127 genes per candidate. Only one of those chromosomes, Chr 15, does not contain obviously recognizable candidate genes.

## 709/W/Poster Board #367

**QuTie - Rare Variant Analysis Tool for Quantitative Traits.** *R. Lawrence[1], A. Morris[1], E. Zeggini[2].* 1) Wellcome Trust Centre for Human Genetics, Oxford, OX3 7BN, UK; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1SA, UK.

We have recently developed rare variant analysis software (CCRAVAT - Case-Control RAre Variant Analysis Tool) for case-control genome-wide association studies (GWAS). The program analyses rare variants by using a collapsing method, which allows the analysis of low minor allele frequency (MAF) single nucelotide polymorphisms (SNPs) by pooling rare variants within defined regions and treating them as a single “super” locus. Genes (usually extended by 50kb either end) or sliding windows of defined sequence length are used to define regions for collapsing multiple rare variants into single loci. We have now also addressed the lack of analytical frameworks for the association analysis of quantitative trait information with rare variants genome-wide. We have developed new analysis software (QuTie) that uses the same collapsing method as CCRAVAT to convert multiple rare variants into single loci. Individuals are grouped into those that contain rare variants within a defined region and those that do not contain rare variants. Using linear regression and student’s t-tests we are then able to test the difference between the two means to determine if any regions demonstrate significant cumulative rare variant associations with the phenotype of interest. QuTie uses PED and MAP files (as used in genetic applications such as PLINK) to analyse rare variants. Summary statistics, including regression and student’s t-test derived p-values, are produced for all genes or windows of defined sequence that contain SNPs with MAFs less than a certain threshold (usually 1-5%). The script also runs permutations on any regions that pass significance thresholds. QuTie normally takes 10-16 hours to run in a GWAS of approximately 500,000 SNPs and 2,000-5,000 individuals. Permutations can add significantly to running time. QuTie can produce a Manhattan plot in addition to lists and summaries of regions genome-wide. Lists of SNPs that are within regions producing p-values that pass specified threshold are also produced to allow the user to verify SNP quality. Also, histograms showing distributions of QTs from individuals with and without rare variants in specified significant regions are produced so the user can check normality of QT distributions. In summary, we have developed software for the analysis of rare variants and quantitative traits. Our program can be applied to genome-wide scans and resequencing data.

## 710/W/Poster Board #368

**Sequencing of highly conserved non-coding regions (HCNRs) surrounding the IRX gene family in families with Kyphoscoliosis.** *C.M. Justice[1], K. Swindle[2], P. Cruz[3], B. Maskeri[3], J. Mullikin[3], N.H. Miller[2], A.F. Wilson[1].* 1) Genometrics Section, IDRB, National Human Genome Research Institute, National Institutes of Health, Baltimore, Maryland; 2) University of Colorado, The Children’s Hospital, Denver, Colorado; 3) NISC,National Human Genome Research Institute, National Institutes of Health, Rockville, Maryland.

Idiopathic scoliosis (IS) affects 2 to 3% of children or adolescents and is defined by a structural lateral curvature of the spine ≥ 10° in individuals which are otherwise phenotypically normal. When patients have a thoracic curve ≥ 40º in conjunction with a scoliotic curve ≥ 10º, the condition is referred to as kyphoscoliosis. The occurrence of kyphoscoliosis is quite rare. Miller et al.[2006] analyzed 7 families in which at least two members had kyphoscoliosis. These 7 families were comprised of 53 individuals, 16 of which had kyphoscoliosis. Genome-wide model-independent linkage analysis identified areas suggestive of linkage on 2q22, 5p13, 13q and 17q11 and analyses of single nucleotide polymorphism (SNP) markers narrowed the region on 5p to 3.5 Mb. This region contains only three genes, IRX1, IRX2 and IRX4, with the largest peak corresponding to the location of IRX1. The Iroquois gene family (IRX) is comprised of six genes which code for homeoproteins grouped in two clusters: IRX1, IRX2 and IRX4 on chromosome 5, and IRX3, IRX5 and IRX6 on chromosome 16 [Peters et al., 2000]. Both clusters are located in regions that are considered to be gene deserts [Nobrega et al., 2003]. Because of the lack of other genes in the candidate region on 5p, IRX1, IRX2 and IRX4 were selected for sequencing. The exons from IRX1, IRX2 and IRX4 were previously sequenced in all 53 individuals in the kyphoscoliosis subset. Sequencing results identified two unpublished synonymous SNPs on IRX4 which did not appear to be significant, but no functional sequence changes were identified. In this study the highly conserved non-coding regions (HNCRs) 500 kb upstream and downstream from IRX1, IRX2 and IRX4 were sequenced in 46 individuals. Selection of these conserved elements was based on the PhastCons Placental Mammal Conserved Elements, 28-way Multiz Aligment, which were limited to LOD scores above 100 within that window. All the exons of a nearby predicted gene, BC035019 (mRNA) were also sequenced. Polyphred 6.11 was used to do the genotype calls. Sequence results from HNCRs include single base pair changes, insertion/deletion sequences and copy number variants. At least one 20 bp homozygous deletion was identified in an individual with kyphoscoliosis in a HNCRs 390 kb upstream from IRX2. The conserved non-coding DNA sequences in this region may be integral to gene transcriptional regulation during embryogenesis.

## 711/W/Poster Board #369

**A polymorphism in the IL1B gene is associated with vertebral fracture independent of bone mineral density.** *X. Wu[1], V. Kondragunta[1], L. Lui[2], K. Stone[2], K. Kornman[1], N. Aziz[1].* 1) Interleukin Genetics, Inc., Waltham, MA; 2) Research Institute, California Pacific Medical Center, San Francisco, CA.

Osteoporosis is a highly prevalent disease that results in loss of bone mass and increased risk of bone fracture. Loss of bone mass is known to be a critical determinant for fracture, however, other factors such as suboptimal microarchitecture of bone tissue have also been proposed to be essential components in developing fractures. Moreover, the genes responsible for low bone mass and bone fracture are not fully understood and in a large pedigree study of 50 Caucasian families the genetic correlation between these two phenotypes was reported to be low. To address the question whether BMD and bone fracture share common genetic determinants, we conducted a genetic analysis to determine if 12 polymorphisms in selected genes (IL1A, IL1B, IL1RN, IL6, ESR1, VDR, and Col1A1) thought to be involved in bone metabolism are associated with these two clinical phenotypes of osteoporosis. DNA from 2500 subjects selected from the Study of Osteoporosis (SOF) cohort were genotyped in this retrospective case-cohort analysis. Vertebral fracture (VF) was assessed at baseline and at follow-up after 3.7 years. Both prevalent and incident VF cases were combined as VF cases for analysis. BMD was measured at the hip and dichotomized into 2 classes with low BMD defined as t score <-1 and normal BMD with t score greater than -1. Association between these SNPs and VF or low BMD was determined by logistic regression analysis with adjustment for age, BMI, estrogen use and other covariates. IL1B rs16944 genotype T/T (OR=1.44, p=0.04) was determined to be associated with VF but not with low BMD. In contrast, ESR1 rs9340799 allele A (OR=1.53, p=0.01) was associated with low BMD but not with VF. Interestingly, IL1B rs16944 was associated with VF even after adjustment for BMD, suggesting that this inflammatory cytokine is associated with VF independent of BMD. Although it is known that one of the causes leading to vertebral fracture may be due to low BMD, our genetic analysis suggests that other mechanisms may come into play in these two distinct phenotypes of osteoporosis - vertebral fracture and low bone mass.

**Genetic variation in NOS2A is associated with risk for anencephaly.** *A. Ashley-Koch, C. Potocky, K. Dunlap, A. Trott, J.M. Rusnak, C. Haynes, H. Cope, K. Soldano, S. Gregory.* Center for Human Genetics, Duke University Medical Center, Durham, NC.

Anencephaly, the failure of formation of the brain and skull, is one of the most common and severe forms of neural tube defects (NTDs). Little is known about the genetic causes of anencephaly, including whether or not anencephaly shares the same genetic risk factors which contribute to other types of NTD. The nitric oxide (NO) pathway has been implicated in the process of neural tube closure, particularly with respect to folate-homocysteine homeostasis (Weil et al., 2004). A previous report demonstrated genetic association between NOS3 and risk for spina bifida (Brown et al, 2004). To explore the possibility that genetic variation in the NO pathway is also crucial to anencephaly risk, we performed a haplotype tagging SNP analysis of the three NO synthases (NOS1, NOS2A and NOS3) in our data set of 86 anencephalic families and 22 families with other cranial NTDs. Three affection models were considered for analysis: anencephaly only, all cranial NTDs, and any NTD regardless of lesion location. Using the pedigree disequilibrium test (PDT; Martin et al., 2000), these phenotypes were analyzed for association with 16 SNPs in NOS1, 16 SNPs in NOS2A and 7 SNPs in NOS3. Contrary to the report by Brown et al (2004), we did not observe any evidence for association with NOS3, including the G894T coding variant associated in their population. Similarly, little evidence for association was observed in NOS1, where only one SNP provided nominal evidence for association (rs11611788, p=0.03 narrow phenotype). The best evidence for association in our data set was observed in NOS2A where five SNPs showed nominal evidence for association with one or more of the phenotype models. Importantly, a nonsynonymous SNP (rs2297518) was nominally associated with all phenotype models, the most significant association occurring with any type NTD (p=0.02). These data provide continued support for the involvement of the nitric oxide pathway in neural tube closure. We are currently testing these genes in our larger collection of NTD families with other NTD lesions (n>1000 families), including spina bifida, to discern whether specific NO genes contribute to specific forms of NTDs.

## 713/W/Poster Board #371

**Frequency report of the 5HTTLPR polymorphism of the SLC6A4 gene in Mexican-mestizo population.** *V. Peralta Leal[1], E. Leal Ugarte[1], JP. Meza Espinoza[1], J. Durán González[2], M. Gutiérrez Angulo[3], G. Castañeda Cisneros[4], MA. Llanas Lira[1].* 1) Genética, Universidad Autónoma de Tamaulipas, Matamoros, Tamaulipas, Mexico; 2) Biological Sciences Dept. University of Texas at Brownsville/Texas Southmost College (UTB/TSC); 3) Universidad de Guadalajara CU ALTOS; 4) Servicio Neurocirugía/Unidad Médica de alta especialidad (UMAE)/Centro Médico nacional de Occidente (CMNO)/instituto Mexicano del Seguro Social (IMSS).

Introduction.The serotonin system is considered as one of the main systems involved in the development of diverse psychiatric and personality traits (Blair IP et al., 2005). The human gene that codifies for the serotonin transporter (5HTT) is denominated SLC6A4 (Solute to carrier family 6, member 4) and it is located at the chromosome 17q12.2. Two functional polymorphisms in the promoter region of the gene SLC6A4 has been described (5HTTLPR Longitudinal Polymorphism Repeat), located at 5' and before the first exon, those LPR are not located in the coding section of the gene and do not alter the structure of the codified protein 5HTT, but they modifies the regulation of the transcription. The LPR polymorphisms consists in an insertion (allele "l") and a deletion (allele "s") of 44 pb, (Paredes B et al., 2008). Through the behavioral perspective has been associated the presence of the s allele with a greater susceptibility to develop anxiety related personality traits and fear conditioned response (Graff A et al., 2004). Material and methods. 60 individuals of Mexican population were analyzed (39 males and 21 females). Genomic DNA was isolated from peripheral blood, and DNA fragments were amplified by PCR, the products were visualized by electrophoresis in 6% polyacrylamide gels and stained with silver nitrate. Results. Distribution of genotypes in our sample was in Hardy-Weinberg equilibrium, 21 (36%) subjects had the s/s genotype, 26 (44%) had l/s, and 12 (20%) were l/l. Frequency of the long allele was lower with 42% versus 58% of the short LPR. No difference in allele or genotype frequencies was found between sex groups. Discussion. Most of the studies all over the Word report high frequency of the l allele, but similar frequencies to this study have been reported before in Japanese and Korean populations by Nakamura ET et al., and Ho Joo et al., The authors suggest that the high frequency of the s allele in Japanese population is related with the interpersonal sensitivity and emotional restrains regarded in their culture.

## 714/W/Poster Board #372

**Schizophrenia susceptible genes are associated with cranial volume variations in Chinese population.** *B. Su[1], J. Wang[1,2], X. Luo[1,2], Y. Li[3], H. Diao[4], X. Shi[3].* 1) Kunming Inst Zoology, Chinese Academy Sci, Kunming, China; 2) Graduate School of Chinese Academy of Sciences, Beijing, China; 3) Biological Resources and Environmental Science College, Qujing Normal University, Kunming, China; 4) Yunnan Mental Health Hospital, Kunming, China.

Schizophrenia is a severe mental illness and affects about 1% of world populations. Cognitive dysfunction and structural brain abnormalities in schizophrenia have been extensively studied and smaller brain volumes of schizophrenia patients were consistently reported. Though genetic studies indicated that more than a hundred genes were associated with schizophrenia, the connections between the genetic makeup and the observed structural brain abnormalities is not well characterized. To examine whether the schizophrenia susceptible genes are involved in brain development and if the disease-associated sequence variations in these genes are correlated with the variation of brain volume in healthy populations. A total of 22 single nucleotide polymorphisms (SNPs) from 10 schizophrenia susceptible genes were genotyped for the 1,013 human subjects. Among the 10 schizophrenia susceptible genes tested, six of them show significant association with brain volume under at least one of the three genetic models in at least one sex. The combined effect of the nominally significant SNPs could explain about 2% of the cranial volume variation observed in the population. Additionally, we also identified two pairs of SNPs (rs951439 and rs35753505 in males; rs2020917 and rs2270335 in females) showing sex specific epistatic association with cranial volume. We demonstrate that a proportion of the schizophrenia susceptible genes are likely involved in brain development by showing a significant correlation with cranial volume in healthy human subjects, providing a possible genetic explanation to the brain volume abnormality of schizophrenia patients. Our data provide further evidence that schizophrenia is likely a neurodevelopmental disorder.

## 715/W/Poster Board #373

**Lung cancer and candidate DNA repair genes: Evidence of significant association with MSH5 and potential interaction between smoking and RAD54B.** *R. Kazma[1,2], E. Génin[2,3], M.-C. Babron[4], P. Brennan[2,3], R.J. Hung[5], H. Krokan[6], A. Metsapalu[7], J.K. Field[8], M. Lathrop[9,10], A. Sarasin[11], S. Benhamou[2,3,11], the ILCCO consortium.* 1) Univ Paris-Sud, Faculté de Médecine, Le Kremlin Bicêtre, France; 2) INSERM UMR-S946, Paris, France; 3) Univ Paris-Diderot, Paris, France; 4) International Agency for Reasearch on Cancer (IARC), Lyon, France; 5) University of California at Berkeley, Berkeley, California, USA; 6) Norwegian University of Science and Technology, Trondheim, Norway; 7) Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia; 8) University of Liverpool Cancer Research Center, Liverpool, UK; 9) Centre National de Génotypage, Commissariat à l'Energie Atomique, Evry, France; 10) Fondation Jean Dausset - CEPH, Paris, France; 11) CNRS FRE2939, Institut Gustave Roussy, Villejuif, France.

Although lung cancer is typically caused by smoking, inherited factors [that can be assessed by single-nucleotide polymorphisms (SNPs)] could contribute to individual susceptibility to tobacco carcinogens. DNA repair genes are good candidates for such susceptibility because of their critical role in maintaining genome integrity. Furthermore, SNPs in these genes could modify the effect of smoking on lung cancer risk.

To assess the role of SNPs in DNA repair genes on lung cancer risk, and their interaction with smoking exposure, we pooled individual data from 6 recent genome-wide association studies for a total of 3,416 lung cancer cases and 4,374 controls, all of European descent. Genotypes for 1,760 SNPs on selected 233 DNA repair genes were available and analyzed assuming an additive model and using unconditional logistic regression, controlling for sex, age and study.

We found a significant increase in risk for lung cancer associated with the rs3131379 on MSH5 gene ($p = 3.57\ 10^{-5}$) with an odds ratio per allele of 1.30 (95% confidence interval (CI): 1.15-1.47).

The interaction analyses yielded potential differences in cancer risk associated with RAD54B rs2930961 polymorphism between never- and ever-smokers but came with a non-significant p-value after correction for multiple testing ($p = 2.31\ 10^{-4}$) for an interaction coefficient estimate of 1.54 (95% CI: 0.78-2.95). Compared to the T/T genotype, the odds-ratios were 0.79 (95% CI: 0.59-1.05) for the T/C genotype and 0.43 (95% CI: 0.25-0.73) for the C/C genotype among never-smokers, and 1.10 (95% CI: 0.98-1.25) and 1.13 (95% CI: 0.94-1.36) respectively, among ever-smokers.

Our results confirmed a previously reported association with the MSH5 gene with a similar risk estimate. This gene encodes a member of the mutS family of proteins that are involved in DNA mismatch repair and in mitotic or meiotic recombination processes. RAD54B, a DNA-dependent ATPase, is similarly involved in mitotic and meiotic homologous repair. Homozygous mutations of this gene are often found in various cancers. These results disclose an association between recombination repair pathways and lung cancer.

**Serum asymmetric dimethylarginine levels are associated with diabetic retinopathy and influenced by sequence variation in the *DDAH1* and *DDAH2* genes.** *S. Abhary[1], N. Kasmeridis[2], K.P Burdon[1], A. Kuot[1], M.J. Whiting[3], Y. Yew[4], N. Petrovsky[2], J.E. Craig[1].* 1) Ophthalmology, Flinders University and Flinders Medical Centre, Adelaide, South Australia, South Australia, Australia; 2) Endocrinology, Flinders University and Flinders Medical Centre, Bedford Park, SA, 5042, South Australia, AUSTRALIA; 3) Chemical Pathology Laboratory, SA Pathology, Bedford Park, SA, 5042, AUSTRALIA; 4) Department of Medical Biochemistry, Flinders University, Bedford Park, SA, 5042.

Objective: Asymmetric dimethylarginine (ADMA) is present at varying levels in serum, and as a substrate for nitric oxide synthase influences nitric oxide production. Dimethylarginine dimethylaminohydrolase (DDAH) is an ADMA degrading enzyme and has two isoforms: DDAH1 and DDAH2. ADMA levels are known to be associated with type 2 diabetes mellitus (T2DM), and some small studies have suggested a correlation with diabetic complications. We aimed to determine: 1) whether serum ADMA levels are correlated with severe diabetic retinopathy (DR) in a large cohort of individuals with type 2 diabetes mellitus, and 2) whether ADMA serum levels are influenced by common polymorphisms in the *DDAH1* and *DDAH2* genes. Methods: A total of 343 participants with T2DM were recruited, ophthalmological assessment performed and peripheral blood obtained for serum and genetic analysis. ADMA concentrations were determined by mass spectroscopy of serum and tested for association with DR. Twenty six tag SNPs in the *DDAH1* and 10 in the *DDAH2* genes were genotyped in all subjects and tested for association with serum ADMA levels. Results: Two hundred and twenty five participants were found to have no DR, 59 had proliferative diabetic retinopathy (PDR), 82 had clinically significant macular edema (CSME), and 27 had severe non-proliferative DR (NPDR). Blinding DR was defined as severe NPDR, PDR or CSME. After adjustment for relevant covariates, the presence of blinding DR, PDR and CSME were associated with significantly increased serum levels of ADMA ($p<0.001$). Several SNPs and haplotypes in the *DDAH1* gene were associated with ADMA levels. Under the additive model, rs669173 (p=1.35E-06) and rs7521189 (p=2.31E-05) and the AATTT haplotype consisting of SNPs rs12132677, rs7521189, rs17388437, rs11161614 and rs553257 (p=1.52E-4) were the most significantly associated with serum ADMA. The rs3131383 SNP (p=0.0049 under a dominant model) and TGCCCAGGAG haplotype consisting of SNPs rs805287, rs6916278, rs805285, rs15574, rs805294, rs805293, rs9267551, rs2272592, rs3131383 and rs3131382 (p=0.0024) in the *DDAH2* gene were also significantly associated with serum ADMA levels. These associations remained significant after Bonferroni correction. Conclusion: Severe forms of DR causing visual impairment were associated with elevated serum concentrations of ADMA, which are in turn determined by genetic variation in the *DDAH1* and *DDAH2* genes.

## 717/W/Poster Board #375

**Nicotinic acetylcholine receptor polymorphism interacts with smoking history to affect lung function decline.** *L. Akhabir[1], X. Zhang[1], J. Connett[2], N. Anthonisen[3], M. Lathrop[4], W. Cookson[5], P.D. Parè[1], A.J. Sandford[1].* 1) The James Hogg iCAPTURE Centre, vancouver, British Columbia, Canada; 2) Division of Biostatistics, University of Minnesota, USA; 3) Faculty of Medicine, University of Manitoba, Canada; 4) Centre National de Génotypage, Institut Génomique, France; 5) National Heart & Lung Institute, Imperial College London, UK.

Single nucleotide polymorphisms (SNPs) in the nicotinic acetylcholine receptor gene cluster have been associated with lung cancer, nicotine addiction, cocaine and alcohol dependence as well as smoking behavior. In particular, the SNP rs16969968 in the CHRNA5 gene was the most significant signal in genome-wide association study data, and its association with nicotine dependence and cancer was consistently replicated. Chronic obstructive pulmonary disease (COPD) is a complex trait caused by a combination of environmental risk factors and suspected genetic factors. Cigarette smoking is by far the most important environmental element in the pathogenesis of COPD. A genetic variant that affects the nicotinic acetylcholine receptor function is thus an important target for investigation in relation to COPD phenotypes. We genotyped 1600 COPD patients' samples for the rs16969968 SNP using the TaqMan genotyping platform. This dataset is part of the Lung Health Study (LHS) cohort, and is comprised of patients in both extremes of lung function decline as measured by FEV1 (slow or fast decline) during the five years of the study. Analysis was performed using Wilcoxon test, Chi Square test and multiple regression models with analysis of gene-environment interaction when appropriate. In agreement with previous results, the rs16969968G allele was associated with amount of cigarette smoking during the LHS (p=0.027). In contrast, this SNP was not associated with cigarette smoking history before the study. After adjusting for smoking, the GG genotype was significantly associated with lung function decline (p=0.0180). Moreover, the rs16969968 SNP significantly modified the effect of smoking on lung function decline (p=0.044). The GG genotype was associated with a stronger relationship between cigarette smoking and lung function decline We successfully replicated the rs16969968 association with cigarette smoking and found a novel gene by environment interaction, namely rs16969968 GG genotype-by-smoking history affecting lung function decline in a COPD cohort. This SNP seems to be associated with level of addiction to nicotine in COPD patients, since after an anti-smoking intervention patients with the GG genotype smoked less than those with GT/TT genotypes. Future directions for this project are to genotype the entire LHS cohort (~4800 samples), and to further investigate other available phenotypes; e.g. successful smoking cessation.

**An investigation of stress response and DNA repair pathways identifies additional risk loci for multiple sclerosis.** *L.F. Barcellos[1], F.B.S. Briggs[1], S.E. Bartlett[2], B.A. Goldstein[3], International Multiple Sclerosis Genetic Consortium.* 1) Division of Epidemiology, School of Public Health, University of California, Berkeley; Berkeley, CA; 2) Ernest Gallo Clinic and Research Center University of California, San Francisco; San Francisco, CA; 3) Division of Biostatistics, School of Public Health, University of California, Berkeley; Berkeley, CA.

Multiple sclerosis (MS) is a complex inflammatory and demyelinating autoimmune disease (AD) of the CNS with a prominent genetic component. The primary genetic risk factor is the HLA-DRB1*1501 (DR2) allele. Additional risk loci with modest effects have been identified using genome wide association and meta-analytical approaches; however, much of the remaining genetic contribution to MS has not been elucidated. Here, we investigated variation in several genes from two candidate pathways relevant to MS pathogenesis: stress response and DNA repair. Previous studies of psychological stress in MS have shown associations with both increased disease risk and greater risk for relapse and exacerbation. A potential role for DNA repair in MS has also been described. A recent gene expression study of MS lymphocytes reported aberrant expression of several DNA repair genes. Further, a role for DNA repair has been implicated in several ADs including autoimmune nephritis, SSc, SLE, and RA. Univariate testing was performed using genotypes from 1,343 MS cases and 1,379 healthy controls of European ancestry. A total of 354 SNPs within 10 genes related to stress response and 485 SNPs within 72 genes related to DNA repair pathways; including BER, NER, NHEJ, and HRR, were investigated. Results meeting our criteria for significance are described here. A significant association with decreased risk was observed for multiple intronic SNPs within CRHR1 on 17q21 (OR=0.7, p=3 x 10-3). Several intronic SNPs within OPRD1 on 1p35 (OR=0.75, p=3 x 10-3) were associated with decreased risk for MS in DR2 positive individuals (N= 702 cases, 345 controls), while intronic SNPs within OPRK1 on 8q11 (OR=1.5, p=3 x 10-4) were associated with increased risk of MS in DR2 negative individuals (N=638 cases, 1,030 controls). Amongst the DNA repair genes, SNP variants within GTF2H4 and XAB2 were significantly associated with MS (OR=0.7, p=7 x 10-8; OR=1.3, p=9 x 10-4). In DR2 positive individuals, a coding variant in XAB2 on 19p13 (OR=1.5, p= 1 x 10-3) was associated with increased risk, while GTF2H4 on chr 6 (OR= 0.7 p=6 x 10-5) was strongly associated with decreased risk of MS in DR2 negative individuals. Using a human protein interaction database software tool, STRING, we were able to construct a subnetwork for each pathway that included our final candidates. Collectively, our results provide strong evidence for the involvement in MS, of variation within genes from these important candidate pathways.

### 719/W/Poster Board #377

**Gender Specific Associations Between Lipid Related Candidate Genes and Carotid Plaque.** *A. Beecham[1], DM. Yanuck[2], H. Gardener[2], S. Slifer[1], SH. Blanton[1], L. Wang[1], RL. Sacco[2], T. Rundek[2].* 1) Institute for Human Genomics, Univ Miami, Miami, FL; 2) Department of Neurology, Univ Miami, Miami, FL.

Introduction: Carotid plaque is a distinct phenotype of atherosclerosis and an important subclinical marker of stroke. Sex differences have been identified in stroke risk and in the distribution of determinants of carotid atherosclerosis; however, the sex specific genetic contribution to carotid plaque is unknown. We sought to examine the sex specific associations between SNPs in candidate genes involved in lipid metabolism and several carotid plaque phenotypes (presence of plaque, multiple, thick, irregular, and calcified plaque). Methods: Two-hundred eighty-seven Dominicans from the Genetic Determinants of Subclinical Carotid Disease study were examined for carotid plaque by high-resolution ultrasound. Data was divided by sex (167 females; 120 males) and multiple logistic regression was used to test for association between 64 SNPs implicated in lipid metabolism and plaque phenotypes, controlling for age and smoking. To test for a SNP*sex interaction, an overall analysis in both females and males was done, controlling for age, smoking, sex, and the SNP. Two SNPs in the OLR1 gene (rs11053646 and rs11053639) were chosen, based on linkage disequilibrium (LD) structure and direction of effects, for haplotype analysis (haplo.stats). Results: Variations in five distinct genes (MTP, OLR1, LPL, APOE, LIPC) may have sex specific roles (p< 0.1 for SNP*sex interaction). In particular, rs11053646 in the OLR1 gene demonstrated a sex specific effect for all plaque phenotypes. Analysis of haplotypes identified an OLR1 2-SNP haplotype (rs11053639 and rs11053646; A-C) associated with an increased risk for irregular (p=3.00E-05), thick plaque (p=0.003), and plaque presence (p= 0.004) in women only. The G-G haplotype showed a protective effect for thick (p=0.039) and irregular plaques (p=0.047) in men but only for irregular (p=0.031) in women. Conclusions: We provide evidence suggesting that variations in lipid metabolism genes have sex-specific roles in carotid plaque burden. Differences in common carotid risk factors between men and women could play a role in gene*environment interactions and may be the subject of further study. Although the mechanism is unknown, variations in lipid metabolism genes may respond differently to sex-hormones and therefore affect lipid metabolism and atherosclerosis in a sex dependent manner.

### 720/W/Poster Board #378

**Genetic variants of the DDR1 gene are associated with vitiligo in a brazilian population.** *C.C.S Castro[1,3], L.M. Nascimento[1], G. Walker[2], E. Nogoceke[2], R.I. Werneck[1], M.T. Mira[1].* 1) Graduate Program in Health Sciences, Pontifical Catholic University of Parana, Curitiba, Parana, Brazil; 2) F. Hoffmann-La Roche Ltd, Basel, Switzerland; 3) Department of Dermatology, Pontifical Catholic University of Parana, Curitiba, Parana, Brazil.

Vitiligo is an acquired, systemic, chronic disease characterized by maculae devoid of melanic pigment and identifiable melanocytes. Adhesion of melanocytes to the basement membrane by integrin CCN3 is mediated through collagen IV receptor DDR1. We hypothesize that genetic variants of the DDR1 gene are associated with the occurrence of vitiligo. To test this hypothesis, we genotyped 10 Tag SNPs spanning DDR1 and the neighbouring gene GTF2H4 in 639 individuals distributed in 213 family trios composed by an affected child and both parents. Associated markers were then genotyped in an additional sample of 134 unrelated individuals with vitiligo and 134 unrelated controls from the same geographic area. Allele “A” of DDR1 intragenic tag SNP rs2267641 was associated with an increase risk for vitiligo on both family-based and case-control population sample (P=0.008, OR=4.00; 95% C.I. = 1.44 - 11.58 and P=0.04, OR=6.00; 95% C.I. = 1.73 - 52.33, respectively). In addition, we observed an age-dependent enrichment of rs4618569 “G” allele and rs2267641 “A” allele in affected individuals younger than 25 years (P=0.008; OR=7.04; 95% CI = 1.66-29.86 and P= 0.01; OR=4.26; 95% CI = 1.28-14.16, respectively). In conclusion, we propose the DDR1 as a new susceptibility gene for vitiligo, possibly implicating a defective cell adhesion on vitiligo pathogenesis.

### 721/W/Poster Board #379

**Fine mapping of Hirschsprung’s disease loci in 9q31.** *S.S. Cherny[1], C.S.M. Tang[1], Y. Sribudiani[4], X.P. Miao[2], M.T. So[2], P.C. Sham[1,3], P.K.H. Tam[2], M.M. Garcia-Barceló[2], R. Hofstra[4].* 1) Psychiatry, The University of Hong Kong, Pokfulam, Hong Kong; 2) Surgery, The University of Hong Kong, Pokfulam, Hong Kong; 3) Genome Research Centre, The University of Hong Kong, Pokfulam, Hong Kong; 4) Genetics, University Medical Center Groningen, Groningen, The Netherlands.

Hirschsprung’s disease (HSCR) is a congenital disorder in which there is an absence of ganglion cells in variable portions of the lower digestive tract, according to which patients are classified. The *RET* gene is the largest risk factor in HSCR, although reduced penetrance of *RET* mutations, absense of *RET* mutations in some patients, and variable expression of the HSCR phenotype indicate that more than one gene is involved. A *RET*-dependent modifier which segregates in families harboring no or hypomorphic *RET* mutations was mapped to 9q31. Fine mapping of the region performed on 142 Dutch trios by genotyping 370 tag-SNPs spanning approximately 7 Mb (from 108.5-115.5 Mb) of 9q31 on an Illumina GoldenGate platform identified two different 9q31 HSCR-associated regions in which genes with biological plausibility lie.

Since evaluation of an association in a population of different origin from that of the initial finding increases the association confidence and, since linkage disequilibrium (LD) differences across populations can be used to narrow the regions of interest, we genotyped 181 Chinese HSCR patients and 179 controls for 38 tag-SNPs chosen from the CHB population spanning the 9q31 regions of interest. In addition, we made use of genotype data for the 9q31 region obtained from a genome-wide association study recently conducted in Chinese HSCR patients.

Only one of the two 9q31 HSCR-associated regions identified in the Dutch population was associated in Chinese ($p = 0.021$), although the most associated SNPs within the region differed, probably due to differences in LD and/or different genotyping densities. Importantly, the associated region encompasses *IKBKAP* and *CTNNAL1*, which have been linked to neurodevelopmental disorders.

## 722/W/Poster Board #380

**Comprehensive resequencing of F2 gene in Systemic Lupus Erythematosus.** *F.Y. Demirci[1], Y. Wang[1], A.H. Kao[2], E.Y. Rhew[3], R. Ramsey-Goldman[3], S. Manzi[2], M.I. Kamboh[1].* 1) Dept of Human Genetics, Univ of Pittsburgh, Pittsburgh, PA; 2) Lupus Center of Excellence, Univ of Pittsburgh, Pittsburgh, PA; 3) Div of Rheumatology, Northwestern Univ, Chicago, IL.

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease that primarily targets women of child-bearing age. SLE women are also at high risk of premature cardiovascular disease. Prothrombin (F2), a key enzyme in blood coagulation, is one of major antigens recognized by antiphospholipid antibodies that are associated with vaso-occlusive events in SLE patients. Prior studies have implicated *F2* variants in thrombosis and cardiovascular disease in non-SLE individuals. The aim of this study was to comprehensively evaluate the role of *F2* genetic variation in SLE risk and related features. We resequenced approximately 22-kb-long genomic fragment that harbors the entire F2 gene and flanking regions in a total of 285 individuals (115 White SLE patients & 105 White normal controls and 40 Black SLE patients & 25 Black normal controls). A total of 217 sequence variants (153 in Whites and 123 in Blacks) were identified. In each ethnic group, more than 2/3 of identified variants were relatively uncommon with ≤5% minor allele frequency (MAF). We identified a large number of novel variants that were not previously reported in publicly available databases. *F2* sequence variants were mostly single nucleotide substitutions, however, a small number of indels were also observed. Only 6.5% of all identified variants were located in exons. The vast majority of rare variants (MAF<1% in each ethnic group) were observed in cases only (~68% of rare variants in Whites and ~80% of rare variants in Blacks) and a higher percentage of cases were found to carry rare variants as compared to controls in both ethnic groups. These observations implicate enrichment of *F2* rare variants in SLE patients. The ongoing screening of identified rare variants and common tag SNPs in the large SLE case-control sample (>1,400 individuals) will document the full spectrum of the contribution of *F2* rare and common genetic variation to SLE pathogenesis and related clinical features.

## 723/W/Poster Board #381

***ELMO1* variants and susceptibility to diabetic nephropathy in American Indians.** *J.K. DiStefano[1], M.P. Millis[1], N.J. Young[1], K.A. Yeatts[1], S. Kobes[2], R.G. Nelson[2], W.C. Knowler[2], R.L. Hanson[2].* 1) Diabetes, Cardiovascular and Metabolic Diseases Division, Translational Genomics Research Institute, Phoenix, AZ; 2) Diabetes Epidemiology and Clinical Research Section, NIDDK, NIH, Phoenix, AZ.

Variants in the engulfment and cell motility 1 gene, *ELMO1*, have previously been associated with diabetic kidney disease attributed to type 2 diabetes mellitus in Japanese and African American individuals. The Pima Indians of Arizona have very high rates of diabetic nephropathy (DN), which is strongly dependent on genetic determinants; therefore, the goal of this study was to investigate the role of *ELMO1* polymorphisms in mediating susceptibility to DN in this population. We sequenced 17.4 kb of *ELMO1* corresponding to all exons, exon-intron boundaries, and 3 kb of upstream regulatory region in 36 Pima Indians and identified 19 single nucleotide polymorphisms (SNPs), six of which were novel. Seven SNPs were excluded from further study; four which were in 100% genotypic concordance with other *ELMO1* variants and three with a minor allele frequency <0.05. The remaining 12 SNPs, along with 21 additional markers showing association with DN in the previously reported Japanese and African American studies, were genotyped in 141 individuals with nephropathy and 416 individuals without heavy proteinuria in a family study of 257 sibships. Association was analyzed using a mixed effects logistic regression model with control for age, sex and duration of diabetes and with a random effect to account for sibship. We saw the strongest evidence for association with rs1345365 (odds ratio [OR]= 2.42 per copy of the A allele [1.35-4.32]; P=0.001) and rs10951509 (OR= 2.42 per copy of the A allele [1.31-4.48]; P=0.002), both of which are located within 13 kb of one another in intron 13 and are in strong linkage disequilibrium ($r^2$=0.97). These markers also showed statistically significant evidence for association with DN in the African American study although the association was in the opposite direction (OR=0.82 per copy of the A allele P<0.004); further, three additional markers showing statistically significant evidence for association with DN in the present study were also located in this region (P<0.05). None of the markers from the Japanese study were associated with DN in Pima Indians (P>0.05). These results identify novel *ELMO1* variants and provide additional support for this gene as a susceptibility locus for diabetic kidney disease across multiple populations.

## 724/W/Poster Board #382

**Allele specific gene expression supports *GABRG3* as a candidate gene affecting risk for alcohol dependence.** *H. Edenberg[1,2], X. Xuei[1], L.F. Wetherill[2], T. Foroud[2], Collaborative Study on the Genetics of Alcoholism.* 1) Dept Biochemistry & Molecular Biology, Indiana Univ School Medicine, Indianapolis, IN; 2) Dept. Medical & Molecular Genetics, Indiana Univ School Medicine, Indianapolis, IN.

We have previously reported evidence from family-based association studies that variations in *GABRG3* are associated with the risk for alcohol dependence (Dick et al. 2004, Alcoholism Clin Exp Res 28, 4). Of the 11 single-nucleotide polymorphisms (SNPs) tested in trios, 7 yielded evidence of association (p<0.05) and 3 others were suggestive; those 10 SNPs were in high LD with each other. Additional analysis indicates that the association is with those subjects who have a later age of onset. One of the associated SNPs, rs140679, is a synonymous SNP in the coding region (Thr321). Because we hypothesized that the association could be based upon differences in gene regulation, we analyzed whether the alleles were differentially expressed in samples of individual human brains. Differential allele expression was measured using allelotyping software on the Sequenom MassARRAY System. We obtained data from 19-22 heterozygous individuals in each of 9 brain regions: prefrontal cortex, cingulated cortex, visual cortex, amygdala, thalamus, hippocampus, caudate nucleus, putamen, and cerebellum. In nearly all of the samples, there was differential allelic expression (median p value = $1.4 \times 10^{-4}$), with the T allele overexpressed (average expression ratio T/C = 1.24). The T allele is overtransmitted to affected individuals. These data strengthen the evidence that variations in *GABRG3* affect alcohol dependence, probably by altering the relative expression of the gamma3 subunit of the $GABA_A$ receptor. [Supported by U10AA008401; brain tissues were provided by the Tissue Resource Center, Univ. of Sydney, supported by R01AA12725.].

## 725/W/Poster Board #383

**Identification of rare variants in the NRG1 gene of Hirschsprung's patients.** *M. Garcia-Barcelo[1], W.K. Tang[1], X.P. Miao[1], C. Tang[2], M.T. So[1], Y.Y. Leon[1], P.C. Sham[2,3], S.S. Cherny[2], P.K. Tam[1].* 1) Dept Surgery, Univ Hong Kong, Hong Kong, Hong Kong; 2) Dept Psychiatry, Univ Hong Kong, Hong Kong, Hong Kong; 3) Genome Research Centre, Univ Hong Kong, Hong Kong, Hong Kong.

Hirschsprung's disease (HSCR, aganglionic megacolon), is a congenital disorder characterized by the absence of enteric ganglia in variable portions of the distal intestine. HSCR has a complex pattern of inheritance and presents mainly sporadically. Besides the major HSCR gene, RET, and other implicating genes (e.g. EDNRB), there is evidence that other loci contribute to HSCR. Recently, through a genome-wide association study, we identified NRG1 as a new HSCR contributing locus. Several lines of evidence indicate that in addition to common variants/SNPs, rare variants may contribute substantially to the multifactorial inheritance of complex diseases, and that the genes with disease-associated SNPs are to be considered candidates for the search of deleterious rare variants. We hypothesized that rare NRG1 variants contributing to HSCR may exist. To identify these variants, we have sequenced the 17 exons (including exon/intron boundaries) of NRG1 of 386 HSCR patients and 100 controls on an ABI 3730xl DNA Analyzer. We have identified 7 novel rare variants in 7 patients that cause 4 non-synonymous amino-acid changes, a truncation of the protein, a disruption of the splice site and an alteration of the conserved region intronic region in the exon boundary. The non-synonymous amino-acid substitutions affect highly conserved residues and have not been found in the controls. The four patients bearing NRG1 rare variants have no disease-associated variants in RET or any other HSCR-associated gene. The finding of rare NRG1 variants with an obvious functional effect on the NRG1 protein, suggest that NRG1 is one of the several molecules contributing to the pathology of HSCR. More controls are currently being sequenced.

## 726/W/Poster Board #384

**ABO blood type is associated with lung function among elderly men of Japanese ancestry in a within sibship association study.** *J. Grove[1,2], E. Tam[2], J. Curb[2].* 1) Biostat Prog, Pub Hlth Sci, Univ Hawaii, Honolulu, HI; 2) John A. Burns School of Medicine, Univ Hawaii, Honolulu, HI.

Research Question: Is ABO histotype associated with lung function among the elderly?

Study Design: Within sibship gene association study based on a birth cohort study of men of Japanese ancestry living in Hawaii (Honolulu Heart Program)

ABO histo-blood type has been reported to be related to the risk of asthma, with presence of type A antigen being associated with lower risk. Reported associations with other aspects of lung function have been inconsistent. ABH antigens are expressed on lung epithelial tissue and differences in antigen type may influence opportunistic bacterial growth and inflammation of the lung's lining. We investigated whether ABO type is associated with normal lung function among participants in the Honolulu Heart Program, a longitudinal study of a birth cohort of men of Japanese ancestry who lived on the island of Oahu in 1965.

Forced expiratory volume in one second (FEV1) and total forced expiratory volume (FVC) were regressed within sibships on age at exam, packs per day smoked, height, bi-achromial diameter, and presence of A antigen, with standard errors estimated using generalized estimating equations. Adjusted for these covariates, the sibling intraclass correlations were 0.25 for FEV1 and 0.24 for FVC. Men with type A antigen had non-significantly greater FEV1 and FVC than their siblings at the first exam (ages 45-67, $p > 0.10$). At a later examination held in 1992-93, when the survivors were elderly (ages 73-93), FEV1 and FVC were very highly significantly greater among men with A antigen than their non-A bearing siblings ($p = 0.0006$ for FEV1, $p = 0.0063$ for FVC, 3098 men with valid measurements); men with A antigen averaged 5.1% greater FEV1 than their siblings without A antigen.

## 727/W/Poster Board #385

**Association of *SPI1* 3' untranslated region polymorphism with systemic lupus erythematosus.** *K. Hikami[1], A. Kawasaki[1], I. Ito[1], M. Koga[1, 2], S. Ito[3], T. Hayashi[3], D. Goto[3], I. Matsumoto[3], A. Tsutsumi[3, 4], Y. Takasaki[5], H. Hashimoto[6], T. Arinami[2], T. Sumida[3], N. Tsuchiya[1].* 1) Mol Genet Epidemiol Lab, Univ of Tsukuba, Tsukuba, Japan; 2) Dept Med Genet, Univ of Tsukuba, Tsukuba, Japan; 3) Div Clin Immunol, Univ of Tsukuba, Tsukuba, Japan; 4) Takikawa Municipal Hospital, Takikawa, Japan; 5) Div Rheumatol, Juntendo Univ, Tokyo, Japan; 6) Juntendo Univ Sch Med, Tokyo, Japan.

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease caused by a complex combination of genetic and environmental factors. In view of the significance of type I interferon (IFN) pathway in the pathogenesis of SLE, 55 IFN-related genes were screened for association with SLE. One of the genes that demonstrated association in the first screening, *SPI1* (also referred to as PU.1), is an Ets family transcription factor that is essential for lymphoid and myeloid development. SPI1 is expressed highly in myeloid cells and B cells, and is known to interact with IRF2, IRF4 and IRF8. In this study, we performed a case-control association study using six tag SNPs in *SPI1* and its promoter, and a SNP located in 17 kb upstream of *SPI1*, previously associated with acute myeloid leukemia, in 400 Japanese patients with SLE and 450 healthy controls. Significant association was detected in an intron 2 SNP rs10769258 ($P = 0.01$, OR = 1.29, 95% CI 1.06-1.57). With respect to the disease subset, the association was observed in the patients with nephritis ($P = 0.007$, OR = 1.40, 95% CI 1.10-1.80) but not in those without nephritis. We next performed resequencing of enhancer, promoter, and all exons in *SPI1* gene to identify functional polymorphisms associated with pathogenesis of SLE. A SNP rs1057233 was identified in *SPI1* 3' untranslated region (3' UTR) that was in linkage disequilibrium with rs10769258. Expression analysis using HapMap database and GENEVAR B cell line expression database showed that the number of risk allele at rs1057233 was strongly correlated with *SPI1* mRNA level ($P = 0.0002$, JPT + CHB data). Furthermore, a reporter assay using luciferase reporter vector demonstrated that the rs1057233 risk allele was associated with higher expression. These results suggested that a functional polymorphism in the 3' UTR of *SPI1* that positively regulates gene expression may be associated with SLE.

## 728/W/Poster Board #386

**Variation in the uric acid transporter gene (*SLC2A9*) is associated with memory performance.** *L.M. Houlihan[1], N.D. Wyatt[2], S.E. Harris[3], A.J. Gow[1], R.E. Marioni[4], J.F. Price[4], J.M. Starr[5], C. Hayward[2], A.F. Wright[2], I.J. Deary[1].* 1) Centre for Cognitive Ageing and Cognitive Epidemiology, Department of Psychology, The University of Edinburgh, 7 George Square, Edinburgh, EH8 9JZ, UK; 2) MRC Human Genetics Unit, The Institute of Genetics and Molecular Medicine, Western General Hospital, Edinburgh, EH4 2XU, UK; 3) Centre for Cognitive Ageing and Cognitive Epidemiology, Medical Genetics Section, The University of Edinburgh, Edinburgh, EH4 2XU, UK; 4) Public Health Sciences Section, Division of Community Health Sciences, The University of Edinburgh, Medical School, Teviot Place, Edinburgh, EH8 9AG; 5) Centre for Cognitive Ageing and Cognitive Epidemiology, Geriatric Medicine Unit, The University of Edinburgh, Royal Victoria, Craigleith Road, Edinburgh, EH4 2DN, UK.

Understanding the basis of human cognitive ageing is important to improve the health and well-being of an expanding elderly population. Serum uric acid levels have been related to cognitive functioning in humans, though the direction of the association is equivocal. SLC2A9 is a urate transporter and its association with serum uric acid levels is well-established. This study tested four *SLC2A9* SNPs for association with cognitive abilities in three cohorts. First, the Lothian Birth Cohort 1921 (LBC1921) were tested on general cognitive ability at age 11 and, at mean ages of 79 (n=520), 83 (n=281) and age 87 (n=177), they completed cognitive ability test batteries. Second, approximately 1,000 Scots, the Lothian Birth Cohort 1936 (LBC1936) were tested on general cognitive ability at age 11 and, at mean age 70, they re-sat the same general cognitive ability test and a battery of diverse cognitive tests. Third, replication is being attempted in another sample of approximately 1,000 elderly Scots aged from 60 and 74 years, namely the Edinburgh Type 2 Diabetes Study (ET2DS) where cognitive testing and serum uric acid levels are also available. *SLC2A9* was associated with logical memory in LBC1921 at age 79, 83 and 87 (all $P$-values < 0.05). Significant associations were detected with *SLC2A9* and a general memory factor in LBC1936 and other individual cognitive ability tests: logical memory, spatial span, verbal paired associates, block design and simple and choice reaction time (best $P$-value = 0.0002). Results of the replication study in ET2DS will also be presented. If *SLC2A9* variants are a proxy for serum uric acid levels, this study would suggest that higher serum uric acid levels are associated with increased performance in memory-related tasks.

## 729/W/Poster Board #387

**Fetal Genetic Risk Factors for Isolated Cleft Lip Only.** *A. Jugessur[1], M. Shi[2], H.K. Gjessing[3,4], R.T. Lie[4,5], A.J. Wilcox[6], C.R. Weinberg[2], K. Christensen[7], A.L. Boyles[6], S. Daack-Hirsch[8], T. Trung Nguyen[5], C. Bille[7], A.C. Lidral[9], J.C. Murray[7,9].* 1) Craniofacial Development, Musculoskeletal Disorders, Murdoch Childrens Research Institute, Royal Children's Hospital, 3052 Parkville, Australia; 2) Biostatistics Branch, National Institute of Environmental Health Sciences (NIEHS), Research Triangle Park, Durham, NC 27709; 3) Department of Epidemiology (EPAM), Norwegian Institute of Public Health, N-0403 Oslo, Norway; 4) Section for Epidemiology and Medical Statistics, Department of Public Health and Primary Health Care, University of Bergen, N-5018 Bergen, Norway; 5) Medical Birth Registry of Norway, Norwegian Institute of Public Health, N-5018 Bergen, Norway; 6) Epidemiology Branch, National Institute of Environmental Health Sciences (NIEHS), Research Triangle Park, NC 27709; 7) Department of Epidemiology, University of Southern Denmark, DK-5000 Odense, Denmark; 8) College of Nursing, University of Iowa, Iowa City, IA 52242; 9) Departments of Pediatrics, Epidemiology and Biological Sciences, University of Iowa, Iowa City, IA 52242.

Cleft lip only (CL) and cleft lip and palate (CLP) are commonly regarded as a single entity and pooled together to form the single group of cleft lip with or without cleft palate (CL/P) prior to analysis. However, recent data suggest that CL may be distinct from CLP and should, when feasible, be analyzed separately. To evaluate the risk of isolated CL from genetic variants carried by the offspring, we analyzed 121 Norwegian and 76 Danish isolated CL trios from two nationwide studies of orofacial clefts in Scandinavia. Genotypes for 1315 SNPs in 334 autosomal candidate genes for clefting were available for analysis in these trios. Two complementary statistical methods (TRIMM and HAPLIN) were used to scan for associations with these genes and to look for consistency in the pattern of associations across the two national samples. TRIMM and HAPLIN both identified strong associations with *FGF12* in both populations, but only TRIMM identified associations with IRF6 and VCL. In contrast, *CX43* was only detected by HAPLIN. Quantile-quantile (QQ) plots of the Fisher-combined p-values from the Norwegian and Danish analyses showed overall association with *IRF6*, *FGF12* and *CX43*. In conclusion, we observed some consistency in the pattern of associations across the two populations, irrespective of the analytic method used. Whereas both *IRF6* and *FGF12* have previously shown strong associations with isolated CL/P, *VCL* and *CX43* appear to be specific for isolated CL and warrant further investigation in other populations.

**A Genome-wide association study in human narcolepsy.** *M. Kawashima[1], J. Hallmayer[1], J. Faraco[1], L. Lin[1], S. Hesselson[2], J. Winkelmann[3], G. Plazzi[4], S. Nevsimalova[5], P. Bourgin[6], S. Hong[7], M. Honda[8], W.T. Longstreth Jr[9], J. Montplaisir[10], D. Kemlink[5], G.A. Rouleau[11], T. Meitinger[3], K. Tokunaga[12], P. Kwok[2], N. Risch[2], E. Mignot[1].* 1) Ctr Narcolepsy Sciences and Department of Psychiatry, Stanford Univ, Palo Alto, CA; 2) Institute for Human Genetics, University of California San Francisco School of Medicine, San Francisco, CA; 3) Institute for Human Genetics, Technische Universität München, Munich, Germany; 4) University of Bologna, Bologna, Italy; 5) Department of Neurology, Charles University in Prague, 1st Faculty of Medicine and General Teaching Hospital, Prague, Czech Republic; 6) Sleep Clinic, Hõpital Civil, Louis Pasteur University, Strasbourg, France; 7) Department of Neuropsychiatry, St. Vincent's Hospital, The Catholic University of Korea, Suwon, Korea; 8) Tokyo Institute of Psychiatry, Setagaya, Japan; 9) Departments of Neurology and Epidemiology, University of Washington, Seattle, Washington; 10) Sleep Disorders Center, Université de Montré al, Montré al, Que'bec, Canada; 11) Center of Excellence in Neuromics, Université de Montré al, Montré al, Canada; 12) Department of Human Genetics, University of Tokyo, Tokyo, Japan.

Narcolepsy with cataplexy is characterized by day time sleepiness and rapid onset into REM sleep. It affects 0.02-0.06% of the population in Caucasians. Narcolepsy is tightly associated with *DQB1*0602* and a loss of hypocretin producing cells in the hypothalamus. An autoimmune basis has long been suspected but remains unproven. We performed a genome-wide association study (GWAS) using the Affymetrix Mapping 500K and 6.0 array sets in Caucasians (1,074 *DQB1*0602* positive controls and 807 *DQB1*0602* positive cases). Four genome-wide significant markers were found and replicated in three additional cohorts (700 Caucasians, 250 Koreans, and 250 African Americans). Three of these markers were located in the T-cell receptor alpha locus, J segment region, on chromosome 14, with highest significance at rs1154155 (allelic odds ratio: 1.83 [1.39-2.42], bonferoni-corrected P = $10^{-5}$) and replicated strongly across ethnic groups. We also tested 14 other markers, all only nominally significant, of higher significance than rs9275523, a marker located in the *HLA-DQ* region. This marker was selected as it likely represents established HLA heterozygote effects in narcolepsy, also demonstrating the well HLA matched nature of our sample. One of these 14 markers is in T-cell receptor beta locus on chromosome 7 (rs2367191). Eight of these markers had non significant but similar direction effects in Caucasians as reported with GWAS. One replicated significantly in Caucasians but showed no effects in the other ethnic groups, although a similar allele frequency was present. Five out of 9 markers also showed same tendency in Koreans and African Americans. Replication in an additional Caucasian sample, and fine typing of the TCR loci effects in underway, but these results strongly suggest autoimmune mechanisms in the cause of narcolepsy.

## 731/W/Poster Board #389

**Common variants in the *IL6R* and *PAI1* genes are associated with PAI-1 levels in pregnant women of European ancestry.** *H. LEE[1], R.M. Freathy[1,2], M. Urbanek[1], L.P. Lowe[1], C. Ackerman[1], T.W. McDade[1], N.J. Cox[3], D.B. Dunger[4], A.R. Dyer[1], A.T. Hattersley[2], B.E. Metzger[1], W.L. Lowe[1], M.G. Hayes[1] for the HAPO Study Cooperative Research Group.* 1) Northwestern University, Chicago, USA; 2) Peninsula Medical School, Exeter, UK; 3) University of Chicago, Chicago, USA; 4) University of Cambridge, Cambridge, UK.

Adipokines control diverse metabolic functions and are implicated in the development of insulin resistance by altering insulin sensitivity in insulin target organs. Our previous study showed a continuous relationship between maternal glucose level in pregnancy and adipokine levels. Therefore, we hypothesized that genetic factors contribute to maternal adipokine levels as well as glucose metabolism during pregnancy and conducted a candidate gene screen to evaluate this hypothesis. The Hyperglycemia and Adverse Pregnancy Outcome is a multicenter study, which examined the impact of maternal glucose levels on fetal outcomes in 25,000 pregnant women from multiple ethnic groups. Of these, 819 mothers of European ancestry (UK and Australia) were selected for the current study. Participants underwent 75-g oral glucose tolerance test (OGTT) between 24 and 32 weeks of gestation. We examined 1536 maternal single nucleotide polymorphisms (SNPs) in 79 candidate loci previously implicated in insulin secretion or sensitivity, fetal growth, or inflammation to determine associations with adipokine levels (adiponectin and PAI-1) at ~28 weeks gestation. Associations were assessed through linear regressions with the single trait or outcome under an additive genetic model adjusting for necessary covariates. Two SNPs in the *IL6R* gene (rs7411976 and rs12090237, both $P$=3.2×$10^{-5}$, $r^2$= 0.9) and rs2227631 in *PAI1* gene ($P$=3.2×$10^{-5}$) were associated with PAI-1 levels. The PAI-1 level in those who carried a rare allele of rs7411976 or rs12090237 was 8 ng/ml lower than in those who did not carry a rare allele (23.7 ng/ml [95% CI: 20.5-27.4] vs. 32.0 ng/ml [95% CI: 31.1-32.8]). The PAI-1 level in rare homozygotes for rs2227631 was 5 ng/ml lower than in common homozygotes (28.2 ng/ml [95% CI: 26.4-30.1] vs. 33.1 ng/ml [95% CI: 31.8-34.6]). The same SNP has previously been associated with PAI-I levels in non-pregnant subjects. No significant associations were found with adiponectin levels. Rs7411976 and rs12090237 in the *IL6R* gene also showed a significant association with 1 hour glucose level at OGTT (both -0.7 mmol/L [95% CI: -1.2- -0.1] per rare allele, $P$<0.05). There was no significant association between rs2227631 and maternal glucose levels. These results suggest that common variants in *IL6R* and *PAI1* have a strong impact on PAI-1 levels in European women with normal pregnancy and that those in *IL6R* may influence maternal glucose levels.

## 732/W/Poster Board #390

**New common IRF6 variant associated with specific risk for cleft lip and palate.** *E.J. Leslie[1], A.L. Petrin[1], M. Marazita[2], M. Cooper[2], F. Rahimov[3], J.C. Murray[1].* 1) University of Iowa, Iowa City, IA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Children's Hospital Boston/Harvard Medical School.

Cleft lip and/or cleft palate (CL/P) is a common birth defect with complex etiology due to multiple genetic and environmental factors. The search for genetic contributors to cleft lip and/or palate has identified several candidate genes and loci including *IRF6*, *FOXE1*, *BMP4*, *MSX1*, and a region on 8q24. *IRF6* is particularly interesting, not only for its contribution to Van der Woude syndrome, but variants in and around *IRF6* have been associated with nonsyndromic CL/P. The common allele of the variant V274I (rs2235371) located in exon 7 of *IRF6* was strongly associated with nonsyndromic CL/P in several populations and recently, Rahimov et. al. (2008) reported a functionally relevant association of rs642961 to cleft lip only (CL) caused by the disruption of an AP-2 binding site upstream of *IRF6*. The rare allele (A) of the rs642961 is in complete linkage disequilibrium with the common allele of V274I (G) explaining the strong association. However, rs642961 seems to play a preferential role in the etiology of CL, raising the hypothesis of a third variant that plays a role in cleft lip and palate (CLP). As a follow-up to this study, we have sequenced 3 highly conserved regions including the 607 bp immediately flanking rs642961 in Philippine cases and controls (673 and 302, respectively) and have identified a previously unreported SNP (G>A) at chromosome position 208055904 (UCSC Browser v206 Build 36.1). The rare allele (A) is in almost complete linkage disequilibrium with the common allele (G) for rs642961, allowing us to exclude any effect of the rare (associated) allele of rs642961. When analyzed individually, neither the rare allele (A) of 208055904 nor the rare allele (A) of rs2235371 is associated with CL/P. Interestingly, when these rare alleles are combined with the common allele (G) of rs642961, the resulting haplotype, AGA (rs2235271, rs642961, 208055904), is significantly associated. When stratified by cleft type, the AGA haplotype is more strongly associated in CLP (p=1.2 x $10^{-9}$) than CL (p=1.072 x $10^{-4}$) supporting the hypothesis of a third variant in the *IRF6* region that plays a preferential role in CLP etiology, at least in a large population from the Philippines. Additional analysis in other populations and functional analysis of this variant should be enable a better characterization of the role of *IRF6* in clefting and help identify other pathway members to investigate.

## 733/W/Poster Board #391

**Sex specific effect of the APLN gene on the metabolic traits and gene expression levels.** *Y. Li[1], Y. Liao[1], M. Yu[4], S. Juo[1,2,3].* 1) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Hepatobiliary Division and Department of Preventive Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

**Background and Purpose** Dysregulation of the production of adipokines plays a pivotal role in the development of metabolic syndrome and cardiovascular comorbidity. Apelin, a newly identified adipokine, is up-regulated by insulin and highly expressed in obese subjects. The Apelin gene is located on X chromosome. The purpose of present study is to investigate whether the polymorphisms at the gene encoding apelin confer risks for metabolic syndrome.

**Methods** The study subjects are volunteers recruited from the general population in southern Taiwan. The diagnosis of metabolic syndrome is based on the modified version of ATPIII where a subject of metabolic syndrome needs to have at least 3 of 5 risk components (HDL-C, triglyceride, waist circumference, blood sugar and blood pressure). To reduce the concern of disease uncertainty, the subjects with two risk components were not included in the analysis. Four tagging SNPs at apelin gene were genotyped. Since we found the SNPs had different effects between men and women, we compared the apelin expression levels between in the human adipocytes obtained from women and men.

**Results** A total of 498 cases and 1311 controls were included in the present study. Men accounted for 51.4 % and the average age was 51.1 ± 13.5 years. The four SNPs were not statistically associated with metabolic syndrome. We further evaluated the SNPs vs. each of the five components of metabolic syndrome. SNP 3 appeared to be associated with abdominal obesity (adjusted p = 0.023) and fasting glucose (adjusted p = 0.002) in women. In addition, SNP 4 was associated with abdominal obesity (adjusted p = 0.026) in women. None of the SNPs were significant in men. The cellular studies showed that apelin levels were higher in female adipocytes than male adipocytes when the adipocytes were treated with TNF-$\alpha$.

**Conclusions** The present study demonstrated that apelin polymorphisms may influence abdominal obesity and insulin resistance, this gene may be more influential in the women subjects in terms of metabolic traits.

## 734/W/Poster Board #392

**Study of 390 candidate genes for obesity using data from genome wide meta-analysis of BMI in 32,387 individuals.** *R.J.F. Loos[1], K.S. Vimaleswara[1], C.J. Willer[2], E.K. Speliotes[3,4], S. Li[1], C.M. Lindgren[5], I.M. Heid[6], G.R. Abecasis[7], J.N. Hirschhorn[4,8,9] for the GIANT consortium.* 1) MRC Epididemiology Unit, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, United Kingdom; 2) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, Michigan 48109, USA; 3) Division of Gastroenterology, Massachusetts General Hospital, Boston, Massachusetts 02114, USA; 4) Metabolism Initiative and Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Boston, Massachusetts 02142, USA; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK; 6) Institute of Epidemiology, Helmholtz Zentrum München, Ingolstaedter Landstr. 1, 85764 Neuherberg, Germany; 7) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, Michigan 48109, USA; 8) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA; 9) Program in Genomics and Divisions of Endocrinology and Genetics, Children's Hospital, Boston, Massachusetts 02115, USA.

In the past 15 years, candidate gene and genome-wide linkage studies have proposed many genes for obesity. However, replication in subsequent studies often provided inconsistent results. Limitations of these traditional gene-discovery methods are 1) small sample size (typically with n<1,000) and thus insufficient power to identify the small effects, and 2) poor coverage of the genetic variation in the genes. Recent genome-wide association (GWA) studies have resulted in a rapid increase in the number of loci associated with body mass index (BMI), although for most of these function is poorly understood. The aim of this study is to pursue a targeted association analysis between previously proposed obesity candidate genes and BMI by using the GWA data of the GIANT (Genetic Investigation of ANthropometric Traits) consortium (Willer et al, 2009). The advantage of this approach is that the sample size is large (n=32,387) and that most common genetic variation in genes is captured. We performed a systematic literature search for candidate genes implicated in obesity by animal studies, genome-wide linkage studies, genetic association studies and studies of Mendelian syndromes relevant to human obesity. The GWA encompassing 15 cohorts and 32,387 individuals of European ancestry was examined at ≈2.5 million genotyped or imputed HapMap SNPs. Association between BMI and SNPs was tested assuming an additive effect. Summary statistics of each study were meta-analysed using the inverse variance method. We captured 10kb up- and downstream of all the identified candidate genes. Out of 390 candidate genes, 16 independent loci ($r^2$<0.5) from 13 candidate genes reached a significance of p<$10^{-3}$. Of these, variants in SH2B1 (p=$10^{-11}$) and BDNF (p=$10^{-4}$) were already identified and replicated by the recent GWA studies. The remaining 11 genes are: ADAM12 (risk allele frequency: 20.4%, beta= 0.04 z-score increase per risk allele, p=6x$10^{-5}$), LEPR (98%, 0.13, p=6x$10^{-5}$), CPE (11%, 0.04, p=$10^{-4}$) MCTP2 (85%, 0.05, p=$10^{-4}$), EBF2 (52%, 0.03, p=$10^{-4}$), TCF7L2 (25%, 0.03, p=2x$10^{-4}$), PRKAG2 (54%, 0.03; p=3x$10^{-4}$), TBC1D1 (83%, 0.04; p=4x$10^{-4}$), SCD5 (91%, 0.05; p=4x$10^{-4}$), SCG3 (62%, 0.03; p=4x$10^{-4}$) and ACACA (77%, 0.03; p=9x$10^{-4}$). By taking advantage of large scale GWA meta-analyses, out of 390 previously proposed candidate genes, we identified 16 independent loci in 13 genes (p<$10^{-3}$). The identified loci may help focus replication efforts and the search for underlying biology.

## 735/W/Poster Board #393

**Study of the possible role of MKX in non syndromic clef lip and palate.** *E. Masiero[1], M.A. Mansilla[3], F. Carinci[2], J.C. Murray[3].* 1) Histology, Embriology I, University of Bologna, Bologna, Italy; 2) Department of D.M.C.C.C., Section of Maxillo-facial Surgery, University of Ferrara, Corso Giovecca, ferrara, Italy; 3) Department of Pediatrics University of Iowa, 500 Newton Road 2182 ML Iowa City IA 52242.

Facial clefts are the most common multifactorial birth defects caused by genetic and environmental factors. The aim of this work is to study the possible role of MKX in non syndromic cleft lip with or without cleft palate (NSCL/P) Mohawk (Mkx) is a novel homeobox gene that is highly expressed, among other tissues, in the frontonasal process and palatal mesenchyme during primary and secondary palate development. This gene maps close to the twirler mutation; mouse homozygotes for this mutation present with cleft lip and cleft palate or cleft palate only. In addition Jugessur et al. 2009 found positive association between facial clefts and SNPs in MKX in NS CL/P trios from Norway and Denmark. To pursue the role of MKX in clefting we sequenced the complete coding region and exon/intron boundaries of the MKX gene in DNA samples of 91 NSCL/P cases from the Philippines to look for possible etiologic mutations. We detected one new missense mutation in exon 2 of MKX, a Arginine (R) to Leucine (L) at position 60 of the protein sequence that has not been reported previously. This amino acid is normally highly conserved in the most of the species. Polyphen analysis of the protein structure suggests this mutation is probably damaging, suggesting it may be etiologic in clefting. We will now sequence family members for this case and additional cases and controls in the same region. We propose that mutations in MKX may interfere with the conformation of the protein and can change its functionality, during palate development, that can result in cleft lip/palate.

## 736/W/Poster Board #394

**Associations of folate and choline metabolism gene polymorphisms with orofacial clefts.** *A. Mostowska[1], K.K. Hozyasz[2], P. Wojcicki[3,4], B. Biedziak[5], M. Dziegelewska[1], J. Misiak[1], M. Holysz[1], P.P. Jagodzinski[1].* 1) Department of Biochemistry and Molecular Biology, University of Medical Sciences in Poznan, Poland; 2) Department of Pediatrics, Institute of Mother and Child in Warsaw, Poland; 3) University Clinic of Medical Academy in Wroclaw, Poland; 4) Department of Plastic Surgery Specialist Medical Center in Polanica Zdroj, Poland; 5) Department of Orthodontics, University of Medical Sciences in Poznan, Poland.

Nonsyndromic cleft lip with or without cleft palate (NCL/P) is a common congenital anomaly in humans. It has been reported that nutritional factors are likely to play a major role in the development of this malformation. Since the mechanism by which folic acid and choline supplementation prevents NCL/P is poorly understood we decided to investigate the relationship between 16 polymorphic variants of 12 genes encoding enzymes involved in metabolism of these nutrients and the risk of facial clefts. SNPs were selected based on validation status, functional relevance and importance, and minor allele frequency >0.1 in Caucasians. Genotyping was carried out either by PCR followed by the appropriate restriction enzyme digestion (PCR-RFLP) or high-resolution melting curve analysis (HRM) in a group of 174 patients with NCL/P and 176 controls. We found that individuals with AA genotype for *BHMT* rs3733890 polymorphism have significantly lower risk of facial clefts. The calculated Odds ratio for homozygotes AA compared to individuals with G allele (AG or GG) was 0.145 (95%CI: 0.042-0.499; p= 0,0005; statistical power=94%). This strong protective association persisted even after correcting for multiple comparisons ($p_{corr}$=0.008). *BHMT* encodes the zinc metalloenzyme that catalyses homocysteine remethylation to methionine using betaine, formed during choline oxidation, as a methyl donor. The expression of *BHMT* is found mainly in human liver, where encoding enzyme is responsible for up to 50% of homocysteine remethylation. Another finding of our study was significant association of *PCYT1A* polymorphism with the risk of NCL/P. Compared with individuals with GG genotype, the A allele carriers had an Odds ratio of 1.891 (95%CI: 1.151-3.107; p=0.011; statistical power=72%). The *PCYT1A* encodes a rate controlling enzyme in the CDP-choline pathway of phosphatidylcholine synthesis. Analysis of the influence of polymorphisms in *CBS*, *MTHFD1*, *MTHFR*, *MTR*, *MTRR*, *TCN2*, *BHMT2*, *CHDH*, *CHKA* as well as *PEMT* on NCL/P recurrence did not reveal any significant correlations. In conclusion, this report demonstrates that choline metabolism may play an important role in etiology of NCL/P. We found that polymorphic variants of *BHMT* and *PCYT1A* might influence the risk of facial clefts in the Polish population. Supported by grant no. 501-01-01124182-08638 from the University of Medical Sciences in Poznan and grant no. N N401 006835 from the Polish Ministry of Science and Higher Education.

**The β2 adrenergic receptor gene (ADRB2) polymorphisms and obesity in Oceanic populations.** *I. Naka[1], N. Nishida[2], R. Kimura[3], T. Furusawa[4], K. Natsuhara[5], T. Yamauchi[6], M. Nakazawa[7], Y. Ataka[8], K. Tokunaga[2], T. Ishida[9], T. Inaoka[10], Y. Matsumura[11], R. Ohtsuka[12], N. Tsuchiya[1], J. Ohashi[1].* 1) Doctoral Program in Life System Medical Sciences, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Ibaraki, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Okinawa, Japan; 4) ASNET Promotion Office, Division for International Relations, The University of Tokyo, Tokyo, Japan; 5) School of Nursing, Fukuoka Prefectural University, Fukuoka, Japan; 6) Department of Health Sciences, Hokkaido University School of Medicine, Hokkaido, Japan; 7) Department of Public Health, Graduate School of Medicine, Gunma University, Gunma, Japan; 8) School of Policy Studies, Kwansei Gakuin University, Hyogo, Japan; 9) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Tokyo, Japan; 10) Department of Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 11) Faculty of Healthcare, Kiryu University, Gunma, Japan; 12) Japan Wildlife Research Center, Tokyo, Japan.

To clarify the genetic factors associated with body mass index (BMI, $kg/m^2$) in Oceanic populations, the associations of two single nucleotide polymorphisms (SNPs) of β2 adrenergic receptor gene (ADRB2), Arg16Gly (rs1042713) and Gln27Glu (rs1042714), and a β3 adrenergic receptor gene (ADRB3) SNP, Trp64Arg (rs4994), with BMI and obesity were examined in 695 adult subjects living in Solomon islands and Tonga. A multiple regression analysis adjusted for age, sex, and population revealed that a copy of 27Glu significantly increased a BMI of 2.3 $kg/m^2$ (P-value = 0.0009). A multiple logisitic regression analysis showed that 16Gly,and 27Glu were weak but significant risk factors for obesity (BMI > 30 $kg/m^2$) (P-value for Arg16Gly = 0.0298 and P-value for Gln27Glu = 0.0347). Trp64Arg showed no association with BMI and obesity. Further conditional logistic regression analysis suggested that Arg16Gly was not an independent risk factor of obesity (P-value for Arg16Gly = 0.1209 and P-value for Gln27Glu = 0.0379). The linkage disequilibrium (LD) analysis revealed that Arg16Gly was in weak LD with Gln27Glu (D' = 0.39 ~ 1 and $r^2$ = 0.01 ~ 0.09 in five Oceanic populations studied), implying that the association of Arg16Gly with obesity may have come from LD with Gln27Glu. Our results suggest that the Gln27Glu polymorphism of ADRB2 plays an important role in the pathogenesis of obesity in Oceanic populations.

## 738/W/Poster Board #396

**The PAX6 promoter in high myopia.** *C.P. Pang[1], T.K. Ng[1], C.Y. Lam[1,2], P.O.S. Tam[1], L.J. Chen[1], S.W.Y. Chiang[1], D.S.P. Fan[1], D.S.C. Lam[1].* 1) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong S.A.R; 2) Department of Surgery, Hong Kong University, Hong Kong S.A.R.

A myopia locus was reported on chromosome 11p13 and the PAX6 gene located at that region was postulated to be associated with myopia development. PAX6 expression levels are tightly regulated and PAX6 gene dosage effects create a range of ocular phenotypes. This study investigated the association of the PAX6 P1 promoter, the major promoter of PAX6 gene, with high myopia (HM) in a Chinese cohort in Hong Kong. The HM patients had refractive errors -6.00 diopters (D) or below and axial length longer than 26 mm. The control subjects had refractive errors greater than -1.00 D and axial length shorter than 24 mm. The P1 promoter, flanking up to 3.5 kb, of the PAX6 gene was screened in 379 HM patients and 349 controls by polymerase chain reaction (PCR) and direct sequencing. No single nucleotide polymorphisms (SNPs) showed association with HM. Two dinucleotide repeats, (AC)m and (AG)n, located around 1 kb upstream of the transcriptional initiation site, were found to be highly polymorphic. Significant association was observed between these two repeats and HM. Higher repeat numbers were observed in HM patients for both (AC)m (global p = 0.016 and trend p = 0.03) and (AG)n dinucleotide polymorphisms (global p = 0.014 and trend p = 0.014) with 1.327-fold of increased risk for (AG)n repeat (p = 0.014; 95% CI: 1.059 - 1.663). Luciferase-reporter analysis showed elevations of transcription activity with increasing individual (AC)m and (AG)n repeat lengths and the combined (AC)m(AG)n repeat lengths. Our results revealed an association between AC and AG dinucleotide repeat lengths in the PAX6 P1 promoter and HM, indicating the involvement of PAX6 in the pathogenesis of myopia.

**The Sortilin-related receptor (SORL1) influences variation in memory in late-onset Alzheimer Disease.** *C. Reitz[1,2,3], J. Lee[1,2,5], R. Cheng[1,2], E. Rogaeva[4], S. Tokuhiro[4], L. Clark[1,2,6], P. St.George-Hyslop[4], R. Mayeux[1,2,3,5].* 1) G.H Sergievsky Ctr, Columbia Univ, New York, NY; 2) Taub Institute, Columbia University, New York; 3) Department of neurology, Columbia University, New York; 4) Centre for Research in Neurodegenerative Diseases, University of Toronto; 5) Departments of Epidemiology and Biostatistics, School of Public Health Columbia University; 6) Department of Pathology, College of Physicians and Surgeons, Columbia University, New York, NY.

Background and Objective. Recent studies implicated the neuronal sortilin-related receptor gene SORL1 as a susceptibility gene for late-onset Alzheimer disease (AD). We explored whether variation in SORL1 is associated with the memory performance using 2 independent datasets. Methods. We first examined the association between measures of cognitive function and the same 29 single nucleotide polymorphisms (SNPs) used our earlier paper (Rogaeva et al, 2007) in 1,180 individuals from 228 families participating in the Caribbean Hispanic Family Study of Familial Alzheimer disease using family-based association analyses. Then we explored the association of the same 29 SNPs with memory performance in 425 Caribbean Hispanics (212 cases vs. 213 controls) from a multiethnic random sample of Medicare recipients ≥65 years and residing in northern Manhattan. Results. In the family cohort, haplotypes at SNPs 1-4 (p=0.0008), 7-10 (p=0.05) and 14-18 (p=0.003) were significantly associated with measures of memory performance. In the epidemiological cohort, we replicated these findings by showing that haplotypes at SNPs 1-3 were significantly associated with total recall (p=0.02) and Benton recognition (p=0.04), haplotypes at SNPs 15-17 were associated with total recall (p=0.05) and Benton recognition (p=0.03), haplotypes at SNPs 21-23 were associated with total recall (p=0.05), delayed recall (p=0.02) and Benton recognition (p=0.03), and haplotypes at SNPs 27-29 were associated with total recall (p=0.02), delayed recall (p=0.0008) and Benton recognition (p=0.02). However, these SNPs that were significant for memory performance were not associated with abstract reasoning and language function. Conclusions. Genetic variation in SORL1 is specifically associated with memory function.

**Association of CRP polymorphisms with obesity severity in Mexican population.** *Y. Saldaña-Alvarez[1], MG. Salas-Martínez[1,2], S. Jiménez-Morales[1], A. Luckie-Duque[3], G. García-Cárdenas[4], H. Vicenteño-Ayala[5], A. Carnevale-Cantoni[6], L. Orozco[1].* 1) Instituto Nacional de Medicina Genómica; 2) Posgrado en Ciencias Genómicas-UACM; 3) Hospital Regional 1° de Octubre-ISSSTE; 4) Clínica de Diagnóstico Automatizado-ISSSTE; 5) Hospital Regional López Mateos-ISSSTE; 6) Coordinación de Medicina Genómica-ISSSTE.

Introduction. Changes in inflammatory status of adipose tissue support a growing evidences that obesity represents a state of chronic low-level inflammation. In this way, some studies has been reported a strong relationship between high circulating level of C-reactive protein (CRP), a systemic pro-inflammatory risk marker and increasing body mass index (BMI). Objective. In this study we examined the relation between polymorphisms located in C-reactive gene (CRP) and BMI, in adult Mexican patients. Methods. We performed a case-control association study in 413 obese cases with a BMI>30 and 263 controls with a BMI <25. Cases and controls were older than 18 years old recruited from two tertiary Hospitals in Mexico City. We analyzed r1205C/T, rs1130864C/T and rs1417938T/A CRP polymorphisms. Genotyping was carried out by 5' exonuclease assay (TaqMan). The association test, Hardy-Weinberg Equilibrium (HWE) and haplotypes were evaluated using EPIDAT, FINETTI and Haploview software, respectively. Results. Genotype distributions were in HWE both in patients and controls. When CRP genotypes and alleles frequencies were compared between cases and controls, no significant differences were observed in the genotype and allelic distribution between obese and no obese. When we stratified by severity rs1130864T and rs1417938A alleles, showed a significantly association with protection to morbid obesity (OR= 0.563, 95% CI 0.382-0.829, p= 0.0034, and OR= 0.585 95% CI: 0.398-0.860, p= 0.006, respectively). Consistently, haplotype analysis reveled a severity obesity protection haplotype (CTA), containing the minor alleles from rs1130864 and rs1417938 polymorphisms (OR= 0.55; 95% CI: 0.36-0.82, p= 0.002). In contrast, we observed that carriers of the rs1205T allele have a high risk to develop severe obesity with a BMI>40 (OR= 2.57; 95% CI: 1.201-5.500, p=0.01). Interestingly, haplotype analysis shown that the polymorphisms rs1130864 and rs1417938 are in high linkage desequilibrium (D' 95), while the rs1205 is harbored in a different haplotype block. Conclusion. Our results suggest that polymorphisms within the CRP gene could be a severity obesity modifier in Mexican population.

## 741/W/Poster Board #399

**Co-segregation of Norrie disease and idiopathic pulmonary hypertension in a family with a microdeletion of the NDP locus at Xp11.4.** *J.F. Staropoli[1], K. Limbo[2], W. Xin[3,4], K. Sims[3,4].* 1) Department of Pathology, Massachusetts General Hospital, Boston, MA; 2) Division of Child Neurology, Huntsville Hospital, Huntsville, Alabama; 3) Neurogenetics DNA Diagnostic Laboratory, Massachusetts General Hospital, CHGR, Boston, Massachusetts; 4) Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts.

Norrie disease is an X-linked congenital retinal vasculopathy that may be accompanied by mental retardation, sensorineural deafness, and other neurological deficits. Idiopathic pulmonary arterial hypertension is a poorly understood, usually adult-onset condition characterized by progressive hypertrophy and narrowing of the small arteries of the lung in the absence of other conditions such as connective tissue diseases, portal hypertension, diet and medicines, and left-sided cardiac anomalies. Here we present a family in which Norrie disease in 3 brothers co-segregated with early-onset idiopathic pulmonary hypertension that led to demise in the first few months or years of life. Molecular analysis of the Norrie disease gene (NDP) and adjacent loci at Xp11.4 was performed by multiplex ligation-dependent probe amplification (MLPA) after failed polymerase chain reaction (PCR) amplification of the 3 exons encoding NDP. DNA from two affected brothers available for testing showed a hemizygous deletion restricted to NDP and two genes immediately centromeric to it: monoamine oxidase-A (MAO-A) and monoamine oxidase-B (MAO-B). These two closely related enzymes metabolize intraneuronal and endothelial pools of biogenic amines including serotonin, dopamine, and norepinephrine. Testing of the mother demonstrated that she is a carrier of the same deletion. Norrie disease is not known to be associated with pulmonary hypertension. Because abnormalities of biogenic amines, particularly serotonin, has been implicated in the pathophysiology of pulmonary hypertension, we propose that presumed MAO deficiency in these patients may represent a novel risk factor for pulmonary hypertension, particularly forms with very early onset.

## 742/W/Poster Board #400

**Association of the *MMP9* gene with cedar pollinosis in the Japanese children.** *Y. Suzuki[1], H. Inoue[1], Y. Mashimo[1], S. Yoneyama[2], S. Horiguchi[2], N. Shimojo[3], Y. Kohno[3], Y. Okamoto[2], A. Hata[1].* 1) Department of Public Health, Chiba University, Chiba, Japan; 2) Department of Otorhinolaryngology, Chiba University, Chiba, Japan; 3) Department of Pediatrics, Chiba University, Chiba, Japan.

**Background:** The matrix metalloprotainase 9 (*MMP9*) gene has been shown to be involved in allergic rhinitis and asthma. It was suggested that SNPs of the *MMP9* gene confer risk for childhood atopic asthma. However there was no report investigating whether the SNPs confer risk for allergic rhinitis.

**Aim:** To investigate whether the SNPs of the *MMP9* gene associate with risk for allergic rhinitis and serum IgE levels.

**Methods:** A total of 670 school children were recruited from two different regions in Japan and genotyped for 2127G/T (SNP1) and 5546G/A (R668Q) (SNP2) of the *MMP9* gene. Serum levels of total and 8 specific IgE were determined. Disease status and other clinical characteristics of the subjects were investigated by a questionnaire. Cedar pollinosis was defined as symptoms evoked in February to May with positive cedar-specific IgE in serum.

**Results:** SNP1 and SNP2 showed a significant association with cedar pollinosis (P=0.002, OR= 2.39, 95%CI=1.38-3.85; P=0.001, OR= 2.33, 95%CI=1.33-3.49, respectively). The frequency of the G-G haplotype was significantly higher in children with cedar pollinosis when compared with the controls (P=0.007). The frequency of the T-A haplotype of the patients was significantly lower than that of the controls (P=0.003). Both SNPs showed a significant association with serum level of cedar-specific IgE (SNP1: P=0.002; SNP2: P=0.001). The similar change in the allele frequencies in the pollinosis patients was observed in the two regions. Association of the two SNPs with mite-positive perennial rhinitis was less evident (SNP1: OR=1.68, 95%CI=0.76-3.04; SNP2: OR=2.20, 95%CI=0.98-3.88). The risk alleles for cedar pollinosis were G in the two SNPs, whereas those for atopic asthma were T (SNP1) and A (SNP2).

**Conclusions:** Our results suggest that the *MMP9* gene confers susceptibility to cedar pollinosis in the Japanese children. The *MMP9* gene is involved in pathogenesis of both cedar pollinosis and atopic asthma. Multifaceted function of this gene may reflect the difference in the risk alleles for cedar pollinosis and mite-sensitive asthma.

## 743/W/Poster Board #401

**Genetic Variation in MECP2 gene is associated with Childhood-onset Systemic Lupus Erythematosus in the Mexican Mestizo population.** *R. Velázquez-Cruz[1], H. García-Ortiz[1], F. Espinosa-Rosales[2], G. Escamilla-Guerrero[3], V. Baca[4], L. Orozco[1]*. 1) Investigacion, Inst Natl de Medicina Genomica; 2) Servicio de Inmunología, Instituto Nacional de Pediatría; 3) Banco de Sangre, Instituto Nacional de Pediatría; 4) Hospital de Pediatría Centro Médico Nacional Siglo XXI, IMSS. Mexico City, Mexico.

Childhood-onset systemic lupus erythematosus (SLE) is present in about 15-17% of all patients with SLE and represents a unique subgroup of patients for genetics studies because their earlier disease onset and a more severe disease. Methyl-CpG-binding protein 2 (MECP2) gene is located on chromosome Xq28 and encodes a protein that function as a key factor in epigenetic transcriptional regulation of methylation-sensitive genes. Recently, two studies have been reported several polymorphisms in this gene associated with the risk to develop SLE in adult-onset disease. Objetive: To determine if SNPs of the MECP2 gene are associated with the occurrence of childhood-onset Systemic Lupus Erythematosus in the Mexican population. Methods: We performed a case-control study in 287 female childhood-onset SLE patients and 332 female controls recruited from Mexico City. Additionally, we analyzed a 225 family set for transmission disequilibrium test (TDT). Genotyping of seven SNPs (rs2075596, rs3027933, rs17435, rs1734787, rs1734791, rs1791792 and rs2239464) previosly reported on the MECP2 gene, was carried out by the 5'nuclease assay (Taq-Man). Hardy-Weinberg equilibrium was tested using chi-square test. The distributions of polymorphisms were compared between SLE patients and healthy controls by contingency table analysis and Pearson's test. P-values smaller than 0.05 were considered to be significant. Results: Genotype frecuencies of all markers were found in Hardy-Weinberg equilibrium in both cases and controls. When SNPs frequencies were compared between cases and controls, the SNP rs2075596 showed the strongest association in the Mexican Mestizo patients (65% vs 56%, P=0.0016, OR=1.45, 95 % CI 1.16-1.84). This finding was confirmed by analysis of the transmission disequilibrium test (rs2075596, P=0.03). The analysis with the Haploview 3.32 software identified only three haplotypes, as previously reported to other populations. The risk haplotype "ACTCAAA" was observed with a frequency of 63% in SLE patients compared to 54% in controls (OR = 1.46, p = 0.0017). Conclusions: These data show that SNPs on MECP2 are associated to childhood-onset SLE and replicate the previous findigs reported in adulthood-onset SLE.

## 744/W/Poster Board #402

**Genetic Study of the Gamma-Aminobutyric Acid type A receptor Gamma Subunit Gene (GABRG2) with Smoking, Alcohol Use Disorder, and Suicidal Behavior in Schizophrenia Patients.** *C. Zai, A. Tiwari, S. Shaikh, V. de Luca, D. Mueller, J. Kennedy.* Dept Neurogenetics, CAMH, Toronto, ON, Canada.

Schizophrenia is a severe neuropsychiatric disorder characterized by symptoms that include auditory or visual hallucinations, paranoid delusions, and disorganized behaviors. It is also associated with increased rate of smoking, alcohol abuse/dependence, and suicide, thus increasing its morbidity and mortality rate. The GABRG2 gene, mapped on chromosome 5q31.1-33.1, a schizophrenia susceptibility region, has nine exons spanning 85kb. The long isoform has an additional eight amino acids in exon 9 that contains an additional regulatory site phosphorylated by Protein Kinase C (Krishek et al, 1994), and may mediate the effects of ethanol (Cheng et al, 1997). We genotyped 19 single-nucleotide polymorphisms and tagged eight for analysis with smoking status, number of cigarettes per day, presence or absence of alcohol dependence or abuse, suicide attempt, and suicide specifier in our sample of Caucasian chronic schizophrenia patients (n= 208). We included age at assessment and sex as covariates in our analyses. Preliminary results from logistic regression showed rs647625 to be associated with alcohol dependence (p=0.004). Analysis of other phenotypes did not yield significant findings. Our results suggest that GABRG2 may be involved in alcohol dependence in schizophrenia. We will be investigating other GABA receptor genes, including GABBR1, GABRB1, in this continuing study. Further studies in other psychiatric populations are required before we can generalize this observed association.

## 745/W/Poster Board #403

**Can aromatase and 5-alpha reductase genes expressions responsible for idiopathic hirsutism.** *M. Dundar[1], A.O. Caglayan[1,4], N.A. Baysal[2], F. Tanriverdi[2], Y. Ozkul[1], K. Unluhizarci[2], M. Borlu[3], F. Kelestimur[2]*. 1) Department of Medical Genetics, Erciyes University, Kayseri, Turkey; 2) Department of Endocrinology, Erciyes University Medical School, Kayseri, Turkey; 3) Department of Dermatology, Erciyes University Medical School, Kayseri, Turkey; 4) Department of Medical Genetics, Kayseri Education and Research Hospital, Kayseri, Turkey.

Objective: Hirsutism affects between 5% and 10% of women. Hirsutism with normal ovulatory function and normal circulating androgen concentrations called idiopathic hirsutism (IH) and little information is available regarding the pathogenesis. We have previously show that patients with idiopathic hirsutism may be associated with decreased aromatse activity. Aim: We evaluated the expression of mRNA for type 2, 5-alpha-reductase isoenzyme gene (SDR5A2) and aromase gene (CYP19) in dermal papillae cells (DPCs) from the lower abdominal region of the skin and from peripheral blood of women with idiopathic hirsutism and controls. Additionally we aimed to investigate the relationship between insulin resistance and hormon profile with target gene expression among women with IH. Methods: Our study population consisted of 10 untreated idiopathic hirsute patients and 10 normal women. In all patients, follicule stimulating hormon, luteinizing hormone, estriol, free and total serum testosterone, androstenedione, 17-OH progesterone, dehydroepiandrosterone sulfate, sex hormone binding globuline, and HOMA values were measured. The expression of the SRD5A2 and CYP19 genes by Real-Time-PCR using peripheral blood mononuclear cells (PBMCs) and subumblical midline hairs plucked from patients and controls. Results: There was a negative correlation among the CYP19 gene expression in tissue r=-0.818, p=0,004 in relation to the SRD5A gene expression in blood in patients with IH according to the spearman's correlation test. Conclusion: More studies in larger numbers of patients should be performed to investigate the role of type 2, 5-alpha-reductase isoenzyme gene and aromatase gene expression in women with IH. By establishing the pathogenetic mechanisms underlying IH, new therapeutic strategies may play an important role in offering more effective therapies.

## 746/W/Poster Board #404

**A positional candidate approach to identifying genes involved in esophageal atresia/tracheoesophageal fistula.** *H. Zaveri[1], E. de Jong[2], T. Beck[1], J. Williams[1], D. Pearson[1], R. Masand[1], C. Fernandes[1], A. Johnson[1], K. Lally[3], D. Tibboel[2], B. Lee[1], A. Klein[2], D.A. Scott[1]*. 1) Baylor College of Medicine, Houston, TX; 2) Erasmus Medical Center, Rotterdam, The Netherlands; 3) University of Texas Health Science Center, Houston, TX.

The sporadic nature of many common structural birth defects makes a linkage-based approach to identifying underlying genetic factors impractical. Array comparative genome hybridization has been shown to be an effective means of mapping and identify genes that predispose to these defects in an unbiased fashion. The genetic factors responsible for most cases of esophageal atresia/tracheoesophageal fistula (EA/TEF)a life threatening birth defects that affects 1:3,500 live birthshave not been identified. EA/TEF is often associated with other structural birth defects and VACTERL (Vertebral, Anal, Cardiac, Tracheo-Esophageal Fistula, Renal, Limb) association is found in approximately 10% cases. A review of all published cases of EA/TEF revealed 11 chromosomal regions that are recurrently deleted/duplicated in EA/TEF. The pattern of these regions is distinct from the pattern identified in a similar review of congenital diaphragmatic hernia, another sporadic birth defect, making it more likely that each of these regions harbors one or more EA/TEF-related genes. To identify new chromosomal regionsand refine those previously reportedwe screened a cohort of patients with EA/TEF for cryptic deletions/duplication in affected individuals using high density genome-wide array comparative genome hybridization. This screen identified ~40 rare genomic variants some of which involve genes known to play an important role in cell migration, adhesion, differentiation, proliferation, and signaling. Using information from both human patients and mouse models with abnormal esophageal/tracheal development, we selected several candidate genes for further investigation. We are presently resequencing these genes in our patient cohort to identify deleterious alleles which may contribute to these disorders. Although identification of rare de novo sequence changes in these genes would be considered strong evidence for causality, we recognize that the majority of cases may result from a combination of inherited changes affecting important developmental pathways combined with environmental stressors. This suggests that inherited deleterious changes may also contribute to these disorders.

## 747/W/Poster Board #405

**Deletion of the late cornified envelope genes, *LCE3C and LCE3B*, is a new susceptibility factor for rheumatoid arthritis.** *E. Docampo[1], R. Rabionet[1], E. Riveira[1], G. Escaramís[1], A. Julià[2], S. Marsal[2], J.E. Martín[3], M.A. González-Gay[4], A. Balsa[5], E. Raya[6], J. Martín[3], X. Estivill[1].* 1) Center for Genomic Regulation CRG-UPF, Barcelona, Barcelona, Spain; 2) Grup de Recerca de Reumatologia, Institut de Recerca Hospital Universitari Vall d'Hebron, Barcelona, Spain; 3) Instituto de Parasitología y Biomedicina López-Neyra, CSIC, Granada, Andalucía, Spain; 4) Rheumatology Unit, Hospital Xeral-Calde, Lugo, Galicia, Spain; 5) Rheumatology Unit, Hospital La Paz, Madrid, Spain; 6) Rheumatology Unit, Hospital Virgen de las Nieves, Granada, Andalucía, Spain.

Rheumatoid arthritis (RA) is a complex disorder involving both environmental and genetic factors, being HLA-DRB1 (shared epitope) and PTPNPN22 the most robust associations, but they only explain 30% of the heritability of this disorder. Copy number variants are being identified as risk factors for several complex disorders. Recently, the *LCE3C_LCE3B* deletion was shown to be a copy number variant associated with psoriasis. There is evidence regarding a common genetic risk for both RA and psoriasis. The purpose of this work was to assess whether this genomic variant could also be a risk factor for RA. Two sets of DNA samples (n1=189 and n2=334) from Caucasians subjects of Spanish origin suffering RA, fulfilling 1989 ACR criteria, were collected at 4 Spanish hospitals. Control samples (n1=411 and n2=567) were obtained from blood donors from matched geographical regions. All samples were directly typed for the presence of the *LCE3C_LCE3B* deletion by PCR, and association analysis was performed with the SNPassoc R package. Association of *LCE3C_LCE3B* deletion with risk to RA was observed in the first dataset (p=0.0055; OR=1.66 (2.38-1.16)), and replicated in an independent case-control set (p=0.027; OR=1.34 (1.04-1.74)). Joint analysis (adjusted by population) showed a total p=0.0012 (1.53 (1.96-1.21)). Since previous studies have reported different association results for RA depending on the antiCCP and rheumatoid factor (RF) status, association analysis for the joint dataset was carried out in the different subsets (antiCCP+/- (n=178/138), RF +/- (n=355/111)), showing an association in the antiCCP (p=0.019; OR=1.51 (2.12-1.06) and RF (p=0.010; OR= 1.38 (1.78-1.07)) positive patients, but not in the negative subsets. This work shows that the *LCE3C_LCE3B* deletion is a new genetic risk factor for seropositive RA, and it verifies a pleiotropic effect of a common genetic risk factor for autoimmune diseases, involved in both psoriasis and RA.

## 748/W/Poster Board #406

**Genome-wide analysis of copy number variation implicates *CHL1* in the etiology of age-related macular degeneration.** *K.J. Meyer[1], L.K. Davis[1], E.I. Schindler[1], J. Beck[2], D.S. Rudd[1], J.A. Grundstad[3], T.E. Scheetz[3,4], T.A. Braun[3,4], J.H. Fingert[4], J.C. Folk[4], S.R. Russell[4], T.H. Wassink[1,5], E.M. Stone[1,4,6], V.C. Sheffield[1,2,6].* 1) Interdisciplinary Genetics Program, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA; 3) Center for Bioinformatics and Computational Biology, University of Iowa, Iowa City, IA; 4) Ophthalmology and Visual Sciences, University of Iowa, Iowa City, IA; 5) Department of Psychiatry, University of Iowa, Iowa City, IA; 6) Howard Hughes Medical Institute, University of Iowa, Iowa City, IA.

In recent years genome wide studies of copy number variants (CNVs) have been highly successful in elucidating genetic risk factors for complex disease. Here we report the results of CNV analysis in a cohort of 400 patients with age-related macular degeneration (AMD) and 500 age matched controls. Patient DNA was hybridized to the Affymetrix GeneChip® Human Mapping 500K Array Set or the Affymetrix Genome-Wide Human SNP Array 5.0 and analyzed for CNVs using Copy Number Analyser for GeneChip® (CNAG) 2.0 and PennCNV or dChip and PennCNV, respectively. A list of high interest CNVs was generated using the following criteria: 1) the CNV must be called by two independent tests, 2) the CNV must be present in two or more patients with AMD, and 3) the CNV must not be present in the control set. All high interest CNVs were validated using qPCR. Multiple CNVs in the AMD cohort met criteria for inclusion in the high interest set including a significant finding in the gene *CHL1*. A second set of age-matched controls and a replication cohort is being screened for copy number variation in *CHL1* and other high interest candidate genes using qPCR. In addition to the screen, we used the Panther Classification System to look for a misrepresentation of any protein families, pathways, and/or ontologies in comparison to the human genome and identified an enrichment of CNVs that affect G-protein coupled receptors in the AMD patient sample but not in the control group. This study has identified many interesting CNVs, including a duplication in the gene *CHL1* that may contribute to the etiology of AMD.

## 749/W/Poster Board #407

**Identification of genomic imbalances in cases with cleft lip and palate using array CGH.** *A. Petrin[1], T. Felix[2], S. Daack-Hirsch[3], J. Murray[1].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA, USA; 2) Serviço de Genética Médica, Hospital de Clínicas de Porto Alegre, RS, Brazil; 3) College of Nursing, University of Iowa, Iowa City, IA, USA.

The application of high resolution whole genome scanning arrays array CGH (Comparative Genome Hybridization) has helped to identify genomic imbalances including copy number variants (CNV) and isolated insertions/deletions. CNVs are being increasingly well defined for the human genome and contribute substantially to genetic diversity. They result from gains and losses of genomic regions that range from 1000 bp to several megabases and may encompass multiple genes. The use of the array CGH enables the simultaneous testing of multiple loci for insertion/deletion differences at high resolution and allows the identification of genomic imbalances that can be involved on the etiology of common complex diseases. In this study we report the ongoing analysis of a group of cases with craniofacial abnormalities. To date, 40 cases have been studied where 32 have cleft lip and/or palate. We are using the Affymetrix 6.0 SNP array platform that contains 1.8 million genetic markers distributed across the whole genome. We identified 10 different microdeletions/microduplications ranging from 1Mb to 44Mb that include candidate genes for clefting such as FGF12, MEF2, TP63, HHAT, CHURC1, SIX6, MTHFD1, TBX1, DLG1, PAK2, SENP5. Some deletions have involved the binding site for transcription factors (MSX1, MEF2, and BACH2) that play a role in craniofacial development and all the reported genes are involved in pathways that play an important role on craniofacial development and are strong candidates for further studies. All the imbalances were validated by a second method like FISH, sequencing or quantitative PCR. Our study confirms that analysis with array CGH is an important approach for screening and detection of submicroscopic chromosomal abnormalities that are undetectable by current cytogenetic and/or molecular methods and highlight its importance on investigation of genes involved on complex traits such as cleft lip and/or palate.

## 750/W/Poster Board #408

**Copy number variation detection in cleft lip and palate using high resolution array-CGH.** *R.J. PETRIN, A.L. PETRIN, J.C. MURRAY.* PEDIATRICS, UNIVERSITY OF IOWA, IOWA CITY, IA.

Copy number variants (CNVs) have been extensively defined for the human genome contributing to the power of microdeletion/microduplication detection. Over the past few years the use of whole genome scanning arrays has increased and, while generating enormous data, also raises new challenges in detecting, validating and interpreting the CNVs. A number of software packages are available and the combined use of them can increase the analysis confidence and decrease the chance of false positive/negative by the comparison of CNV calls and boundaries. We report the use of 3 software packages: Affymetrix Genotyping Console 3.0.2, Partek® Genomics Suite 6.4TM and Nexus CGH to analyze a group of 40 cases with cleft lip and palate (CL/P) and other craniofacial abnormalities using Affymetrix SNP Array 6.0. All software performs normalization, scaling and signal intensity extraction to enable the detection of CNVs. GTC uses an algorithm called Canary that makes CN state calls that can be exported and treated as SNP genotypes for CNV association studies while Partek uses HMM-based (Hidden Markov Model) based algorithm to detect regions of genomic gains and losses and estimate their boundaries. Nexus CGH uses the built-in Rank Segmentation algorithm for identification of CN change and SNPRank Segmentation that combines B-allele frequency values with log ratios for allelic calls. Both GTC and Partek use Birdseedv2 to perform genotyping calls, perform a multiple analysis to estimate signal intensity for each allele of each SNP and then makes genotype calls using a Gaussian mixture model. Besides the use of software packages it is also very important to use public databases such as UCSC and Database of Genomic Variants that hold a comprehensive summary of structural variation in the human genome and provides a useful catalog of control data for studies that correlate genomic variation with phenotypic data. Among the CNV regions identified by our study we defined as good candidates for causal variants the ones that are not in common region of CNV, that were detected by at least 2 software packages and were validated by a second method (sequencing or qPCR). By using this method we excluded 2 false positive results. Our study shows that the use of high resolution array CGH is a very important tool to detect CNV that can have etiological role in complex diseases such as CL/P and highlights the importance of using different analytical methods to guarantee the data accuracy.

## 751/W/Poster Board #409

**A CNV in chromosome 5 generating a chimaeric gene is a common protective variant for stroke.** *R. Rabionet[1], J. Aigner[1], S. Villatoro[1], L. Armengol[2], M. García-Aragonés[2], E. Cuadrado-Godia[3], J. Jiménez-Conde[3], A. Ois[3], A. Rodríguez-Campello[3], J. Roquer[3], I. Fernández-Cadenas[4], J. Montaner[4], A. Carracedo[5], E. Martí[1], X. Estivill[1].* 1) Genes & Disease, Center for Genomic Regulation CRG-UPF, Barcelona, Spain; 2) Quantitative Genomics, Barcelona, Spain; 3) Unitat d'Ictus, Servei de Neurologia, Hospital del Mar, Barcelona, Spain; 4) Neurovascular Research Lab, Institut de Recerca, Hospital Vall d'Hebron, Barcelona, Spain; 5) Universidad de Santiago, Santiago de Compostela, Spain.

Stroke is a neurological disease with a high impact in the aging population, being the most important neurological cause of death and disability. Stroke is a heterogeneous disorder with both environmental and genetic risk factors. Up to this date, three genes have been shown to be related to stroke by whole genome analysis, namely, *PDE4D* and *ALOX5AP* in the Icelandic population, and a variant in chromosome 12 (*NINJ2*), recently identified in a GWAS study in four different populations. In this study we have evaluated structural variants as potential risk factors for stroke. We have screened an initial dataset of 169 haemorrhagic stroke, and 729 ischemic stroke cases, and 477 controls, and found an association of an insertion/deletion variant on chromosome 5. The breakpoints of this variant have been identified, and an allele-specific PCR assay has been designed and used for genotyping. Carriers of the intact allele are more frequently affected by stroke, while carrying one or two copies of the deleted allele confers protection against stroke. Association is significant in both the ischemic stroke (p=0.0005; OR= 0.66) and the haemorrhagic stroke subsets (p=0.002; OR=0.58). This result has been replicated in an additional dataset with 475 ischemic stroke cases (p=0.0087; OR=0.71), and further replication in a second haemorrhagic stroke dataset is underway. Surrounding SNPs have been genotyped in order to assess linkage disequilibrium in the region, and identify potential tagging SNPs. The deletion spans 55 kb and affects two genes from the same family, generating a chimaeric gene. Expression in EBV transformed lymphocytes of the two intact genes is correlated with copy number state, while the chimaeric gene is expressed at a lower mRNA level. Downstream expression analysis from expression array data from HapMap samples carriers of zero, one, or two copies of the deleted allele shows differential expression of several genes, including genes involved in blood vessel formation and angiogenesis.

## 752/W/Poster Board #410

**The Crohn's Disease IRGM Copy Number Variant is associated with IgE level in asthma.** *A.J. Rogers[1, 2, 4], J.A. Lasky-Su[1], T. Chilson[1], B. Klanderman[1], K. Darvishi[2, 4], I. Ionita-Laza[3], C. Lee[2, 4], B.A. Raby[1, 2, 4].* 1) Channing Laboratory, Boston, MA; 2) Brigham and Women's Hospital, Boston, MA; 3) Harvard School of Public Health, Boston, MA; 4) Harvard Medical School, Boston MA.

**Rationale**: A common 20kb deletion/insertion copy number variant (CNV) upstream of Immunity-related GTPase Family M (IRGM) is associated with Crohn's disease. This variant is associated with differential IRGM expression in human bronchial smooth muscle cells. We therefore investigated whether the deletion also influences asthma, another common immune-related disease characterized by hyperresponsive airway smooth muscle.

**Methods**: We genotyped 651 asthmatic children and their available parents participating in the Childhood Asthma Management Program, using a TaqMan genotyping assay that interrogates both the deletion and insertion CNV states. We tested for association of the deletion with asthma susceptibility and several intermediate phenotypes, including log-transformed IgE and airway hyper-responsiveness as measured by methacholine bronchoprovocation challenge.

**Results**: Our genotyping success rate was 99.6%. Deletion frequency was 9% among non-Hispanic whites (N=479) and 44% in black subjects (N=67), consistent with HapMap frequency data. The deletion was associated with increased total IgE and increased sensitivity to methacholine in black subjects (p=.02 and .05 in population-based testing). These findings were confirmed by family-based testing for both phenotypes (p=.02 and .03, for IgE and methacholine hyperresponsiveness, respectively). No associations were noted in the non-Hispanic white population. IRGM copy number status was not associated with asthma affection in either subgroup.

**Conclusions**: We provide evidence that a common ancestral CNV upstream of IRGM, known to be associated with Crohn's disease, is also associated with IgE level and methacholine sensitivity in black asthmatic children.

**Funding**: R01 HL093076, R01 HL086601, P01 HL083069, P41 HG004221, and K12 HL089990.

## 753/W/Poster Board #411

**SPAG16 Gene Variants are Associated with Fasting Glucose and Insulin Sensitivity.** *W.D. Li[1], G.M. Yuan[1], S.F.A. Grant[2], H. Hakonarson[2], R.A. Price[1].* 1) Dept Psychiatry, Univ Pennsylvania Medical Ctr, Philadelphia, PA; 2) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

In our previous genome scan, we found a significant linkage of total cholesterol on human chromosome region 2q34. To fine map the 2q34 region, we selected 65 nuclear families that ranked by family specific LOD scores. We genotyped 125 SNPs within a 6 Mb 2q34 candidate region in those 65 families, FBAT and QTDT analyses showed significant associations on SNPs of the SPAG16-ABCA12 gene region. We further tested SPAG16 gene polymorphisms in a case-control data set. We selected 1,125 unrelated individuals, including 583 cases (BMI>35kg/m2) and 542 controls (BMI<25kg/m2). Body weight (BMI, % fat, waist circumferences), lipids (total cholesterol, triglyceride, LDL and HDL), insulin sensitivity related phenotypes (fasting glucose, insulin, HOMA and QUICKI) were collected in cases/controls. One hundred ninety-six (196) SNPs in the SPAG 16 (Sperm Associated Antigen 16) gene region (213.8-215.0 Mb) were genotyped using ABI and Illumina platforms. Quantitative association studies were performed by PLINK, the most significant result was on SNP rs11677793 for fasting glucose (P = 0.000025). Multiple SNPs were associated with fasting glucose, insulin, HOMA, QUICKI, total cholesterol, triglyceride, %fat and waist circumferences. Haplotype analyses showed multiple significant associations among SPAG12 haplotypes and insulin sensitivity related phenotypes, including a three-SNP haplotype (rs17364234-rs11677793-rs7580474) yielded P = 0.000027 for fasting glucose. Associations among SPAG16 SNPs and glucose and insulin sensitivity phenotypes suggested that the SPAG16 gene could have more functions other than spermatogenesis.

## 754/W/Poster Board #412

**TFAP2A is associated with nonsyndromic Cleft Lip and Palate.** *S. Suzuki[1,6,7], ML. Marazita[2,3], ME. Cooper[3], B. Smith[1], A. Mansilla[1], N. Natsume[6], T. Niimi[6], H. Furukawa[6], K. Minami[6], E. Dragan[1], T. Erkhembaatar[8], JC. Murray[1,4,5].* 1) University of Iowa, Department of Pediatrics, S Grand Avenue, 2182 ML, Iowa City, IA 52242, USA; 2) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA 15219, USA; 3) Center for Craniofacial and Dental Genetics, and Department of Oral Biology, and Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA 15219, USA; 4) College of Nursing, The University of Iowa, Iowa City, IA 52242, USA; 5) University of Iowa, Departments of Pediatric Dentistry, Epidemiology and Biology, Iowa City, IA 52242; 6) Maxillofacial Congenital Anomalies, School of Dentistry, Aichi-Gakuin University, 2-11 Suemori-Dori, Chikusa-Ku, Nagoya 464-8651, Japan; 7) Faculty of Psychological and Physical Science, Aichi-Gakuin University, 12 Araike, Iwasaki-cho, Nisshin 470-0195 Japan; 8) Maternal and Children's Health Research Center Hospital, Ulaanbaatar 210624, Mongolia.

Nonsyndromic cleft lip with or without cleft palate (CL/P), a common birth defect, is a complex trait, arising from the influence of genetic variants interacting with environmental factors. A recent study of variants in the IRF6 gene (Rahimov, 2008) showed variants in an AP-2alpha binding site in an IRF6 enhancer is associated with cleft lip. We have also previously reported the linkage of NS CL/P to the 6p23 region that contains TFAP2A gene. TFAP2A is highly expressed in the craniofacial region and knock out mice have multiple facial anomalies. We genotyped 7 SNPs in and near TFAP2A for 175 case-parents trios with nonsyndromic CL/P from Mongolia, large collection of families from Philippines and the US using the TaqMan assay. FBAT was used for transmission disequilibrim test. A statistically significant association between CL/P and TFAP2A (p < 0.001) was shown for rs 1675414. These results support a direct role for variation of TFAP2A in orofacial clefting and suggests that examination of additional members of this pathway and deeper investigation of SNPs at the TFAP2A locus may disclose etiologic variants.

## 755/W/Poster Board #413

**Expression of a unique neuroendocrine splicing form of TCF7L2 in human and mouse tissues.** *J.L. Hall[1], C. Welch[1], C. Weaver[1], D. Schuweiler[1], N. Adhikari[1], L. Peihl[1], L. Prokunina-Olsson[2].* 1) Medicine, Lillehei Heart Institute, University of Minnesota, Minneapolis, MN; 2) Laboratory of Translational Genomics/DCEG, NCI/NIH, Bethesda, MD.

Background: Genetic variants within the TCF7L2 gene have been identified as the strongest common risk factors for development of type 2 diabetes. Methods and Results: We used expression assays targeting the majority of the TCF7L2 splicing forms observed in human tissues. A unique splicing form of TCF7L2 detected by assay "ex13-13b" was identified in human pancreatic islets, pancreas, gut, and the brain. Further analysis of expression using quantitative reverse-transcriptase PCR (qRT-PCR) showed that compared to the level in the gut/pancreatic islets, expression of this assay was 300 fold higher in the thalamus/hypothalamus area of the brain. Expression of TCF7L2 assay "ex13-13b" was found in 10 human tissues of 25 tissues examined and it was coexpressed with neurohormone Cocaine and Amphetamine Regulated Transcript (CART) in these tissues (n=10, r2=0.88, p= 0.00078) suggesting a neuroendocrine pattern of TCF7L2 expression. Expression of assay "ex13-13b" of TCF7L2 and CART was also detected in murine brain, pancreatic islets, pancreas and gut. Murine expression of "ex13-13b" in the gut was decreased in adults compared to newborn mice by 5 fold (p=0.0021) and 3.6 fold (p=1x10-6) in duodenum and colon, respectfully. Similarly, expression of CART was also decreased 2.7 fold in duodenum (p=0.001) and 2.3 fold in colon (p=0.067) of adult animals compared to newborns. In contrast, expression of 11 other TCF7L2 expression assays was significantly increased up to 10 fold in adult animals compared to newborns. Conclusions: A unique splicing form of TCF7L2 detected by assay "ex13-13b" was identified in human and mouse pancreatic islets, pancreas, gut and brain. Expression of this splicing form correlated with expression of neurohormone CART in human and mouse tissues. Studies are underway in murine tissues to further define the relationship between CART and TCF7L2.

## 756/W/Poster Board #414

**A Non-synonymous *HNF4A* Variant is Associated with Glycemia During Pregnancy and Offspring Head Circumference in Populations of European Ancestry in the HAPO Study.** *M.G. Hayes[1], H. Lee[1], R.M. Freathy[1,2], M. Urbanek[1], L.P. Lowe[1], C. Ackerman[1], N.J. Cox[3], D.B. Dunger[4], A.R. Dyer[1], A.T. Hattersley[2], B.E. Metzger[1], W.L. Lowe[1], The HAPO Study Cooperative Research Group.* 1) Northwestern Univ, Chicago, IL; 2) Univ Exeter, UK; 3) Univ Chicago, Chicago, IL; 4) Univ Cambridge, UK.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study is a multicenter, international study, which examined the association of maternal glucose levels with fetal growth and outcome in 25,000 pregnant women from multiple ethnic groups to demonstrate a continuous relationship between maternal glucose measures and birth size throughout the range of glucose concentrations. We hypothesize genetic factors contribute to these phenotypes, and examined 1536 fetal and maternal SNPs in 79 candidate loci previously implicated in insulin secretion or sensitivity to determine associations with maternal glycemia and insulin secretion (fasting glucose and C-peptide and 1-hr glucose from the OGTT) at ~28 weeks gestation and/or offspring size at birth (birth weight, length, head circumference, and sum of skinfolds) for HAPO mothers of European (Belfast and Manchester, UK, and Brisbane and Newcastle, Australia; N=3828) and Asian (Bangkok, Thailand; N=1813) ancestry and their offspring. Associations were assessed through linear regressions with the single trait/outcome under an additive genetic model adjusting for known confounders. Among our strongest signals was rs1800961G>A, which encodes a Thr>Ile amino acid change in exon 4 of *HNF4A*, recently identified in a GWAS meta-analysis as a variant associated with decreased HDL levels. In the HAPO study, this SNP was strongly associated with increased fetal head circumference (0.5cm [95%CI: 0.3-0.7] per maternal minor allele; $P=1.2x10^{-7}$) in those of European descent. The maternal minor allele was also weakly associated with 1-hour glucose (4.3mg/dL [95%CI: 0.5-7.9]; P=0.03), birth length (0.7cm [95%CI: 0.2-1.1]; P=0.003), birth weight (52.6g [95%CI: -8.0-113.3]; P=0.09), and sum of skinfolds (0.3cm [95%CI: -0.1-0.6]; P=0.13). This same minor allele in the fetal genome was weakly associated with cord C-peptide (0.1ug/dL [95%CI: 0.01-0.22]; P=0.03), and head circumference (0.2cm [95%CI: -0.1-0.4]; P= 0.08). The same trends were observed among the Thai, although not significantly probably due to a reduction in power from the low risk allele frequency (<2%). These results suggest that *HNF4A*, a locus previously implicated in insulin secretion and sensitivity and dyslipidemia, has a significant impact on birth size, particularly head circumference at birth.

## 757/W/Poster Board #415

**Leveraging Gene Ontology Information to Identify Gene-gene Interactions Underlying Type 2 Diabetes-related Traits.** *R.M. Watanabe[1,2], D.V. Conti[1], N. Cremer[3], H. Allayee[1,4], J.M. Lawreance[5], A.H. Xiang[1], T.A. Buchanan[6,2].* 1) Dept. of Preventive Medicine, USC Keck School of Medicine, Los Angeles, CA; 2) Dept. of Physiology & Biophysics, USC Keck School of Medicine, Los Angeles, CA; 3) Dept. of Cancer Epidemiology, German Cancer Research Center, Heidelberg, Germany; 4) Institute for Genetic Medicine, USC Keck School of Medicine, Los Angeles, CA; 5) Research and Evaluation, Kaiser Permanente of Southern California, Pasadena, CA; 6) Dept of Medicine, Division of Endocrinology, USC Keck School of Medicine, Los Angeles, CA.

Complex traits are thought to be partly determined by gene-gene (GxG) interactions. Genome-wide association (GWA) studies have identified loci underlying complex diseases like type 2 diabetes (T2D), but provide no context for how these loci may be interacting. Recent development of gene ontology (GO) databases provides a rich resource regarding known biology of specific loci. We sought to leverage this information to identify potential GxG interactions underlying T2D-related traits. We downloaded GO terms for a list of 81 candidate loci underlying T2D risk or variability in T2D-related traits identified by GWA. We generated pair-wise correlations among loci based upon the congruence of GO terms. The analysis dataset comes from the BetaGene study, consisting of Mexican American families of a proband with or without previous gestational diabetes. DNA and fasting blood (glucose, insulin, and lipids) were collected on all subjects (n=1,650), and the proband generation (n=976) were additionally phenotyped by oral and intravenous glucose tolerance test to obtain measures of glucose effectiveness, insulin sensitivity, insulin secretion, and beta-cell function. The GO-based correlations can be utilized in two ways. First, pairs of loci with the strongest correlations can be directly tested for interactions with T2D-related traits. Second, the correlation matrix can be used to guide a Bayes model selection approach to detect interacting loci. The GO correlation analysis revealed two loci, *PPARG* and *HNF4A*, that were correlated (r=0.35), which we previously showed interacted to alter insulin sensitivity, thus acting as a positive control. Preliminary pair-wise interaction analysis of loci using traditional linear modeling methods revealed the interaction between *KCNJ11* and *G6PC2* to be associated with glucose effectiveness (interaction p=0.018) and *FTO* and *IGF2BP2* to be associated with 2-hour insulin levels (interaction p=0.028). Both of these interactions tend to cluster together in a hierarchical clustering of GO terms. These initial analyses suggest the biologic information in GO can be used to inform GxG analyses. Additional analyses based on linear modeling and on a Bayes model selection approach are on-going.

**Biological and statistical interaction between type 1 and type 2 diabetes genes.** *J.J. Zhang[1,2,3], K. Pearce[1,2,3], S.H. Li[4], M. Serafin[1,2,3], J. Basken[1,2,3], R. Hoffmann[4], P. Simpson[4], C. Sarti[5], S. Ghosh[1,2,3].* 1) 1Max McGee National Research Center for Juvenile Diabetes, Department of Pediatrics, Medical College of Wisconsin, Milwaukee, Wisconsin; 2) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, Wisconsin; 3) Children's Research Institute, Children's Hospital of Wisconsin, Milwaukee, Wisconsin; 4) Quantitative Health Sciences, Department of Pediatrics and Population Health, Medical College of Wisconsin, Milwaukee, Wisconsin; 5) National Public Health Institute, Helsinki Finland.

Type I diabetes (T1D) is a polygenic, T-cell-dependent autoimmune childhood disease, characterized by the selective destruction of the $\beta$ cells of the islets of Langerhans. In contrast, Type 2 diabetes (T2D) is the end point of a progressive insulin secretory defect on a background of insulin resistance and typically occurs later in life. Both diseases are of multifactorial etiology, in which genetic predisposition plays a critical role and underpins each complex trait. In T1D, even though about 40 loci have been discovered, the class II HLA region (HLA-DRB, HLA-DQA and HLA-DQB) and insulin genes (INS) have the largest effect. Insulin is thought to be a major type 1 diabetes autoantigen presented to the immune system by HLA molecules. For T2D, there are at least 20 gene loci with the largest effect due to TCF7L2. To date, no genetic overlap exists between T1D and T2D loci. INS functions at the level of the thymus in T1D to reduce the impact of clonal deletion of insulin-specific, autoreactive T cells. In contrast, some T2D susceptibility genes could reduce insulin production at the level of the beta cell and potentially decrease insulin antigen load, giving rise to delayed autoimmune, T-cell dependent diabetes that would manifest later and only in young adults. To test this genetic hypothesis, we studied a sample of 748 T1D cases (age of onset 15-39) and 1549 control subjects from Finland, which has the highest incidence of T1D in the world. Our results showed that INS (p<0.0001) and HLA (p<0.0001) are strongly associated with disease, but none of the T2D genes tested were (TCF7L2, PPAR$\gamma$, SLC30A8, KCNJ11, MTNR1B). In contrast, using logistic regression, there was an interaction seen between INS and TCF7L2 under a risk model which assumed INS was recessive whereas TCF7L2 was acting in a dominant manner (p=0.02). Results were verified using a non-parametric, classification tree approach. The finding will be confirmed in a second, independent sample. In summary, our data suggest that the delay in T1D in a young adult sample could be due to an interaction between a T1D and a T2D gene. The biological significance of the finding is that diminished insulin secretion due to a T2D gene could reduce the extent of autoimmunity by decreasing antigen load and hence delaying onset of disease. Thus, even though there is no overlap between T1D and T2D genes, they may interact to produce delayed diabetes in young adult life.

## 759/W/Poster Board #417

**Evidence for two susceptibility loci for epilepsy on chromosomes 9q33-q34 and 20p12-q13 in a Finnish family.** *A. Polvi[1], A. Siren[1,2], H. Rantala[3], A.-E. Lehesjoki[1].* 1) Dept Medical Genetics, Biomedicum Helsinki, Helsinki, Finland; 2) Department of Pediatrics, University Hospital of Tampere, Finland; 3) Department of Pediatrics, Oulu University Hospital, Finland.

Epilepsy is a brain disorder characterized by recurrent epileptic seizures and divided to many syndromes with distinct seizure types. In many epilepsy families, the patients do not share the same seizure phenotype. Idiopathic epilepsies occur in the absence of detectable brain abnormalities and are assumed to be mainly polygenic or multifactorial in origin. Mutations in single genes, mostly encoding ion-channels, have been reported in rare families with apparently dominant inheritance. In the majority of idiopathic epilepsy patients the underlying genetic defect remain unknown. A multiplex family including four patients with febrile seizures, 11 with focal seizures and two with generalized and febrile seizures was recognised and clinically characterized. Blood samples from 59 family members were collected after obtaining informed consent. A genome-wide microsatellite marker scan (GWS) was performed. Multipoint location scores were calculated with the SIMWALK2 2.91 program using the nonparametric linkage (NPL) analysis option. Regions with a multipoint location score > 1.5 were fine mapped and further analysed by NPL. Functional candidate genes were sequenced from genomic DNA. In the GWS two loci (9q33-34 and 20p12-q13) gave evidence for linkage by showing multipoint location score values of 2.11 and 2.85. After fine mapping, maximum multipoint NPL scores of 2.16 (p= 0.0069) at 9q33-34 and 2.314 (p=0.0049) at 20q11-12 were detected. The susceptibility regions on 9q33-34 and 20p12-q13 were 20.5 and 21.0 Mb long and contained 284 and 290 genes, respectively. Sequencing of one functional candidate gene, STXBP1, did not reveal a pathogenic alteration. Clinical variability within the family suggests the contribution of several genes. Our data support the existence of at least two epilepsy susceptibility loci in the family.We are in the process of recruiting more family members with epilepsy to increase the statistical power with the ultimate aim of narrowing the regions of interest to allow identification of the underlying genes.

## 760/W/Poster Board #418

**Genome-wide study of families with absolute pitch reveals linkage to 8q24.21 and locus heterogeneity.** *E. Theusch, A. Basu, J. Gitschier.* Univ California, San Francisco, San Francisco, CA.

Absolute pitch (AP) is the rare ability to instantaneously recognize and label tones with their musical note names, without using a reference pitch for comparison. The etiology of absolute pitch is complex, with prior studies implicating both genetic and environmental factors in its genesis, yet the molecular basis for absolute pitch remains unknown. To locate regions of the human genome that may harbor AP-predisposing genetic variants, we performed a genome-wide linkage study on 73 multiplex absolute pitch families by genotyping them with 6,090 single nucleotide polymorphism (SNP) markers. Non-parametric multipoint linkage analyses were conducted, and the strongest evidence for linkage was observed on chromosome 8q24.21 in the subset of 45 families with European ancestry (exponential logarithm of the odds (LOD) score = 3.464, empirical genome-wide P = 0.03). Other regions with suggestive LOD scores included chromosomes 7q22.3, 8q21.11, and 9p21.3. Of these four regions, only the 7q22.3 linkage peak was also evident when 19 families with East Asian ancestry were analyzed separately. Though only one of these regions has yet reached statistical significance individually, we detected a larger number of independent linkage peaks than expected by chance overall, indicating that absolute pitch is genetically heterogeneous.

## 761/W/Poster Board #419

**ADIPOQ gene variation is associated with plasma adiponectin and HDL cholesterol in Yup'ik Eskimos: The CANHR study.** *B. Boyer[1], R. Pasker[1], M. Irvin[2], H. Weiner[2], D. O'Brien[1], M. Jeannet[1], K. Stanhope[3], P. Havel[3], G. Mohatt[1], H. Tiwari[2].* 1) Institute of Arctic Biology, University of Alaska-Fairbanks, Fairbanks, AK; 2) Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 3) Department of Nutrition, University of California Davis, Davis, CA.

Background: Adiponectin is an insulin-sensitizing hormone, and several linkage and association studies implicate the adiponectin locus in the development of obesity and diabetes. Dietary factors including marine derived polyunsaturated fatty acids (EPA/DHA) may decrease the risk of obesity and diabetes by modifying the association of genetic variants with obesity phenotypes. Objectives: The objective of this study was to determine if EPA/DHA modify the association between obesity phenotypes and four candidate genes in the pathway leading to adiponectin synthesis (PPARG, PPARA, PPARGC1A and ADIPOQ). Design: 981 non-pregnant Yup'ik Eskimos $\geq$14 years old were selected from the CANHR study - a cross sectional study investigating genetic, nutritional, and behavioral risk factors for obesity. A total of thirteen single nucleotide polymorphisms (SNPs) were genotyped. Mixed models were used to assess whether EPA/DHA influence the relationship between candidate genes and obesity phenotypes, using a biomarker of red blood cell EPA/DHA that was recently validated for Yup'ik Eskimos (the nitrogen isotope ratio, $\delta$15N). Results: Two SNPs in ADIPOQ, rs1784686 and SNP 2 (identified through re-sequencing), were associated with plasma adiponectin levels, while rs17300539 was associated with HDL cholesterol. EPA/DHA also modifies the association between PPARG rs3856806 (H447H) with plasma adiponectin. Conclusions: Polymorphisms in ADIPOQ are associated with plasma adiponectin and HDL levels. Associations between rs3856808 in PPARG and plasma adiponectin levels is modified by EPA/DHA intake.

## 762/W/Poster Board #420

**Polymorphisms in *IFNG* show sex-specific associations with IFN-γ response and asthma in early childhood.** *D.A. Loisel[1], Z. Tan[1], G. Du[1], C. Tisler[2], K.A. Roberg[2], R.E. Gangnon[3], M.D. Evans[3], J.E. Gern[2], R.F. Lemanske[2,4], C. Ober[1,5].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Pediatrics, University of Wisconsin-Madison, Madison, WI; 3) Department of Biostatistics and Medical Informatics, University of Wisconsin-Madison, Madison, WI; 4) Department of Medicine, University of Wisconsin-Madison, Madison, WI; 5) Department of Obstetrics and Gynecology, University of Chicago, Chicago, IL.

Sex differences in the prevalence and severity of asthma begin in childhood and are maintained through adulthood. The activation and expression of the Th1 cytokine, IFN-γ, may play a central role in the development of sex-specific differences in immune response and asthma risk. Previously, we reported sex differences in the IFN-γ response to PHA in peripheral blood mononuclear cells from children in the Childhood Origins of ASThma (COAST) birth cohort study; boys had significantly higher IFN-γ responses at 1 and 3 years of age (Uekert et al. *JACI* 2006; 118:1375). Here we examined sex-specific effects of 5 polymorphisms in the *IFNG* gene on two phenotypes, IFN-γ response (at ages 3 and 5 years) and asthma (assessed at age 8), in 134 boys and 100 girls. The median IFN-γ response was significantly higher in boys compared to girls at age 5 years ($P$=0.0004), similar to ages 1 and 3 years. Only the -1616 SNP (C/T), located in the *IFNG* promoter region, showed main effects on IFN-γ response ($P$=0.024 for age 3; $P$=0.047 for age 5). The effect of the -1616 SNP on IFN-γ response differed by sexthe association was significant in girls ($P$=0.0038 and 0.045, respectively) but not in boys ($P$=0.47 and 0.78, respectively). Moreover, the -1616 SNP was associated with asthma in girls ($P$=0.032) but not in boys ($P$=0.38) or in the full cohort ($P$=0.36) (genotype-by-sex interaction $P$=0.059). Girls homozygous for the minor allele at -1616 had the lowest IFN-γ responses and highest prevalence of asthma. Two other polymorphisms, a 3'UTR SNP (A/G) and a microsatellite in intron 1, were also associated with asthma in girls ($P$=0.048 and 0.00013, respectively) but not in boys or in the full cohort. These two loci, which were in strong LD with each other but not with the -1616 SNP, showed significant genotype-by-sex interactions on asthma status ($P$=0.0043 and 0.0010, respectively). Overall, we found that IFN-γ response was sexually dimorphic throughout early childhood (ages 1 through 5) in COAST children. We identified an *IFNG* promoter SNP that was associated with sex-specific variation in IFN-γ response, and an intronic and/or 3'UTR SNP showing significant interaction effects with sex on risk for developing asthma by age 8. The observed sex-specific associations and genotype-by-sex interactions on asthma suggest that variation in the IFN-γ pathway may contribute to asthma risk during childhood in a sex-specific manner. Supported by NIH grant P01 HL070831.

## 763/W/Poster Board #421

**The cellular role of DYX1C1 - estrogen receptor pathways and cell migration.** *K. Tammimies[1], I. Tapia-Páez[1], S. Massinen[2], S. Le Guyader[1], I. Fransson[1], H. Matsson[1], M-E. Hokkanen[3], E. Castrén[3], S. Strömblad[1], J-A. Gustafsson[1,4], E. Treuter[1], J. Kere[1,2,3].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Department of Medical Genetics, University of Helsinki, and Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Neuroscience Centre, University of Helsinki, Finland; 4) Center for Nuclear Receptors and Cell Signaling, Department of Biology and Biochemistry, University of Houston, Houston, Texas, USA.

The focus of research in molecular biology of dyslexia has shifted towards explaining the function of genes associated with increased risk for dyslexia. So far six dyslexia candidate genes have been identified: DYX1C1, ROBO1, DCDC2, KIAA0319 MRPL19 and C2ORF3. Four of these genes, including DYX1C1, have been implicated in neuronal migration and/or axon guidance suggesting a role for specific neurobiological pathway/s in dyslexia. Although some common biological mechanisms have been identified, relatively little is known about the interactions and interplay of the known dyslexia candidate genes. We have focused on identifying the cellular role and regulation of DYX1C1. The DYX1C1 gene encodes a 420-aa protein with a p23 domain in the N-terminus and three tetratricopeptide repeat domains (TPRs) towards the C-terminus. We have previously shown that allelic differences in the promoter or 5' UTR of DYX1C1 affect transcription factor binding and also regulation of the gene. Recently, we have also identified that DYX1C1 interacts with the estrogen receptors alpha and beta (encoded by the ESR1 and ESR2 genes), and overexpression of DYX1C1 downregulates their protein levels and activity on estrogen responsive elements (EREs). We are now studying the consequences of the DYX1C1-ER protein interactions by testing rapid signaling pathways such as mitogenin-activated protein kinases ERK1/2. To investigate other effects of overexpression of DYX1C1 in a cell line, in particular cell migration and its molecular mechanisms, we are using transient transfections of the neuroblastoma SH-SY5Y cell line, live cell imaging and transcriptome analyzes. Our preliminary results using single cell tracking show that overexpression of DYX1C1 increases random migration of SH-SY5Y cells. The total and final distance of the DYX1C1 cells (n= 73) were approximately 50% more than GFP transfected control cells (n= 79). Taken together, the dyslexia candidate gene DYX1C1 can modulate estrogen signaling by direct effects on estrogen receptors, and current work aims at elucidating the molecular mechanisms of DYX1C1 effects on cell migration.

## 764/W/Poster Board #422

**Comprehensive evaluation of FTO genetic variation shows associations with obesity in two populations of African origin.** *A. Adeyemo[1], G. Chen[1], J. Zhou[1], D. Shriner[1], Y. Chen[2], A. Doumatey[1], H. Huang[1], C. Rotimi[1].* 1) CRGGH/IDRB, National Human Genome Research Institute, Bethesda, MD; 2) National Human Genome Center, Howard University, Washington, DC.

The FTO gene has been one of the most consistently replicated loci for obesity. However, data from populations of African origin are scanty. We have undertaken a comprehensive evaluation of variation in the FTO gene by genotyping a set of 262 tag SNPs across the entire span of the gene in two populations of African origin. The study samples comprised 968 African Americans (59% female, mean age 49 years, mean BMI 30.8 kg/m$^2$) and 517 West Africans (58% female, mean age 54 years, mean BMI 25.5 kg/m$^2$). Both samples showed weaker linkage disequilibrium (LD) patterns across the gene when compared with other continental (e.g. European and Asian) populations. Multiple SNPs in intron 8 and the downstream region showed significant associations with body mass index, waist circumference and percent fat mass in both study samples. Two reported associations with intron 1 SNPs (rs1121980 and rs7204609) were replicated at a p level of 0.05 among the West Africans. In summary, the FTO gene shows significantly differences in allele frequency and LD patterns between populations of African ancestry compared to other continental populations. Despite these differences, we observed significant associations with obesity in African Americans and West Africans. This comprehensive approach of characterizing genetic variation within candidate gene improved our study design and chances of identifying novel variants and successful replication of reported variants.

## 765/W/Poster Board #423

**Positional cloning of a quantitative trait locus in KCNQ5 gene influencing lung function.** *E. Bouzigon[1], H. Aschard[1], H. Tharrault[1], M-H. Dizier[1], R. Matran[2], M. Lathrop[3], F. Kauffmann[4], F. Demenais[1], EGEA cooperative group.* 1) U946, INSERM, Paris, France; 2) Univ Lille Nord de France, CHU, Lille, France; 3) Commissariat à l'Energie Atomique, Institut de Génomique, Centre National de Génotypage, Evry, France; 4) U780, INSERM, Villejuif, France.

A previous genome-wide linkage scan conducted in French EGEA families (Epidemiological study on the Genetics and Environment of Asthma) identified linkage of 6q14 to $FEV_1$ (forced expiratory volume in one second expressed as a percentage of predicted values based on age, height and gender), with a higher signal detected in adult offspring (16 years of age or older). We investigated further this region by genotyping a panel of 399 SNPs (spanning 30Mb) in 203 EGEA families (337 adult offspring). To reduce the problem of multiple testing, we used a two-stage approach based on two multi-marker methods: the Local Score and multi-marker FBAT (FBAT-M). This strategy allows detection of sets of adjacent markers showing aggregation of high statistical scores while taking into account linkage disequilibrium between markers. We identified five marker sets associated with $FEV_1$ (P-values ranging from 0.005 to 0.0008). The most significant marker set was located within *KCNQ5* gene and included 11 SNPs of which four were strongly associated with $FEV_1$ (P-values ranging from 0.0007 to 0.0001). We checked that these polymorphisms explained the original linkage signal. These associations were replicated in two independent samples: 1) 476 parents of EGEA families (P-values ranging from 0.05 to 0.01 for five SNPs) and 2) a set of 267 adult French controls (P-values ranging from 0.03 to 0.002 for four SNPs). The combination of P-values from our three samples, using Fisher's combined probability test, enhanced the evidence for association of $FEV_1$ with three SNPs (combined P-values ranging from $2x10^{-4}$ to $2x10^{-5}$). KCNQ5 belongs to a family of genes which encode voltage-gated potassium channels which are key regulators of cellular activity. KCNQ5, which is expressed in bronchial epithelium and is a determinant of airway-surface liquid, is therefore a strong candidate for lung function regulation. Funded by: French Ministry of Higher Education and Research, Afsset-APR-SE-2004, ANR 06-CEBS, GABRIEL.

## 766/W/Poster Board #424

**Missense mutations in the MEFV gene are associated with fibromyalgia syndrome and correlate with elevated IL-1β plasma levels.** *J. Feng[1,2], Z. Zhang#[2], W. Li[1], X. Shen[1], W. Song[1], C. Yang[1], F. Chang[2], J. Longmate[3], C. Marek[4], R.Paul St.Amand[4], T. Krontiris[5], J. Shively*[2], S. Sommer*[1].* 1) Department of Molecular Genetics; 2) Department of Immunology; 3) Department of Biostatistics, City of Hope Natl Medical Ctr, Duarte, CA; 4) The Fibromyalgia Treatment Center, Los Angeles, CA; 5) Department of Molecular Medicine, City of Hope Natl Medical Ctr, Duarte, CA.

Fibromyalgia syndrome (FMS), a common, chronic, widespread musculoskeletal pain disorder with a preponderance of 85% in females has both a genetic and environmental factor basis. Patients and their parents have high plasma levels of the chemokines MCP-1 and eotaxin, providing evidence for both a genetic and an immunological origin for the syndrome (Zhang et al., 2008, Exp. Biol. Med. 233: 1171-1180). Since FMS symptoms are similar to, but milder than, Familial Mediterranean Fever (FMF), a disease linked to compound heterozygous mutations in the FMF gene, MEFV, we have analyzed the exons in this gene in 100 probands with FMS and their parents. A total of 2.63 megabases of genomic sequence of the MEFV gene were scanned by direct sequencing. One common and 10 rare missense mutations were identified, all of which are found in the FMF database. The rare missense mutations had a significantly elevated frequency of transmission to affecteds (p= 0.017). Our data provide evidence for an association between rare missense variants of the MEFV gene and a subset of 15% of FMS patients. When this subset was reanalyzed for plasma cytokine and chemokine levels, a correlation (p= 0.019) was found with high levels of IL-1β, a cytokine associated with fever and muscle aches. Since mis-regulation of IL-1β expression has been predicted for patients with mutations in the MEFV gene, we conclude that heterozygotes for rare variants of this gene may be predisposed to FMS, possibly a milder form of FMF, while FMF requires compound heterozygotes. # J.Feng and Z.Zhang contributed equally to the results.*Corresponding authors.

**The functional variant (gly307ser) in CD226 is associated with susceptibility to multiple autoimmune diseases.** *A. Maiti[1], X. Kim-Howard[1], P. Viswanathan[1], L. Guillén[2], X. Qian[3], A. Rojas-Villarraga[4], C. Sun[1], C. Cañas[5], G. Tobón[5], K. Matsuda[6], N. Shen[3], A. Cherñavsky[2], J. Anaya[4], S. Nath[1].* 1) Genetic epidemiology Unit, Oklahoma medical Research Foundation, Oklahoma, OK; 2) Immunogenetic Laboratory, Universidad de Buenos Aires, Buenos Aires, Argentina; 3) JiaoTong University School of Medicine, China; 4) Center for Autoimmune Diseases Research (CREA), Universidad del Rosario, Bogota, Colombia; 5) Rheumatology Unit, Fundación Valle del Lili, Cali, Colombia; 6) Human Genome Center, the University of Tokyo, Tokyo, Japan.

Objectives: Recently, A non-synonymous (Gly307Ser) variant, rs763361, in the CD226 gene is shown to be associated with multiple autoimmune diseases (ADs) in European populations. However, shared autoimmunity with CD226 has not been evaluated in non-European populations. The aim of this study is to assess the association of this SNP with ADs in Hispanic and Asian populations Methods: To replicate its association with other ADs, we evaluated case-control association between rs763361 and celiac disease (CED) samples from Argentina; systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), Type-1 diabetes (T1D) and primary Sjögren's syndrome (pSS) from Colombia; and SLE samples from China and Japan. We genotyped rs763361 for evaluation of association and 3 other unlinked SNPs for assessing population substructure. Genetic associations were tested with the chi-square test. Results: All our populations are homogenous as both cases and controls are collected from endogenous local populations and association results are not affected by population substructures. In population substructure analysis, the subdivision coefficient among the Argentinean and Colombian cases and controls, was not significantly different from zero (Fst = 0.01). We show that rs763361 is significantly associated with CED (p=0.0009, OR=1.60), RA (p=0.047, OR=1.25), and SLE (p=0.01, OR= 1.19) from China. We also observed a trend of possible association with SLE (p=0.0899, OR=1.24) and pSS (p=0.09, OR=1.33) in Colombians. A meta-analysis across all ADs reinforces the association with this coding variant (Pmeta=2.9x10-6, OR (95% CI)=1.23 (1.13-1.33). Conclusions: Our results demonstrate that this coding variant rs763361in cd226 gene is associated with multiple ADs in non-European populations.

## 768/W/Poster Board #426

**A *RET* founder mutation in Chinese Hirschsprung's patients.** *B.K. Cornes[1], C.S. Tang[2], T.Y.Y. Leon[1], M.T. So[1], P.C. Sham[2], P.K.H. Tam[1], M.M. Garcia-Barcelo[1].* 1) Paediatric Surgery Division, Department of Surgery, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong SAR, China; 2) Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR, China.

Hirschsprung's disease (HSCR) is a congenital disorder associated with the lack of intramural ganglion cells in the myenteric and sub-mucosal plexuses along varying segments of the gastrointestinal tract. Rearranged during transfection (*RET*) gene is implicated in HSCR and is the major gene of this gastrointestinal disease. To date, over 200 low frequency recurrent RET coding sequence (CDS) mutations have been identified in HSCR patients. However, a highly recurrent $RET^{R114H}$ mutation has been identified in 10% of the Chinese HSCR patients which has never been found in Caucasians patients or controls nor in 400 Chinese controls. The high frequency of $RET^{R114H}$ in our population together with the fact that it is not a *"de novo"* mutation in the context of the most HSCR-associated *RET*-haplotype, suggests that it may be a founder HSCR mutation in the Chinese population. Initial investigation involved applying a Bayesian method to 21 single nucleotide polymorphisms (SNPs; across a ~62kb region of *RET*) genotyped in 421 Chinese HSCR patients (of which 24 individuals had the mutation) to predict the approximate age of $RET^{R114H}$. The approach allowed the inference of the mutation age based on the observed linkage disequilibrium (LD) at multiple SNPs which predicted the mutation to be between 12 and 13 generations old. Including SNPs from a recently obtained genome-wide 500K dataset for 181 of the above mentioned patients (which now only included 14 patients who had the $RET^{R114H}$ mutation), we applied haplotype estimation methods to determine whether there were any segments shared between patients with the $RET^{R114H}$ compared to those without the mutation and controls. Data consisted a total of 92 SNPs spanning a 510kb region over the RET gene. Analysis yielded a 256kb (76 SNP) shared segment over the *RET* gene (and downstream) in only those patients with the mutation with no similar segments found among other patients or controls. This suggests that $RET^{R114H}$ is a possible founder effect for Hirschsprung's disease in the Chinese population.

**Association analysis of exonic polymorphisms in TNIP1 and TNFAIP3 with psoriasis.** *R.P. Nair[1], P.E. Stuart[1], T. Tejasvi[1], H.W. Lim[2], J.J. Voorhees[1], J.T. Elder[1].* 1) Dept Dermatology, Univ Michigan, Ann Arbor, MI; 2) Henry Ford Hospital, Detroit, MI.

Psoriasis is a complex disease with genetic, environmental and imunological etiology. Our recent genome-wide association study (GWAS, Nair et al, Nature Genetics, 2009) identified seven replicated associations, including three previously known ones, and implicated IL-23 and NF-κB mediated pathways in psoriasis pathogenesis. Here we examine the association of exonic polymorphims in two of the genes identified by the GWAS - TNIP1 and TNFAIP3 - that act downstream of TNF in NF-κB regulation. The best associated GWAS markers near these genes are rs17728338, 18 kb upstream of TNIP1 on chromosome 5q33.1, and rs610604 in intron 3 of TNFAIP3 on chromosome 6q23.3. By data mining of public databases we identified 13 potential non-synonymous variations in TNIP1 and 6 in TNFAIP3. Testing of these variations in a subset of DNA samples showed that only 4 SNPs in TNIP1 and one in TNFAIP3 are present in our samples with a minor allele frequency > 1%. These SNPs and the associated GWAS SNPs were genotyped in our entire sample of 2,302 psoriasis cases and 2,132 controls of European ancestry. The GWAS marker for TNIP1 (rs17728338) showed allelic association with genome-wide significance ($p = 1.1 \times 10^{-9}$, OR=1.67) and the TNFAIP3 marker (rs610604) approached genome-wide significance ($p = 4.5 \times 10^{-6}$, OR = 1.23). None of the exonic SNPs tested showed significant association. When multi-marker haplotypes for each gene were tested for association, only haplotypes containing the risk allele for the GWAS markers showed significance (TNIP1: $p = 2.2 \times 10^{-6}$, OR = 1.6; TNFAIP3: $p = 5.2 \times 10^{-7}$, OR = 1.26). These results show that the known non-synonymous SNPs in TNIP1 and TNFAIP3 are unlikely to be causal in psoriasis. A detailed characterization of these loci by re-sequencing and testing of the full spectrum of allelic variations in our large case-control collection is in progress.

**Evaluation of Pooled Sequence Variation in SERPINE2 Using the Illumina Genome Analyzer.** *M.H. Cho, G.M. Oliveria, A.L. Donohue, B.J. Klanderman, B.A. Raby, E.K. Silverman.* Channing Lab, Brigham & Women's Hosp, Boston, MA.

Background: Genetic association and expression studies have implicated SERPINE2 in the pathogenesis of COPD; however the SNPs responsible for these genetic associations are not known. We sought to sequence the exons and conserved regions of this gene in a pilot project using subject and amplicon pools in the Illumina Genome Analyzer. Methods: We created 7 equimolar pools of genomic DNA each from 20 subjects from 80 cases from the National Emphysema Treatment Trial and 60 controls from the Normative Aging Study. We performed standard PCR amplification, and ligated amplicons to create large concatamers for Illumina sequencing. Sanger sequencing was performed on 20 individuals from one of the pools as a reference. Sequences were aligned with maq, and variants were called and compared based on allele frequency. Results: In our reference pool, 29/30 Sanger sequenced SNPs were identified; with the missing SNP present at a frequency of < 1% in the pool. Of the total discovered SERPINE2 variants, there were no significant differences in allele frequency between the pooled cases and controls. Conclusions: Pooling DNA is a feasible option for comprehensive variant discovery in case-control studies, though variability in pooling must be considered. In this limited sample, we found no obvious conserved region or exonic variation accounting for the role of SERPINE2 in COPD.

## 771/W/Poster Board #429

**Development of methods for resequencing of genes using indexed DNA samples and the SureSelect target enrichment system.** *E.M. Kenny, A.S. Gates, L.E. Cochrane, M. Gill, A.P. Corvin, D.W. Morris.* Neuropsychiatric Genetics Research Group, Dept. of Psychiatry, Trinity College Dublin, Dublin, Ireland.

Next-generation sequencing technology has allowed sequencing of whole genomes to be carried out in standard molecular genetics laboratories. However, an important application of this technology is sequencing of specific genomic regions, for example disease genes in patient samples. In order to sequence parts of the genome of interest, a number of methods have been developed including long range (LR) PCR and microarray capture. Both methods have been shown to work but are costly in terms of time for LR PCR and DNA for microarray capture (20μg input DNA required). Agilent Technologies have developed the SureSelect Target Enrichment System. This method allows targeting of 3.3Mb of the genome by using cRNA baits. Indexing methods have been developed for next generation sequencing that allow multiplexing of samples in one sequencing library. We have combined the SureSelect Target Enrichment System with an indexing protocol to develop a cost-efficient method for targeting smaller regions of the genome (e.g. 200Kb) in multiple DNA samples. We evaluated this method by comparing sequence data produced to data generated by a LR PCR enrichment of the same target sequence. For the LR PCR method, primers were designed to generate amplicons that tile across the genomic region of interest. All amplicons for each individual sample were pooled such that an equimolar amount of PCR-amplified DNA was added for each fragment and the total amount of DNA in the pool was 1-5ug. For the SureSelect method, unique baits were designed to capture genomic fragments in the target region and 3μg of genomic DNA was used as input for the Illumina genomic DNA library prep method. For both enrichment methods, the Illumina genomic DNA library prep method was modified to allow indexing of more than one sample in each sequencing library according Craig et al (2008). We will present data on the performance of the SureSelect method in comparison to the LR PCR method in HapMap test samples and present a protocol that will be extremely useful in the rapid sequencing of target genomic regions.

## 772/W/Poster Board #430

**Replication of genome-wide association signal on 8q associated with cleft lip and palate.** *T. Goto[1,5], M.A. Mansilla[1], A.L. Petrin[1], S.A. Bullard[2], J. Dierdorff[2], A.L. Lidral[2], K. Christensen[3], K. Durda[1], M. Marazita[4], M. Cooper[4], K. Arakaki[5], H. Sunakawa[5], L.M. Moreno-Uribe[2], J.C. Murray[1].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) University of Iowa, Department of Orthodontics, Iowa City, Iowa 52242; 3) University of Southern Denmark, Odense, Denmark; 4) University of Pittsburgh, Department of Oral Biology, Pittsburgh, Pennsylvania 15219; 5) University of the Ryukyus, Department of Medicine,Okinawa, Japan.

Cleft lip and/or palate is a common birth defect of complex etiology with modest success in finding genetic contributors. The first genome-wide association published on cleft lip and palate (Birnbaum et al.,2009) has reported a highly significant association with markers in a gene poor region at 8q24 in a German population. We have replicated the associated SNP (rs987525) with the lowest p value in multiple world-wide populations (US (684 cases), Denmark (571 cases), Colombia (744 cases), Brazil (284 cases), Philippines(1470 cases)) using case/parent trios and the TDT test. In European derived populations, there is very strong association (excepting Brazil) with the rs987525 (US p=0.0000024; Denmark 0.0000015; Colombia 0.0029; Brazil 0.101995). We also stratified the results by cleft phenotype and found stronger association with cleft lip with cleft palate than for cleft lip alone. However, no association with this marker was noted in a large Filipino sample set (1470 case-parent trios, 5850 persons); nor is there an association identified with any of an additional 20 SNPs tested in Filipinos in the 640 kb critical region identified in the published work. We have also sequenced 180 Filipino cleft cases and controls, as well as 90 US cases and controls in two highly conserved regions in the 8q24 critical region but failed to identify any obvious etiologic mutations. These results confirm the previous report of genome-wide association in cleft lip and palate for this novel locus but fail to identify any specific causal variations. This suggests that the effect may be European-population specific; at present, there is no evidence for association in South Asian populations.

## 773/W/Poster Board #431

**Genomewide association scan of neurophysiological endophenotypes reveals transregulational effects on *SLC2A3* in dyslexic children.** *P. Hoffmann[1,2], D. Roeske[3], K.U. Ludwig[1,2], N. Neuhoff[4], J. el Sharkawy[4], J. Becker[1,2], J. Schumacher[1], B. Müller-Myhsok[3], G. Schulte-Körne[4], M.M. Nöthen[1,2].* 1) Intitute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany; 3) Max-Planck Institute of Psychiatry, Munich, Germany; 4) Department of Child and Adolescent Psychiatry and Psychotherapy, University Hospital Munich, Munich, Germany.

In the present study we tested for association with mismatch-negativity (MMN), an endophenotype measuring the children's reaction to a change in speech stimuli, in a whole-genome association data set of 200 German dyslexic children. We selected 19 SNPs showing significant p-values and being located in chromosomal regions with previous linkage evidence for independent replication in a sample of 186 German dyslexics. We found that SNP rs4234898 on chr 4 was significantly associated with the subphenotype MMN3 in both samples. The association result in the combined sample withstood genome-wide correction for multiple testing (p=6.09e-08 carrier T model). rs4234898 lies within a gene desert, with the nearest genes being more than 150kb away. None of the neighboring genes shows evidence for brain-specific expression or function or is known to be related to neurophysiological phenotypes. Analysis using publicly available GWA expression data yielded evidence for possible trans-regulation effects of rs4234898 on *SLC2A3* (also called *GLUT3*), the predominant facilitative glucose transporter in neurons. We could confirm the trans-regulation of *SCL2A3* by own experiments in EBV-transformed cell lines from 17 dyslexic children, with 10 individuals carrying at least one T-allele showing lower expression of SLC2A3 (p=0.028 one-sided Wilcoxon-test). When performing further analysis we found that rs11100040 on chr 4 was also significantly associated the differential expression of SLC2A3 in the public expression databases. Interestingly, rs4234898 and rs11100040 form a haplotype which is associated with MMN3 (p=6.71e-08 in combined sample). In conclusion, we performed the first genome-wide association study focussing on a neurophysiological endophenotype of dyslexia. Our results suggest a genomic region on chromosome as a factor contributing to variable expression of this trait, possibly conferring its functional effect through trans-regulation of *SLC2A3*.

## 774/W/Poster Board #432

**Variants in *GIPR* are associated with insulin response to oral glucose load: results from the first genome-wide meta-analysis of 2h glucose levels.** *V. Lyssenko[1], R. Saxena[2,3], M-F. Hivert[3], C. Langenberg[4], T. Tanaka[5], J.S. Pankow[6], P. Vollenweider[7], N. Boutia-Naji[8], L. Groop[1], R.M. Watanabe[9].* 1) Clinical Sciences, Lund University, Malmö, Sweden; 2) Massachusetts General Hospital, Boston, MA, USA; 3) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 4) MRC Epidemiology Unit, Cambridge, UK; 5) Medstar Research Institute, Baltimore, MD , USA; 6) University of Minnesota, Minneapolis, MN, USA; 7) Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 8) Pasteur Institute, Lille, France; 9) University of Southern California, Los Angeles, CA, USA.

Genome-wide association studies (GWAS) have largely contributed to our understanding of the pathogenesis of T2D in the past. The collaborative effort called MAGIC (Meta-Analyses of Glucose and Insulin-related traits Consortium) has now extended the search for genetic variants influencing diabetes-related traits to postprandial insulin and glucose levels during OGTT. A meta-analyses of 2h glucose levels using 24 studies totaling up to 40,442 non-diabetic individuals identified a SNP in the *GIPR* (glucose-dependent insulinotropic peptide receptor) gene achieving genome-wide significance level (meta $P=2.05x10^{-9}$). GIP (Glucose-dependent Insulinotrophic Peptide or Gastric Inhibitory Polypeptide) is released after food ingestion from intestinal K cells to stimulate insulin secretion in a glucose-dependent manner (insulinotropic effect). We investigated whether the SNP in *GIPR* would influence insulin response to oral glucose in more than 22,000 non-diabetic subjects from 17 studies, insulin response to intravenous glucose in 562 subjects as well as incretin effect in 351 Botnia Study participants. The 2hr glucose raising allele of the *GIPR* variant was associated with lower 2h insulin levels (adjusted for 2h glucose $P=4.40x10^{-15}$; BMI-adjusted $P=8.18x10^{-11}$, n= 28,965), lower insulinogenic index ($P=2.44x10^{-20}$; BMI-adjusted $P=1.00x10^{-17}$, n=22,529) and lower ratio insulin-to-glucose area under the curve (AUC) during the OGTT ($P=3.39x10^{-20}$; BMI-adjusted $P=9.50x10^{-17}$, n=22,251). There was no association of *GIPR* with acute insulin response during the intravenous glucose tolerance test (IVGTT; P= 0.28, n=562), consistent with its presumed role in the incretin effect. Finally, *GIPR* did influence the incretin effect estimated as 100% x (AUCins OGTT-AUCins IVGTT)/AUCins OGTT (P=0.003). In conclusion, genetic variation in GIPR is associated with elevated postprandial glucose levels and impaired insulin secretion during OGTT, consistent with a receptor defect in mediating the incretin effect of GIP.

## 775/W/Poster Board #433

**Investigating the complex associations of MHC with RA susceptibility.** *G. Orozco, W. Thomson, A. Barton, S. Eyre, X. Ke.* arc Epidemiology Unit. University of Manchester, Manchester, United Kingdom.

The major rheumatoid arthritis (RA) susceptibility locus is *HLA-DRB1*, which lies within the major histocompatibility complex (MHC) at 6p21. There is evidence of additional RA loci in this region, although interpretation of these associations is made difficult by the presence of strong linkage disequilibrium. Our aim was to investigate the complex association pattern of the MHC region with RA susceptibility to identify effects independent of *HLA-DRB1*. A total of 1,804 RA cases and 1,474 1958 Birth Cohort controls were included in the study. High resolution HLA-DRB1 typing was performed using Dynal RELITM SSO kits. Subjects were genotyped for 1,546 single nucleotide polymorphisms (SNPs) using Affymetrix GeneChip 500K, as part of the Wellcome Trust Case Control Consortium (WTCCC) study. Statistical analysis was carried out using PLINK and Stata. Shared epitope (SE) alleles were strongly associated with RA (OR 4.25 95% CI 3.52-5.12 and OR 17.44 95% CI 13.18-23.07) for the carriage of one and two copies of the SE, respectively). In particular, the *0101, *0404 and *0408 alleles showed the strongest association with increased RA risk. Therefore, our RA cohort showed a similar pattern of HLA associations to that previously shown for other European populations. We found 745 SNPs significantly associated with RA (*P* trend<0.05). Of these, 398 SNPs showed association at a significance level of P trend<0.001. Many of the strongest associations were observed in the vicinity of the *HLA-DRB1* locus. To avoid confounding by RA-associated DRB1 alleles, we analyzed MHC SNPs using a data set with pairwise matching of cases and controls on DRB1 genotypes. A total of 594 case-control pairs with identical DRB1 genotypes were identified and used in a subsequent meta-analysis and conditional logistic regression. After this adjustment, 104 SNPs remained significantly associated with RA (*P*<0.05), suggesting that additional effects can be found in the HLA region. Of these, 3 loci showed the strongest associations with RA (*P*<0.003): Locus 1: close to *ZNF391* in extended class I Locus 2: close to *OR2H1* in extended class I Locus 3: close to *HLA-DPB1/DPB2* class II In conclusion, this analysis has revealed that multiple independent effects contribute to RA susceptibility in the MHC region. Validation is now being carried out using independent external datasets.

## 776/W/Poster Board #434

**Characterization of Candidate Loci for Autism Spectrum Disorders.** *M. Rossi[1, 2], K. Rehnström[1, 2, 3], E. Kempas[1, 2], L. von Wendt[4], L. Peltonen[1, 2, 3, 5, 6].* 1) Institute for Molecular Medicine Finland, Helsinki, Finland; 2) National Institute for Health and Welfare, Public Health Genomics Unit, Helsinki, Finland; 3) University of Helsinki, Department of Medical Genetics, Helsinki, Finland; 4) Hospital for Children and Adolescents, Unit of Child Neurology, Helsinki, Finland; 5) Program in Medical and Population Genetics, The Broad Institute, MIT and Harvard University, Cambridge, MA, USA; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Autism and Asperger syndrome (AS) are the most common of autism spectrum disorders (ASDs). These disorders are characterized by impairments in social interaction and communication, and restricted and repetitive interests and activities. Despite several cytogenetic, candidate gene, linkage and association studies conducted in ASDs only a few susceptibility loci have been successfully replicated. Here we have genotyped the best SNPs (n=65) from a genome-wide association (GWA) study performed in autism and AS families originating from an internal isolate of Finland, in our nationwide autism and AS samples as well as in the Autism Genetic Research Exchange (AGRE) families. The Finnish autism and AS families were genotyped with iPLEX and the analysis were performed using PLINK, Pseudomarker and HBAT software. Publicly available AGRE data, genotype using Illumina 550 BeadChip was obtained from the AGRE website. This replication study revealed several susceptibility loci, the most promising being ALS2CR11. This locus on chromosome 2 showed evidence for contributing to ASDs in the AGRE sample, both in single SNP association (rs10931963 and rs12464623, both p<0.018) and haplotype analysis (haplotype consisting of rs4675170, rs10931963, rs12464623, rs17384203, p= 0.02). The Finnish autism and AS families instead showed the most significant associations to several loci (2q32.3, 4p16.2, 6q14.3 and PSD3 at 8p22), many of which have previously been reported in association and linkage studies. Of these the most significant was PSD3 at 8p22 (Pseudomarker analysis, rs7009615 p<0.013). PSD3 codes for Pleckstrin and Sec7 domain containing protein 3 that acts as a guanine nucleotide exchange factor for ADP-ribosylation factor (ARF6) and is located in cell junction, synapse, postsynaptic cell membrane and postsynaptic density. These results agree well with previous reports of synaptic dysfunction in ASDs. The most significant results of this replication do not overlap with previously reported ASD linkage studies and the association is less significant in this replication study compared to the original autism GWA study. The results point towards several genomic regions in different chromosomes, and the predisposing variants differ between populations. Differences in the results between autism and AS families suggest that the predisposing variants are phenotype specific.

## 777/W/Poster Board #435

**Germline variation at the micro-seminoprotein beta (*MSMB*) locus results in physiological differences in serum and seminal levels of MSP/PSP94 and other major prostate secretory products.** *X. Xu[1], C. Valtonen-André[2], C. Sävblom[2], C. Halldén[2], A. Giwercman[3], H.G. Lilja[2,4], R.J. Klein[1].* 1) Program in Cancer Biology & Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA; 2) Department of Laboratory Medicine, Division of Clinical Chemistry, Lund University, Malmö University Hospital, 205 02 Malmö, Sweden; 3) Reproductive Medicine Centre, Lund University, Malmö University Hospital, 205 02 Malmö, Sweden; 4) Department of Clinical Laboratories, Surgery (Urology) and Medicine (GU-Oncology), Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA.

**Objectives**: Prostate cancer is a very common and highly heritable disease. Recent association screens have identified a single nucleotide polymorphism (SNP) consistently associated with prostate cancer risk, rs10993994. rs10993994 is located 57bp upstream of the transcription start site of a gene, micro-seminoprotein beta (*MSMB*). *MSMB* codes for one of the three major secretory products of the prostate, MSP/PSP94. Though its physiological functions are unknown, MSP has been implicated in prostate cancer tumorigenesis. Meanwhile, rs10993994 genotype has also been associated with blood levels of prostate specific antigen (PSA), a major prostate-specific secretory product and widely used diagnostic biomarker for prostate cancer. Thus, we hypothesize that germline variation at the *MSMB* locus results in physiologically detectable differences in MSP and PSA levels.

**Methods**: Serum and seminal fluid collected from 304 healthy young Swedish men (aged 18-21) were assayed for levels of MSP, PSA and other prostate biomarkers. Matching genomic DNA was extracted from blood and genotyped for several SNPs around the *MSMB* locus. SNPs passing quality control filters were analyzed for association with blood or semen biomarker levels. Empirical p-values were obtained through label-swapping permutation testing, with independence of each SNP's effect determined through conditional haplotyping.

**Results**: In healthy young Swedish men, rs10993994 was significantly associated with serum and semen levels of MSP and PSA. Additional copies of the risk allele for prostate cancer resulted in lower levels of MSP in semen and serum, but higher levels of PSA in semen and serum. Additionally, novel SNPs further upstream of the *MSMB* locus existing as part of a single large linkage disequilibrium block were - independent of rs10993994 - significantly associated with MSP levels in semen and serum. Finally, a novel SNP was found to be associated with semen levels of PSA, but not MSP itself.

**Conclusions**: rs10993994 genotype is significantly associated with physiologically detectable variation in MSP and PSA levels in seminal fluid and serum of healthy young men. Additionally, novel SNPs near the *MSMB* locus are independently associated with MSP and PSA levels.

## 778/W/Poster Board #436

**HLA-DRB1 and Pediatric Multiple Sclerosis.** *A.D. Sadovnick[1,2], G. Disanto[3,4], A. Handel[3,4], K.M. Morrison[3,4], G. Ebers[3,4], B. Banwell[5], D. Arnold[6], A. Bar-Or[6], Canadian Pediatric Demyelinating Disease Study Group.* 1) Department of Medical Genetics, University of British Columbia, Vancouver, Canada; 2) Faculty of Medicine, Division of Neurology, University of British Columbia, Vancouver, Canada; 3) Wellcome Trust Centre for Human Genetics, Oxford UK; 4) Department of Clinical Neurology, Oxford University, Oxford UK; 5) Department of Pediatrics, Division of Neurology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario; 6) Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, Quebec.

Susceptibility to adult onset multiple sclerosis (AOMS) in Northern European populations has been fine mapped to the extended HLA class II haplotype. HLA-DRB1*15 allele frequency is 0.33 in AOMS and 0.13 in controls. We studied 21 children with pediatric onset MS (POMS) [16/21 Caucasian], 148 children with Acquired Demyelinating Syndrome (ADS) [117 Caucasian] and 196 Caucasian controls. HLA-DRB1 alleles were typed by an allele-specific PCR amplification method. Allele frequencies were calculated using the Unphased-2.404-w32 program. Chi-square distribution or Fisher's exact test was used to assess significance. To avoid any population stratification, the analysis was first restricted to Caucasian individuals. Allelic frequencies of HLA-DRB1 alleles for Caucasians were 0.31 (POMS), 0.19 (ADS) and 0.14 (controls). The frequency of HLA-DRB1*15 in POMS was significantly higher than healthy controls (p=0.011) with an odds ratio of 2.73. When non-Caucasian POMS and ADS were included, the HLA-DRB1*15 allele frequencies were 0.36 and 0.21 respectively (OR=2.05, $\chi 2=4.31$, p=0.03). The association of HLA-DRB1*15 with POMS very closely resembles that seen in AOMS, thus unifying these phenotypes. Genotyping data distinguished ADS from adult clinically isolated syndrome (CIS). Thus studies of the interactions of this allele with known environmental factors associated to MS (e.g. vitamin D; Epstein Barr virus) may be key in elucidating the causal cascade of POMS.

**In search for biological basis of music listening: Association analysis of five candidate genes in Finnish families with musical aptitude.** *L. Ukkola[1], P. Onkamo[2], P. Raijas[3], K. Karma[4], I. Järvelä[1,5].* 1) Dep Med Gen, Univ Helsinki, Helsinki, Finland. M.Sc; 2) Dep Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland, Ass. Prof; 3) Sibelius Academy, DocMus Department, Helsinki, Finland, D.Mus., M.Soc.Sc; 4) Sibelius Academy, Department of Music Education, Helsinki, Finland, Adj. Prof; 5) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland, Adj. Prof.

Listening to music is able to evoke a wide spectrum of emotions that are unique in its scale. Listening to music has been seen as rewarding, and pleasurable human experience. The reasons why music is commonly practiced in all societies as well as why music has been preserved in human evolution remain largely unknown. During human history, music has been used as therapy for neuropsychiatric disorders, to ameliorate anxiety and pain. Still, the biological mechanisms underlying the therapeutic effects of music are largely unknown. In order to understand the neurobiological pathways of listening to music we analyzed polymorphisms of the arginine vasopressin receptor 1A (AVPR1A), serotonin transporter (SLC6A4), catecol-O-methyltranferase (COMT), dopamine receptor D2 (DRD2) and tyrosine hydroxylase 1 (TPH1), genes associated with cognitive functions and emotions in 19 Finnish multigenerational families (n=343 members) with professional musicians and/or active amateurs. All family members were tested for musical aptitude using the auditory structuring ability test (Karma Music test; KMT) and Carl Seashores tests for pitch (SP) and for time (ST) and their education in music, active and passive listening to music and creative functions in music (composing, improvising and/or arranging) were surveyed using a web-based questionnaire. The motivations to listen to music were asked using four questions, whether music was listened due to: 1) relaxation, 2) different emotional states, 3) learning and/or 4) concentration. We found that active listening to music before 20 years of age was associated with higher music test scores. Active music listening at the ages of 12-20 years had a significant effect on KMT (Kruskall Wallis Test (K-W) p=0.005) and suggestive effect on SP (K-W p=0.025). Here, average 7+ weekly hours of active music listening resulted in the highest music test scores. We found statistically significant correlation between active listening to music during childhood and creative activity in music (p<0.0001;K-W). Our preliminary results suggest an association with the AVPR1A gene (marker RS1;allele 3) and active listening to music between age 12-20 years (corrected p=0.007) using FBAT. Listening to music due to different emotional states was associated with 5-HTTLPR+VNTR haplotype of the SLC6A4 gene (S+LG/12 repeats) (p=0.006;corrected 0.005) and the AVPR1A gene AVR+RS1 haplotype 5 4 (corrected p=0.005).

## 780/W/Poster Board #438

**Comprehensive analysis of genes in the type I interferon pathway and their association with SLE.** *J.K. Sandling[1], S. Garnier[1], S. Sigurdsson[1,2], C. Wang[1], M-L. Eloranta[3], G. Nordmark[3], I. Gunnarsson[4], E. Svenungsson[4], G. Sturfelt[5], A. Jönsen[5], A. Bengtsson[5], L. Truedsson[6], C. Eriksson[7], S. Rantapää-Dahlqvist[8], R.R. Graham[9], T.W. Behrens[9], G. Alm[10], L. Rönnblom[3], A-C. Syvänen[1].* 1) Molecular Medicine, Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 2) Current address: Functional Genomics, Department of Medical Biochemistry and Microbiology, Uppsala University, Uppsala, Sweden; 3) Section of Rheumatology, Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 4) Rheumatology Unit, Department of Medicine, Karolinska Institutet/Karolinska University Hospital, Stockholm, Sweden; 5) Department of Clinical Sciences, Section of Rheumatology, Lund University, Lund; 6) Institute of Laboratory Medicine Section of MIG, Lund University, Lund, Sweden; 7) Department of Clinical Immunology, Umeå University Hospital, Umeå, Sweden; 8) Department of Rheumatology, Umeå University Hospital, Umeå, Sweden; 9) Genentech Inc., South San Francisco, CA, USA; 10) Department of Biomedical Sciences and Veterinary Public Health, Swedish University of Agricultural Sciences, Uppsala, Sweden.

Systemic Lupus Erythematosus (SLE) is a complex systemic autoimmune disorder in which the interferon system plays a crucial role. Increased levels of interferon-alpha (IFN-$\alpha$) in patient serum and increased expression of type I IFN-inducible genes in cells playing key roles in the development of SLE have been observed. The serum IFN-$\alpha$ levels correlate both with disease activity and severity, and individuals treated with IFN-$\alpha$ have been known to develop autoimmune diseases such as SLE as a treatment side-effect. We have previously found that three genes in the type I interferon pathway, the interferon regulatory factor 5 *(IRF5)*, the tyrosine kinase 2 *(TYK2)* and the signal transducer and activator of transcription 4 *(STAT4)*, are strongly associated with risk for SLE. Here we investigate the association of 87 genes involved in this pathway with the aim of identifying additional risk genes for SLE. In the first stage 1536 single nucleotide polymorphisms (SNPs) from these 87 genes were genotyped in 485 Swedish SLE patients and 563 controls. Ten genes showing p-values < 0.01 in the initial screen were followed up in an additional 376 Swedish patients and 679 controls. In order to find further support for the importance of the most promising genes we also present data from a genome-wide association study on SLE performed in American Caucasian cases and controls. Analysis of gene expression in lymphoblastoid cell lines reveals that the SLE associated alleles are expressed in an allele-specific manner, indicating the mechanism by which these polymorphisms could influence SLE susceptibility. Our results further highlight the importance of type I IFN system genes in SLE.

## 781/W/Poster Board #439

**Association of HTR3a with Autism.** *O.J. Veatch[1], N. Schnetz-Boutaud[1], A.M. Wotawa[1], B.M. Anderson[1], A.M. Halstead[1], K. Brown[1], H.H. Wright[3], R.K. Abramson[3], M.L. Cuccaro[2], J.R. Gilbert[2], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) Miami Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) W.S. Hall Psychiatric Institute, University of South Carolina, Columbia, SC.

Autism is the most severe form of a broad spectrum of complex neurodevelopmental disorders known as Autistic Spectrum Disorders (ASDs). It has a high degree of heritability but due to the complexity and heterogeneity of the disorder, genome-wide screens have been unsuccessful in identifying a single risk locus for autism. However, multiple studies have proposed association of the disease to variations in genes in the dopaminergic and serotonergic pathways. Individuals with autism are also known to have increased levels of serotonin in their blood when compared with unaffected individuals. In this study, a total of 75 single nucleotide polymorphisms (SNPs) were genotyped in 13 genes related to the serotonin pathway in an independent dataset of 400 Caucasian American families (1656 individuals). We used the Pedigree Disequilibrium Test (PDT) to assess family-based allelic association and the Genotype-PDT (GenoPDT) to look for genotypic association with autism risk. The most significant result from the GenoPDT, with a p-value of 0.0002, was found for SNP rs1150220 located in the HTR3a gene. Multifactorial Dimensionality Reduction (MDR) analysis was also used to detect multilocus interactions. We tested for all two-way and three-way interactions in a total of 400 cases and 400 “pseudo” controls, using the non-transmitted alleles of the parents. A significant three-way interaction (p-value < 0.01) was found among rs1150222 in the HTR3a gene, rs4947644 in the dopa decarboxylase gene, and rs37020 in the SLC6A3 dopamine transporter gene showing interaction across the dopaminergic and serotonergic pathways. SNP rs1150222 is not only located in the HTR3a gene, it is also in linkage disequilibrium (LD) with the most significantly associated SNP determined via GenoPDT, rs1150220 (D’ = 0.93), indicating strong non-random association between the two loci. These results suggest association of risk for autism with variations in the HTR3a gene which is a member of the serotonin receptor family and is unique from other family members because it contains an integral agonist ion channel and is not a G protein-coupled receptor. Also, these data point to the possibility of interaction across two neurotransmitter pathways.

## 782/W/Poster Board #440

**Different IRF5 Alleles Associate with Distinct Serologic Subphenotypes in Lupus, Revealing Ancestral Differences in Association.** *T.B. Niewold[1], J.A. Kelly[2], S.N. Kariuki[1], K. Thomas[2], D. Walker[2], S. Kamp[2], J.M. Frost[3], A.K. Wong[4], J.T. Merrill[2,5], M.E. Alarcón-Riquelme[2,6], M. Tikly[3], P.ROFILE Study Group[7], D.L. Kamen[8], G.S. Gilkeson[8], T.J. Vyse[9], J.A. James[2,5], P.M. Gaffney[2], K.L. Moser[2], M.K. Crow[10], J.B. Harley[2,5,11].* 1) Section Rheumatology, University of Chicago, Chicago, IL; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) University of the Witwatersrand, Johannesburg, South Africa; 4) MRC Unit for Longlife, Health & Ageing, London, UK; 5) Department of Medicine, University of Oklahoma, Oklahoma City, OK; 6) University of Uppsala, Uppsala, Sweden; 7) Northwestern University Feinberg School of Medicine, University of Texas-Houston Health Science Center, Johns Hopkins University, and University of Alabama at Birmingham; 8) Medical University of South Carolina, Charleston, SC; 9) Imperial College, London, UK; 10) Mary Kirkland Center for Lupus Research, Hospital for Special Surgery, New York, NY; 11) US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

Interferon-alpha (IFN-$\alpha$), interferon regulatory factor 5 (IRF5) haplotypes, and various specific autoantibodies all are strongly associated with systemic lupus erythematosus (SLE). Logistic regression of phenotypic variation in European-derived subjects resolved the IRF5 SLE-risk haplotype into allelic associations with particular autoantibodies [rs2004640T with anti-dsDNA (OR=2.41, p=3.3x10-14), rs10488631C with anti-Ro (OR=2.46, p=2.8x10-13), and a minor haplotype with anti-La (OR=1.96, p=0.035)]. Anti-nRNP and anti-Sm autoantibodies were not associated with IRF5 haplotypes. Meanwhile, in African-Americans SLE risk is confined to the same IRF5 haplotype, which in African-Americans is of European genomic origin and similarly associated with anti-dsDNA and anti-Ro. IFN-$\alpha$ levels are elevated in SLE cases with IRF5 risk haplotypes only in the setting of anti-dsDNA and anti-Ro autoantibodies. This suggests that specific SLE-associated autoantibodies cooperate with IRF5 variants to dysregulate IFN-$\alpha$ production and consequently increase risk of SLE. These results demonstrate the power of phenotypic variability when informed by genomic origin to disentangle complex genetic relationships.

## 783/W/Poster Board #441

**Association study of citokines genes with juvenile rheumatoid arthritis in Mexican population.** *J. Ramirez[1,4], V. Baca[2], S. Jimenez[1], G. Escamilla[3], L. Orozco[1,4].* 1) Instituto Nacional de Medicina Genómica, Ssa. Mexico City, Mexico; 2) Centro Médico Nacional Siglo XXI, IMSS, Mexico City, México; 3) Instituto Nacional de Pediatría, Ssa. Mexico City, Mexico; 4) Posgrado en Ciencias Genómicas, Universidad Autónoma de la Ciudad de México. Mexico City, México.

Introduction. Juvenile rheumatoid arthritis (JRA) represents the most common chronic autoimmune disease in childhood. Like in others autoimmune disorders, there are strong evidences suggesting that multiple genes are involved in the JRA etiopathogenesis. Genes encoding to central mediators of inflammation, such as IL2, IL8, IL17 and IL18 cytokines are important candidate genes for susceptibility to immune diseases. Actually, single nucleotide polymorphisms (SNPs) located in these cytokines have been identified as genetic risk factors to rheumatoid artrhitis susceptibility, systemic lupus erhytematosus, multiple esclerosis, etc. Objective. The present study was undertaken in order to investigate whether there is association between polymorphisms in IL2, IL8, IL17 and IL18 and JRA in Mexican patients. Samples and methods. This study included 170 pediatric Mexican patients that fulfilled the American College of Rheumatology (ACR) criteria for JRA, and 370 healthy controls without antecedents of JRA or other autoimmune diseases; all them were recruited from Mexico City. The genomic DNA was extracted from peripheral blood leukocytes according to standard protocols (Genomic DNA Kit; Qiagen). This study included five SNPs (IL2: -91A/C, IL8: -251T/A, IL17: -692T/C and IL18-667A/C and -618G/T). Genotyping analysis was performed using TaqMan assay. The association test and Hardy-Weinberg equilibrium (H-WE) were determined using EPI-DAT and FINETTI softwares, respectively. Results. Both cases and controls were in H-WE. Non differences between cases and controls were observed when we compared the genotype and allele distributions (-91A/C IL2: genotype A/A vs A/C, OR 1.16, p=0.45, C allele OR 1.13, p=0.38. -251T/A IL8: genotype T/T vs TA, OR 0.92, p=0.67, A allele OR 0.93, p=0.59. -692T/C IL17: genotype T/T vs T/C, OR 1.33, p=0.17, C allele, OR 1.14, p=0.41. -667A/C IL18: genotype A/A vs A/C, OR 1.16, p=0.51, C allele, OR 1.10, p=0.45. -618G/T IL18: genotype G/G vs G/T, OR 1.15, p=0.53, T allele, OR 1.12, p=0.38). Gender stratification showed association of -91A/C IL2 with JRA only in the male group (genotipe A/A vs A/C, OR 2.08, p=0.015, C allele, OR 1.57, p=0.03). Conclusion. SNP analyzed in the cytokine genes did not show association with susceptibility to JRA in Mexican population. Our results suggest that -91A/C IL2 SNP could be a risk genetic factor to JRA in a gender-dependent manner.

**Loss of *TLR1* function is under selection and protects against leprosy.**
*S.H. Wong[1], S. Gochhait[2], D. Malhotra[2], Y.Y. Teo[1], A. Rautanen[1], C.C. Khor[3], S.J. Chapman[1], A. Srivastava[2], S. Ali[2], S. Aggarwal[2], R. Chopra[2], B.S.N. Reddy[4], V.K. Garg[4], S.K. Hazra[5], B. Saha[5], C. Kim[6], H. Hakonarson[6], R.N.K. Bamezai[2], A.V.S. Hill[1], F.O. Vannberg[1].* 1) WTCHG, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) National Centre of Applied Human Genetics, School of Life Sciences, Jawaharlal Nehru University, New Delhi 110067, India; 3) Host Susceptibility to Infection Program, Singapore Institute for Clinical Sciences, Agency for Science, Technology and Research, Singapore; 4) Department of Dermatology and Sexually Transmitted Diseases, Maulana Azad Medical College, Lok Nayak Jai Prakash Hospital, New Delhi 110002, India; 5) Calcutta School of Tropical Medicine, 108 Chittaranjan Avenue, Kolkata, India; 6) Center for Applied Genomics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, PA, USA.

Natural selection has driven population differentiation in humans and shaped genomic regions affecting complex phenotypes. Several genome-wide studies have shown that the Toll-like receptor (*TLR*) locus at chromosome 4p14 is highly differentiated between populations. We genotyped polymorphisms in this locus and show that the *TLR1* I602S variant is extremely differentiated between populations ($F_{ST}$>99$^{th}$ percentile). This non-synonymous variant prevents receptor translocation to cell surface and abrogates TLR1 signalling. Mapping the allele frequency in 15 human populations indicated that this variant has expanded out of Africa consistent with strong positive selection. We further investigated this locus in infectious diseases by genotyping 76 SNPs in the 80kb flanking region, and observed strongly significant association of the variant with protection against leprosy in a New Delhi case-control cohort of 558 cases and controls ($P$=1.3x10$^{-6}$, OR=0.27, 95% CI=0.15-0.47). The association was replicated in an independent cohort of 393 cases and controls from Kolkata of India ($P$=0.022, OR= 0.48, 95% CI=0.26-0.91). Our results identify *TLR1* as a major susceptibility locus for leprosy and strongly support the hypothesis that *TLR1* has evolved through positive selection.

## 785/W/Poster Board #443

**Association between HLA-A, -B and -DRB1 alleles and pulmonary tuberculosis in Western Javanese Indonesia.**
*R. Yuliwulandari[1, 2], K. Kashiwase[3], F. Nakajima[3], A. Mabuchi[1], ASM. Sofro[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Japan; 2) Faculty of Medicine, Yarsi University, Jakarta-Indonesia; 3) Tokyo Red Cross Blood Center, Tokyo-Japan.

Pulmonary tuberculosis (PTB) is caused by the interplay between environmental and genetic factors and still one of the deadliest diseases in the world. The genetic studies of PTB have been reported in several populations, including human leukocyte antigen (HLA) gene. However the results are still conflicting. The stronger role of the gene in more severe form of tuberculosis also has been reported. In the present study, HLA class I and class II alleles and haplotypes were investigated to ascertain the role of those alleles in the susceptibility/resistance to new PTB and recurrent PTB in Western Javanese Indonesia. HLA typing was performed for HLA-A, -B and -DRB1 loci on 237 ethnically matched healthy control individuals and 257 PTB patients (216 new and 41 recurrent PTB patients) by the high resolution PCR-Luminex method using WAKFLOW typing kit. The statistical analyses were performed using the Arlequin software based on the expectation maximization (EM) algorithm to determine the haplotypes and using Chi-square and Fisher's exact tests to calculate the frequency difference of the alleles between case and control groups. A total of 18 A, 40 B and 20 DRB1 alleles were identified. The most frequent HLA-A, -B and -DRB1 alleles in control group were HLA-A*2407 (21.6%), HLA-B*1502 (11.7%), HLA-B*1513 (11.2%) and DRB1*1202 (37.5%), respectively. The frequently observed 2-locus and 3-locus haplotypes were HLA-A*2407-B*3505 (7%), HLA-B*1513-DRB1*1202 (9.2%), HLA-A*3401-B*1521-DRB1*150201 (4.6%), HLA-A*2407-B*3505-DRB1*1202 (4.3%) and HLA-A*330301-B*440302-DRB1*070101 (4.2%), respectively. None of the indentified alleles in 3 HLA loci was found to be significantly associated with new PTB. Interestingly, among recurrent PTB, the allele frequency of HLA-B*1802 was significantly higher than that in control sample (p=0.0026). However, when the correction for multiple comparisons was applied, the result became insignificant. The possible role of the allele was supported by the fact that in two-factor analysis, the presence of both HLA-B*1802 and HLA-DRB1*1202 among recurrent PTB was more frequent than that among both new PTB and healthy control with odd ratio 4.15 and 3.98, respectively. This study suggested that HLA-B*1802 had a tendency to be associated with recurrent PTB rather than new PTB. The result of this study need to be further confirmed using more recurrent PTB samples.

## 786/W/Poster Board #444

**Muscle contracture genes play a role in isolated clubfoot.**
*K.S. Weymouth[1,2], X. Tang[1], A. Burt[3], S.H. Blanton[3], J.T. Hecht[1,2].* 1) Univ Texas Medical Sch, Houston, TX; 2) Graduate School of Biomedical Sciences, Houston, TX; 3) University of Miami Miller School of Medicine, Miami, FL.

Clubfoot is a common birth defect that affects 4000 newborns in the US each year. Isolated clubfoot (no other malformations) is characterized by an inward turning of the foot towards the midline of the body and is held in a rigid, downward position. Calf muscles in the affected leg(s) are underdeveloped and remain small even after corrective treatment. Clubfoot is a complex multifactorial disorder caused by both genes and environmental factors. Syndromes with a complex phenotype have been used to identify candidate genes for isolated conditions. Distal Arthrogryposis (DA) is a rare genetic disorder that is characterized by congenital contractures with clubfoot associated with some DA subtypes. Currently, there are nine different types of DA classified. Mutations in five different genes that encode for proteins that play a key role in muscle contracture are the cause for four types of DA. This study was undertaken to investigate whether variation in muscle contracture genes (n= 15), including those that cause DA, contribute to clubfoot. Seventy-four single nucleotide polymorphisms (SNPs) spanning these genes were genotyped in 160 nonHispanic whites (NHW) and 213 Hispanic simplex trios and 121 NHW and 93 multiplex families. The analysis was stratified by population, because the allele frequencies differed between populations. In the NHW group, one SNP in TPM2 and MYH3 showed strong association (p<0.01). Pairwise haplotype analysis detected strong altered transmission for 5 haplotypes with the strongest haplotype association identified for rs3744550 and rs2240579 in MYH13 (p=0.000038). In the Hispanic group, one SNP in TNNT3 and MYH13 were significantly altered transmitted (p=0.006 and p=0.003, respectively). All the genes interrogated play vital roles in muscle contracture, thus gene-gene interaction analysis was performed. Multiple significant interactions (p<0.01) were identified in both the nonHispanic White (19 interactions) and Hispanic groups (26 interactions). Identification of an association with MYH13 and clubfoot is a novel finding as this gene has not been implicated in any type of DA. These results suggest that genetic variation in genes involved in muscle contracture could play a role in clubfoot. These findings further support our working clubfoot model in which variation in multiple genes play a key role in the onset of clubfoot and its severity.

## 787/W/Poster Board #445

**Integration of human and mouse genome-wide association studies (GWAS) to identify genetic determinants for lung development and asthma.**
*A. Berndt[1], A. Leme[2], L. Williams[2], A. Murphy[3], J. Su[3], S. Shapiro[2], E. Silverman[3], S. Weiss[3], D. DeMeo[3], B. Paigen[1].* 1) The Jackson Laboratory, Bar Harbor, ME; 2) University of Pittsburgh, Pittsburgh, PA; 3) Harvard Medical School, Boston, MA.

Objectives: Chord length, the distance between alveolar walls, can assess lung development. Reduced chord length may result in low lung reserve and predispose to lung diseases such as asthma. A critical phenotype in asthma is airway hyper-responsiveness (AHR). We hypothesize that integration of GWAS for chord length and AHR may identify disease-causing alleles that determine lung development and asthma. Methods: We measured chord length in 6-10 female mice in 30 inbred strains and used strain means for haplotype association mapping. This method detects associations between haplotype blocks and strain phenotypes with a Hidden Markov Model to identify SNPs. Using the gene lists from Biomart, we searched for the genomic location of such SNPs and identified the mouse genes that included or were in close proximity to a detected SNP. Because disease-causing genes are often the same in mouse and human, we integrated these mouse data with human asthma GWAS data. SNP genotyping was performed in 422 families (parent-child trios) from the Childhood Asthma Management Program (CAMP) cohort using the Infinium II HumanHap550v3 Genotyping BeadChip (Illumina, San Diego, CA). We searched these data for SNPs that were in, or close to, the orthologous genes previously identified in the mouse. Results: We identified 23 genes in the mouse by a total of 71 SNPs ($P$<10-5) within or very close to the genes. We then asked whether any of these mouse genes were also detected as significant for asthma in the human GWAS. To do this, we used the mouse genes to find the orthologous region in humans, and examined each region to determine whether it contained any of the SNPs that were significantly different between case and control in the CAMP GWAS at $P$<0.05. Of the 23 genes identified in the mouse, 9 had significant SNPs in the orthologous human gene and the remaining 14 had a significant SNP in very close proximity (<700 kb) to the human gene. Interestingly, one gene, *Irx1*, is expressed during early lung development. Conclusion: Integrating murine and human GWAS data and application of bioinformatics tools may speed the identification of disease causing genes that are important in lung development and asthma.

## 788/W/Poster Board #446

**Skin pigmentation and the *MC1R* gene are associated with central corneal thickness.**

*D.P. Dimasi[1], K.P. Burdon[1], A.W. Hewitt[1], K.A. Marshall[1], P. Mitchell[2], D.A. Mackey[3], J.E. Craig[1]*. 1) Ophthalmology, Flinders University, Adelaide, South Australia, Australia; 2) Centre for Vision Research, Department of Ophthalmology and Westmead Millennium Institute, University of Sydney, Westmead, Australia; 3) Department of Ophthalmology, Royal Hobart Hospital, University of Tasmania, Hobart, Australia.

The cornea is the transparent cover at the front of the eye. It plays a critical role in maintaining normal vision through both refraction of light and maintaining a transparent visual axis. The thickness of the cornea, termed central corneal thickness (CCT), is a normally distributed quantitative trait. Thin CCT is a known risk factor for the sight-threatening condition open-angle glaucoma and extreme CCT measurements have been reported in a variety of Mendelian disorders. CCT is highly heritable ($h^2$=0.7-0.95) but as yet no genes have been identified for normal CCT variation. CCT varies significantly between different ethnic groups. We have previously observed an association with degree of skin pigmentation. To further assess the relationship between CCT and skin pigmentation we measured CCT in 13 different inbred strains of mice. There were significant differences in CCT between strains ($p < 0.001$). A general trend was noted, with pigmented strains trending to the lower end of the range and albino strains to the upper end. CCT was significantly associated with pigmentation when the 13 strains of mice were stratified into pigmented and albino strains: Albino = 83.5 ± 11.1 μm (n = 79), Pigmented = 78.3 ± 8.8 μm (n = 53) ($p = 0.008$). To explore this association further in humans, we genotyped SNPs in several genes known to influence pigmentation in humans including *TYR, OCA2, ASIP, SLC45A2* and *MC1R*. All genes were screened in a population based cohort of 953 Caucasian subjects from Australia. The strongest association was found with the MC1R gene. Two tag SNPs in MC1R were significantly correlated with CCT under a dominant model: rs2270459 ($p = 0.0008$) and rs3212346 ($p = 0.0062$). This gene is known to control eye and hair colour in Caucasians. The finding of an association between *MC1R* and CCT in Caucasians provides support for the hypothesis of pigmentation playing a role in the development of the clear cornea suggesting that these genes may have a broader function than what is currently recognized. Through discovery of the genes involved in the determination of CCT, the association of this trait with open-angle glaucoma will become better understood which may lead to improved methods of diagnosis and treatment of this important disease.

## 789/W/Poster Board #447

**Variation in *FGFR2* Expression Correlates with Genotype at SNPs Associated with Nonsyndromic Cleft Lip/Palate and Breast Cancer.**

*B.N. Erickson[1], J. Kim[3], K. Christensen[4], M.L. Marazita[5], J.C. Murray[1,2]*. 1) Molec & Cellular Biol, Univ Iowa, Iowa City, IA; 2) Pediatrics, Univ Iowa, Iowa City, IA; 3) Anatomy & Cell Biol, Univ Iowa, Iowa City, IA; 4) Epidemiology, Univ of Southern Denmark, Odense, Denmark; 5) Oral Biol, Univ of Pittsburgh, Pittsburgh, PA.

**Background:** Epidemiologic data has shown an increased incidence of breast cancer in women born with nonsyndromic cleft with or without cleft palate (CL/P). GWAS studies of both breast cancer and nonsyndromic CL/P have found association within intron 2 the *FGFR2* locus. We have confirmed that single nucleotide polymorphisms (SNPs) within intron 2, rs2981582 and rs3750817 previously associated with breast cancer, are significantly associated with CL/P in three populations, Denmark, Iowa and Filipino ($p < 0.01$). We have also identified a single SNP downstream of *FGFR2* (rs10466215) that is significantly associated with CL/P in these populations ($p < 0.01$) which is near two SOX9 binding sites. **Objectives:** Continue fine mapping sequencing techniques to identify rare SNPs associated with CL/P that may have functional importance and correlate significant SNPs associated with CL/P to functional changes at the *FGFR2* locus. **Methods:** Sequencing areas of high conservation near associated SNPs to identify rare alleles, not initially screened, associated with CL/P. Analysis of *FGFR2* expression in mRNA isolated from foreskin of healthy term males (n = 150) by qRT-PCR. DNA from the same foreskin samples was genotyped at SNPs in intron 2. Analysis of variance (ANOVA) of expression levels was performed on the three genotype groups. **Results:** Preliminary sequencing results identified one rare variant near a SOX9 binding site near rs10466215 in the Filipino population. ANOVA results at 3 SNPs show significant genotypic differences in FGFR2 expression normalized to ACTB expression with the most significant SNP being rs2912787 (ANOVA p = 0.02). **Conclusions:** Two areas of *FGFR2* are focal points of significant association with CL/P. One of those areas, intron 2, is also significantly associated with breast cancer. Current sequencing analysis of samples from Iowa will expand the number of cases in the study and add information from another population. In addition, work is currently ongoing to expand the number of intron 2 SNPs genotyped and determine *FGFR2* isoform specific expression based on SNP genotype. This work continues to narrow in on the region of *FGFR2* association with CL/P as well as provide functional clues of the role *FGFR2* plays in CL/P and breast cancer risk.

## 790/W/Poster Board #448

**Linkage analysis in a large Amish pedigree with von Willebrand Disease identifies regions suggestive of linkage and candidate modifier genes.**

*J. Hinckley[1], K. Wang[2], T. Burns[2], J. Murray[3], A. Shapiro[4], J. Di Paola[1]*. 1) Department of Pediatrics and Human Medical Genetics Program, University of Colorado, Denver, Aurora, CO; 2) Program in Public Health Genetics, University of Iowa Carver College of Medicine and College of Public Health, Iowa City, IA; 3) Department of Pediatrics, University of Iowa Carver College of Medicine, Iowa City, IA; 4) Indiana Hemophilia and Thrombosis Center, Indianapolis, IN.

Von Willebrand Disease (VWD), the most common genetic bleeding disorder, is characterized by incomplete penetrance and variable expressivity. The ABO blood group is the only well-characterized modifier of VWF levels. We identified and characterized an Amish pedigree composed of more than 3000 members of whom 828 have been enrolled to identify genetic modifiers of VWD. To date we have evaluated 395 individuals. Sequence of VWF demonstrated heterozygosity for a missense mutation at position 4120 (C>T) in 71 individuals, that predicts an arginine to cysteine change at position 1374 (R1374C) in the A1 domain of the mature VWF molecule. Variability of both von Willebrand factor levels and bleeding phenotype (determined by a bleeding survey) are present among family members with and without the mutation. Significant heritability was found for different measures of the VWF molecule: VWF:Ag (h2=0.49, p< 0.00001), VWF:RCo (h2=0.54, p< 0.00001), and FVIII:C (h2=0.51, p< 0.00005). A primary genetic screen with 400 microsatellites was performed to construct a 10 cM-resolution genetic map of the first 395 pedigree members. Dichotomous trait two-point linkage analysis was performed using MLINK for five traits: bleeding score ≥3, bleeding score ≥4, VWF:RCo ≤50 IU/dL, VWF:RCo ≤25 IU/dL, and mutation status. All individuals with VWF:RCo ≤25 IU/dL are heterozygous for the C>T mutation. Modeling VWF:RCo ≤25 IU/dL as an autosomal dominant trait (allele frequency=0.1, penetrance=0.6), the highest LOD score (19.27) corresponded to marker GATA49D12 on chromosome 12p13.3 (to where VWF maps). Other regions suggestive of linkage to VWF levels include 6q25.3 (LOD = 2.18), 9q22.3 (LOD =1.03), 9q34 (LOD = 1.32), 14q12, (LOD =1.21), 16q12.2 (LOD = 1.20), 18q12.1 (LOD = 1.16) and 21q22 (LOD= 2.46). Three regions suggested linkage with both bleeding score phenotypes: 7q32 (LOD=2.52 and 1.52), 12q12 (LOD=1.13 and 1.26) and 16q12 (LOD=1.23 and 1.48). Regions suggestive of linkage were identified for both VWF:RCo ≤25 IU/dL and bleeding score phenotypes: 12p13.3, 16p12.2 and 21q22. Similar results were obtained by MCMC multipoint linkage using MORGAN. Candidate modifier genes include ABO (9q34), ADAMTS13 (9q34), ADAMTSL2 (9q34), CD9 (12p13), MMP2 (16q13), and COL6A1 and COL6A2 (21q22). This analysis in a very large pedigree with a homogeneous primary cause for VWD has identified several regions that will be investigated at higher resolution for the presence of modifier genes and alleles.

## 791/W/Poster Board #449

**Two novel associations between the fractalkine receptor (CX3CR1) common polymorphisms and overweight.**

*D. Sirois-Gagnon[1], A. Chamberland[1], S. Perron[1], D. Brisson[2], D. Gaudet[2], C. Laprise[1,2]*. 1) Fundamental Sciences, UQAC, Saguenay, Québec, Canada; 2) Department of Medicine, Université de Montréal, ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, Québec, Canada.

Overweight is a sub-phenotype of obesity characterized by an inflammatory component. The CX3CR1 gene, which encodes the fractalkine (CX3CL1) receptor, has two coding single nucleotide polymorphisms (SNPs), V249I and T280M, which have been linked to a decrease in the incidence of other inflammatory diseases, such as coronary artery disease and asthma. To determine whether CX3CR1 is involved in overweight expression, we genotyped the V249I and T280M polymorphisms of the CX3CR1 gene using High Resolution Melt (HRM) technique in 267 subjects with a body mass index (BMI) ≥ 30 kg/m2 and 453 control subjects with a BMI < 27 kg/m2. Binary logistic regression models revealed that 280MM genotype is associated with an increased risk of presenting a BMI ≥ 30 kg/m2 (P corrected = 0.044). A gender-specific one-way analysis of variance was also conducted to investigate mean BMI and waist circumference differences between genotypes of each polymorphism. Significant mean BMI differences were observed for the two polymorphisms between heterozygotes and wild homozygotes in men (TM > TT, P = 0.032 for the T280M polymorphism; VI > VV, P = 0.021 for the V249I polymorphism). The results showed that for each polymorphism, mutant homozygotes had significant increased waist circumference compared to wild homozygotes in women (MM > TT, P = 0.016 for the T280M polymorphism; II > VV, P = 0.008 for the V249I polymorphism). Significant increase of waist circumference was also observed for the mutant homozygotes compared to heterozygotes for the V249I polymorphism (II > VI, P = 0.025). Men mean waist circumference was also increased in heterozygotes when compared to wild homozygotes for the T280M polymorphism (TM > TT, P = 0.027). In conclusion, this study demonstrates that the T280M and V249I polymorphisms of the CX3CR1 gene are associated with overweight. Further genetic and functional studies are required to better define the role of the CX3CR1 in overweight.

## 792/W/Poster Board #450

**Association studies of continuously distributed traits: dissection of human sweet taste perception.** *A. Fushan[1], C. Simons[2], J. Slack[2], D. Drayna[1].* 1) NIDCD/National Institutes of Health, Rockville, MD; 2) Givaudan Flavors Corp., Cincinnati, OH.

Substantial heritable variation for the perception of sweet taste compounds exists in humans. However, sweet taste sensitivity phenotypes display a unimodal continuous distribution in the population, and Mendelian transmission has not been reported for variation in sweet sensitivity. We evaluated candidate genes encoding the components of the sweet taste transduction pathway by DNA sequencing, and used R-index analysis to generate area under the curve (AUC) scores for threshold and suprathreshold perception of sucrose in a group of 166 normal, unrelated subjects. Using ANOVA analysis, we observed strong association of AUC scores with two C/T SNPs, residing 1266 bp and 1572 bp upstream of the coding sequence of the TAS1R3 gene, which encodes a component of the G protein coupled sweet taste receptor. Together these SNPs explain 16% of the variance in sucrose AUC scores, with the T alleles associated with reduced sucrose sensitivity in vivo. Luciferase reporter constructs assayed in HuCCT1 and NCI-H716 cells demonstrate that the T alleles of these SNPs significantly reduce TAS1R3 promoter activity, suggesting lower protein expression in vivo. Worldwide population surveys demonstrate highest frequency of the T alleles in sub-Saharan African populations, and a gradient of frequency extending across Eurasia, with lowest frequencies of the T alleles in western European populations. Our results suggest that population-specific genetic differences in sweet taste perception may have significant effects on differences in food choices and consumption.

## 793/W/Poster Board #451

**Genetic polymorphism of the type II deiodinase (DIO2) gene is associated with bipolar disorder.** *N. Zhong[1, 2], B. He[2], E.C. Jenkins[1], G. Wang[2], W.T. Brown[1].* 1) Department of Human Genetics, New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China.

Genetic factors play a critical role in the etiology of bipolar disorder. Previous studies suggested an association between thyroid dysfunction and bipolar disorder. We hypothesized that genetic variations in the type II deiodinase (DIO2) gene that possibly alter the bioactivity of thyroid hormones are associated with bipolar disorder. A case-control association study was conducted in a subset of Chinese Han population. Two single nucleotide polymorphisms (SNP), open reading frame a (ORFa)-Gly3Asp (rs12885300) and Thr92Ala (rs225014) with potential functions on the activity of DIO2, were selected. The frequencies of allele, genotype and haplotype of the two SNPs were compared between the bipolar disorder patients and the control group. Statistical significance between the bipolar disorder patients and the control group was observed for the allele ($\chi2$=7.746, P=0.005, df=1) and genotype frequencies ($\chi2$=8.158, P=0.017, df=2) at the locus of ORFa-Gly3Asp, and for the allele ($\chi2$=15.838, P=7.00e-005, df=1) and genotype frequencies ($\chi2$=17.236, P=0.0002, df=2) at Thr92Ala. Distribution of allele 3Gly and 92Ala were significantly higher in the bipolar disorder patients, with odds ratios of 1.489 and 1.616, respectively. Individuals with two copies of the variant 3Gly or 92Ala were at greater risk of bipolar disorder than individuals with one copy (dose-response manner). Haplotypes ORFa-3Asp-92Ala and ORFa-3Gly-92Ala indicated higher susceptibility for bipolar disorder with odds ratios of 3.759 and 1.292, respectively, while ORFa-3Asp-92Thr probably played a protective role with an odds ratio of 0.395. Data generated from this study supported our hypothesis that genetic variations of the DIO2 gene were associated with bipolar disorder and suggested further consideration on the possible involvement of these functionally active variants in the pathophysiology of bipolar disorder.

## 794/W/Poster Board #452

**Variants of gene for microsomal prostaglandin E synthase 1 show association with disease and severe inflammation in rheumatoid arthritis.** *M. Korotkova[1], M. Seddighzadeh[1], B. Ding[2], N.A. Daha[3], S. Lindblad[1], T. Huizinga[3], R.E.M. Toes[3], L. Alfredsson[2], L. Klareskog[1], P-J. Jakobsson[1], L. Padyukov[1].* 1) Department of Medicine, Rheumatology Unit, Karolinska Institutet/Karolinska University Hospital, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Leiden University Medical Center, Leiden, The Netherlands.

mPGES1 is a terminal enzyme in induced state of PGE2 synthesis and constitutes a novel therapeutic target for rheumatoid arthritis (RA) treatment. SNPs in the mPGES1/PTGES gene could modify enzyme expression levels or activity, alter induced PGE2 biosynthesis and lead to the inter-individual differences in susceptibility to or severity of RA. Aim: to study the association of the PTGES gene polymorphism with susceptibility to and severity of RA and to relate variations in the gene to its expression and function. Methods: The PTGES gene polymorphism (SNPs and haplotypes) was analyzed in 2157 incident RA cases and 1068 age and sex matched controls from EIRA, a population based case-control study in Sweden, using TaqMan allelic discrimination. We generated the dense map of the locus including neighboring PRPX2 and TOR1 genes. Baseline disease activity score (DAS28) was employed as disease severity measure. mPGES1 mRNA and protein expression in LPS-stimulated PBMC was analyzed by qPCR and flow cytometry respectively in 25 healthy individuals with known genotypes. PGE2 was measured in cell supernatants by EIA. Results: Among women, a significant association with RA risk was observed for three SNPs from the same recombination block (rs10988484, rs11999368 and rs16931419, p=0.0014, 0.0028, 0.0011, significant after permutation test). In addition, haplotype frequency analysis based on 3 SNPs in a recombination block downstream to PTGES demonstrated a significant association between haplotype TTC and susceptibility to RA in women (p=0.0054) that was substantiated in an independent study from the Dutch population with overall OR 1.28 (95%CI 1.09-1.51). No significant association with RA either for a single SNP or in the haplotype analysis was found in men. One of the SNPs (rs4837404) was associated with lower DAS28 in women with RA (p=0.0028). Rare genotypes of another two SNPs, rs2241270 and rs230282 were consistent with 3 and 10 years earlier onset of RA (p<0.05). There were no significant differences in the expression of mPGES1 protein or PGE2 production by LPS-stimulated PBMC from healthy individuals in relation to genotypes. mRNA expression tended to be lower in PBMC from individuals with protective haplotype. Conclusions: Our data reveals an association between polymorphisms at the PTGES gene locus and susceptibility to and severity of RA in women, which may contribute to the differences in the expression of PTGES at the site of inflammation.

## 795/W/Poster Board #453

**Functional Validation of Variants in Interleukin-23 Receptor (IL23R) Associated with Crohn's Disease.** *S. Pidasheva, N. Ghilardi, HF. Clark.* Bioinformatics & Immunology, Genentech, S San Francisco, CA.

Crohn's disease (CD) is an inflammatory bowel disease (IBD), which occurs when the immune system attacks the gastrointestinal tract. Genome-wide association (GWA) studies for CD in several populations demonstrated that one of the strongest association signals mapped to the IL23R gene. IL23 promote, the expansion and development of pro-inflammatory Th17 cells. Thus, perturbation of IL23 signaling in Th17 cells could play a pivotal role in the pathogenesis of CD. In this study, we investigated the effect of coding single nucleotide polymorphisms (cSNP) in IL23R for potential functional roles in susceptibility to CD. To address this issue, we have analyzed wild type (WT) and ten IL23R cSNPs. The main focus of this study was on R381Q a highly associated protective variant. To investigate the effects of cSNPs we used retrovirally transduced BaF3 cells as well as polyclonal T cell lines. We analyzed cell surface expression, proliferation in response to IL23R agonist and STAT3 phosphorylation. CD4+ T cell lines were generated from healthy donors with WT and R381Q haplotypes. Donors with protective haplotype had significantly reduced STAT3 phosphorylation compared to the WT counterparts. Reduced STAT3 signaling may lead to decreased production of pro-inflamatory cytokines like, IL17, explaining the protective effect of this variant. Our genetic research provides better understanding of the pathogenic mechanisms of IL23R's contribution to CD and may contribute to the development of targeted drug therapy.

## 796/W/Poster Board #454

**A comprehensive strategy for uncovering functional elements underlying non-genic disease associations.** *N.F. Wasserman, M.A. Nobrega.* Department of Human Genetics, The University of Chicago, Chicago, IL.

In the classical model of human disease genetics, mutations in coding regions of the genome are assumed to underlie disease phenotypes. It is only recently that functional non-coding regions - such as enhancers, silencers, and insulators - have been implicated in disease states. Numerous genome-wide association studies (GWAS) have identified risk variants in non-genic regions for common diseases, including various cancers and obesity. We propose a novel framework within which to view these GWAS results, hypothesizing that the genetic reasons for the non-genic associations stem from mutations in long-range *cis*-regulatory elements controlling the temporal- and tissue-specific expression of nearby genes. Our platform builds upon recent association studies and illustrates an efficient strategy to identify, map, and functionally characterize long-range regulatory elements implicated in complex human diseases. We use this approach to analyze two associations; between multiple cancers and a gene desert on 8q24, and between an intronic region of *FTO* and obesity. GWAS investigations have identified independent risk alleles within a 620kb non-genic region on 8q24 for prostate, colorectal, breast, ovarian, and urinary bladder cancer. Although there are no well-characterized genes in the interval, the proto-oncogene *MYC* lies just downstream, suggesting that the associated region may contain functional elements implicated in *MYC* regulation. Using a combination of bioinformatics, comparative genomics, and mouse transgenic *in vivo* assays, we have successfully identified a prostate-specific enhancer within the associated interval; other tissue-specific enhancers implicated in *MYC* mis-regulation are currently being mapped. A tissue-specific brain enhancer has also been identified in the associated region of *FTO*, partially recapitulating the endogenous gene expression pattern. *In vivo* and *in vitro* studies are being performed to characterize the functional implications of variation within these enhancers, as polymorphisms within the elements are theorized to predispose to and/or cause the tissue-specific mis-regulation of *MYC/FTO*, leading to the initiation and/or progression of cancer/obesity. These findings strongly support the hypothesis that long-range *cis*-regulatory elements are localized within non-genic regions associated with human diseases, and emphasize that investigations into regulatory potential should be a priority in the follow-up to GWAS inquiries.

## 797/W/Poster Board #455

**The single nucleotide polymorphisms in the VEGF, MMP-2 and MMP-9 are associated with risk of endometriosis.** *M. SAARE[1,5], M. Lamp[1], T. Kaart[3], H. Karro[1,4], Y. Kadastik[4], A. Metspalu[2,5], M. Peters[1,5], A. Salumets[1,2].* 1) Department of Obstetrics and Gynaecology, University of Tartu, Estonia; 2) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Estonia; 3) Estonian University of Life Sciences, Institute of Veterinary Medicine and Animal Sciences, Estonia; 4) Tartu University Hospital's Women's Clinic, Estonia; 5) Estonian Biocentre, Estonia.

Background: The extracellular matrix remodeling and excessive endometrial angiogenesis are proposed to be two important mechanisms in pathogenesis of endometriosis. It has been proposed that vascular endothelial growth factor (VEGF) and matrix metalloproteinases (MMP) play an active role in the establishment and progression of endometriosis since altered VEGF, MMP-2 and MMP-9 gene expression profiles have been reported in eutopic and ectopic endometrial tissues obtained from women with endometriosis. The aim of this study was to investigate the associations between the promoter region polymorphisms of VEGF, MMP-2 and MMP-9 and risk of endometriosis. Methods: 150 Estonian patients with endometriosis and 199 healthy women were studied. PCR based restriction fragment length polymorphism analysis was used to detect SNPs in VEGF (-2578 C/A, -1154 G/A; -634 C/G, -936 C/T), MMP-2 (-735 C/T, -790 T/G, -1575 G/A) and MMP-9 (-1562 C/T). Results: Women with VEGF-2578 (rs699947) AA/AC genotype had more than twofold higher risk (p=0.008) of endometriosis than women with CC genotype and women with MMP-2 -735 (rs2285053) TC and TT genotype had a lower risk (p=0.016) of developing endometriosis compared to the CC genotype carriers. MMP-9 -1562 (rs3918242) TT genotype or TT/TC genotype carriers had higher risk to develop moderate-severe endometriosis than CC genotype carriers (p=0.013 and p=0.027, respectively). There were no significant differences in the distribution of the MMP-2 -790 T/G,-1575 G/A and VEGF-1154 G/A; -634 C/G, -936 C/T SNPs between studied groups. Conclusions: Current study showed that polymorphisms in VEGF, MMP-2 and MMP-9 promoter regions may influence the development of endometriosis.

## 798/W/Poster Board #456

**Detection of Excess Rare Damaging Variants in Surfactant Associated Genes among Infants with Respiratory Distress Syndrome Using Pooled Next Generation Sequencing.** *D. Wegner[1], S. Robison[1], K. DePass[1], T. Druley[1,2], F. Vallania[2], R. Mitra[2], A. Hamvas[1], F.S. Cole[1].* 1) Pediatrics, Washington Univ, St. Louis, MO; 2) Genetics, Washington Univ, St. Louis, MO.

**Background:** Heritability of neonatal respiratory distress syndrome (RDS), a complex disease, is likely associated with rare, damaging variants in many genes related to the pulmonary surfactant metabolic pathway.

**Objective:** To determine the contribution of rare damaging variants associated with neonatal RDS in surfactant associated pathway genes.

**Methods:** We evaluated race-specific, collapsed frequencies of disruptive, rare variants (MAF <0.02) in 5 genes in the pulmonary surfactant metabolic pathway (*SFTPC, ABCA3, CHPT1, LPCAT1,* and *PCYT1B*) in 346 African-American infants (160 cases and 186 controls) and 331 European-American infants (200 cases and 131 controls). We used an Illumina next generation sequencing platform and normalized pooled samples. Identification of rare variants was performed with our in-house software program (SPLINTER). Statistical approaches included Fisher's exact tests on collapsed rare variant frequencies and in silico evaluation of genetic disruption with SIFT, PolyPhen, and Pmut.

**Results:** Among African-American infants, we found no disruptive, rare variants in *SFTPC, ABCA3, CHPT1,* and *PCYT1B*. We found 17 disruptive, rare alleles in *LPCAT1* among 346 infants (collapsed frequency 0.049). The difference in frequency between cases and controls was not significant (P= 0.46). Among European-American infants, we found no disruptive, rare alleles in *SFTPC, LPCAT1,* and *PCYT1B*. We found 11 disruptive, rare *ABCA3* alleles among 331 infants (collapsed frequency 0.033), and the difference in frequency between cases and controls was significant (P= 0.004). We also found 4 disruptive, rare variants in *CHPT1* (collapsed frequency 0.012), and the difference in frequency between cases and controls was significant (P=0.02). However, the disruptive variants were overrepresented in the control infants.

**Conclusion:** Rare disruptive variants in pulmonary surfactant metabolic pathway genes contribute to the relative risk of neonatal RDS. Collapsing rare variants at individual gene loci permits sufficient statistical power to identify genes and gene pathways associated with complex diseases despite modest case-control cohort sizes.

## 799/W/Poster Board #457

**Genome-wide association study for osteoarthritis- Novel polymorphisms in TIMP-2 are associated with susceptibility to osteoarthritis.** *B. Keam, J.Y. Heo, M.S. Park, J.Y. Lee, J.Y. Lee, B.G. Han, J. Lee.* Center for Genome Science, National Institute of Health, Korea Centers for Di, Seoul, Seoul, Korea.

Objective: Osteoarthritis (OA) can cause serious medical, social and economic problems affecting the elderly population worldwide. Not only clinical factors such as age, sex, and obesity but also genetic factors contribute to the risk of OA. The aim of this study was to identify the associations between single nucleotide polymorphisms (SNPs) and OA using a genome-wide approach and to find novel candidate genes for OA. Methods: We conducted a genome-wide association study using 3,793 subjects recruited from a community-based epidemiological study. A total 476 OA cases and 3,317 controls were genotyped on a single platform using the Affymetrix Genome-Wide Human SNP array 500K chip. Of the SNPs assayed on the chip, 179,626 SNPs were excluded because they showed: 1) a call rate lower than 96.0% in cases or controls; or 2) a minor allele frequency (MAF) <1% in the population; or 3) a significant distortion from Hardy-Weinberg equilibrium in the controls (p<0.05). The population stratification was negligible ($\lambda$= 1.008772). Results: A total of 320,942 SNPs passed all quality control filters. We identified 42 SNPs that were significantly associated with OA. Two SNPs (rs4789934 and rs9914634) in the TIMP-2 (tissue inhibitor of metalloproteinase-2) gene exhibited the most significant association with OA (age, sex adjusted odd ratio, 2.064 and 2.174, adjusted p-values, 4.01×10-6 and 6.69×10-6, respectively). Six SNPs in NKAIN2 (Na+/K+ transporting ATPase interacting 2) and one SNP in SPOCK1 (sparc/osteonectin) also showed significant associations with OA. SNPs in several other genes, FLJ44379, HDAC9, SH3GL2, RASEF, SH3RF1, PALLD, LHFPL4, VSTM2L, ZFHX3, and C10orf72, exhibited a significant association with OA. Additionally, 18 significantly associated SNPs were located in intergenic regions. To consider the joint effects and SNP-SNP interactions among the identified 42 SNPs, we conducted multiple stepwise logistic regression analyses, and SNPs in TIMP-2 and NKAIN2 remained significantly associated with OA. Conclusion: We identified novel genetic polymorphisms in TIMP-2 and NKAIN2 that are associated with OA. Further investigations are warranted to fully characterize these associations.

## 800/W/Poster Board #458

**Are there common genes affecting both hip osteoarthritis and lumbar disc degeneration?** *A. Näkki[1,2,3,4], T. Videman[4,5], U.M. Kujala[6,7], M. Suhonen[8,9], L. Peltonen[1,2,10], M.C. Battie[4,5], J. Kaprio[1,4,11], J. Saarela[1,2].* 1) Institute for Molecular Medicine Finland FIMM, Helsinki, Finland; 2) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 3) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Department of Public Health, University of Helsinki, Helsinki, Finland; 5) Faculty of Rehabilitation Medicine, University of Alberta, Edmonton, Canada; 6) ORTON Orthopedic Hospital, Invalid Foundation, Helsinki, Finland; 7) Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland; 8) Suomen Terveystalo, Helsinki, Finland; 9) Department of Clinical radiology, Kuopio University Hospital, Kuopio, Finland; 10) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 11) Department of Mental Health, National Institute for Health and Welfare, Helsinki, Finland.

Objective. Our aim was to study if the gene variants, previously identified to associate lumbar disc degeneration phenotypes (Videman et al. 2009; Arthritis and Rheumatism), were also associated with another degenerative connective tissue disease, hip osteoarthritis (OA). Methods. We used a population based twin cohort, consisting of 588 Finnish monozygotic or dizygotic male twins, aged 35-70 years. Osteoarthritis-related changes that extend to bone were graded using magnetic resonance imaging (MRI) and used as the hip OA phenotype. A total of 99 single nucleotide polymorphisms (SNPs) in 25 structural, degenerative and inflammatory candidate genes were genotyped and the association was monitored using the Pseudomarker analysis package, which can utilize combined data of individuals and sib pairs. Results. Of the 18 SNPs previously shown to associate with disc degeneration, only one SNP in the COL9A2 gene (rs7533552) was also significantly associated with the hip OA phenotype ($p = 9*10^{-5}$) in this twin cohort. The G allele of this non-synonymous SNP, changing a codon of a glutamine to either arginine or to tryptophan, was observed to predispose both to hip OA and lumbar disc degeneration. Conclusion. A common non-synonymous SNP (rs7533552, other alias rs2228564) in the COL9A2 gene was identified to associate with hip OA and disc degeneration in a Finnish population based twin cohort. It was located next to the rare variant (rs12077871) coding for the degenerative connective tissue disease associated Trp2 allele together with the G allele in rs7533552. Our finding identifies the COL9A2 gene as an interesting target for future studies in common degenerative connective tissue diseases.

**Analysis of Multiple Sclerosis Candidate Genes Stratified by HLA Genotype Reveals Novel Associations.** *J. Haines[1], R. Zuvich[1], J. McCauley[2], Y. Bradford[1], N. Schnetz-Boutaud[1], A. Compston[3], P. De Jager[4], D. Hafler[4], S. Hauser[5], J. Oksenberg[5], S. Sawcer[3], M. Pericak-Vance[2].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN 37232; 2) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL 33136; 3) Department of Clinical Neurosciences, Addenbrooke's Hospital, University of Cambridge, Box 165, Hills Road, Cambridge CB2 2QQ, United Kingdom; 4) Division of Molecular Immunology, Center for Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 5) Department of Neurology, School of Medicine, University of California, San Francisco, CA 94143.

Multiple sclerosis (MS) is etiologically a complex disease that is primarily characterized as a neurodegenerative, autoimmune disorder. The autoimmune nature of MS led to the early discovery of the Major Histocompatibility Complex (MHC) involvement in the pathogenesis of MS. The strongest association has been subsequently localized to the HLA-DRB1*1501 allele. Since this discovery, numerous genome-wide linkage screens have been performed to identify disease loci, but have had little success. Through these and more recent linkage studies, it became clear that the only reliably strong linkage signal exists in the MHC. Because of the strong signal (odds ratio ~2) and the difficulties in identifying other loci harboring disease alleles, it is plausible that common alleles with much smaller effects are being masked by the strong MHC signal. Given this hypothesis, we stratified the results of a SNP analysis on a set of candidate genes derived from a candidate pathway analysis of MS by the presence of an HLA risk allele. In a case-control dataset of 2,722 samples genotyped for 7,865 single-nucleotide polymorphisms (SNPs), we found several genes that had suggestive association only in the stratum of individuals without HLA-DRB1*1501 (HLA-), which contained 1,668 individuals. Before stratification, the genes IRS1, BCL2, IL12A, and SOCS1 had p-values of 1.66x10-3, 0.04, 1.43x10-3, and 2.53x10-3, respectively. After stratification, the results were much stronger, with max p-values of 5.90x10-5, 1.90x10-4, 5.47x10-4, and 5.55x10-4, respectively in the HLA- subset. In an independent balanced case-control dataset of ~4,000 samples, two of these gene regions (IL12A and SOCS1) replicated in the HLA- stratum. The SNP near SOCS1 has a p-value of 5.55x10-4 with an estimated genotype relative risk (GRR) of 1.47; whereas, in the overall dataset, the SNP has a p-value of 2.5x10-3 with an estimated GRR of 1.28, and in the stratum of individuals with HLA-DR*1501 (HLA+), the SNP has a p-value of 0.24. The SNP in IL12A has a p-value of 6.67x10-4 with an estimated GRR of 1.28; whereas, in the overall dataset, the SNP has a p-value of 1.9x10-3 with an estimated GRR of 1.18, and in the HLA+ stratum, the SNP has a p-value of 0.25. These results suggest effects that are independent of HLA.

## 802/W/Poster Board #460

**A Pathway Approach to Decoding Multiple Sclerosis reveals several new associated loci.** *R. Zuvich[1], J. McCauley[2], Y. Bradford[1], N. Schnetz-Boutaud[1], A. Compston[3], P. De Jager[4], D. Hafler[4], S. Hauser[5], J. Oksenberg[5], S. Sawcer[3], M. Pericak-Vance[2], J. Haines[1].* 1) Human Gen,519 Light Hall, Vanderbilt Univ, Nashville, TN 37232; 2) Miami Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL 33136; 3) Department of Clinical Neurosciences, Addenbrooke's Hospital, University of Cambridge, Box 165, Hills Road, Cambridge CB2 2QQ, United Kingdom; 4) Division of Molecular Immunology, Center for Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115; 5) Department of Neurology, School of Medicine, University of California, San Francisco, CA 94143.

Multiple sclerosis (MS) is characterized as an autoimmune, demyelinating disease. Through various family studies, there is strong evidence of a genetic component underlying its etiology. After several decades of frustration in identifying genetic risk factors beyond the MHC, technological advances have enabled the identification of new genes associated with MS. In this study, we used the paradigm of examining genes within the extended pathway of previously identified genetic loci to find novel associations. Using available pathway information, we identified 73 genes associated with the IL7RA pathway, a gene recently identified and subsequently confirmed as a risk locus for MS. These genes are involved in the signaling cascade downstream of IL7RA or affected by varying IL7 concentrations. Genes were represented by single-nucleotide polymorphisms (SNPs) within the gene or in the 50kb region upstream and downstream of each gene. We genotyped the resulting 7,865 SNPs on 2,722 case-control samples using the Illumina iSelect Custom BeadChip assay. Our results suggest that five gene regions are associated with MS risk: IL7 with max p-value 2.46x10-5, the region flanking SOCS1 with max p-value 4.33x10-4, PRKCE with max p-value 3.47x10-4, Tyk2 with max p-value 3.97x10-4 and BCL2 with max p-value 4.32x10-4. Two of the gene regions, IL7 and SOCS1, had SNPs that replicated in an independent case-control dataset of ~2,000 cases and 2,000 controls. The SNPs in IL7 had a combined max p-value of 8.29x10-6 with an estimated genotype relative risk (GRR) of 1.14. The SNPs around SOCS1 had a combined max p-value of 3.48x10-7 with an estimated GRR of 1.25. Both of these genes have biological relevance: IL7 is the ligand of a known susceptibility gene (IL7RA) and vital for the development, maturation, and survival of T cells and SOCS1 is involved in suppression of cytokine signaling. Thus, our data indicates that using the pathway approach is an effective way to identify novel associations in a complex disease. This experiment lends further support that multiple common alleles with modest effects contribute significantly to MS susceptibility.

## 803/W/Poster Board #461

**Modeling Complex Genetic and Environmental Influences on Comorbid Bipolar Disorder with Tobacco Use Disorder.** *R. McEachin[1,4], N. Saccone[2], S. Saccone[3], L. Bierut[3], J. Cavalcoli[4], M. McInnis[1,4].* 1) Psychiatry, Univ Michigan, Ann Arbor, MI; 2) Genetics, Washington Univ, St. Louis, MO; 3) Psychiatry, Washington Univ, St. Louis, MO; 4) National Center for Integrative Biomedical Informatics, Univ Michigan, Ann Arbor, MI.

Comorbidity of psychiatric and substance use disorders represents a significant complication in the clinical course of both disorders. Bipolar Disorder (BD) is a psychiatric disorder that has significant negative effects on the lives of those affected, as well as a high rate of comorbid Tobacco Use Disorder (TUD). For patients with BD, the risk for TUD is almost 3 times that for the general population, based on our meta-analysis of the seven epidemiological studies that have been published to date. Notably, the observed bi-directional increased relative risk for both disorders is consistent with some common underlying etiology for BD and TUD. Given this potential for common etiology, as well as evidence of genetic influences on both BD and TUD, we hypothesized a common underlying genetic etiology, interacting with environmental nicotine exposure, influencing susceptibility to both BD and TUD. We used multiple bioinformatics resources to establish validated candidate genes for comorbid BD with TUD and explore the likely roles of these genes in the comorbidity. We then hypothesized networks of candidate genes for the comorbidity, based on their interactions with the validated candidate genes, and tested these hypothesized networks for association with BD and TUD. Consistent with our hypothesis, the selected genetic network shows statistically significant over-representation of genes associated with both BD and TUD, as well as significant over-representation of genes differentially expressed with exposure to tobacco smoke. This network reveals novel inference on the multiple genetic influences on the comorbidity of BD and TUD, establishes novel candidate genes for follow-on testing, and models the environmental effect of nicotine on the genetic network. We provide two sets of SNPs that have been prioritized for follow-on testing. The first set is prioritized by functional and conservation data and includes variants in our validated candidates (COMT, SLC6A3, and SLC6A4), as well as their interactors. The second set, a subset the first, also incorporates evidence of association with nicotine and BD.

## 804/W/Poster Board #462

**Peptide YY (PYY): Discrete polymorphisms in the 3'-UTR and proximal promoter regulate gene expression in cella as well as PYY secretion and metabolic syndrome traits in vivo.** *P. Shih, L. Wang, G. Wen, C. Nievergelt, M. Mahata, F. Rao, D. O'Connor.* Sch Med, Univ California, San Diego, San Diego, CA.

Rationale: Obesity is a heritable trait that contributes to hypertension and subsequent cardio-renal disease risk; thus the investigation of genetic variation that predisposes individuals to obesity is an important goal. Circulating Peptide YY (PYY) is known for its appetite and energy expenditure-regulating properties; linkage and association studies have suggested that PYY genetic variation contributes to susceptibility for obesity, rendering PYY an attractive candidate for study of disease risk. Study Design: To explore whether common genetic variation at the human PYY locus influences plasma PYY or metabolic traits, we systematically resequenced the gene for polymorphism discovery, then genotyped common SNPs across the locus in an extensively phenotyped twin sample to determine associations. Finally, we experimentally validated the marker-on-trait associations using in cella PYY 3'-UTR/reporter analysis in neuroendocrine cells. Results: 4 common genetic variants were discovered across the locus, and 3 were typed in phenotyped twins. Plasma PYY was highly heritable ($p<0.0001$), and pleiotropy was noted for plasma PYY and body mass index (BMI) ($p=0.03$). A PYY haplotype extending from the proximal promoter (A-23G) to the 3'-UTR (G1134A) predicted not only plasma PYY ($p=0.009$) but also other metabolic syndrome traits. 3'-UTR variant G1134A disrupted a microRNA recognition motif, while proximal promoter variant A-23G extended the TATA box by one base. Functional studies with transfected luciferase reporters confirmed regulatory roles in altering gene expression for both 3'-UTR G1134A ($p<0.001$) and promoter A-23G ($p=0.0016$). Conclusions: Functional genetic variation at the PYY locus influences multiple heritable metabolic syndrome traits, likely conferring susceptibility to obesity and subsequent cardio-renal disease.

## 805/W/Poster Board #463

**The asthma associated G-protein coupled receptor NPSR1 affect downstream signalling in a splice variant specific manner.** *C. Orsmark Pietras[1], J. Vendelin[2], S. Bruce[1], F. Anedda[1], M. D'Amato[1], C. Söderhäll[1], J. Kere[1,2,3].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Clinical Research Centre, Karolinska University Hospital, Stockholm, Sweden.

Neuropeptide receptor 1 (NPSR1, GPRA) was first identified as an asthma candidate gene through positional cloning. Since then many studies have shown that NPSR1 not only is an asthma susceptibility gene, but also involved in settings such as inflammatory bowel disease, sleep and circadian phenotypes and anxiety. NPSR1 encodes two functional membrane receptors, NPSR1-A and NPSR1-B, generated by alternative splicing of the last exon resulting in unique intracellular C-termini. The isoforms show distinct expression patterns in tissues and cells, but previous studies have failed to show any functional difference between NPSR1-A and -B. To investigate differences in NPSR1 isoform specific signalling we looked at regulation of genes downstream the receptors. Human epithelial kidney cells were transiently transfected with NPSR1-A or -B. The transfected cells were stimulated with NPS, the ligand for NPSR1, and RNA was collected. We performed an isoform specific expression array experiment, looking at 30 000 potential target genes. The results showed that NPSR1-A and -B regulated the same genes but with a clear difference between the two isoforms, NPSR1-A constantly yielded a stronger induction of genes than NPSR1-B. These results were verified by both NPS dose-response and time series analyses that showed NPSR1-A responses consistently above those of NPSR1-B. We verified the results on selected genes also in human lung epithelial cells and neuroblastoma cells relevant for NPSR1 signalling. Using luciferase-based reporter assays we could confirm that NPSR1-A is the stronger activator of transcription factors in three different pathways, cAMP/PKA, MAPK/ERK and MAPK/JNK, providing a mechanistic explanation for the difference between the two isoforms. In conclusion, we show that NPSR1-A and -B regulate the same set of genes but that -A is a more potent activator, possibly based on differences in phosphorylation between the two isoforms.

## 806/W/Poster Board #464

**Role of Genetic Polymorphisms in the Chemokine Pathway in Asthma and Atopy: Molecular and Clinical Genetic Study.** *S.A. AL-ABDULHADI[1], M.W AL-RABIA[2].* 1) MOLECULAR PATHOLOGY, SAAD SPECIALIST HOSPITAL, KHUBAR, Saudi Arabia; 2) IMMUNOLOGY DEARTMENT, UM AL-QURA UNIVERSITY, MAKKAH, Saudi Arabia.

Chemokines and their receptors contribute to the asthmatic airway inflammation by acting on mononuclear cells. Their expression has been reviewed for a number of human diseases with an inflammatory component. Possible associations between CCR5Δ32, CCR2V64I, CCR3Y17Y, and the RANTES-G403A promoter and asthma and related phenotypes in high-risk families. 154 families (453 individuals), with at least two affected children with physician-diagnosed asthma (PDA) and atopy were studied. Both TDT and PDT demonstrated similar non-significant associations between CCR5Δ32 with asthma or atopy. CCR2V64I was significantly associated with absence of asthma FEV1% but not with s-IgE. CCR3Y17Y was preferentially transmitted with asthma and BHR. The -403 G/A RANTES polymorphism was transmitted with atopy and atopic asthma although its contribution appeared to relate more to atopy than asthma and BHR. Both linkage and haplotype analyses confirmed the association between chromosome 3 and asthma status. Haplotype analyses suggested significant linkage disequilibrium between these three polymorphisms and asthma status. Log linear analyses revealed that the CCR2 mutant allele was most strongly associated with protection against atopic asthma whereas the CCR3 mutant allele was associated with increased the risk of disease. Imprinting analyses failed to demonstrate an increased risk of disease when effector alleles were transmitted from the mother. A significant interaction was found between maternal smoking, and carriage of the -17YCCR3 for an increased the risk of atopic asthma in child probands. Domestic animal exposure (cat or dog) showed no significant interaction with the polymorphisms of interest. The bioinformatic databases BLAST, and MatInspector analyses suggested the SNP-64I within the CCR2 gene and the SNPs -17Y, -21G, and 5UTR within CCR3 were functional. The -403A and -28C SNP's in the RANTES promoter were identified as belonging to common functional binding sites. These analyses suggested that environmental exposures could interact with genetic constitution in influencing disease expression. Overall this study suggested new mechanisms relevant to asthma that might effect into the future therapy and genetic counseling education session and clinical pathway. However, this suggested mechanisms and the possible functional effects of the studied polymorphisms clearly need verification in model biological systems and possible multi-ethnic large populations.

## 807/W/Poster Board #465

**Genome wide meta-analysis for Crohn's disease and celiac disease identifies new shared risk loci.** *E. Festen[1,2], T. Green[3], P. Goyette[4], G. Trynka[2], P. Dubois[5], R. Scott[6], S. Celiac disease and Crohn's disease are chronic inflammatory diseases, most commonly affecting the small intestine. Several studies have reported the co-occurrence of celiac disease and Crohn's disease within families and individual patients. GWAS studies have identified some 40 Crohn's disease loci and more than 15 celiac disease loci. Interestingly, two risk loci are shared between the diseases: IL2/IL21 (interleukin 2 and 21) and IL18RAP (interleukin 18 receptor accessory protein). This suggests that these diseases have a shared genetic background. We hypothesize that the two identified shared genes represent the tip of the iceberg, leaving more shared risk loci to be discovered. The aim of our study is to perform a meta-analysis on GWAS data from both diseases in order to identify new shared genes for celiac disease and Crohn's disease. For Crohn's disease, data was used from a meta-analysis on three GWAS containing 3230 Crohn's disease cases and 4829 controls (Barrett e.a. Nat Gen 2008). Data for the replication in Crohn's disease was obtained by sequenom genotyping of 973 Crohn's disease cases and 1000 controls. Celiac disease data was taken from a GWAS on 768 cases and 1422 controls (Hunt e.a. Nat Gen 2008). Data for the replication was obtained from a recently completed GWAS on celiac disease containing 3149 cases and 6325 controls. The meta-analysis was performed using an unweighed Z-score method, to control for the differences in study sizes. We took all loci associated to Crohn's disease with P<1x10-3, associated to celiac disease with P<1x10-2 and an overall P value in the meta-analysis of <1x10-5 for replication. The most associated markers in loci meeting the replication criteria were analyzed in the replication cohorts. Sixteen loci met these criteria and eleven of these loci have not yet been implicated in either Crohn's disease or celiac disease. Replication is currently ongoing. Our meta-analysis has identified 11 potentially new loci for Crohn's disease and celiac disease. Most of these risk loci contain genes involved in T cell development and function, similar to those already proven to be shared between celiac disease and Crohn's disease. This finding is in agreement with the known pathology of both diseases in which the initial inflammatory response follows a T helper 1 pattern and a subsequent T helper 17 response in longstanding inflammation.

## 808/W/Poster Board #466

**TNFR2 associated with hand OA and evidence of quantitative trait loci (QTL) on chromosome 16: the CARRIAGE family study.** *HC. Chen[1], D. Thompson[1], SH. Shah[2,3], YJ. Li[2], S. Nelson[2], C. Haynes[2], J. Johnson[2], T. Stabler[1], ER. Hauser[2], SG. Gregory[2], WE. Kraus[3], VB. Kraus[1].* 1) Division of Rheumatology; 2) Center for Human Genetics; 3) Division of Cardiology, Department of Medicine, Duke University Medical Center.

Background: Osteoarthritis (OA) is a multifactorial disorder with genetic predisposition. Tumor necrosis factor alpha (TNF) has been identified as an important role in cartilage degeneration which initiates a cascade of inflammatory reactions via the TNFR1 and TNFR2 receptors. The aim of this study was to evaluate the soluble tumor necrosis factor (TNF) receptor levels in individuals with hand osteoarthritis (OA) and their genetic contribution in an extended family. Methods: The extended CARRIAGE (CARolinas Region Interaction of Aging Genes and Environment) family consists of 3357 pedigreed members dating back ten generations in the USA. Hand OA status (by American College of Rheumatology Criteria), and serum levels of TNF alpha and TNF receptors were evaluated in 271 family members. The levels of TNF alpha and TNF receptors were measured by ELISA (Biosource, Camarillo, California, USA). Statistical significance between groups (hand OA and non-hand OA) was analyzed using unpaired t test. The genotyping was performed using Illumina BeadChip with 6,090 SNP markers with average spacing of 0.58 cM covering the whole genome. The SOLAR (Sequential Oligogenic Linkage Analysis Routines) package was used to calculate two-point and multi-point probabilities of identical by descent (IBD) using a polygenic model. Results: Mean ln TNFR2 was significantly higher in the hand OA group, compared with the non-hand OA group (7.96+0.65 vs 7.61+0.66, p<0.01), but was not significant after age-adjustment (p=0.16). However, the difference was significant with age-adjustment comparing hand OA and non-hand OA in the > 60 year old individuals (8.08+0.70 vs 7.75+0.68, p=0.039, age-adjusted). There was no difference in TNF alpha and ln TNFR1 between the two groups (2.95+0.50 vs 3.05+0.49, p=0.35 and 8.59+0.49 vs 8.68+0.48, p=0.40, respectively). The maximum multipoint LOD score of 2.0 was achieved for TNFR2 on chromosome 16q12.1 between 51-71 cM. For TNFR1, the maximum QTL were also identified on chromosome 16q (LOD=1.2, 65-87 cM). TNF alpha was also observed to have a peak (LOD=1.2, 49-67 cM) overlapping the regions of TNFR1 and TNFR2. Conclusion: We demonstrated that TNFR2 levels are significantly increased in hand OA individuals in this extended family. This finding has been shown for the disease of rheumatoid arthritis (RA) but not previously for OA phenotypes. We hypothesize that genetic variations linked to TNFR2 may influence the risk for the hand disease of OA.

## 809/W/Poster Board #467

**Linkage and association studies of joint morbidity from rheumatoid arthritis.** *K. Min[1], J. Min[2], S. Cho[3], J. Sung[3].* 1) Ajou University School of Medicine, San 5, Wonchon-dong, Yeontong-gu, Suwon, 443-721, Republic of Korea; 2) Institute of Health & Environment, Seoul National University, 28 Yeongun-dong, Jonno-gu, Seoul, 110-460, Republic of Korea; 3) Department of Epidemiology, School of Public Health, Seoul National University, 28 Yeongun-dong, Jonno-gu, Seoul, 110-460, Republic of Korea.

Purpose.Rheumatoid arthritis (RA) is a chronic and progressive inflammatory disease occurring in the synovial membrane that can lead to joint deformity and cartilage destruction. We investigated the relationship between genetic susceptibility and rheumatoid arthritis (RA) severity in terms of joint morbidity, using a linkage study and family-based association tests. Methods. The dataset included 723 families with 990 affected sibling pairs with RA. The Illumina linkage panel IV included 5,858 SNPs, with 5,744 SNPs passing quality control filters. The phenotypic variables analyzed were the level of rheumatoid factor (RF) and score on the Joint Alignment and Motion (JAM) scale. In affected siblings, the mean values were 261.6 IU/ml (range = 8-6920 IU/ml) for RF levels and 30.8 (range = 0-118) on the JAM scale. We modified the scale dividing by RF values relevant to disease severity (JAM-RF ratio = JAM scale score/RF). Patients with lower ratios presented more severe symptoms in terms of joint mobility and/or higher RF levels. Linkage analysis for affected sibling pairs was done using the MERLIN program, and family-based association tests were carried out by using PLINK and FBAT software. Results. For linkage analysis, we found a high peak (log of the odds [LOD] = 2.66; nonparametric linkage [NPL] Z = 3.23) near the HLA-DRB1 region on chromosome 6; HLA-DRB1 may be not only the major region of genetic susceptibility to RA but may be also a potential region for the joint deformity and loss of joint motion that occurs with RA. The linkage at 6p24 at rs1410766 (LOD = 3.29; NPL Z = 4.07) was statistically significant. The linked region on chromosome 6p24 is located less than 1 cM from the bone morphogenetic protein 6 (BMP6) gene. Two other regions also showed possible linkage peaks: chromosome 7q30 at rs322812 (LOD = 2.47; NPL Z = 3.39) and chromosome 15p34 at rs347117 (LOD = 1.95; NPL Z = 2.80). For the family-based association study, there were seven SNPs, for which only three genes could be found: triadin (TRDN), Src homology 2 domain containing family member 4 (SHC4), and hypothetical protein FLJ23834 (FLJ23834). Conclusion. We found two significant linkage at 6p21-24 and suggestive linkage peaks at 7q30 and 15p34. Seven SNPs were detected from family-based association tests. Our results imply that genetic variations may lead to an enhanced risk of joint damage and increased levels of RF.

## 810/W/Poster Board #468

**Percent African Ancestry is Significantly Related to Hip Structural Geometry.** *L. Qi[1], Z. Chen[2], T. Beck[3], J. Robbins[4], G. Wu[2], B. Lewis[5], J. Cauley[6], N. Wright[2], M. Seldin[1].* 1) Rowe Program in Human Gen, Univ California, Davis, Davis, CA; 2) Division Epi/Biostat, U Arizona, Tucson, AZ; 3) Quantum Medical Metrics, LLC, Baltimore, MD; 4) Dept. General Med., Univ California, Davis, Davis, CA; 5) Univ of Alabama at Birmingham, Birmingham, AL; 6) Univ of Pittsburgh, Pittsburgh, PA.

African Americans have a significant lower fracture risk in comparison to non-Hispanic whites in the United States. Higher bone density and favorable femur geometry have been found in African Americans, but the relative contributions of genetic vs. environmental components to apparently stronger bones in African Americans remains an interesting research area. In this study we investigated the association between percentage of African ancestry and femur BMD and geometry in a subgroup of participants from the Women's Health Initiative. All participants underwent hip dual-energy x-ray absorptiometry (DXA) and femoral narrow neck structural geometry was analyzed using Beck's method on hip DXA scans. Based on >1000 well distributed ancestry informative markers that distinguish between sub-Saharan African and European ancestry, the percentage of African ancestry for each African American individual was determined. Of the 739 African American Women, 19 women had <50% African ancestry, 162 women had 50-74% and 558 women had 75-100% African ancestry. A total of 8,206 self-identified non-Hispanic white were included as the comparison group. BMD, cross-sectional area and section modulus (an index of bone bending strength) significantly increased with increased % African ancestry. Buckling ratio (an index of susceptibility to cortical failure under compression) reduced significantly with increasing % African ancestry. Outer diameter at the femoral narrow neck region was slightly smaller in women with high % African ancestry. While women with higher percent African ancestry were younger and heavier, the racial differences in femoral neck geometry still existed after adjusting for age, weight, total calcium intake and hormone use. In conclusion, indices of bone strength increased in women with higher percentage of African heritage, suggesting a significant genetic contribution to reduced fracture risk observed in the African Americans. Larger cross-sectional area plays a major role in the increased bone strength in older African American women.

## 811/W/Poster Board #469

**Failure to confirm association of three polymorphisms of rheumatoid arthritis susceptibility identified by the Wellcome Trust Case Control Consortium in a Japanese population.** 
*T. Suzuki[1,2], K. Ikari[1], A. Taniguchi[1], H. Yamanaka[1], S. Momohara[1].* 1) Institute of Rheumatology, Tokyo Women's Medical Univ, Shinjuku, Tokyo, Japan; 2) Dept of Orthopaedic Surgery, School of Medicine, Keio Univ, Shinjuku, Tokyo, Japan.

Rheumatoid arthritis (RA) is believed to be a complex multifarious disease that is influenced by both genetic and environmental factors. There is increasing evidence that genome-wide association studies (GWAS) represent a powerful approach to the identification of genetic markers. The Wellcome Trust Case Control Consortium (WTCCC) published GWAS using 1860 RA patients and 2938 controls in a British population. The WTCCC study confirmed the association of SNPs with previously identified loci within the HLA region and PTPN22 gene, and nine more loci were found to be associated in the next level (our replication study on these SNPs have been presented at the ASHG meeting 2008). Subsequently, they reported 49 SNPs were that associated with RA in the third level ($P=1 \times 10^{-4}$ - $1 \times 10^{-5}$). Three of these could be replicated in a validation cohort of 4106 patients and 11238 controls; PRKCQ (rs4750316), KIF5A (rs1678542) and IL2RB (rs3218253). The aim of our study is to replicate the association of these SNPs with susceptibility to RA in a Japanese RA cohort. The present study is part of a RA cohort project with an enrollment of nearly 5000 patients established by the Institute of Rheumatology, Tokyo Women's Medical University. DNA samples from 1504 patients and 752 controls were used for the study. Genotyping was performed using the TaqMan assay according to the manufacture's instructions (Applied Biosystems, Japan). Chi-squared test was performed for statistical analysis, using the R software package. No significant differences were observed in allele frequencies of the three SNPs between cases and controls (rs4750316 [P=0.51, OR=1.07, 95%CI= 0.87-1.32], rs1678542 [P=0.15, OR=1.12, 95%CI=0.95-1.31], rs3218253 [P=0.88, OR=1.02, 95%CI=0.78-1.34]). Our data could not support the evidence of association between these SNPs and RA. Although strong association was found in European descents, these reported susceptibility genes analyzed here are not associated with RA susceptibility in a Japanese population. The result suggests that the SNPs may be associated with RA susceptibility in a specific ethnic group.

## 812/W/Poster Board #470

**The histidine-triad nucleotide binding protein is associated with nicotine dependence and is increased in the nucleus accumbens after chronic nicotine exposure.** 
*K.J. Jackson[1,2], Q. Chen[1], J. Chen[1], M.I. Damaj[2], K.S. Kendler[1], X. Chen[1].* 1) Psychiatry, VIPBG, Richmond, VA; 2) Pharmacology/Toxciology. Virginia Commonwealth University, Richmond, VA.

The histidine triad nucleotide binding protein (HINT1) is widely expressed in mesocortical and mesostriatal brain regions; however, little is known about the physiological function of this protein. Recent expression and association studies indicate that the HINT1 gene is associated with schizophrenia. Additionally, HINT1 knockout mice display altered responses to morphine and amphetamine. Nicotine dependence is highly comorbid with other substance abuses and schizophrenia. Although studies implicate a role for HINT1 in schizophrenia and drug dependence, there are no available studies assessing the role of this protein in nicotine dependence. Thus, using association and expression studies, this study aimed to examine the involvement of the HINT1 gene in nicotine dependence. Association analyses revealed that variants in the HINT1 gene previously found to be associated with schizophrenia, are also associated with nicotine dependence. Further, human mRNA expression data revealed that smoking significantly influences HINT1 expression in the brain. Additionally, western blot analysis of HINT1 protein level in the mouse PFc, hippocampus, nucleus accumbens (NAc), and ventral tegmental area (VTA) were assessed following acute or chronic nicotine, and after nicotine withdrawal. Results show no change in protein level after acute nicotine; however, there was a significant increase in HINT1 protein level in the NAc after chronic nicotine exposure, which was reduced after precipitated and spontaneous nicotine withdrawal. These results demonstrate a genetic association between variants in HINT1 and nicotine dependence, and indicate that nicotine-induced increases in HINT1 level may compensate for the HINT1 deficiency observed in the PFc of schizophrenia patients. Future studies will further examine the role of this gene in nicotine dependence by testing HINT1 knockout mice in established nicotine reward and withdrawal behavioral models. Overall, these studies will aid in elucidation of genetic and molecular mechanisms that contribute to excess smoking in schizophrenia patients.

## 813/W/Poster Board #471

**Familial aggregation of melanoma and co-aggregation with other cancers.** 
*S.V. Ward[1], R.J. Webster[1], J.G. Dowty[2], J.L. Hopper[2], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, Nedlands, Western Australia, Australia; 2) Centre for Molecular, Environmental, Genetic and Analytic (MEGA) Epidemiology, The University of Melbourne, Melbourne, Victoria, Australia.

Melanoma is the most aggressive form of skin cancer and Australia has one of the highest rates in the world. Epidemiological research has identified some of the environmental and genetic risk factors of the disease, including family history of melanoma. However, little is known about the relationship between family history of melanoma and an individual's risk of developing other forms of cancer. Some evidence exists for familial aggregation of melanoma with pancreatic cancer and glioma but little research has been undertaken in the Australian population. The purpose of this study was to investigate the familial aggregation of melanoma and its co-aggregation with other types of cancer in the Western Australian (WA) general population. WA has the second highest rate of melanoma in Australia. All data were obtained from the WA Data Linkage System, a population based database linking WA's core health datasets. Linked data from the Family Connections database, which maps family history, and the WA Cancer Registry were used for this study. Cancers considered were invasive breast, lung, prostate, cervical, colorectal, thyroid, brain, mouth, testicular, and kidney cancers, non-melanoma skin cancers, lymphoma and melanoma, and were all diagnosed between 1981 and 2006. The total sample size was 1,530,147 individuals, which included 5,478 individuals with invasive melanoma. The number and type of cancers diagnosed during the time period were calculated for each individual. Risk models were then developed using Cox regression modeling and survival analyses. Analyses showed that individuals who had one or more first degree relatives (FDRs) with melanoma had an increased risk of developing melanoma themselves ($p<0.001$). The risk increased by a factor of 4.15 (95% confidence interval (CI) 3.25-5.3) for each FDR with melanoma. This result is consistent with findings in other populations that family history of melanoma is a risk factor for the disease. Individuals who had one or more FDR with melanoma were also at an increased risk of developing non-melanoma cancer (p=0.047). For each FDR with melanoma, the risk of developing non-melanoma cancer increased by a factor of 1.32 (95% CI 1-1.73). Further, the risk of melanoma increased for individuals by a factor of 1.43 (95% CI 1.09-1.87) for each FDR with a non-melanoma cancer (p=0.0094). These findings provide additional support for familial aggregation between melanoma and other forms of cancer.

## 814/W/Poster Board #472

**Familial aggregation of breast cancer with cancers at other sites: Survival analysis of data from the Western Australian Data Linkage System.** 
*R.J. Webster[1,3], J.G. Dowty[2,3], J.L. Hopper[2], L.J. Palmer[1].* 1) Centre for Genetic Epidemiology and Biostatistics, The University of Western Australia, WA, Australia; 2) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, The University of Melbourne, VIC, Australia; 3) Authors contributed equally.

Family history is one of the biggest known risk factors for many common cancers, indicating that factors pertaining to the shared environment and/or genetic makeup of family members predispose to these diseases. Numerous epidemiological studies have also shown familial aggregation of different types of cancer, suggesting that those cancers may have similar such risk factors in common. Breast cancer risk has a strong familial component, and among the many susceptibility alleles now identified are the BRCA1 and BRCA2 mutations, which predispose to both breast and ovarian cancer. The purpose of this study was to investigate the co-aggregation of breast cancer with cancers at other sites within families in a Western Australian population. The study group was derived from the Western Australian Data Linkage System (WADLS), a dataset that comprises over 30 years of linked pedigree and health data on the entire population of the state of Western Australia, and is one of the largest population-based datasets in the world. The study group includes 1,530,147 individuals with a median age of 31 (95% confidence interval (CI) 3-60) years. The median family size is 4 (95% CI 3-10). Analyses aimed to determine whether the relatives of women with breast cancer have a heightened risk of other cancers. Survival analyses using the Cox proportional hazards model were performed with the time to development of different types of cancer as the end-points. Risk ratios corresponding to covariates derived from the individual's family history of breast cancer were estimated. The risks of invasive melanoma and colorectal cancer were found to be greater in the first degree relatives of patients with invasive breast cancer (p=0.04 and p=0.04, respectively), with the risks multiplicatively increased by a factor of 1.76 (95% CI 1.02-3.04) and 3.20 (95% CI 1.03-9.97), respectively, for each first degree relative with invasive breast cancer. These results suggest that familial risk factors for breast cancer may also increase susceptibility to melanoma and/or colorectal cancer.

## 815/W/Poster Board #473

**Association of Sirtuin 1 (SIRT1) gene variation and transcription levels with severe obesity.** *J. Andersson[1], M. Falchi[1], S. Clark[1], B. Olsson[2], D. Meyre[3], C. Lecouer[3], P. Jacobson[2], L. Sjöström[2], L. Carlsson[2], P. Froguel[1,3], A. Walley[1].* 1) Section Genomic Medicine, Imperial College London, London, United Kingdom; 2) Department of Molecular and Clinical Medicine and Center for Cardiovascular and Metabolic Research, The Sahlgrenska Academy, Gothenburg, Sweden; 3) CNRS 8090-Institute of Biology, Pasteur Institute, Lille, France.

**Background:** The SIRT1 gene is important in the regulation of lipid and glucose metabolism. Variants in the gene have been associated with levels of energy expenditure and activators of the SIRT1 protein protect against obesity making it a clear candidate gene for common polygenic obesity. This study was designed to investigate a possible association between SIRT1 variants and obesity in both severely obese adults and children and to examine whether expression levels of the SIRT1 gene affect susceptibility to the disease. **Subjects and Methods:** Three tag-SNPs together with twenty-four additional SNPs chosen for even coverage of the 34kb SIRT1 gene were selected for genotyping purposes. The genotyping was carried out using Sequenom iPLEX assays. Case-control analyses were performed using 1533 obese subjects (896 adults with BMI over 40kg/m$^2$ and 637 children with a BMI>97$^{th}$ percentile for age and sex) and 1237 non-obese controls, all French Caucasians. Expression of SIRT1 was measured in the siblings from the SibPair cohort, which comprises 154 nuclear families (732 subjects) from Sweden, each containing an obesity-discordant sib pair (at least 10 kg/m$^2$ difference in body mass index). Subcutaneous adipose tissue was obtained via punch biopsy. Analysis was only carried out using the same sex BMI-discordant sibpairs to avoid the effect of gender-discordance. **Results:** Two SNPs, rs33957861 and rs11599176 were found to be associated with adult obesity (p-values: 0.005 and 0.003 respectively) and a third SNP, rs2234975 was associated with childhood obesity (p=0.006). These p-values remained significant after correction for multiple testing using the method of Nyholt. However, no significant association was observed with BMI adjusted for age and sex in either adults or children. SIRT1 transcript expression was found to be negatively correlated to BMI and lower SIRT1 expression was associated with obesity (p-values: 3.7x10$^{-19}$ in 76 female sibpairs and 0.0025 in 12 male sibpairs). Genotyping in these families also revealed an association between four SIRT1 SNPs (rs11599176, rs12413112, rs33957861 and rs35689145) and BMI (p values= 0.0004, 0.0006, 0.0004 and 0.002 respectively). **Discussion:** We have demonstrated that variants in the SIRT1 gene are associated with severe obesity in both adults and children and that SIRT1 expression is associated with the disease.

## 816/W/Poster Board #474

***NRF2* polymorphisms are not associated with the childhood-onset asthma susceptibility in Mexican population.** *E. Cordova[1], F. Centeno[1], S. Jiménez[1], NE. Martínez-Aguilar[2], BE. Del Rio-Navarro[3], J. Gómez-Vera[4], E. Navarro-Olivos[5], L. Orozco[1,6].* 1) Investigacion, Inst Natl de Medicina Genomica, Mexico D.F., Mexico; 2) Servicio de Alergia, Hospital Regional 1 de Octubre, ISSSTE; 3) Departamento de Alergia, Hospital Infantil de México; 4) Servicio de Alergia, Hospital Regional Adolfo López-Mateos; 5) Programa de Maestría en Ciencia Médicas, Instituto Politécnico Nacional; 6) Posgrado Ciencias Genómicas, Universidad Autónoma de la Ciudad de México.

Oxidative stress has been recognized as an important factor in asthma pathogenesis. Recent reports have shown that the activation of the Nuclear erythroid 2-related factor 2 (*NRF2*) gene confers cellular protection against different asthma-related factors such as cigarette smoke, DEPs and atmospheric particulate matter. Nrf2 is a basic leucine zipper transcription factor that regulates the expression of antioxidant and detoxificant genes. Germinal deletion of *nfr2* in mice increases cell susceptibility to several environmental insults and pathogenic states. In addition, SNPs located in the promoter region of *NRF2* (-653G/A, and -617C/A), which decrease NRF2 gene expression, have been associated to different diseases. In this same context, *nrf2* -/- mice showed a higher susceptibility to asthma development, after a challenge with ovoalbumine. These data strongly suggest a possible role of Nrf2 in asthma susceptibility. Thus, the aim of this study was to determine whether the -653G/A, and -617C/A *NRF2* polymorphisms are associated to susceptibility to childhood-onset asthma in a Mexican-Mestizo population. We studied 242 unrelated patients with childhood-onset asthma and 358 unrelated sex-matched healthy individuals. All the participants were recruited from four tertiary level Institutions from Mexico City and have Mexican-mestizo origin. Genotyping of -653G/A and -617C/A SNPs was performed by TaqMan assay. The association test, Hardy-Weinberg equilibrium (H-WE) and haplotypes were determined using EPIDAT, FINETTI and Haploview softwares, respectively. The two Nrf2 SNPs were found in Hardy-Weinberg equilibrium, both in cases and controls. The *NRF2* polymorphisms, showed an strong linkage disequilibrium (LD) (D'=0.97) and a high frequency of the risk alleles -653A and -617A was observed (0.40; an 0.24;, respectively). No significant differences were observed in the genotype and allelic distribution between healthy and asthma individuals, even after gender stratification. Similarly, haplotypes analysis failed to detect any association with asthma. Despite we were unable to observe an association between *NRF2* gene variants and asthma manifestation, we cannot discard that this gene could be associated with severity of asthma. Further studies with careful and deep emphasis in clinical manifestation of asthma are necessary to define the role of *NRF2* in this disease.

**Functional Variant of the Bitter Taste Receptor Gene Associated with Oral Microbial Profiles in the COHRA Study.** *K.T. Cuenco[1,2,3], S.K. Wendell[1,2], J.G. Thomas[4], D.M. Gray[4], X. Wang[1,2], R.J. Weyant[5], R.M. Crout[6], D.W. McNeil[7], M. Marazita[1,2,3,8].* 1) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 4) Department of Pathology, School of Medicine, West Virginia University, Morgantown, WV; 5) Department of Dental Public Health/Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 6) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 7) Dental Practice and Rural Health, West Virginia University, Morgantown, WV; 8) Clinical and Translational Sciences Institute and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA.

Our understanding of the role of host genetics and oral microbes on caries has been evolving. Estimates of caries heritability range from 0.39 to 0.66 (see abstract submission #21309). Host susceptibility to pathogen colonization in the oral cavity may be dictated by innate taste preference, establish preferential microbial profiles, and explain the shared genetic component underlying caries. A major pathogen related to caries is *Streptococcus mutans*, but recent evidence suggests that other flora in addition to *S mutans* affect caries development. Microbial testing for *S mutans*, periodontal-related flora, and common nosocomial pathogens (including *Staphylococcus aureus*) found in the oral cavity and proximal throat sites have been assessed in COHRA families from the Appalachian region. We evaluated 8 SNPs in taste genes (TAS2R38, TAS1R1, TAS1R2, and GNAT3) with selected microbial joint outcomes in 705 families. Single outcome association between *S mutans* and caries was mild. However, joint assessment of multiple microbial organisms suggested an association with increased odds of severe caries. Based on these epidemiologic evaluations of microbes, the joint microbial profile of nosocomial and oral disease pathogens were implemented in family based SNP association analyses. A mis-sense mutation (rs10246939) in TAS2R38 was associated with a specific microbial profile (125 informative families, $p = 0.0146$) and persists after adjustments for potential confounding by oral disease. This finding suggests that a taste receptor variation can impact host microbial communities in the oral cavity and may have a fundamental role in microbial colonization that dictates subsequent oral health outcomes. We are currently more closely assessing the effects of oral disease, evaluating other potential health outcomes (e.g. body mass index, caries endophenotypes), and their relationship with this taste receptor variant and corresponding microbial profiles. These findings additionally highlight the importance of assessing joint microbial profiles in genetic epidemiologic studies. R01 DE 014899.

## 818/W/Poster Board #476

**ITGAM and Systemic Lupus Erythematosus (SLE) Susceptibility: A Meta-analysis.** *X. Kim-Howard, S. Nath.* Oklahoma Medical Research Foundation, Oklahoma City, OK.

Introduction: We identified ITGAM as a strong systemic lupus erythematosus (SLE) susceptibility gene which was also replicated in 3 genome-wide association studies (GWAS). We narrowed down the association interval and pinpoint the causal association with a coding variant, rs1143679 (A/G) at exon-3. Using imputation-based association analysis followed by conditional analysis we showed that rs1143679 was the only causal SNP within ITGAM. We also replicated this association in 5 ethnically diverse populations. Recently 2 other reports also replicated this association. Objectives: The objectives of this study are to 1) perform a meta-analysis on 23 independent data sets and 2) perform geographic region-specific meta-analyses and assess the heterogeneity of the genetic effect between these regions. Methods: For our meta-analysis we used 23 independent data sets from 17 countries which represented 5 geographic regions. To test for geographic region-specific effect associated with rs1143679, we performed broad region-specific meta-analyses including European (10 data sets, N=4324), European-American (2 data sets, N=5602), African-derived (2 data sets, N=1560), Latin-Americans (4 data sets, N=2832), and Asians (5 data sets, N=3849). Results: The overall meta-analysis combining European-derived, African-derived, Latin-American, and some Asian independent data sets greatly reinforces the genetic association (Pmeta=2.15x10-67, OR=1.79, 95% CI=1.68-1.92). The overall heterogeneity of the odds ratio (OR) was not significantly different across populations (p=0.50). Robustness of rs1143679 association with SLE was confirmed in 5 ethnically diverse groups, including European (Pmeta=1.13x10-25), European-American (Pmeta=1.20x10-24), African-derived (Pmeta=1.00x10-5), Latin-Americans (Pmeta=9.55x10-13), and some Asian populations (Pmeta=4.68x10-6; 2 data set) but not in other Asian populations (3 data sets), where rs1143679 was monomorphic for the non-risk allele (G). The heterogeneity of the ORs were not significant across any of the regional associations (lowest p=0.26) Conclusions: The SNP rs1143679 has shown robust association across geographically diverse populations. From the allele frequency spectrum it is shown that the risk allele (A) is most prevalent in European populations (12%-31%) and least prevalent in Asian populations (0%-6%). Although significant differences exist in allele frequency heterogeneity, ORs were homogeneous across populations.

## 819/W/Poster Board #477

**Association and interaction analyses of GABBR1 and GABBR2 with nicotine dependence.** *M. Li[1], J.E. Mangold[1], G.-B. Chen[1], C. Seneviratne[1], J.Z. Ma[2], X.-Y. Lou[1], T.J. Payne[3].* 1) Department of Psychiatry and Neurobehavioral Sciences, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 3) ACT Center for Tobacco Treatment, Education and Research, Department of Otolaryngology and Communicative Sciences, University of Mississippi Medical Center, Jackson, MS.

Previous studies demonstrate that the $\gamma$-aminobutyric acid type B (GABAB) receptor plays an essential role in modulating neurotransmitter release and regulating the activity of ion channels and adenyl cyclase. However, whether GABAB receptor subunit genes are associated with nicotine dependence (ND) remains largely unknown. In this study, we genotyped 6 and 33 single nucleotide polymorphisms (SNPs) for GABAB receptor subunit 1 and 2 genes (GABBR1, GABBR2), respectively, in a sample of 2037 individuals from 602 nuclear families of African American (AA) or European American (EA) origin. Association analyses were conducted for each gene with ND at both the individual SNP and haplotype levels. We also conducted interactive analysis of the two genes in affecting ND by using a pedigree-based generalized multifactor dimensionality reduction method. We found that several SNPs and haplotypes in GABBR2 were significantly associated with ND in both ethnic samples. Interestingly, these significant haplotypes were located in different protein domains for the AA and EA samples. In addition, we found two minor haplotypes in GABBR1 to be associated with ND in the EA sample. Finally, we demonstrated the presence of epistasis of SNPs in GABBR2 for both samples, as well as between GABBR1 and GABBR2 in the EA sample. We conclude that variants of GABBR1 and GABBR2 are significantly associated with ND. Our findings imply that both GABAB receptor subunit genes are involved in the etiology of ND, although the involvement of GABBR1 is primarily through its interaction with GABBR2, whereas GABBR2 has a direct effect on ND. (This study is being supported by NIH grants DA-12844 and DA-025095.).

## 820/W/Poster Board #478

**Strong association between an ADRB2 haplotype and obesity in Mexican Population.** *M. Salas-Martínez[1,2], Y. Saldaña-Alvarez[1], S. Jiménez-Morales[1], A. Luckie-Duque[3], G. García-Cárdenas[4], H. Vicenteño-Ayala[5], A. Carnevale-Cantoni[6], L. Orozco[1,2].* 1) Instituto Nacional de Medicina Genómica-INMEGEN; 2) Posgrado en Ciencias Genómicas-UACM; 3) Hospital Regional 1° de Octubre-ISSSTE; 4) Clínica de Diagnóstico Automatizado-ISSSTE; 5) Hospital Regional López Mateos-ISSSTE; 6) Coordinación de Medicina Genómica-ISSSTE. Mexico City, Mexico.

Introduction. Beta-2-adrenergic receptor gene (ADRB2) is involved in several mechanisms related with obesity, like thermogenesis regulation and lipolysis activation. Several single nucleotide polymorfisms (SNPs) located in this gene have been identified as genetic risk factors to obesity in several populations, such as Caucasians and Asian. Objective. The aim of this study was to investigate the association of the Gly16Arg (rs1042713 G/A), Glu27Gln (rs1042714 C/G) and Leu84Leu (rs1042717 G/A) polymorphisms located in the ADRB2 gene with obesity in Mexican population. Methods. We performed a case-control association study in 423 obesity cases with a BMI>30 and 268 unrelated non-obese subjects with a BMI<25. Cases and controls were recruited from two tertiary Hospitals in Mexico City. Genotyping was carried out by the 5' exonuclease assay (TaqMan). The association test, Hardy-Weinberg equilibrium (HWE) and haplotypes were determined using EPIDAT, FINETTI and HAPLOVIEW softwares, respectively. Results. All genotypes distribution in patients and controls were in HWE. We did not observe significant differences in the genotype and allelic distribution between obese and non-obese individuals. However, the haplotype analysis reveled five common haplotypes ( frequencies higher than 1%: ACG, GCA, GGG,GCG and ACA). Interestingly, haplotype frequencies distribution analysis between cases and controls showed a susceptibility obesity haplotype (GCG) harboring all ancestral alleles, showing a higher frequency in cases than in controls [7% Vs 1,7%; OR= 4.16; 95% CI=(1.96-9.09), p=0.000017 ]. Conclusion. Our results suggest that ADRB2 haplotypes could be a genetic factor conferring one of the highest risk to develop obesity. Further studies are necessary to understand the role of ADRB2 gene in obesity.

## 821/W/Poster Board #479

**SNPs associated with C-reactive protein levels in a cohort of young Filipino adults.** *G. Curocichin[1,2], T. McDade[3], C. Kuzawa[3], J. Borja[4], L. Qin[1], D. Croteau-Chonka[1], A. Marvelle[1], E. Lange[1,5], L. Adair[6], K. Mohlke[1], L. Lange[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Family Medicine, Moldova State Medical and Pharmaceutical University, Chisinau, Moldova; 3) Department of Anthropology, Northwestern University, Evanston, IL; 4) Office of Population Studies, University of San Carlos, Cebu City, Philippines; 5) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 6) Department of Nutrition, University of North Carolina, Chapel Hill, NC.

C-reactive protein (CRP) is an important risk factor for cardiovascular disease. However, the effect of genetic variants on risk in young adults and in Asian populations is not clear. Studies in European midlife-to-older adult populations have identified SNPs rs1205 in the 3'UTR of CRP and rs1169288 (Ile27Leu) in HNF1A as associated with serum CRP levels. We tested these SNPs for association with plasma CRP levels in young adults (21-23 years) from the Cebu Longitudinal Health and Nutrition Survey (CLHNS) and their mothers both separately, using analysis of variance, and in a combined analysis, using general linear mixed models. A total of 1,692 young adults and 1,782 mothers (35 to 69 years) were analyzed. Median CRP levels (inter-quartile range) were 0.2 (1.0) mg/L in the young adults (range 0 to 85.9) and 0.9 (2.5) mg/L in the mothers (range 0 to 122.6). CRP levels were log-transformed and genotype was modeled as an additive effect. Log-CRP was significantly lower in the young adults than the mothers (p<0.0001). Both SNPs were strongly associated with log-CRP in the young adults and their mothers analyzed separately (all p<2x10-7) and in the combined sample (rs1205, p=6.3x10-15; rs1169288, p=2.6x10-11). In the young adults, rs1205 explains 1.7% and rs1169288 explains 1.1% of the variability in log-CRP levels. In the mothers, rs1205 explains 2.0% and rs1169288 explains 1.6% of the variability. There was no evidence for either a genotype-by-BMI or genotype-by-genotype interaction in either group. The role of hygiene remains to be analyzed. These results indicate that the CRP SNP rs1205 and the HNF1A SNP rs1169288 are associated with CRP levels in both the young adults and the mothers in this Filipino cohort, and confirm associations identified in European populations in a population of Asian descent. While CRP levels are significantly higher in the mothers versus the young adults, the effect sizes are similar in both subsets, suggesting a consistent effect of these genes on CRP levels across a wide age range. The strong evidence for association in the young adults suggests that younger populations may also be valuable in identifying genetic loci for cardiovascular disease risk factors.

## 822/W/Poster Board #480

**GENETICS OF COMITANT STRABISMUS: A STUDY BASED AT CHILDREN'S HOSPITAL BOSTON.** *C. Andrews[1, 3], S. Mackinnon[2], D.G. Hunter[2], E.C. Engle[1,2,3].* 1) Dept Neurology and Pediatrics (Genomics), Children's Hosp, Boston, Boston, MA. USA; 2) Dept Ophthalmology, Children's Hosp, Boston, Boston, MA. USA; 3) Howard Hughes Medical Institute.

Strabismus is a misalignment of the eyes that includes various forms of horizontal and vertical deviations. The most common forms of strabismus are comitant, with a similar magnitude of deviation in all gaze positions. Comitant strabismus affects 2-4% of the population, and it can cause vision loss through amblyopia (vision loss in a structurally normal eye) or by reducing binocular vision and stereopsis. The etiology of comitant strabismus is generally unknown, although hyperopic refractive error is a recognized risk factor, and amblyopia may sometimes occur in the absence of strabismus as a result of refractive error. Comitant strabismus clusters in families and appears to segregate as a complex trait. To identify genetic contributions to comitant strabismus and amblyopia, we have undertaken a prospective study of Children's Hospital Boston Department of Ophthalmology patients with comitant strabismus or its risk factors, enrolling probands and all available family members, whether affected or unaffected. Participants undergo an ophthalmic examination, and provide a blood/salivary specimen as well as medical, birth, and family history. To date, 605 probands (51% male, 49% female; 70% Caucasian), 199 affected family members, and 1290 unaffected family members have been enrolled in the study. Of the affected probands, 382 have esotropia, 151 have exotropia, 62 have anisometropia, and 10 have high hyperopia. Within this population, 51% of the pedigrees report at least one additional affected first, second, and/or third degree relative (6 or more individuals affected in 9 pedigrees, 5 affected in 13 pedigrees, 4 affected in 28 pedigrees, 3 affected in 88 pedigrees, and 2 affected in 173 pedigrees). The calculated relative risk of strabismus to a sibling of an affected individual (lS) is 4, presuming an incidence of strabismus within the general population of 3%. These preliminary data support a genetic contribution to strabismus and a significantly high lS to support a search for strabismus genes in this population. We are now beginning linkage analysis of the pedigrees to the several potential loci identified to date, including STBMS1, and are continuing ascertainment for a comitant strabismus GWAS study.

## 823/W/Poster Board #481

**Heritable and lifestyle effects on sleep/wake patterns in the Old Order Amish.** *D.S. Evans[1], S.-H. Wu[1], A. Mody[2], A.R. Shuldiner[3], S. Snitker[3], W.-C. Hsueh[1].* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) Department of Medicine, Duke University, Durham, NC; 3) Department of Medicine, University of Maryland, Baltimore, MD.

Sleep/wake patterns in humans are regulated by at least two factors: the biological circadian rhythm and entraining environmental stimuli. The goal of our study is to characterize both the non-genetic and heritable factors that are associated with sleep patterns in the Old Order Amish, whose agrarian lifestyle is more homogeneous than modern societies.

The study population of 868 healthy adults (53% men) had a mean age of 43.8 ± 14.0 years (range: 20-80 yrs). 81% of men were farmers or skilled tradesmen and 75% of women were home-makers. Subjects wore accelerometers 24 h/day for 7 days. The actigraphy records were analyzed to determine weekly averages for (1) the time of day when subjects fell asleep (sleep time), (2) wake-up time, (3) sleep duration, and (4) physical activity levels (total counts). Subject-specific sleep and wake-up times were validated in a substudy of 179 subjects who kept sleep diaries (r = 0.83 for wake-up time and 0.76 for sleep time, both P < 0.001). All analyses were performed conditioned on the relatedness of individuals using the SOLAR program.

On average, both men and women went to sleep at 10:00PM ± 44 min, but men woke up earlier than women (4:59AM ± 46 min and 5:12AM ± 44 min, respectively, P = 0.0001). Correspondingly, mean sleep duration was shorter in men compared to women (7.0 ± 0.9 hours and 7.2 ± 0.8 hours, respectively, P = 0.03). Seasonal and household effects were significantly associated with all three sleep parameters. In addition, the average wake-up time was significantly associated with sex, age, occupation, and physical activity levels, the average sleep time with age, and the average sleep duration with occupation and total activity levels. Subjects with higher activity levels had shorter sleep durations and earlier wake-up times. Older subjects had earlier wake-up times and sleep times, but sleep durations were not affected by age. After adjusting for the aforementioned factors, there was no significant heritability for sleep times or sleep duration, while the heritability for wake-up times was 0.19 ± 0.10 (P = 0.02). In conclusion, in the Amish, wake-up times appear to have a significant heritable component even after adjusting for household effects.

**Genetic variations in genes of the axon guidance pathway associated with Adolescent Idiopathic Scoliosis (AIS) etiology and progression.** *R.A. Macina, J. Gu, L. Nelson, R. Chettier, K. Ward.* Axial Biotech, Inc., Salt lake City, UT.

Adolescent Idiopathic Scoliosis (AIS) is a complex, familial disorder characterized by a lateral deformity of the spine, affecting 2-3% of the pediatric population. Up to this date, no single causative factor for the development of AIS has been described. Even though neurological defects have been associated with scoliosis, it is not clear whether these observations are causative or secondary to the development of the disease. Genomic DNA samples from 700 severe AIS patients and 1500 controls were used in a genome-wide association study (GWAS)utilizing Affymetrix 6.0 HuSNP arrays.This genome-wide study identified, among others, 53 single nucleotide polymorphisms (SNPs) thoroughly validated in clinical settings to provide significant predictive value for AIS progression. These 53 genetic markers are the components of our AIS prognostic Test (AIS-PT). Two of these 53 genetic markers map to genes that belong to the axon guidance pathway. These SNPs are rs6693477 (P value=1.92E-.05, OR=1.331) in the proximity of EFNA1 and EFNA3, and rs7802114 (P value=9.21E-05, OR=0.4875) intronic to PLXNA4. To further investigate the role of this pathway in the etiology of AIS, we used a genomic pathway approach to mine the genome-wide association dataset to identify SNPs that are within axon guidance pathway genes. Preliminary results of this genomic pathway approach identified a number of SNPs with a significant association to the disease in an additional axon guidance gene, SLIT3 when comparing severe AIS patients to controls. We will show results of applying this genomic pathway approach to a large number of axon guidance pathway genes and we will use the SNPs that show association to the disease to determine if they have a predictive value for AIS progression and could enhance the current AIS-PT. Our results demonstrate that genetic variations in multiple genes in the axon guidance pathway are associated with the etiology of AIS and the progression of the disease. This is the first report of single nucleotide polymorphisms within genes involved in nervous system development contributing to the pathogenesis of AIS and its progression. Moreover, this discovery could lead to the development of additional novel diagnostics and prognostics tests as well as novel therapeutic approaches for adolescent idiopathic scoliosis.

## 825/W/Poster Board #483

**Differential Expression of Cytokines as an Indicator for Classification of Autism Phenotypes.** *T.L. Pawlowski[1], A.N. Allen[1], J.J. Corneveaux[1], J. Pruzin[1], A. Sekar[1], E. Salomon[1], C.J. Smith[2], S. Brautigam[2], J. Kirwan[2], S. Ober-Reynolds[2], D.C. Craig[1], M.J. Huentelman[1].* 1) Neurogenomics, TGen, Phoenix, AZ; 2) Southwest Autism Research and Resource Center, Phoenix,AZ.

Autism is a devastating neurobiological disorder affecting an estimated 1 out of every 150 children. The incidence of autism appears to be growing at a rate of approximately 10% per year, making it the most common developmental disorder. Children with the diagnosis of autism vary widely in the severity and presentation of their symptoms. Current theory in the field supports the idea of many sub-types of autism characterized by clusters of behavioral and physical traits. There is growing evidence that immune system dysfunction is one possible cause of autism. Through the use of quantitative antibody microarrays we investigated the correlations between specific autism physical and behavioral phenotypes and cytokine levels in two well phenotyped cohorts of autistic cases and controls. One cohort is from the Southwest Autism Research and Resource Center (SARRC), and the second from the Autism Genetic Resource Exchange (AGRE). The examination of the IgG levels of 33 autistics and their normal siblings from AGRE revealed significant differences in levels of IgD (p=0.03), IgE (p=0.03), IgM (p=0.009) and IgG1 (p=0.04). A measurement of the same immunoglobulins in 87 autistics and 73 age-matched, unrelated controls from SARRC did not find the same significant differences, but did find significant correlations with several physical features and ADI-R scores. A measurement of 40 cytokines in both cohorts found significant correlations between physical traits and behaviors. In particular, a significant negative correlation between BDNF (p=0.0054), E-Selectin (p=0.017), IGFBP-1 (p=0.019), IGFBP-2 (p=0.019), MIP-1b (p=0.007) and VCAM1 (p=0.03) levels and total ADI-R scores was found in the SARRC population. Also in this cohort a significant correlation between head circumference and IL-1a (p=0.03), IL-2 (p=0.02), IL-5 (p= 0.02), IL-6 (p=0.006), IL-8 (p=0.04), IL-10 (p=0.03), IL-13 (p=0.01), IL-17 (p=0.02), MIP-1a (p=0.02) and IFN-gamma (0.02) was noted. Eotaxin was significantly negatively correlated (p=0.025) with ADI-R scores in the AGRE cohort and other groups of cytokines were correlated with social and stereotyped behaviors. Better understanding of how dysregulated cytokines influence the brain could translate into pharmalogical targets for the treatment of some types of autism, help characterize sub-types of autism and ultimately may help to clarify the pathobiology behind autism.

## 826/W/Poster Board #484

**Thrombotic Storm: definition of an extreme clinical phenotype.** *T.L. Ortel[1], C.S. Kitchens[2], M.A. Pericak-Vance[3], D. Erkan[4], A.H. James[5], R. Kulkarni[6], R.W. Hoffman[7], L. Brandao[8], S.E. Hahn[3], J.M. Vance[3].* 1) Hemostasis & Thrombosis Center, Duke University Medical Center, Durham, NC; 2) Division of Hematology/Oncology, University of Florida, Gainesville, FL; 3) Miami Institute for Human Genomics and The Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miller School of Medicine, Miami, FL; 4) Hospital for Special Surgery, New York, NY; 5) Department of Maternal-Fetal Medicine, Duke University, Durham, NC; 6) Michigan State University, East Lansing, MI; 7) Division of Rheumatology and Immunology, University of Miami, Miami, FL; 8) The Hospital for Sick Children, Toronto, Ontario, Canada.

Thrombotic storm (TS) was first described in 1998 as a self-perpetuating process in which an initial thrombotic event could lead to multiple thromboses and even death. 6 cases were initially used to demonstrate the features of this disorder: (1) an underlying hypercoagulable state; (2) provocation to initiate thrombosis; (3) rapid development of new thromboembolic events; (4) response to prompt intervention; and (5) good prognosis if the cycle of thrombosis is successfully interrupted. Collaborators representing eight sub-specialties (adult and pediatric hematology, immunology, maternal fetal medicine, laboratory medicine, neurology, genetics, and rheumatology) met in March 2009 to initiate a study to further elucidate this rare disorder. We hypothesize that individuals who develop TS have an underlying genetic predisposition to this severe, frequently life-threatening, response to an initial thrombotic stimulus. In order to search for this inherited risk factor, we have developed a set of inclusion/exclusion criteria that define this severe syndrome. Inclusion criteria include individuals age 55 years or younger who manifest 2 or more of the following: 1) acute, 2 or more arterial and/or venous thromboemboli, and/or thrombotic microangiopathy; 2) unusual location (e.g., cerebral sinus thrombosis); 3) progressive/recent unexplained recurrence; and 4) refractory to acute therapy and/or an atypical response to therapy. This must be in the absence of 1) active cancer, 2) advanced coronary artery disease; 3) cocaine use associated with symptom onset; 4) intravascular devices; 5) paroxysmal nocturnal hemoglobinuria or myeloproliferative syndromes; 6) subtherapeutic treatment; 7) multiple/severe trauma, and 8) pre-morbid clinical status. Using these criteria, we identified six new cases with TS, confirming the phenotype and clinical course, who represent the initial members of a patient cohort to investigate the genetics of TS through a nationwide recruiting strategy.

## 827/W/Poster Board #485

**Investigation of the genes PTCH1 and GLI2 in the etiology Anophthalmia and Holoprosencephaly in Brazilian cases.** *C. Bertolacini[1], AL. Petrin[2], LA. Ribeiro-Bicudo[1], AR. Costa[1], JC. Murray[2].* 1) Hosp of Rehabilitation of Craniofacial Anomalies, Bauru, SP., Brazil; 2) Department of Pediatrics, University of Iowa, Iowa City, IA, USA.

Craniofacial anomalies are alterations of the cranium and face that can be associated with central nervous system malformations. They represent a frequent cause of congenital anomalies in newborns. Craniofacial midline defects are directly related to the lack of closure of the neural tube and are among the most common of central nervous system malformations. These defects have both genetic and environmental etiological factors. We report the molecular analysis by direct sequencing of coding regions and exon-intron boundaries of the genes PTCH11 and GLI2 in 2 cohorts of Brazilian individuals with midline defects: 39 with anophthalmia/microphthalmia and 77 with holoprosencephaly spectrum (HPE). In the cohort with anophthalmia/microphthalmia we found 2 missense mutations in gene GLI2 and 6 variants in splicing site in gene PTCH1.In the cohort of HPE we found 3 missense and 2 nonsense mutations in the gene GLI2. For PTCH1 we found another 6 variants in splicing region, one of them was present in 7 unrelated individuals out of the 77 cases and was not present in 96 control samples. These genes belong to SHH (Sonic Hedgehog) pathway that plays a critical role in early midline craniofacial and central nervous system development that make them very strong candidate genes for midline defects studies. Mutations in the gene PTCH1 may affect the ability to bind SHH, or perturb the intracellular interactions of PTCH1 with other proteins involved in SHH signaling. The mutations can also enhance the repressive activity of PTCH1 on the SHH pathway and so decrease SHH signaling. GLI2 is a transcription factor implicated as obligatory mediators of SHH signal transduction, mutations on GLI2 have been previously reported on HPE individuals but we report it for the first time in anophthalmia cases. In conclusion our study shows the role of GLI2 and PTCH1 genes in the etiology of midline the cranium and face development that can be associated with the central nervous system malformations and report new mutations increasing the etiological knowledge of these anomalies.

## 828/W/Poster Board #486

**An increase in the TLR7 gene dosage is associated with childhood-onset systemic lupus erythematosus in Mexican population.** *H. García-Ortiz[1,2], R. Velázquez-Cruz[2], F. Espinosa-Rosales[3], V. Baca[4], L. Orozco[2].* 1) Programa de Doctorado en Ciencias Biomédicas- UNAM; 2) Investigacion, Inst Natl de Medicina Genomica; 3) Servicio de Inmunología, Instituto Nacional de Pediatría; 4) Hospital de Pediatría, Centro Médico Nacional Siglo XXI, IMSS. Mexico City, Mexico.

Congenic dissection of lupus-prone mouse strains has provided important insights of the role of Toll-like receptor 7 gene (TLR7) in the pathogenesis of systemic lupus erythematosus (SLE). The BXSB male mice develop a severe form of murine lupus. The autoimmune enhancing-effect in BXSB males was attributed to a Y-linked autoimmune accelerator (Yaa) locus, resulting from a duplication and translocation to the Y-chromosome of a cluster of X-linked genes. This duplication in male mice carrying Yaa leads to a higher expression of several of the translocated genes, including Tlr7, the major candidate gene for causation of the Yaa-associated autoimmune phenotypes. In this context, we investigate if there is an increase in the number of TLR7 gene copies in childhood-onset SLE in Mexican population. We performed a case-control study in 326 (268 female, 58 male) unrelated patients with childhood-onset SLE and 326 sex matched controls recruited from Mexico City. We estimated the relative TLR7 gene copy number by real time PCR normalizing with two housekeeping genes (TBP and HPRT1) and using two pairs of specific primers for TLR7 (Xp22.3) within a distance of 1.8 kb. The TLR7 gene copy number was determined by the standard curve and ΔΔCt methods. Association analysis was performed using the Mann-Whitney U test. To calculate the Odds Ratio (OR), we used a multivariate logistic regression model. Additionally, a stratification analysis was performed in the SLE cohort to investigate the association of TLR7 gene copy number with renal disorder. We found a significantly increased in the relative TLR7 gene copy number in SLE pediatric patients compared with controls ( P=0.0015). However, when we stratified by gender, only female patients showed a significant association (P<0.0001). By logistic regression analysis we found an increased risk for development of SLE in female patients with three or more copies of TLR7 (OR = 2.94; 95% CI 1.72-4.94). Otherwise, we did not find a significantly difference in the TLR7 gene copy number in patients with lupus nephritis compared with those without renal disease. In conclusion, our data show that the gene dosage of TLR7 is an important risk factor for disease susceptibility in childhood-onset SLE in Mexican population. In addition, our results also support the notion that the female predominance of SLE may in part be explained by an X-chromosome gene dosage.

## 829/W/Poster Board #487

**Genome-wide screen for common and rare copy number variation in metabolic syndrome.** *K. Kristiansson[1], C. Barnes[1], M. Perola[2,3,4], A. Jula[5], V. Salomaa[6], S. Ripatti[2,3], M. Hurles[1], L. Peltonen[1,2,3,4,7].* 1) The Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Dept. of Molecular Medicine, The National Institute for Health and Welfare, Helsinki, Finland; 3) FIMM, Institute for Molecular Medicine Finland, Helsinki, Finland; 4) Dept. of Medical Genetics, University of Helsinki, Helsinki, Finland; 5) Dept. of Health and Functional Capacity, The National Institute for Health and Welfare, Helsinki, Finland; 6) Dept. of Health Promotion and Chronic Disease Prevention, The National Institute for Health and Welfare, Helsinki, Finland; 7) The Broad Institute of MIT and Harvard, Boston, MA, USA.

Metabolic syndrome (MetS) is a common disorder characterized by a clustering of risk factors, such as impaired fasting glucose, insulin resistance, dyslipidemia, and central obesity. The prevalence of MetS, which is highly age-dependent, has greatly increased during the last few decades. The overlap between T2DM, CVD, and MetS suggests that the same genetic determinants may contribute to the complex pathophysiology, which even more emphasizes the significance of identifying the largely unknown genetic loci underlying MetS. We carried out a genome-wide screen for copy number variation (CNV) in the genome, with two distinct strategies to assess the contribution of common and rare CNVs as risk factors for MetS. Probe signal intensity data from Illumina human610 beadchip, which is enriched for CNV-targeted probes, was analyzed for 1,100 MetS cases and their matched controls using several CNV analysis programs (PennCNV, QuantiSNP, CNVtools) in parallel for improved quality assessment of our results. The search for common CNVs utilized two recent genomic maps of known CNVs: a study of 11 diverse HapMap populations, and a higher-resolution study of 40 individuals of European or African ancestry. We also identified CNV-tagging SNPs from a reference set of CNV and SNP genotypes in the same population from which the MetS cases and controls were sampled. This allowed us to use robust SNP genotypes to evaluate the role of a subset of CNVs in MetS. In parallel to our analysis of common CNVs, we searched for rare CNV associations, concentrating on those overlapping with genes or covering large genomic regions, with the hypothesis that these structural variants may have large effects on individual phenotypes. So far, we have identified common CNV loci with putative association to MetS as a whole, along with its component traits. One of these loci is 5p12-q11.2, where two CNVs show suggestive association with MetS (p<0.05), and SNPs spanning a 4 Mb region adjacent to insulin gene enhancer protein (*ISL-1*) gene associate with insulin levels (p=0.05-0.0000016). Furthermore, we detected a gene region (*ANKRD23*, 2q11.2), implicated in insulin resistance and energy metabolism, where few of our study subjects, who are located at the far ends of the population distribution of relevant phenotypes, carry large CNVs. These results provide ground for replication studies in large population cohorts and hopefully eventually elucidate the genetic background of MetS and its components.

## 830/W/Poster Board #488

**CETP, HDL and CVD: A detailed genetic analysis.** *I.M Stylianou, A.P Kent, A.C Edmondson, B.J. Keating, M. Wolfe, S. DerOhannessian, M.P Reilly, M. Li, D.J Rader.* ITMAT, Sch Med, Univ Pennsylvania, Philadelphia, PA.

Cholesteryl ester transfer protein (CETP) is known in humans to regulate high-density lipoprotein (HDL) cholesterol levels. Indeed, the association between common polymorphisms in CETP with HDL is among the most significant reported for any gene-phenotype to date. HDL is an independent risk factor for cardiovascular disease (CVD) and its physiological role in reducing atherosclerosis through reverse cholesterol transport is compelling. However, despite concerted efforts, there has been little to link CETP genetic polymorphisms with CVD, presumably due to underpowered efforts or an underlying complex genetic architecture which has thus far prevented a comprehensive assessment. Here we lay bare the detailed complex genetic architecture of CETP using the CVD 50K IBC array. We demonstrate at least 10 independent linkage disequilibrium (LD) groups that are significantly associated (genome-wide threshold) with plasma levels of HDL, replicated across several populations. Examining each of these LD groups independently and in combination against associations with CVD phenotypes is aiding in the unraveling of the CETP-HDL-CVD paradox.

## 831/W/Poster Board #489

**Genetic prediction of diabetic nephropathy - A multi-factorial model.** *I. Blech[1], M. Katzenellenbogen[5], A. Katzenellenbogen[5], C. Norymberg[2], A.E. Buchs[3], I. Harman-Boehm[4], T. Pollin[6], B. Glaser[1], Israel Diabetes Research Group.* 1) Endocrinology & Metabolism, Hebrew Univ-Hadassah, Jerusalem, Israel; 2) Diabetes Department, General Health Services, Natanya, Israel; 3) Department of Internal Medicine "C" and Diabetes Unit, Assaf Harofe Medical Center, Zerifin, Israel; 4) Department of Internal Medicine, Soroka University Medical Center, Beer-Sheva, Israel; 5) The Mina & Everard Goodman, Faculty of Life Science, Bar Ilan University, Ramat-Gan, Israel; 6) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

Diabetes-associated metabolic dysregulation causes devastating multi-organ complications, including nephropathy, the risk of which is partially genetically determined. **AIMS:** We hypothesize that combined analysis of multiple genetic markers will improve the ability to predict nephropathy. **METHODS:** We selected 27 SNPs in 15 genes based on previous publications and their association with relevant metabolic pathways, and genotyped them in 1274 well-phenotyped Ashkenazi or Sephardic patients with Type 1 or Type 2 diabetes of ≥10y duration. A backward stepwise logistic regression model was developed as described below. The model was validated by randomly dividing the primary population into "training" (75%) and "test" (25%) subgroups and by replication in an independent Ashkenazi Jewish sample set. **RESULTS:** Five SNPs in 5 genes (*HSPG2*, *eNOS*, *ADIPOR2*, *AGER*, and *RANTES*) showed nominally significant association with nephropathy. The logistic model based on these 5 SNPs and 4 conventional variables (age, sex, diabetes type and duration), and allowing for all possible 2 way interactions, predicted nephropathy in our initial population (C-statistic = 0.66) better than a model based on conventional variables only (C= 0.57). Re-modeling using the "training" subset of the population produced a model identical in structure and predictive ability in both the "training" (C= 0.65) and the "test" (C=0.68) subsets. While in the replication set of 906 Ashkenazi patients the C-statistic was lower than in the original population (C=0.57), it was still higher than for the model including only conventional risk factors (C=0.54). The lower predictive ability in the replication set may in part be related to differences in ethnicity and prevalence of T1DM. Association of the genetic model with nephropathy was highly significant in the replication set ($\chi 2$ =17.43, p<0.0001), whereas the conventional variable model was not ($\chi 2$=1.62, p=0.2). **CONCLUSIONS:** Using 5 SNPs and 4 conventional risk factors and allowing for 2 way interactions between all variables, we developed and validated a model that can predict nephropathy more efficiently than was previously possible using conventional risk factors. Similar models, based on a larger number of relevant SNPs are likely to provide even better predictive ability. Further refinement may permit creation of population-specific models.

## 832/W/Poster Board #490

**Comprehensive metabolic trait association analysis using gene expression and single nucleotide polymorphisms.** *M. Inouye[1,2], K. Silander[3], E. Hamalainen[1], V. Salomaa[3], K. Harald[3], P. Jousilahti[3], S. Mannisto[3], M. Perola[3], E.T. Dermitzakis[1,4], L. Peltonen[1,5,6].* 1) Department of Human Genetics, Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Department of Human Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 3) THL-National Institute for Health and Welfare, Helsinki, Finland; 4) University of Geneva, Geneva, Switzerland; 5) Institute for Molecular Medicine, Finland (FIMM) and Department of Molecular Medicine, National Public Health Institute, Helsinki, Finland; 6) The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

Genome-wide association studies have been immensely successful in finding statistically significant associations of single nucleotide polymorphisms (SNPs) with complex traits. In particular, the genetic basis of metabolic traits and disorders has benefited with several dozen SNPs identified to date. However, studies of whether these SNPs drive gene expression and whether the expression of these or other genomic loci predict trait status has not been thoroughly studied. Here, we attempt to answer these questions using over 500 unrelated Finnish individuals from the Helsinki area recruited during 2007 as part of the Dietary, Lifestyle, and Genetic determinants of Obesity and Metabolic syndrome (DILGOM) study. For these samples, detailed metabolic trait measurements and lifestyle factors were available as well as genome-wide genotypes from the Illumina 610K array and genome-wide Illumina HT-12 expression profiles from total blood. While implementing stringent quality control filters and controlling for population structure, we use multiple regression to test the association of each expression probe with each trait and investigate different approaches to control for multiple testing, such as the Bonferroni correction and generating null distributions of P values by permutation. Initial analysis shows the presence of previously known associations, e.g. blood fasting glucose with the jun oncogene, insulin with alpha defensins, and free fatty acids with carnitine/acylcarnitine translocase, in addition to suggesting several novel findings including a shared loci between C-reactive protein and diastolic blood pressure. Further, genomic loci with significant or strong previous evidence of trait association are modeled as a function of both cis gene expression and SNP variants. With these loci models, we hope to better understand the functions and dynamics underlying metabolic traits.

**The Genetic Association of Copy Number Variation and Type 1 Diabetes.** *H.Q. Qu[1], Q. Li[1], J.T. Glessner[2], K. Wang[2], S.F.A. Grant[2], H. Hakonarson[2], C. Polychronakos[1].* 1) Pediatrics and Human Genetics, McGill University, Montreal, PQ, Canada; 2) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA USA.

**Background:** Genome-wide association studies (GWAS) have revealed many genetic associations of type 1 diabetes (T1D) with common variants which, however, leave much of the familial clustering of T1D unexplained. Copy number variations (CNVs) are the attractive candidates to explain the unknown genetic susceptibility. This study aims to genotype deletion loci using the data of fluorescence signals from the *Illumina* Hap550 SNP genotyping arrays. **Methods:** The subjects were a family cohort with 466 T1D case-parents pairs, and a Case-Control cohort with 499 cases and 1000 controls. The genotype calling of a deletion locus was based on the normalized fluorescence signal intensity ($log_2R$) of pairs of consecutive SNPs. The genotype clustering was performed by the K means method, optimized by Silhouette scores. The genotyping quality was assessed by Silhouette scores, Hardy-Weinberg equilibrium test, Mendelian error in the 466 families, and one-copy genotype miscalled in the presence of heterozygous SNP. **Results:** Four quality criteria were well correlated in the assessment of the genotyping quality. The number of miscalled heterozygous deletion with heterozygous genotype (A/B) was sensitive to detect genotyping error. Altogether, 216 deletion loci tagged by 323 SNPs had Silhoutte score>0.64, Mendelian errors ≤3 in the family cohort, miscalled A/B≤3 in each cohort, and Hardy-Weinberg Equilibrium test *P*>0.01. Five deletion loci had *P*<0.01, and 10 deletion loci had *P*=0.01~0.05, in the combined results of the family cohort and the Case-Control cohort. The most significant association (*P*= $2.73x10^{-5}$) was tagged by the SNP rs743862, ~25kb upstream of the *HLA-DRA* gene, which effect may be due to the LD with HLA class II genes. The most interesting functional candidate is the deletion tagged by the SNP rs4529574 (*P*=$9.84x10^{-4}$), an intronic SNP on the spleen tyrosine kinase gene (*SYK*) at Chr9q22. SYK plays critical roles in T and B lymphocyte development. The deletion allele has frequency=0.046, OR (95%) = 0.573 (0.412, 0.798). **Conclusion:** The two neighboring $log_2Rs$ algorithm can genotype deletion loci with high genotyping quality and thus enables further association test of the deletion loci. The potential T1D genetic susceptibility from the deletions will be confirmed by direct genotyping (TaqMan) in independent T1D samples and other T-cell autoimmune diseases that may share common genetic susceptibility with T1D.

## 834/W/Poster Board #492

**Functional classification based on gene expression data indicates that T2D genes play a role in liver, subcutaneous adipose tissue, and visceral adipose tissue.** *M.G.M. Wolfs[1], L. Franke[2, 3, 4], E.J. Bruin[1], S.S. Rensen[5], J.W. Greve[5], W.A. Buurman[5], T.W. van Haeften[1, 6], C. Wijmenga[2], M.H. Hofker[1].* 1) Department of Pathology and Medical Biology, Molecular Genetics Section, University Medical Center Groningen, Groningen, Netherlands; 2) Department of Genetics, University Medical Center Groningen, Groningen, Netherlands; 3) Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, London, UK; 4) Complex Genetics Section, DBG-Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Netherlands; 5) Nutrition and Toxicology Research Institute Maastricht (NUTRIM), Department of General Surgery, Maastricht University Medical Center, Maastricht, Netherlands; 6) Department of Internal Medicine, G 02-228, University Medical Center Utrecht, Utrecht, Netherlands.

Recently 19 common genetic variants associated to type 2 diabetes (T2D) have been identified through GWAS. Although the functions of the candidate genes located close to these genetic variants are largely unknown, preliminary evidence has been obtained for several of the identified T2D variants to be also associated to β-cell function. However, a systematic analysis of the novel diabetes genes is still lacking. This study has evaluated expression levels of the candidate diabetes genes in three different tissues that are involved in the development of insulin resistance, and thus are crucial in the development to T2D. Our study was carried out in 90 morbidly obese individuals (BMI over 35). During bariatric surgery, biopsies were obtained from human liver, visceral adipose tissue, and subcutaneous adipose tissue. mRNA from each of these tissues was hybridized to Illumina HumanHT12 BeadChips and quantile-normalized. We focused on 43 probes representing 24 genes that map to well established T2D loci. 18 out of these 24 genes are expressed throughout the tested tissues, indicating that they are likely to have a function within those tissues. Moreover, the expression of 9 of these genes was significantly correlated to metabolic traits of the patients, including levels of free fatty acids, HDL, and triglycerides. In order to further strengthen the evidence for a functional role of these tissues, co-expression networks were constructed. These networks were based on co-expression between the 43 probes and all the other probes present on the array (T2D genes were connected if they share at least 3 genes with a correlation coëfficient > 0.5). We found that in these networks strong correlations exist between T2D genes, of which many are tissue-specific. Remarkably, in both adipose tissues the expression levels of PPARγ are significantly correlated with WFS1 and CDKN2B expression. In visceral adipose tissue these genes also correlate with IGF2BP2, NOTCH2, and TSPAN8 whereas in subcutaneous adipose tissue these genes significantly correlate with IDE, FTO, and CDC123. Hence, on the basis of phenotypic correlations and network analysis, we predict that ADAMTS9 and IGF2BP2 play a role in liver, PPARγ, CDKN2B, WFS1, IGF2BP2, NOTCH2, and TSPAN8 play a role in visceral adipose tissue, and PPARγ, CDKN2B, WFS1, IDE, FTO, and CDC123 play a role in subcutaneous adipose tissue. The majority of these results could be replicated in a morbidly obese mouse model.

## 835/W/Poster Board #493

**Searching for mitochondrial mutations involved in age-related hearing impairment.** *E. Fransen[1], S. Bonneux[1], E. Van Eyken[1], L. Van Laer[1], HJM. Smeets[2], G. Van Camp[1].* 1) Center for Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Genetics and Cell Biology, Clinical Genetics, Maastricht University, Maastricht, The Netherlands.

Age-related hearing impairment (ARHI) is a condition whereby hearing acuity declines with ageing. Although this occurs in every individual, some persons are more severely affected than others. About half of the phenotypic variance is attributable to genetic factors. We have previously identified SNPs within two nuclear genes (GRHL2 and GRM7) that are associated with ARHI, and reported significant linkage between the ARHI phenotype and chromosomal region 8q24, but much of the variance remains unexplained Mitochondrial (mt) DNA mutations have been implicated in several ageing processes, and certain forms of nonsyndromic hearing loss are caused by mitochondrial mutations. In this study we explore whether mt variation contributes to ARHI. We have fully sequenced the 16 kb mt genome in 199 good-hearing and 200 bad-hearing persons, using the GeneChip Human Mitochondrial Resequencing Array (Affymetrix). Of the 399 participants, 369 could be classified into one of the European mt Haplogroups. No association was found between Haplogroup and affection status. When accounting for known ARHI risk factors (occupational noise, smoking, bmi, alcohol consumption, solvent exposure), no association was found either. With regard to the revised Cambridge Reference Sequence (rCRS, Genbank Accession Number AC_000021), a total of 818 distinct mutations were found across the dataset. More than half of these mutations (451 = 55%) were found in only one individual. The average number of mutations per individual was not significantly different between cases and controls, even when weighting the mutations according to conservation. For the more common variants, a Fisher-exact test was used to screen for allele frequency differences between cases and controls. The most significant signal was observed for position 10876. Seven of the cases carry a G at this position instead of a C, which was not observed among any of the controls. (p=0.01). Apart from the C10876G variant, we found eight additional variants with p-values between 0.01 and 0.1, that were all specific to subhaplogroup U2e. Six of the 9 disease-associated variants are located within the protein-coding region, but none of them alters the protein sequence. One of the variants belongs to a tRNA gene, while the last variant is part of the control region (D-loop).

## 836/W/Poster Board #494

**Development of a lung disease severity phenotype in Cystic Fibrosis and its application in the Canadian CF Modifier study.** *C. Taylor[1,2], R. Dorfman[3], L.J. Strug[1,2], W. Li[1], A. Cojocaru[1], N. Anderson[4], A. Sandford[5], P. Paré[5], J. Zielenski[3], P. Durie[4], M. Corey[1,2].* 1) Child Health Evaluative Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 3) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 4) Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, Canada; 5) James Hogg Research Centre, University of British Colombia, Vancouver, Canada.

To minimize non-genetic variation and maximize the ability to find the contribution of genetic variation, a phenotype measure must be accurate, precise, and informative. Ideally it will apply to all populations and ascertainment schemes, allowing valid comparisons between studies. In Cystic Fibrosis (CF), Forced Expiratory Volume in 1 second as a percent of predicted (Wang/Hankinson) based on height, age, and sex (FEV1pp) is a clinically useful and relevant measure of severity of lung disease. However, since CF is a progressive lung disease, average values of FEV1pp in older patients are lower than those in younger patients, making it difficult to define “mild” vs. “severe” across ages. Mortality selection further compromises the comparison. We propose a lung phenotype adjusted for age and survival censoring. Between 2000 and 2006, we recruited a representative sample of 2474 CF patients across Canada (approximately 75% of the Canadian CF population). FEV1pp was calculated and plotted against age the 1948 patients with available data. A local smoothing regression procedure (LOESS) was used to obtain age specific predicted FEV1pp values and residuals. Using the Canadian CF Patient Data Registry we determined survival probabilities to Dec 31, 2002 for each birth year cohort, and smoothed estimates of survival at decimal ages. Ranked FEV1pp residuals and age-specific survival estimates were combined to produce an adjusted cohort percentile for each patient relative to others who had lower lung function or had died. LOESS regression produced a flat pattern of age specific mean FEV1pp up to age 12, declining values to age 28, followed by a second plateau, due to mortality of those with the lowest lung function, leaving those with milder disease. Survival-correction increased percentile scores in all patients, with larger increases in older patients. For example, two patients with FEV1pp scores of 60% - one 11 years old and the other 30 years old - had age-adjusted FEVpp at the 10th percentile and 50th percentile, respectively. After adjustment for survival, the 11 year old remains at the 10th percentile while the 30 year old rises to above the 70th percentile. Correction for mortality attrition, after non-linear age-adjustment provides a phenotypic score that can be used in genetic studies for the entire age range of CF patients.

**Evidence for different autophagy genes in Crohn's disease susceptibility.** *I. Cleynen, L. Henckaerts, W. Van Moerkercke, P. Rutgeerts, S. Vermeire.* Gastroenterology, KU Leuven, Leuven, Leuven, Belgium.

Variants in two autophagy genes, *ATG16L1* and *IRGM*, have been associated with susceptibility to Crohn's disease (CD), highlighting the role for autophagy in CD pathogenesis. Our aim was to identify other autophagy genes possibly involved in CD pathogenesis. All known human functional homologues of yeast autophagy genes were screened for their location near a known IBD locus, a region of linkage previously reported in the Belgian cohort, or a genomic region surrounding a hit from the CD genome-wide association study (GWAS) meta-analysis. In the thus prioritized 12 genes, 75 haplotype tagging SNPs (tSNPs) were selected. tSNPs were genotyped in an exploratory cohort (cohort A) of 911 CD patients, and 407 healthy controls, and in a replication cohort (cohort B) of 374 CD patients, and 196 healthy controls, using the Sequenom® platform. Groups were compared using Haploview 4.1. All p-values were corrected for multiple testing with the FDR method in R 2.7.1. A corrected p-value ≤0.05 was considered to be significant. In cohort A, significant associations were found in two of the 12 genes: *ULK1* and *MAP1LC3B*. The frequency of the T-allele of the intronic tSNP rs12303764 in *ULK1* was significantly lower in CD patients (36%) vs healthy controls (42%, p=0.03) of cohort A. This association was replicated in cohort B ($MAF_{patients}$=37%, $MAF_{controls}$=44%, p=0.05), with a p-value of 0.001 in the combined cohort (A+B). In addition, the T-allele of rs3923716 in *ULK1* had at a higher frequency in CD patients (10%) vs controls (5%, p=0.03) in group B, but not in group A, with a combined p-value of 0.005. In cohort A, three variants in *MAP1LC3B* (rs933717, rs7204722, and rs2241617) were found to be associated with CD (all p <0.005). None of these were replicated in cohort B, but they remained significant in the combined cohort (all p =0.009). None of the other tSNPs tested were associated with susceptibility to CD in this cohort. These results show that different autophagy genes are involved in CD pathogenesis. *ULK1* (*ATG1*) is the key signal in autophagy induction, and is known to intervene in cell growth, differentiation and survival. MAP1LC3B is 1 of 3 human orthologs of the yeast protein Atg8, an autophagosome membrane marker. Upon induction of autophagy, Atg8 (cytosolic LC3-I) is cleaved and lipidated to form LC3-II. Investigation of the influence of these polymorphisms on gene function or expression will be essential to clarify their specific role in CD pathogenesis.

## 838/W/Poster Board #496

**Gene Expression Profiles Associated with Lack of Response to Intravenous Corticosteroids in Children with Severe Ulcerative Colitis.** *B. Kabakchiev[1,10], D. Turner[9], J. Hyams[5], D. Mack[4], N. Leleiko[7], W. Crandall[8], J. Markowitz[6], A. Otley[3], W. Xu[10], P. Hu[2], A. Griffiths[2], M. Silverberg[1,10].* 1) SLRI, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Toronto, ON, Canada; 3) Izaak Walton Killam Hospital, Halifax, NS, Canada; 4) Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Connecticut Children's Medical Center, Hartford, CT, USA; 6) Schneider's Children's Hospital, Long Island, NY, USA; 7) Brown University, Providence, RI, USA; 8) Columbus Children's Hospital, Columbus, OH, USA; 9) Shaare Zedek Medical Center, Jerusalem, Israel; 10) University of Toronto, Toronto, ON, Canada.

**Background**: Microarray analysis of RNA expression allows examination of specific pathways operative in inflammation. In the context of a multicenter pediatric study of outcomes and predictors of outcome in acute severe UC, we aimed to determine whether genes expressed in whole blood early following initiation of intravenous corticosteroid (IVCS) treatment can predict response. **Methods**: From a prospectively accrued cohort of 110 pediatric patients hospitalized for IVCS treatment of severe UC (mean PUCAI 73±12), we selected for analysis 10 steroid responsive (PUCAI<35 by day 5) and 10 steroid-refractory patients (persistence of PUCAI≥65 by day 5 and need for 2$^{nd}$ line medical therapy or colectomy by hospital discharge). Mean age of the twenty children was 14.5±2.2 yrs; mean disease duration 0.9±1.5 yrs.; mean PUCAI score at admission 75±11. Total RNA was extracted from blood samples collected on the 3$^{rd}$ day of IVCS therapy. The eluted transcriptomes were run on Affymetrix Human Gene 1.0 ST arrays and analysed by the LPE method for discovery of differentially expressed genes. False discovery rate (FDR) correction for multiple comparisons was applied to all p-values. **Results**: Our analysis returned 63 statistically significant genes whose transcript levels correlate with therapy outcome. A gene whose overexpression correlated strongly with IVCS refractoriness was *CD177*, a member of the *Ly-6* gene superfamily (FDR p = 3.29E-11). *CD177* is polymorphic and has at least two known alleles - *PRV-1* and *NB1* - encoding surface glycoproteins found on neutrophils. Other genes overexpressed in IVCS refractory subjects include defensin alpha 1 and alpha 3 (*DEFA1*, *DEFA3*, FDR p = 1.39E-07), genes also expressed primarily in neutrophils. By contrast, HLA DQ beta 1 (*HLA-DQB1*, FDR p = 0.002), a gene previously associated with UC, was more highly expressed in IVCS responsive subjects. Overall, at least one third of the 63 significant genes are known to be directly involved in the human inflammatory response and more specifically with neutrophils. Absolute neutrophil counts were similar among responders and non-responders (p = 0.98). **Conclusion**: Several genes involved in neutrophil function are associated with response to IVCS therapy early in the course of treatment. Gene expression profiles may be useful to predict response to IVCS in children with severe UC and assist with clinical management decisions. **Note**: B. Kabakchiev and D. Turner contributed equally to the abstract.

## 839/W/Poster Board #497

**Genetics of Gene Expressions under Perturbation of Environments.**
*S. Lai[1], X. Zhou[2], L. Luo[3], M. Xiong[3].* 1) Dept Pathology, BCM, Michael E DeBakey VA Med Ctr, Houston, TX; 2) Dept Internal Medicine, Univ. of Texas, Medical School at Houston, Houston, TX; 3) Department of Biostatistics, University of Texas School of Public Health, Houston, TX.

Complex phenotypes are the consequence of the interplay of genetic and environmental factors. Development of disease is a dynamic process of gene-gene and gene-environment interactions within a complex biological system which is organized into complicated interacting networks. Despite current enthusiasm for investigation of gene-environment interactions, published results that document these interactions in humans are limited, and the essential issue of how to define and detect gene-environment interactions remains unresolved. The concept of gene-environment interactions is often used, but rarely specified with precision. In this report, we developed longitudinal genetic models for investigation of dynamic gene-environment interactions influencing gene expressions under stimulus of environments. Specifically, gene expressions are taken as a quantitative trait. A locus influencing gene expression variation is referred to as eQTL. Time course gene expressions as responses to genetic and non-genetic perturbations are a function of time t. We can view the time-course gene expressions as a realization of a stochastic process and decompose them into mean function, and genetic additive effect and dominance effect functions using Fisher's factor analysis and variation method, which leads to a general genetic model of functional trait and formulates genetic effect functions as function of genotypic values and allele frequencies. As a proof of principle, the proposed models for studying dynamic gene-environment interaction were applied to 79 fibroblast strain obtained from our Tissue Culture Core of the Specialized Center of Research (SCOR) in Scleroderma. We use RT-PCR to measure expressions of the genes of COL1A2, COL3A1, CTGF, SPARC and TIMP3 with and without perturbation of 10 μg silica at 24-, 48-, 72-, 96- and 120-hour exposure. All 79 fibroblast strains were genotyped by Illumina 317K SNP array. After checking the quality of typed SNPs, total of 313,932 SNPs were left for analysis We identified 23, 9, 5, and 18 SNPs which interacted with silica to significantly affect the expression of genes CoL1A2, COL3A1, CTGF and TIMP3 under stimulus of silicon.

## 840/W/Poster Board #498

**Sequence variants in PPARG and TCF7L2 are associated with plasma calcium and glucose levels in an island population of the eastern Adriatic.**
*R.A. Karns[1], G. Zhang[1], N. Jeran[2], D. Havas[2], S. Missoni[2], G. Sun[1], H. Cheng[1], S.R. Indugula[1], J. Mallik[1], Z. Durakovic[2], R. Chakraborty[1], P. Rudan[2], R. Deka[1].* 1) Environmental Health, University of Cincinnati, Cincinnati, OH; 2) Institute for Anthropological Research, Zagreb, Croatia.

We performed an association analysis of 97 Single Nucleotide Polymorphisms (SNPs) in eight candidate genes (FTO, INSIG2, PPARG, MC4R, SLC30A8, CDKN2A, TCF7L2 and HHEX) with 17 metabolic traits in a sample of >950 unrelated adult individuals from the island of Hvar in the eastern Adriatic coast of Croatia. This population of Slavic origins, living in relative isolation for over 400 years, has a high prevalence (~26%) of metabolic syndrome despite maintaining traditional life style patterns and adherence to a Mediterranean diet. The traits include anthropometric, blood pressure measurements, fasting plasma glucose, insulin, total cholesterol, HDL-C, LDL-C, triglyceride, uric acid, calcium, creatinine, fibrinogen and HbA1c levels. SNPs were either selected from published GWAS (SNPs with genome-wide significance in FTO, INSIG2, MC4R, SLC30A8, CDKN2A, TCF7L2, and HHEX) or tagSNPs (FTO, INSIG2, and PPARG). Three SNPs maintain significance after permutation tests and Bonferroni adjustments (p values reported here are permutation p-values multiplied by the number of traits). Two SNPs in TCF7L2, rs7903146 and rs1225536, are significantly associated with fasting plasma glucose (p=.0042 and p=.0069, respectively) and HbA1c (p=.0031 and p=.0046, respectively). These results are consistent with previous findings that variants in TCF7L2 influence Type 2 diabetes related phenotypes. Our most important finding is an association between plasma calcium concentration and rs1152005, a tagging SNP downstream of PPARG (p=.011). Calcium dysregulation in platelets, reported in patients with diabetes, causes hyperactivity and increased aggregation of platelets. While variants in PPARG have been implicated in the development of obesity and diabetes, to our knowledge, this is the first reported association between a variant in or near PPARG and plasma calcium concentration. Eight SNPs, including five previously reported with genome-wide significance, within a 45Kb region in FTO show nominal significance with BMI and waist circumference. Although their significance do not hold after multiple test adjustments, the FTO region needs further investigation given the gene being strongly implicated in obesity related traits. The study is supported by NIH grant R01DK069845.

## 841/W/Poster Board #499

**Genome-wide haplotype association mapping in mice identifies a genetic variant in CER1 associated with bone mineral density and fracture in southern Chinese women.**
*YQ. Song[1], PLF. Tang[1], CL. Cheung[2], PC. Sham[3], P. McClurg[4], B. Lee[1], DK. Smith[1], JA. Tanner[1], AI. Su[4], KSE. Cheah[1], AWC. Kung[2].* 1) Dept Biochemistry, Univ Hong Kong, Hong Kong, hk, Hong Kong; 2) Department of Medicine, Univ Hong Kong, Hong Kong, hk, Hong Kong; 3) Department of Psychiatry, Univ Hong Kong, Hong Kong, hk, Hong Kong; 4) Genomics Institute of the Novartis Research Foundation, San Diego, USA.

**Introduction:** Osteoporosis is characterized by a decrease in bone mass, deterioration of bone tissue, impaired bone strength and increased fracture risk. It is a medically, socially, and economically important disease, especially among the aging population. Bone Mass Density (BMD) is a quantitative index of osteoporosis. Acquisition of bone mineral is a complex process involving genetics and environmental factors. **Methods:** A genome-wide Haplotype Association Mapping (HAM) approach was performed by using inbred mice strains which had been genotyped and phenotyped in the Mouse Phenome Project. In HAM, a dense SNPs map was first partitioned into blocks of three SNPs with an average length of 1Mb. Modified F-statistics were calculated for the whole genome to test if blocks exist where the haplotypes can partition inbred strains into high and low BMD groups. In this study, the candidate gene Cerberus 1 (Cer1) suggested from HAM analysis was eventually tested by a human case-control cohort of 1,083 subjects. **Results and conclusion:** In this study, we used a HAM approach to identify a haplotype block within Cer1 that partitions inbred mice strains into high and low BMD groups. A cohort of 1083 high and low BMD human subjects were studied and a non-synonymous SNP (rs3747532) in human CER1 was identified to be associated with increased risk of both low BMD in premenopausal women (OR 2.2; 95% confidence interval: 1.0 - 4.6; $p < 0.05$) and increased risk of vertebral fractures (OR 1.82, p=0.025) in the post-menopausal cohort. We also showed that Cer1 is expressed in mouse bone and growth plate by RT-PCR, immunohistochemistry and in situ hybridization, consistent with polymorphisms potentially influencing bone mineral density. Our successful identification of an association with CER1 in humans together with our mouse study suggests that CER1 may play a role in the development of bone or its metabolism.

## 842/W/Poster Board #500

**Negative association of CD244 with susceptibility and radiographic joint damage of rheumatoid arthritis in a Japanese population.**
*A. Tokita, K. Ikari, Y. Kawaguchi, A. Taniguchi, H. Yamanaka, S. Momohara.* Inst Rheumatology, Tokyo Women's Med Univ, Tokyo, Japan.

Recently, CD244 was reported to be associated with susceptibility to rheumatoid arthritis (RA) in a large Japanese RA cohort(1). To validate this association, we tested the association in another Japanese cohort. Further, since susceptible gene is often associated with disease severity, association between the CD244 SNPs and radiographic joint damage in the RA patients was studied. DNA samples of 1504 RA patients were obtained from the IORRA (Institute of Rheumatology RA cohort) DNA collection and 752 population-based controls were obtained from the DNA collection of Health Science Research Resources Bank (Osaka, Japan), which is entrusted by Pharma SNP consortium (Tokyo, Japan). All the RA patients fulfilled the American College of Rheumatology 1987 revised criteria for RA. Sharp/ van der Heijde score (SHS) of the hands at 5-year disease duration, which represents radiographic joint damage, were measured in 628 RA patients. Genotyping was performed using TaqMan assay for the CD244 SNPs, rs3766379 and rs6682654 (Applied Biosystems Japan). Associations of the SNPs with RA susceptibility were estimated by Chi-square test, and associations between the SNPs and SHS were analyzed using regression analysis. Genotype distributions for the SNPs were in Hardy-Weinberg equilibrium. The SNPs were not associated with RA in the tested populations. Odds ratio were 1.03 (P = 0.69) and 1.02 (P=0.72), respectively for rs3766379 and rs6682654. In addition, we could not detect the impact of the CD244 SNPs on SHS (P=0.71 and 0.43, respectively). We conclude that the CD244 SNPs is not associated with RA and radiographic joint damage in the tested Japanese population. The result indicates that more replication studies are needed to reveal the association between CD244 and RA susceptibility.

## 843/W/Poster Board #501

**Identification of *KIAA1529* as a novel susceptibility gene for Behçet's disease.** *A.H. Sawalha[1,2,3], Y. Fei[1,2], R. Webb[2,4], B.L. Cobb[2,5], J. Wren[2], H. Direskeneli[6], G. Saruhan-Direskeneli[7].* 1) Department of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; 2) Arthritis & Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK, USA; 3) US Department of Veterans Affairs Medical Center, Oklahoma City, OK 73104, USA; 4) College of Public Health, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; 5) JK Autoimmunity, Inc., Oklahoma City, OK, USA; 6) Division of Rheumatology, Department of Internal Medicine, Marmara University Medical School, Istanbul, Turkey; 7) Department of Physiology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey.

Behçet's disease is a chronic vasculitis characterized by recurrent orogenital ulcers, skin lesions, uveitis, recurrent venous thrombosis and arterial aneurysms. The disease also affects the brain, joints, and in some cases the gastrointestinal tract. Behçet's disease is poorly understood, and treatment options currently available are nonspecific and frequently ineffective. There is clear evidence to suggest a genetic contribution to the pathogenesis of Behçet's disease. The genetic association with HLA-B51 is the only established and repeatedly confirmed genetic association with this disease. The association in the HLA region, however, accounts for less than 20% of the genetic risk for Behçet's disease. We have performed the first genome-wide association scan (GWAS) in a cohort of 152 Behçet's disease patients and 172 ethnically-matched healthy controls using DNA pooling and the Affymetrix 500K arrays, followed by TaqMan® genotyping in individual samples in candidate susceptibility loci. Our results identified 5 novel candidate genes for Behçet's disease (*KIAA1529*, *CPVL*, *LOC100129342*, *UBASH3B*, and *UBAC2*). Cluster analysis of the GWAS data identified 14 SNPs in the *KIAA1529* locus (9q22) that are associated with Behçet's disease. Among the associated SNPs, the Behçet's disease risk allele in rs2061634 located within *KIAA1529* leads to the change in the amino acid at position 995 to cysteine (S995C) in the KIAA1529 protein (odds ratio= 2.04, 95%CI= 1.45-2.88, P value= 4.2X10-5). By identifying genes specifically and consistently co-expressed with *KIAA1529* over 3,651 human 2-color microarray datasets from NCBI's GEO, we used an algorithm to infer function using a "guilt by association" method. The 20 genes most closely matching *KIAA1529*'s expression trends (i.e., up and down-regulated with it) were analyzed for commonalities using a literature mining software (IRIDESCENT). Through these analyses, we predict that the transmembrane protein KIAA1529 is expressed on the nuclear membrane and is involved in nuclear trafficking.

**Psorasis prediction from genome-wide SNP profiles.** *S. Fang[1,2], X. Fang[2,3], M. Xiong[2].* 1) Breast Medical Oncology, The University of Texas M.D. Anderson Cancer Center, Houston, TX; 2) Human Genetics Center The University of Texas Health Science Center at Houston Houston, TX; 3) School of Mathematical Sciences, Bejing University, Beijing.

With the availability of high-throughput genotyping technology, data on hundreds of thousands of SNPs are available through genome-wide association studies (GWAS). One of main goals of GWAS is to identify an optimal set of SNPs that can predict disease status with greatest possible accuracy. Prediction of genetic risk will be increasingly useful in diagnosis, treatment, and prognosis of complex diseases. In this study, a new classifier, the sequential information bottleneck (sIB), was proposed to perform classification on a big dataset with 2,798 observations and 451,724 SNPs. We first reduced the GWAS feature set into a manageable one through an effective filter method and then performed a feature selection wrapped around a classifier to identify an optimal SNP subset for predicting psoriasis. To deal with an unbalanced distribution of positive and negative observations, HMSS was used as the performance measurement of the predictive models. This study aimed to select optimal subsets of SNPs with maximum classification performance for psoriasis prediction. Process for searching a set of SNPs to predict psoriasis consisted of two steps. The first step was to search top 1,000 SNPs with high accuracy for prediction of psoriasis from GWAS dataset. The second step was to search for an optimal SNP subset for predicting psoriasis. The sequential information bottleneck (sIB) method was compared with classical linear discriminant analysis for classification performance. A chi-square test was also performed to look at the relationship between each SNP and disease. The proposed methods were applied to a GWAS dataset of psoriasis with a total of 2,798 samples and 451,724 SNPs. The best test harmonic mean of sensitivity and specificity for predicting psoriasis by sIB was 0.6745. If the test accuracy in the case group or control group was required to be not less than 0.4, then the highest test accuracy of sIB in the other group (i.e., control or case) reached 0.8503 or 0.7494, respectively. The fact that a small set of SNPs can predict disease status with average accuracy of 0.68 is of great value in clinical practice.

## 845/W/Poster Board #503

**COPACETIC, a Genome-wide association study on chronic obstructive pulmonary disease (COPD).** *J. Smolonska[1], HM. Boezen[2], H. Groen[3], A.E. Dijkstra[3], D.S. Postma[3], M. Oudkerk[4], B. de Hoop[5], B. van Ginneken[6], W. Mali[4], J.W. Lammers[7], P. Zanen[7], C. Wijmenga[1], COPACETIC consortium.* 1) Department of Genetics UMCG, Groningen, Groningen, Netherlands; 2) Department of Epidemiology UMCG, Groningen, Netherlands; 3) Department of Pulmonology UMCG, Groningen, Netherlands; 4) Department of Radiology UMCG, Groningen, Netherlands; 5) Department of Radiology, UMCU, Utrecht, Netherlands; 6) Image Sciences Institute, UMCU, Utrecht, Netherlands; 7) Department of Pulmonology, UMCU, Utrecht, Netherlands.

Chronic obstructive pulmonary disease (COPD) is characterized by persistent, progressive airway obstruction that is a result of emphysema and chronic bronchitis. The disease is responsible for almost 5% of all mortalities. COPD is a complex genetic disease which is triggered by tobacco smoking and/or air pollution. Alpha1-antitrypsin deficiency is responsible for 1-2% of COPD cases whereas the remainder of the genetic factors is largely unknown. The aim of our study is to identify novel genetic factors for COPD using a genome-wide association study (GWAS). Study participants were recruited from the Nelson study, a 4-year follow-up study on the incidence of lung cancer in heavy-smokers of Dutch descent (>20 pack years). A GWAS was performed on 1273 individuals with obstruction, 1389 individuals with emphysema and 1083 "supercontrols" (i.e. individuals without airway obstruction and emphysema). In addition we have access to 900 blood bank controls with unknown smoking history. All samples were genotyped using Illumina Human610-Quad arrays. Furthermore, from nearly 600 individuals we obtained RNA expression data from peripheral blood lymphocytes on 48,000 transcripts using Illumina HT12 arrays. Genotyping has been finished recently and we are currently at the stage of quality control of the data. Our GWAS study on COPD is unique since it includes both CT scan data and lung function for each participant and detailed smoking history. Therefore we expect to identify loci associated with COPD in heavy-smokers and possibly also loci that distinguish between the different COPD phenotypes emphysema and airway obstruction. Expression data will allow us to link genetic variation to differences in gene expression levels and may assist in identifying the culprit genes. We will next proceed with replication of the top 384 SNPs in five independent cohorts comprising 3687 COPD cases and 10491 controls.

## 846/W/Poster Board #504

**Studies of Genetic and Phenotypic Variations under Environmental Stimulation.** *X. Zhou[1], L. Luo[2], X. Guo[1], F. Tan[1], F. Arnett[1], M. Xiong[2].* 1) Deptartment of Internal Medicine, University Texas, Medical School at Houston, Houston, TX; 2) Department of Biostatistics, University of Texas School of Public Health, Houston, TX.

Despite extensive searches for genes causing complex diseases, connections between DNA variation and complex phenotypes, which is essential for unraveling the pathogeneses of complex diseases and predicting variation in human health, has proved to be elusive. In the past several decades, biologists have mainly focused on testing association of single markers or haplotypes with diseases attempting to find connections between the genotype and phenotype. However, health states of individuals remain a complex, multidimensional phenomena. Clinical manifestations arise from integrated actions of multiple genetic substracts(such as mutation, insertion/deletion, copy number variation, RNA regulation, etc) and environmental factors (such as infections, nutrition, stress and activity), through dynamic, epigenetic, and regulatory mechanisms. The analytic tools for this simple approach are unable to take comprehensive looks at entire systems that lead to changes from genomic and environmental variation to complex phenotypic variation. Holistic views of complex path from genotypes to phenotypes holds a key to unravel the mechanism of diseases. In this report, we developed longitudinal genetic models for the investigation of genetics of time-course gene expressions under the perturbation of environments. We genotyped 79 fibroblast strains with the genome-wide single nucleotide polymorphism (SNP) profiling (Illumina Human 317 K SNP panel). We examined gene expression changes of COL1A2, COL3A1, CTGF, SPARC and TIMP3 of these fibroblasts at five different time points (0, 1, 2, 3, and 5 days) in response to silica stimulation. We identified 38, 27, 19, and 15 eSNPs significantly affecting the expression of genes COL1A2, COL3A1, CTGF and TIMP3 after silica stimulation, respectively.

## 847/W/Poster Board #505

**Small, hard macular drusen and peripheral drusen: Associations with *CFH* Y402H in the Inter99 Eye Study.** *J. Ek[1], I.C. Munch[2,3], L. Kessel[2], A. Linneberg[3], B. Sander[2], G.J. Almind[1], K. Brondum-Nielsen[1], M. Larsen[1,2].* 1) Med Genetics Lab Cen, Kennedy Center, Glostrup, Denmark; 2) Department of ophthalmology, Glostrup Hospital, University of Copenhagen, Denmark; 3) Research Centre for Prevention and Health, Glostrup Hospital, Copenhagen Denmark.

**Background:** Age-related macular degeneration (AMD) is the most common cause of legal blindness in elderly people. The hallmark of AMD is retinal drusen >125 μm consisting of extracellular deposits accumulated on Bruch's membrane below the retinal pigment epithelium. AMD is a complex disease with multiple environmental and genetic risk factors. Several single nuclear polymorphisms (SNPs) in genes encoding CFH, CFB, and LOC387715 are strongly associated to the development and progress of AMD. The presence of numerous small, hard retinal drusen < 63 μm is a highly hereditary feature that predisposes development of AMD but the association between this feature and AMD-related SNPs is unknown. **Objective:** To investigate the associations between the presence of ≥ 20 small, hard retinal drusen and other AMD-related retinal changes to known AMD-associated SNPs. **Participants:** The study included 1007 participants aged 30 to 66 years. **Methods:** Digital greyscale, red-free fundus photographs were graded for the presence of drusen and other fundus elements. The participants were genotyped for AMD-related polymorphisms in *CFH* (Y402H), *CFB* (R32Q and L9H), and *LOC387715* (A69S and rs11200638). **Main Outcome Measures:** Prevalence of ≥ 20 small, hard macular drusen per eye, stippling, macular drusen > 63μm, peripheral drusen and genotype associations. **Results:** The prevalence of ≥ 20 small, hard macular drusen, peripheral drusen and drusen > 63μm increased with age. Peripheral drusen were significantly associated with macular drusen > 63μm (OR 2.5 (CI95 1.2-5.4)) as was ≥ 20 small, hard macular drusen (1.7 (1.1-2.9)). The *CFH* Y402H polymorphism was associated with peripheral drusen (4.7 (1.5-15) for CC versus TT genotype) and macular drusen > 63μm (1.9 (1.1-3.1), for CC versus TT genotype) but not with ≥ 20 small, hard macular drusen. No further genotype associations were found. **Conclusions:** Although previous investigations have shown that the presence of many small, hard drusen is highly hereditary and related to future development of AMD, this study found no association between major genetic polymorphisms that predispose to AMD and the characteristic of having ≥ 20 small, hard macular drusen. This indicates the existence of additional, hitherto unidentified genotypes associated with AMD. Associations between peripheral drusen, macular drusen > 63μm and *CFH* Y402H were confirmed.

## 848/W/Poster Board #506

**The polygenic nature of open-angle glaucoma is supported by WDR36 acting as a modifier gene.** *V. Raymond[1], P. Belleau[1], K. Lebel[1], S. Dubois[1], R. Arseneault[1], J.L. Anctil[2], E. Shink[1], M.A. Rodrigue[1], G. Côté[2], M. Amyot[3], The Quebec Glaucoma Network.* 1) Biology of Sensory Systems and, Ocular Genetics & Genomics, CREMOG, Laval University Hospital (CHUL) Research Center, Québec City, PQ, Canada; 2) Department of Ophthalmology, Laval University, Québec City, PQ, Canada; 3) Department of Ophthalmology, Univ of Montréal, Montréal, PQ, Canada.

Open angle glaucoma (OAG) is primarily considered a common complex hereditary disease. More than 20 loci have been mapped for OAG but only three genes, *myocilin* (*MYOC*), *optineurin* and *WDR36*, have been implicated in mendelian forms of the disorder. To test for the polygenic nature of open-angle glaucoma we assessed if variations in *WDR36* changed the severity of OAG in heterozygotic carriers of *MYOC* mutations. To do so, we screened WDR36 variations and performed genotype/phenotype correlation studies in a large French-Canadian glaucoma family in which the primary disease-causing mutation was the MYOC K423E variation. One hundred and forty-two (142) MYOC K423E heterozygotes were investigated. Ninety-five (95) of them were diagnosed with either juvenile OAG (JOAG, a severe form of OAG diagnosed at or before 35 years old), primary OAG (POAG, diagnosed after 35 years of age), or intraocular hypertension (OHT) with treatment. Nineteen (19) were OHT without treatment, while the remaining 28 carriers were asymptomatic. All 23 exons of *WDR36* were screened for variations in these 142 heterozygotes. Our screening revealed that 24 heterozygotes carried simultaneously the MYOC K423E mutation plus one of five non-synonymous amino acid changes in WDR36. These individuals were named double variants. Since almost all K423E carriers had yearly ocular examinations, we determined age-at-onset (AAO) of the disorder in each one of them, and assessed for an effect of WDR36 variations on AAO by comparing AAO of glaucoma in the double variants versus the median of AAO of MYOC K423E carriers who were WDR36 wild-type and shared a kinship coefficient equal to or less than 0,0625 with their respective double variants. Of the 24 double variants detected, 18 had a neighborhood available for such comparison. Of these 18 double variants, 10 showed AAOs younger than the median AAO of their neighborhood while 5 of them displayed similar AAO. Surprisingly, 4 of these 10 double variants harbored the D658G WDR36 variation and showed an AAO 10 years or younger than the medians of their neighborhood. Two other double variants also displayed younger AAOs. We conclude that three WDR36 variants acted as susceptibility modifier genes by increasing glaucoma severity in heterozygotes for the MYOC mutation. Our findings support the polygenic inheritance of open-angle glaucoma and support *WDR36* as a modifier gene.

## 849/W/Poster Board #507

**Comparative Haplotypic Congruence Analysis of Addison's Disease and Type 1A Diabetes.** *E.E. Baschal, J.C. Siebert, T.M. Triolo, T.K. Armstrong, J.M. Jasinski, K.N. Johnson, S.R. Babu, P.A. Gottlieb, P.R. Fain, J.M. Barker, M.J. Rewers, G.S. Eisenbarth.* Barbara Davis Center, University of Colorado Denver, Aurora, CO.

Addison's disease (AD) is a rare autoimmune disorder of the adrenal cortex that affects approximately 1:10,000 individuals. AD is associated with type 1 diabetes (T1D), with the highest risk HLA genotype for AD being DR3-DQB1*0201/DRB1*0404-DQB1*0302. We analyzed HLA-DR-DQ-stratified patients with AD (N=70) and T1D [Type 1 Diabetes Genetics Consortium (T1DGC): 2300 affected sibling-pairs and their parents genotyped for both SNPs and HLA alleles across the MHC region, N=2873 T1D patients]. The HLA-B8 allele is greatly increased in patients with AD compared to controls and to those with T1D [DR3+ individuals (%B8+): AD 51/56 (91%) vs. DR3/4 controls 174/271 (64%), p=1.9E-6, odds ratio=6.3; AD vs. T1D patients 1775/2873 (62%), p=2.9E-5, odds ratio=5.7]. In that 91% of all DR3+ AD cases had B8, AD may be associated with the DR3-B8-A1 extended HLA haplotype. The DR3-B8-A1 haplotype is conserved for millions of base pairs as revealed by high density MHC SNP typing. Data from the exon-centric Illumina SNP panel were analyzed for 35 of the AD patients, and 96% of those with DR3-B8 have SNPs matching the DR3-B8-A1 extended haplotype. AD patient chromosomes were phased by comparing genotypes to the DR3-B8-A1 consensus sequence established in homozygous DR3-B8-A1 AD patients and phased T1DGC chromosomes. We developed a computerized algorithm to evaluate long-range SNP congruence between chromosomes. Our congruence methodology attempts to find a long contiguous SNP identity (e.g., 100 contiguous SNPs) that characterizes a high percentage of the chromosomes. We inspected multiple overlapping 100-SNP sequences across the MHC, ranging from position 29,299,390 to 33,883,424 Mb. These analyses demonstrate that regions that approached or were at 100% congruence were similar for AD DR3-B8 chromosomes and T1DGC control DR3-B8 chromosomes. In addition, AD DRB1*0404 chromosomes showed a region of 100% congruence not seen in DRB1*0404 chromosomes from T1D patients or controls. We conclude that the DR3-B8 conserved extended haplotype is particularly and uniquely high risk for AD (DR3-B8-A1 is lower risk for T1D), and the DRB1*0404 haplotype in AD patients may be particularly congruent between 31,947,288 and 32,326,821 Mb, which encompasses the 21-hydroxylase gene (CYP21A2), a candidate gene for AD. The 21-hydroxylase molecule is the major adrenal autoantigen targeted by antibodies in AD.

## 850/W/Poster Board #508

**NPSR1 polymorphisms affect neuropeptide S receptor function and expression.** *M. D'Amato[1], F. Anedda[1], D. Schepis[2], G. McInerney[2], A. Hellquist[1], L. Corrado[3], A. Achour[4], M. Zucchelli[1], J. Kere[1].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Stockholm, Sweden; 2) Department of Microbiology Tumor and Cell Biology, Karolinska Institutet, Stockholm, Sweden; 3) Department of Medical Sciences and IRCAD, University of Eastern Piedmont, Novara, Italy; 4) Center for Infectious Medicine, Karolinska Institutet, Stockholm, Sweden.

Background: The neuropeptide S (NPS) receptor gene, NPSR1, is mainly expressed in the brain and in enteroendocrine cells, but increased levels have been detected in lymphocytes and mucosal epithelia of asthma and inflammatory bowel disease (IBD) patients. Although still poorly characterized, the NPS-NPSR1 system appears to act along the gut-brain axis, and to contribute to the modulation of responses to stress, anxiety, nociception and inflammation. Remarkably, NPSR1 polymorphisms have been shown to associate with asthma, IBD and rheumatoid arthritis, but causative variations have not yet been identified. The NPSR1 gene spans 200 kb on chromosome 7p15, and more than 1400 SNPs have been described in different ethnic populations. To gain insight into the mechanisms leading to NPSR1 disease-predisposing effects, we performed functional analyses of all its promoter and coding SNPs occurring in Caucasians. Methods: NPSR1 promoter was predicted with bioinformatic tools. Five SNPs mapping within this region were studied by means of electrophoretic mobility shift assays (EMSAs), luciferase reporter assays on NPSR1-expressing Colo205 cells transfected with promoter variants, and Real-Time PCR quantification of NPSR1 expression in whole blood samples from genotyped healthy donors. Molecular modeling was used to evaluate the effect of four coding SNPs on receptor structure. NPSR1 coding variants were transfected in NPSR1-negative HEK293 cells, to evaluate their expression on the cell membrane by immunofluorescence and FACS analysis. Relative potency and specificity of NPSR1 downstream signaling was studied by microarray whole transcriptome analysis of HEK293 cells transfected with individual NPSR1 coding variants and stimulated with NPS. Kinetics studies (specific dose- and time-dependent responses to NPS) were performed on HEK293 cells co-transfected with NPSR1 coding variants and either cAMP response element binding (CREB-) or mitogen-activated protein kinase (MAPK/JNK- and MAPK/ERK-) driven luciferase reporter constructs. Results: One promoter SNP correlated with both altered luciferase activity and a significant effect on NPSR1 mRNA expression in white blood cells. Three NPSR1 coding variants were associated with considerable changes in receptor properties and signaling capacity. Conclusion: Specific SNPs at the NPSR1 locus affect receptor function and expression. Previous associations with disease(s) should be re-evaluated in the light of these findings.

**Genetic predisposition to asthma in Mexican pediatric patients.** *S. Jimenez-Morales[1], N.E. Martínez-Aguilar[2], B.E. Del Rio-Navarro[3], J.L Jiménez-Ruíz[1], F. Cuevas[4], J. Gómez-Vera[5], G. Escamilla-Guerrero[6], E. Navarro-Olivos[7], R. Gamboa-Becerra[8], D.Y. López-Ley[8], Y. Saldaña-Alvarez[1], L. Orozco[1,9].* 1) Laboratorio de Enfermedades Complejas, Instituto Nacional de Médicina Genómica, Mexico City, Mexico Periferico Sur 4124, Torre Zafiro II, ExRancho de Anzaldo, Méx., D.F., Mex. CP 01900; 2) Servicio de Alergia, Hospital Regional 1° de Octubre, ISSSTE; 3) Departamento de Alergia, Hospital Infantil de México; 4) Departamento de Neumología y Cirugía de Tórax, Instituto Nacional de Pediatría; 5) Servicio de Alergia, Hospital Regional Adolfo López Mateos, ISSSTE; 6) Banco de Sangre, Instituto Nacional de Pediatría; 7) Programa de Maestría en Ciencias Médicas, Instituto Politécnico Nacional; 8) Programa de Licenciatura en Farmacobiología, Universidad Autónoma de Chiapas; 9) Programa de Posgrado en Ciencias Genómicas, Universidad Autónoma de la Ciudad de México.

Introduction: Asthma is an inflammatory chronic airway disease, which shows a high prevalence in Mexican population; actually the epidemiological studies suggest that nearby of 15% of the childhood population has asthma. Increasing evidences show that this disease has a highly complex genetic background and important ethnicity differences. At least one hundred candidate genes have been associated with this disease so far. Objective: The present study was undertaken to investigate the genetic risk factors associated with asthma in Mexican pediatric patients. Methods: Two hundred and forty one unrelated asthmatic patients from four tertiary Medical Centers in Mexico City and 400 healthy blood donor controls were included. All patients were diagnosed by a pediatric pneumologist or alergologist. Genotyping of 95 single nucleotide polymorphisms (SNPs) in 29 candidate genes was performed using TaqMan assay. False association due to stratification of the samples was discarded analyzing 10 informative markers which have been validated in previous analyses performed in Mexican population. To evaluate Hardy-Weinberg equilibrium we used FINETTI software. Stratification, haplotypes and statistical analyses were performed using STRUCTURE, STRAT, HAPLOVIEW and EPIINFO programs. Results: In this study we identified five genes associated to asthma: two as new genetic risk factors (CHRM2 and STAT1) and three previously reported (IL13, TNFa and MMP9). Four SNPs located in CHRM2 (rs324640:p= 0.04, rs324650: p= 0.03, rs8191992: p= 0.001 y rs6962027: p= 0.01), two in STAT1 (rs2280234: p= 0.0367 and rs2030171: p= 0.009), two in IL13 (rs1881457: p= 0.009 y rs1800925: p=0.05), one in TNFa (-308 GA: p= 0.014) and two in MMP9 (rs2274755: p= 0.002 y rs2274756: p=0.003).) showed significantly differences between cases and controls. On the other hand, some differences between cases and controls in the distribution of genotypes of CSF2, PDCD1, FCRL3 genes were observed. Conclusion: Complex genetic predisposition to asthma in pediatric Mexican patients was observed, inasmuch as only five of the 29 genes studied are associated with asthma in our sample. To know if these genes could be associated with severity of the disease, the number of patients is being increased.

## 852/W/Poster Board #510

**Role of IBD Risk Factor *MAST3* in TLR4 Signaling.** *C. Labbe[1], G. Charron[1], P. Goyette[1], C. Stevens[2], T. Green[2], M.K. Tello-Ruiz[2], Z. Cao[3], A.L. Landry[3], J. Stempak[4], V. Annese[5], A. Latiano[5], S. Brant[6], R. Duerr[7], K. Taylor[8], J. Cho[9], A.H. Steinhart[4], M. Daly[2], M. Silverberg[4], R. Ramnik[3], J.D. Rioux[1].* 1) Université de Montréal, Montreal Heart Inst, Montreal, PQ, Canada; 2) The Broad Institute of MIT and Harvard, Cambridge, MA; 3) Center for Computational and Integrative Biology and Gastrointestinal Unit, MGH, Harvard, Boston, MA; 4) Mount Sinai Hospital IBD Center, U. of Toronto, Toronto, On, Canada; 5) Gastrointestinal and Endoscopy Units, I.R.C.C.S. Hospital, San Giovanni Rotondo, Italy; 6) Meyerhoff Inflammatory Disease Center, Johns Hopkins University School of Medicine, Baltimore, MD; 7) School of Medicine, University of Pittsburgh, Pittsburgh, PA; 8) IBD center, Cedars-Sinai Medical Center, Los Angeles, CA, USA; 9) IBD Center, Department of Medicine, Yale University, New Haven, CT.

Inflammatory bowel disease (IBD) is a chronic disorder caused by multiple factors in a genetically susceptible host. Significant advances in the study of genetic susceptibility have highlighted the importance of the innate immune system in this disease. We previously completed a genome-wide linkage study and found a significant locus (IBD6) on chromosome 19p. We identified IBD risk factor *MAST3* through a two-stage association study of the region. We identified four *MAST3* coding variants, including a non-synonymous SNP rs8108738, associated to IBD. *MAST3* belongs to a gene family of serine/threonine protein kinases. To test whether *MAST3* was expressed in cells of interest, we performed expression assays which showed abundant expression of MAST3 in antigen presenting cells and in lymphocytes. The knockdown of *MAST3* specifically decreased TLR4 dependent NF-κB activity. In an effort to characterize the precise role of MAST3 in inflammation in general and in the TLR4 pathway leading to the activation of NF-κB specifically, we are studying: 1. the interactions of MAST3 with other proteins in the pathway (using a biotin/avi tag approach as well as a candidate protein approach) 2. the effects of MAST3 on phosphorylation of the partners in the TLR4-NF-κB pathway 3. the effects of the rs8108738 genotype on the expression of *MAST3* and pro-inflammatory cytokines downstream of the signaling cascade. In this genome-wide association studies era, one of the greatest challenges that geneticists are faced with is to understand the biological role of the numerous genes identified through association studies. Our findings highlight a role for MAST3 in the TLR4 pathway leading to the activation of NF-κB and provide additional proof of the pivotal role played by modulators of NF-κB activity in IBD pathogenesis.

## 853/W/Poster Board #511

**Association of polymorphisms in SPINK5 with atopic dermatitis is replicated in Korean.** *J. Namkung[1,2], J. Yang[1,3].* 1) Samsung Medical Center, Seoul; 2) Bioinformatics Program, Seoul National University, Seoul; 3) Department of Dermatology, Sungkyunkwan University School of Medicine, Seoul.

Background: Atopic dermatitis (AD) is a chronic inflammatory skin disease that is characterized by intense itching and significantly deteriorates life quality. The importance of AD is growing as the prevalence increase in developed countries. Mutations in the gene encoding serine protease inhibitor Kazal-type 5 (SPINK5) has been reported to be responsible for Netherton syndrome, a severe recessive congenital skin disease associated with atopy. Recent studies reported that numbers of single nucleotide polymorphisms (SNPs) in SPINK5 are associated with AD in Japanese. Method: We genotyped 21 SNPs in SNPINK5 for 631 patients with AD and 459 normal controls. AD can be classified as extrinsic and intrinsic types based on the existence of manifest allergic reaction or not. Among our 631 AD patients, 417 presented extrinsic type of AD (ADe) and 214 presented intrinsic type (ADi). Association between SNPs and AD was tested using age, sex adjusted logistic regression. Haplotype association was also tested for haplotypes constructed across sliding windows of sizes 2-4 using haplo.stats in R package. Association test was conducted for severity for AD (SCORAD) index, total IgE level, eosinophil count, and eosinophilic cationic protein level. Result: Significant association was detected with rs17718511, rs17860502 (D106N), rs60978485, rs17718737 (A617A) in the single SNP analysis. None of the SNPs showed significant association with ADi. Three locus haplotype of rs60978485, rs6892205 (Q267R), rs2303064 (D386N) showed significant association with AD. This haplotype had OR 0.687 (95% CI: 0.501- 0.941) for ADe with the p-value of 0.02. Haplotypes of the three loci (rs2303067 (K420E), rs880687 (G518G), rs41291431) showed the most significant association with log-transformed eosinophil counts (p-value=0.003). Previously we have reported that SNPs in DEFB1 are associated with ADe. In order to find the most significantly associated interacting pair of SNPs from the two genes, we conducted gene-gene interaction analysis using imputeMDR in R packages. ImputeMDR allows the multifactor dimensionality reduction (MDR) analysis in the presence of missing values. The statistical significance and the effect size for the selected SNP pair via logistic regression. As a result, the alleles of the rs60978485 in SPINK5 and rs5743399 in DEFB1 act additively to increase the susceptibility of ADe. Conclusion: Our result replicates the association of SNPINK 5 with AD in Korean.

## 854/W/Poster Board #512

**Genetic association studies of IL-13 gene in adult asthma in Japanese populations.** *M. Tamari[1], T. Hirota[1], M. Harada[1], Y. Hitomi[1], A. Miyatake[2], Y. Suzuki[3], Y. Nakamura[4].* 1) Lab Resp Dis, RIKEN Ctr Genomic Medicine, Yokohama, Japan; 2) Miyatake Asthma Clinic, Osaka, Japan; 3) Public Health Dept, Chiba Univ, Chiba, Japan; 4) Lab Mol Medicine, Hum Genome Ctr, The Univ of Tokyo, Tokyo, Japan.

(Background) Interleukin (IL-) 13 is a crucial mediator of allergic inflammation and induces airway hyperreactivity, epithelial cell damage, eosinophilia and goblet cell hyperplasia with mucus hyperproduction. Recent study has shown that *IL-13* polymorphisms are associated with allergic phenotypes. To assess genetic variants of *IL-13* related to susceptibility and clinical phenotypes in adult asthma, we conducted association analyses. Bronchial epithelial cells play a central role in the Th2-cell sensitization process by influencing the function of DCs and target cells of IL-13. The proinflammatory chemokines chemokine (C-C motif) ligand (CCL) 5 and chemokine CXC ligand (CXCL) 8 initiate airway inflammation by enhancing inflammatory cell recruitment, and a recent study has shown that poly(I:C) induces the synthesis of these chemokines by bronchial epithelial cells. We investigated whether IL-13 affects the poly(I;C)-induced chemokine expression in normal human bronchial epithelial cells (NHBE). (Method) After screening for polymorphisms, we identified a total of 14 variants and conducted linkage disequilibrium (LD) mapping. Pairwise LD was measured among 10 SNPs with a frequency of greater than 10%. Four variants (rs1881457, rs1800925, rs2066960, rs20541) were selected for genotyping, and these SNPs captured 10 of 10 alleles with a mean $r^2$ of 1.00. Genotyping was performed by the TaqMan allele-specific amplification method. The expression of *CCL5* and *CXCL8* was determined by real-time quantitative reverse transcription polymerase chain reaction (RT-PCR) using SYBR Premix Ex Taq. (Results) We found significant associations between the SNPs of the *IL-13* gene and adult asthma susceptibility in two independent case-control studies. (P = 0.00086, OR=1.81; P = 0.00068, OR=1.80; meta-analysis). We also found that *IL-13* polymorphisms were significantly associated with susceptibility to aspirin-induced asthma and asthma severity. We could confirm that IL-13 enhanced mRNA levels of *CCL5* and *CXCL8*, which were induced by poly(I:C) in NHBE. (Conclusion) These findings suggest that the *IL-13* gene variants are involved in the development of adult asthma, asthma severity, and susceptibility to AIA through genetic polymorphism in the Japanese population, and IL-13 appears to influence chemokine induction in airway epithelial cells during viral infections.

## 855/W/Poster Board #513

**Caspase-12 and the inflammatory response to Yersinia pestis.** *B. Ferwerda[1], M.B.B. McCall[1,2], M.C. de Vries[3], J. Hopman[2], B. Maiga[4], A. Dolo[4], O. Doumbo[4], M. Daou[4], D. de Jong[5], L.A.B. Joosten[1], R.A. Tissingh[3], F.A.G. Reubsaet[3], R. Sauwerwein[2], J.W.M. van der Meer[1], A. van der Ven[1], M.G. Box 9101, 6500 HB Nijmegen, The Netherlands.

Caspase-12 functions as an antiinflammatory enzyme inhibiting caspase-1 and the NOD2/RIP2 pathways. It has been proposed that due to increased susceptibility to sepsis in individuals with functional caspase-12, an early-stop mutation leading to the loss of caspase-12 has replaced the ancient genotype in Eurasia and a significant proportion of individuals from African populations. In African-Americans, it has been suggested that caspase-12 inhibits the pro-inflammatory cytokine production. We assessed whether similar mechanisms are present in African individuals, and whether evolutionary pressures due to malaria and plague may have led to the present caspase-12 genotype population frequencies in Africa and Eurasia. Whole blood was collected in two independent African populations. Whole blood stimulation with the TLR4 and TLR2 ligands lipopolysaccharide (LPS) and Pam3Cys was conducted. Stimulation with three pathogenic Yersinia species, namely Y. enterocolitica, Y. pseudotuberculosis and Y. pestis was done in one of the African populations. From all volunteers the caspase-12 genotype was also determined. To investigate if Yersinia spp recognition involved the NOD2/RIP2 pathway a total of 10 Dutch Caucasian controls and 5 Dutch Caucasian volunteers homozygous for the loss-of-function 3020insC NOD2 mutation were used for the stimulation experiments. No difference in cytokine induction through the caspase-1 and/or NOD2/RIP2 pathways was observed in two independent African populations, among individuals with either an intact or absent caspase-12. In addition, stimulations with Yersinia pestis and two other species of Yersinia were preformed to investigate whether caspase-12 modulates the inflammatory reaction induced by Yersinia. We found that caspase-12 did not modulate cytokine production induced by Yersinia spp., although we demonstrate for the first time the involvement of the NOD2/RIP2 pathway for recognition of Yersinia. Caspase-12 does not modulate innate host defense against Gram-negative bacteria and Y. pestis. Hereby it is unlikely that pathogenic selective pressure leading to sepsis caused the loss of caspase-12 in Eurasia. Therefore alternative explanations for the geographical distribution of caspase-12 should be sought.

**Several of the genes showing association to SLE in the recent GWA studies are associated and show evidence of gene-gene interaction in the Finnish population.** *A. Hellquist[1], T.M. Jarvinen[1,2,3,4], M. Zucchelli[1], S. Koskenmies[3,5], H. Julkunen[6], M. D'Amato[1], U. Saarialho-Kere[2,7], J. Kere[1,3,4].* 1) Dept Bioscience & Nutrition, Karolinska Inst, Huddinge, Sweden; 2) Departments of Dermatology University of Helsinki, Helsinki, Finland; 3) Medical Genetics, University of Helsinki, Helsinki, Finland; 4) Folkhälsan Institute of Genetics, Helsinki, Finland; 5) Department of Dermatology, Helsinki University Central Hospital, Helsinki, Finland; 6) Peijas Hospital, Helsinki University Central Hospital, Vantaa, Finland; 7) Section of Dermatology and Department of Clinical Science and Education, Karolinska Institutet at Stockholm Söder Hospital, Stockholm, Sweden.

Systemic lupus erythematosus (SLE) is a complex autoimmune disease, characterized by production of pathogenic autoantibodies against self. This subsequently leads to the formation of immune complexes, followed by tissue inflammation in multiple organs. The genetic component in SLE is strong and in the last couple of years we have seen a dramatic increase of identified and confirmed SLE genes and loci by genome wide association (GWA) studies. We have analyzed SNPs in several genes shown to be associated in the recent GWA studies, including *STAT4*, *PXK*, *BANK1*, *ATG5*, *TNFAIP3*, *ICA1*, *IRF5/TNPO3*, *XKR6*, *BLK/FAM167A*, *LYN*, *KIAA1542*, *LRFN5*, *ITGAM*, *SCUBE1* and rs10798269 on chromosome 1q25.1 in a Finnish SLE cohort consisting of 275 SLE patients and 356 healthy controls. Strong associations were seen to several SNPs in STAT4 (best $P = 1.12 \times 10^{-6}$, OR = 1.92), *IRF5/TNPO3* (best $P = 2.06 \times 10x\ 10^{-7}$, OR = 1.95) and *ITGAM* (best $P = 8.29 \times 10^{-6}$, OR = 2.13). Furthermore, several SNPs in *TNFAIP3* (best $P = 4.50 \times 10^{-3}$, OR = 2.86) and *BLK/FAM167A* (best $P = 1.50 \times 10^{-3}$, OR = 1.52) showed significant but more modest association. Borderline significance was also seen for one SNP in *BANK1* (P = 0.04, OR = 1.30) and one SNP in *KIAA1542* (P = 0.02, OR = 1.35). None of the analyzed SNPs in *PXK*, *ATG5*, *ICA1*, *LYN*, *LRFN5* and *SCUBE1* showed significant association to SLE in our Finnish cohort, possibly due to low power. It has been suggested that gene-gene interaction may contribute to the risk of developing SLE and thus we wanted to investigate if any of the genes included in the present study have epistatic effects. A multiple logistic regression under a codominant model was used to test gene-gene interaction by adding an interaction term between the genotypes of interest using the R software v. 2.6.2 (www.r-project.org). Our preliminary results suggest epistatic interaction between SNPs in *STAT4* and *BANK1*, *STAT4* and *IRF5/TNPO3*, *BANK1* and *IRF5/TNPO3*, *ATG5* and *LYN*, *BLK/FAM167A* and *ITGAM*. In summary we have replicated several of the previously associated GWA genes in our Finnish SLE cohort, further supporting their importance in SLE pathogenesis. In addition we show preliminary evidence of epistasis, or gene-gene interaction between several of these genes.

## 857/W/Poster Board #515

**Replication of 5q22.1 region for Intraocular Pressure in Mongolian population by linkage and Association analyses: The GENDISCAN Project.** *M. Lee[1], J. Sung[1], S. Cho[1], J. Kim[2], J. Seo[2], H. Kim[2].* 1) Department of Epidemiology, Seoul National University, Seoul, Korea; 2) Department of Biochemistry and Molecular biology, Seoul National University College of Medicine.

Primary open-angle glaucoma (POAG) is the most common type of glaucoma, the second most frequent cause of visual impairment worldwide, and elevated intraocular pressure (IOP) is an important risk factor. A study using healthy population, particularly Asians, has academic and public health significance, since genetic studies of IOP have been mainly accomplished in glaucomatous families among Caucasians. The GENDISCAN study recruited large families from two isolated populations (Selenge and Dashibalbar) in Mongolia. IOP level, epidemiologic data, and clinical information were collected. Selenge population comprised 1451 individuals from 142 families and 390 short tandem repeat (STR) markers were genotyped. In Dashibalbar we collected 1490 individuals from 95 families and the genotyping is done with 1097 STR markers, and 610K genome-wide SNPs (Illumina) for 652 individuals. Candidate loci underlying IOP variation were investigated, using variance component-based genome-wide linkage analysis (SOLAR). We performed a family-based association analysis on chromosome 5, of which linkage evidence was replicated in both Mongolian populations. The heritabilities of IOP level among two populations were 0.48 and 0.50, adjusted for age, sex and age by sex interaction. The 5q22.1 region showed linkage signal: LOL score of 2.4 for Selenge and LOD of 2.05 for Dashibalbar. Genome-wide association analysis revealed two candidate genes, Zinc Finger protein 608 (ZNF608) and WD repeat domain 36 (WDR36), which are 1Mb apart. In test (Dashibalbar) we found closely-located 9 significant SNPs (p-value <0.0005) in ZNF608. The most significant SNP was rs12659606 (p-value=1.889e-07). We also detected a haplotype with 7 SNPs (p-value = 0.0009). In WDR36, associated with POAG in previous studies, we identified 4 SNPs and a haplotype with 8 SNPs with statistical significance. C alleles on rs7723819 increased IOP level by 7% and 2% for having one more C allele (WDR36, C allele frequency 0.39%). Our findings indicate that quantitative trait loci (QTL) regulating IOP in the general population are linked to regions harboring POAG genes, suggesting a QTL influence both normal variation and disease occurrence. This provides a new example showing that some genes may regulate both normal variation and the development of disease. In addition, the common genes shared in Whites and Mongolians suggest that the mutation causing high IOP and glaucoma should be old in the history of human evolution.

## 858/W/Poster Board #516

**Differential expression of microRNAs in peripheral blood mononuclear cells of Multiple Sclerosis patients.** *G. Solda'[1], E.M. Paraboschi[1], D. Gemmati[2], P. Zamboni[3], S. Duga[1], R. Asselta[1].* 1) Dipartimento di Biologia e Genetetica per le Scienze Mediche, Università degli Studi di Milano, Milan, Italy; 2) Center of Hemostasis and Thrombosis, University of Ferrara, Ferrara, Italy; 3) Vascular Diseases Center, University of Ferrara, Ferrara, Italy.

MicroRNAs (miRNAs) are a class of short (21-23 nucleotides) single-stranded RNAs that modulate the expression of multiple target mRNAs by inducing either translational repression or mRNA degradation. MiRNAs have emerged has key post-transcriptional regulators of diverse biological processes and their deregulation has been implicated in several complex human diseases, including neurodegenerative and inflammatory disorders. Multiple sclerosis (MS) is a multifactorial disease of the central nervous system characterized by chronic inflammation, demyelination, axonal damage, and progressive neurological dysfunction. In spite of extensive research, the molecular events involved in the initiation and progression of MS are still poorly understood. To be relevant for MS pathogenesis, candidate genes would be expected to be expressed either in tissues relevant for immune response, or in tissues affected by the disease process. Several miRNAs are known to be expressed specifically in the immune system and miRNA-dependent alterations in gene expression in hematopoietic cells are critical for mounting an appropriate immune response. Moreover, deregulation of hematopoietic-specific miRNA expression may result in defects in both central and peripheral tolerance. Therefore, we sought to explore the possible involvement of miRNAs in MS by monitoring for differential expression of specific miRNAs in peripheral blood mononuclear cells (PBMCs) of Italian MS patients and healthy controls. We selected a set of 22 candidate miRNAs that are expressed in the immune system and/or are transcribed from previously reported MS susceptibility loci. The differential expression of candidate miRNAs in cases versus controls was evaluated using a microbead-based technology. In a pilot experiment, performed on PBMC RNA of relapsing-remitting MS patients and controls, 4 miRNAs resulted >3 folds up-regulated in MS vs controls, whereas only the miR-150 resulted down-regulated (2-fold decrease). Interestingly, two of the most up-regulated miRNAs, mir-155 and mir-146a, have been reported to be altered also in rheumatoid arthritis and systemic lupus erythematosus, suggesting shared pathogenic mechanisms between different chronic inflammatory diseases. This is, to our knowledge, the first evidence that the expression of specific miRNAs is altered in MS.

**Clinical features of mitochondrial encephalopathy, lactic acidosis and stroke-like episodes syndrome (MELAS) in 47 Chinese families.** *Y. MA[1], F. FANG[2], Y. CAO[1], Y. ZHANG[1], S. WANG[1], Y. YANG[3], Y. XU[1], P. PEI[1], Y. QI[1].* 1) Central Lab, Peking Univ First Hosp, Beijing, China; 2) Neurology Dept, Beijing Children's Hospital, Beijing, China; 3) Pediatrics Dept, Peking University First Hospital, Beijing, China.

Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes syndrome (MELAS) is the most common form of mitochondrial encephalomyopathy. Molecular genetic studies have shown that 80% of MELAS patients have the A3243G mtDNA mutation. In order to further elucidate the symptoms and clinical course of MELAS patients and their relatives in larger population, the clinical symptoms, natural history, characteristics of inheritance, mitochondria-related complication of 47 Chinese families were analyzed. 47 MELAS patients known to harbor A3243G mutation and their 61 maternal relatives including proband's mothers and siblings were colleted and analyzed. Informed consent in accordance with the Helsinki Declaration was obtained from all participants. The age of probands ranged 2-36 years old (mean ± SD = 11.18 ± 6.51 years), and the male to female ratio is 1.35. The age of probands' mother ranged 27-57 years old (mean ± SD = 39.04± 6.96 years), and the age of probands' siblings ranged 3 months to 40 years old (mean ± SD = 17.09± 13.34 years) and the male to female ratio is 1.8. The lactic acidaemia (100%), exercise intolerance (97.5%), seizures (89.4%), short stature (89.4%), hairiness (89.4%) and weight loss (85.1%) are the most common clinical features in probands. 59.6% probands' mother have not any symptom, and lactic acidaemia (40.4%), exercise intolerance (36.2%), short stature (21.3%), weight loss (34.0%) are the most common clinical features in their mothers. And they have no symptoms of stroke-like episodes, seizures and hairness. A3243G mutation ratio of probands was 11.1~70.0% (40.45 ± 12.65) in blood and 48.8~91% (67.47 ± 12.65) in urine. Positive A3243G mutation was found in blood in 32 mothers with the ratio of 2.7~50% (14.23±10.85), in urine in 42 mothers with the ratio of 4.6~76.1% (35.63±17.10). A3243G were not detected in 5 mothers. In MELAS patients and their mothers A3243G mutation ratio is significantly higher in urine than in blood (p<0.01). 3 siblings whose mother carries A3243G mutation have no A3243G mutation. In conclusion, (1) lactic acidaemia, exercise intolerance, seizures, short stature, hairiness and weight loss are the most common clinical feature, but not the "stroke" in younger patients; (2) measurement of A3243G mutation ratio in urine is more powerful than that in blood; (3) the probands' A3243G mutation ratio is higher than their mothers but not linear correlated; (4) the "mutant mother" can have "healthy baby".

## 860/W/Poster Board #518

**Associations of functional polymorphisms in NLR genes with susceptibility to food-induced anaphylaxis.** *Y. Hitomi[1], M. Ebisawa[2], T. Hirota[1], M. Harada[1], Y. Suzuki[3], Y. Nakamura[4], M. Tamari[1].* 1) Laboratory for Respiratory Diseases, Center for Genomic Medicine, RIKEN, Yokohama, Japan; 2) Clinical Research Center for Allergy and Rheumatology, Sagamihara National Hospital, National Hospital Organization, Sagamihara, Japan; 3) Department of Public Health, Graduate School of Medicine, Chiba University, Chiba, Japan; 4) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

(Background) Anaphylaxis is a life-threatening allergic reaction, and food is one of the most common responsible allergens. Although anaphylaxis is a severe side effect of both the food challenge test and oral desensitization therapy, there is no completely reliable method to predict which subjects have a high risk for food-induced anaphylaxis. Furthermore, little is known about the genetic factors of food allergies or anaphylaxis. The nucleotide-binding domain, leucine-rich repeat-containing (NLR) family controls the activity of inflammatory caspase-1 by forming inflammasomes, which leads to cleavage of the proinflammatory cytokines IL-1$\beta$ and IL-18. To clarify the pathophysiology of food-induced anaphylaxis, we performed an association study between the polymorphisms in NLR family genes and food-induced anaphylaxis in a Japanese population. (Method) We selected tag SNPs of NLR genes using the HapMap Japanese data set and conducted association analyses using a total of 309 pediatric patients with food allergies diagnosed by oral food challenge tests (included 95 patients who had experienced anaphylaxis) and a total of 234 control children. Genotyping was performed by the TaqMan allele-specific amplification method. We further performed functional analyses of the susceptible SNPs. (Results) Two SNPs of a NACHT, LRR and pyrin domain- containing protein (NALP) gene were significantly associated with susceptibility to food-induced anaphylaxis (P = 0.00086, OR=1.81; P = 0.00068, OR=1.80). A haplotype of the gene also showed a significant association with susceptibility to food-induced anaphylaxis (P = 0.000098, OR=2.21). Since we could not find any SNP that was in strong linkage disequilibrium with these SNPs by resequencing and searching the dbSNP database, we focused on the functional effects of the two SNPs. Luciferase and electrophoretic mobility shift assays for these SNPs using human monocyte cell line THP-1 revealed that the risk alleles of two SNPs increased the enhancer activity of NLRP expression and mRNA stability, respectively. (Conclusion) Our results indicate that the NALP SNPs might play an important role in the development of food-induced anaphylaxis. Further research on the NLR family will contribute to the development of novel diagnostic and therapeutic methods for food-induced anaphylaxis.

## 861/W/Poster Board #519

**Positive association for FOXE1 and loci in 8q24 in CL/P cases.** *M.A. Mansilla[1], S. Patte[1], K. Ryckman[1], M.L. Feldkamp[2], R.G. Munger[3], J.C. Murray[1].* 1) Deparment Pediatrics, Univ Iowa, Iowa City, Iowa; 2) Utah Birth Defects Network and University of Utah , Salt Lake City, Utah; 3) Department of Nutrition and Food Sciences, Utah State University, Logan, Utah.

Non syndromic cleft lip with or without cleft palate (NSCL/P) is a common multifactorial birth defect caused by the interaction of genetic and/or environmental factors. To date a number of genes have been described positively associated with this trait, including IRF6, MSX1, FGFR2 and FOXE1. For the environmental role, smoking and vitamin intake have been extensively studied. The purpose of this study was to test SNPs known to be associated with NSCL/P as well as some involved in the folate pathway in a case control study of oral cleft birth defects conducted in Utah during 2000-2005 in collaboration with the Utah Birth Defects Network (UBDN). This study collected samples from 510 cases and 565 controls and their parents; a total of 29 SNPs in different genes including IRF6, FOXE1, BMP4, FGFR2, MTHFR, MTRR, MTR, MTHFD1, DHFR, NNMT, FOLR1, RFC1 and GART, were tested for association. Two markers in the 8q24 region recently described as associated with NSCL/P in a genome wide study were also analyzed (Birnbaum et al 2009). The Transmission Disequilibrium Test (TDT) showed significant results for SNPs in FOXE1 (rs3748249, p value=0.00457) and in 8q (rs987525, p value=5.63E-06), these results were also confirmed by case-control analysis of the probands, allelic p values 0.002 and 0.0001, respectively. Our study replicates the association found in FOXE1 (9q22.3) and the 8q24 region by TDT and is the first confirmation of these results in a case control study, therefore reinforcing the important role of these two loci in the etiology of NSCL/P.

## 862/W/Poster Board #520

**Mapping of genetic risk for severe dengue virus infection to the *NFKB1-MANBA* region on chromosome 4 (4q21).** *M. Yasunami[1], TPL. Nguyen[1,2], N. Okuda[1], H. Horie[1], S. Kurata[1], TQH. Vu[2], TTN. Vu[2], TT. Tran[3], MT. Ha[3], VT. Vo[4], VD. Tran[4], M. Kikuchi[1], K. Morita[1], H. Hirayama[1].* 1) Immunogenetics,Inst Trop Med, Nagasaki Univ, Nagasaki, Japan; 2) Pasteur Institute in Ho Chi Minh City, Vietnam; 3) Nhi Dong Hospital No.2, Ho Chi Minh City, Vietnam; 4) Center for Preventive Medicine, Vinh Long Province, Vietnam.

Dengue fever is acute febrile disease caused by infection of dengue virus. A small fraction of the patients with dengue fever (DF) develop more severe form with hemorrhagic tendency, dengue hemorrhagic fever (DHF) or that with symptoms of profound plasma loss in addition, dengue shock syndrome (DSS). Multiple factors have been proposed for the development of these severe forms, and excessive or inappropriate host response would contribute to pathogenesis to significant extent. Therefore we explored genetic polymorphisms in the immune-related candidate genes, which may account for individual variations in responsiveness to pathogens, including the gene for a subunit of nuclear factor kappa B (NFKB1) on 4q21. Microsatellite polymorphism D4S3043 in the downstream region of NFKB1 exhibited bimodal distribution of allele frequency in the population and the shorter alleles were associated with the risk for disease progression. Because the microsatellite locates in the 12th intron of the gene encoding lysosomal beta mannosidase (MANBA), we further examined the association of two non-synonymous coding SNPs in MANBA as well as two SNPs in NFKB1. As a result, polymorphisms in downstream of NFKB1 gene form a LD block and exhibited significant association with severe forms of dengue virus infection. Variations in the function of these two gene conferred by these polymorphisms may influence host-pathogen interaction upon the infection of dengue virus.

## 863/W/Poster Board #521

**Prognostic significance of FTO genotype in the development of obesity in Japanese: the J-SHIPP study.** *Y. Tabara[1, 6], H. Osawa[4, 6], R. Kawamoto[3], H. Onuma[4, 6], I. Shimizu[5], Y. Takata[4], W. Nishida[4], H. Makino[4], H. Guo[2], K. Kohara[2,6], T. Miki[2,6].* 1) Department of Basic Medical Research and Education, Ehime University Graduate School of Medicine, Ehime, Japan; 2) Department of Geriatric Meidicne, Ehime University Graduate School of Medicine, Ehime, Japan; 3) Department of Community Meidicne, Ehime University Graduate School of Medicine, Ehime, Japan; 4) Department of Molecular and Genetic Medicine, Ehime University Graduate School of Medicine, Ehime, Japan; 5) Department of Internal Medicine, Ehime Prefectural Hospital, Ehime, Japan; 6) Ehime ProteoMedicine Research Center.

**Objective:** Susceptibility of fat mass and obesity-associated (FTO) gene polymorphisms to obesity has been reported in various populations. Polymorphisms in melanocortin 4 receptor (MC4R) gene were recently explored as another susceptible locus. However, prognostic significance of these genetic variations has not been fully elucidated. Here, we investigated the involvement of FTO rs9939609 and MC4R rs17782313 polymorphisms in a development of obesity. Association with type 2 diabetes (T2DM) was also investigated. **Subjects;** We analyzed 2,806 community-dwelling middle-aged to elderly subjects (61±14 years). Basic clinical parameters were obtained from the subjects' personal health records, evaluated at their annual medical check-up. Genomic DNA was extracted from peripheral blood and all SNPs were analyzed by TaqMan probe assay. **Results;** FTO but not MC4R genotype was significantly associated with current body mass index (BMI; TT 23.2±3.2, TA 23.7±3.2, AA 24.4±3.2 kg/m2, p=2.5*10$^{-6}$) and frequency of obesity (BMI >25kg/m$^2$) (26.6, 32.0, 43.0% respectively, p=2.0*10$^{-4}$). Age and sex adjusted odds ratio for obesity was 1.30 (p=0.004) in TA and 2.07 (p=0.002) in AA genotype. To clarify the prognostic significance of FTO genotype in the development of obesity, we retrospectively analyzed the association between SNP rs9939609 and the development of obesity with 9.4 years follow-up. During 9.4 years follow up period, 214 new cases of obese were diagnosed among 1,718 subjects whose retrospective data was available, and who were not obese at baseline (BMI less than 25 kg/m2; TT (n=1191), 21.8±2.0; TA (n=485), 22.1±1.8; AA (n=42) 22.6±1.6 kg/m$^2$, p<0.001). A-allele frequency of the FTO genotype was significantly higher in obese-developed subjects (22.2, 15.8%, p=0.001). Multiple logistic regression analysis identified A-allele of the FTO genotype as an independent determinant for the development of obesity (odds ratio 1.46 (95±37; confidence interval 1.04-2.04), p=0.031) after adjusted for age, sex and initial BMI. However, association studies and meta-analysis for T2DM did not actively support the involvement of FTO genotype. **Conclusion;** FTO genotype is an independent risk factor for future development of obesity. Since body weight is a trait which is modifiable by dietary and exercise interventions, early detection of at-risk populations using genetic information may be useful in preventing future obesity-related diseases.

## 864/W/Poster Board #522

**Genetic diagnosis of rheumatoid arthritis using one major and several minor risk gene markers.** *W. Li, J. Freudenberg, P.K. Gregersen.* Genomics & Hum Genet, Feinstein Ins Med Res, Manhasset, NY.

Rheumatoid Arthritis (RA) is a complex disease caused by genetic and environmental risk factors. Standard parameters describing genetic associations, such as the odds-ratio (OR) and p-value are not informative regarding the percentage of RA cases and controls that are explained by the presence of absence of the associated alleles. Towards this goal of predictive genetic test, we distinguish the classification rate of case group (sensitivity) and that of control group (specificity). Using a dataset with 908 RA patients and more than 1000 controls, we constructed single-gene and multiple-gene classifiers using the HLA-DRB1 (the major RA risk gene, shared-epitope (SE)=0,1,2), and SNP data for PTPN22, BLK, TRAF1, as well as other minor risk genes. The sensitivity of the classifier with DRB1-SE alone under the dominant model reaches 98%, and the specificity under the recessive model is 94%. However, the average classification rate ((sen+spe)/2) is reduced to 76% and 67% under the dominant and the recessive models, versus the 50% baseline classification rate. The receiver operating characteristic (ROC) curve shows the dominant model for the major gene to be only slightly better than the recessive model. Adding minor genes to the classifier does not increase the classification rate notably (only a few percent) for various types of classifiers including logistic regression, recursive partitioning, and random forests. We further used a threshold model that considers the total number of risk alleles in both major and minor RA genes. Multi-dimensional scaling showed graphically, for DRB1-SE=1 samples, that RA cases and controls overlap in the projected space. This conclusion that SE=1 group is the hardest to classify group is confirmed by the recursive partitioning result that for SE=1 samples, other minor risk genes can only achieve classification rates around the 60% range.

## 865/W/Poster Board #523

**Host Genetic Susceptibility Factors for Severe West Nile Virus Infection.** *K.J. Buckingham[1], A.W. Bigham[1], S. Husain[1], J. Kriesel[2], A. Rutherford[2], N.M. Astakhova[3], A.A Perelygin[3], M.P. Busch[4], K. Murray[5], M.A. Brinton[3], M.J. Bamshad[1].* 1) Dept. of Pediatrics, University of Washington, Seattle, WA, USA; 2) Dept. of Medicine, University of Utah, Salt Lake City, UT, USA; 3) Dept. of Biology, Georgia State University, Atlanta, GA, USA; 4) Blood Systems, San Francisco, CA, USA; 5) Dept. of Medicine, University of Texas Health Sciences Center at Houston, Houston, TX, USA.

West Nile Virus (WNV), a category B pathogen representative of the *Flavivirus* family, is the etiologic agent of WNV disease, and is endemic in parts of Africa, Asia, and Europe. In 1999, WNV emerged in Eastern North America, and over the past decade, WNV infections have spread across the U.S. The outcome of infection with WNV ranges from asymptomatic to severe neuroinvasive disease manifested as encephalitis, paralysis, and/or death. Severe WNV disease occurs in fewer than 5% of cases and risk of disease may be influenced by host genetic factors, although the identity of these genetic factors remains largely unknown. In animal models, host innate and adaptive immune networks are both essential for protection against severe WNV disease. Accordingly, we tested 360 common haplotype tagging SNPs and/or functional SNPs in 58 genes that encode key regulators of immune function in 760 WNV infection cases including 439 patients with mild or severe disease, and 321 viremic blood donors with asymptomatic infections. It is important to note that individuals with asymptomatic infection served as "controls" and this is presumably more robust than using individuals with unknown WNV exposure as controls. Comparison of WNV disease vs. asymptomatic infections identified several significant associations, after applying a false discovery rate correction for multiple tests, with SNPs in three genes using a dominant model (*IRF3*; OR 2.06 (p<0.005), *TLR8*; OR 2.17 (p<0.05), and *TBK1*; OR 2.06 (p<0.05)) and a suggestive association with a SNP in *CD40LG* (OR 1.81 (p<0.1)). This is consistent with the observation that mice lacking *Irf3* are uniformly susceptible to WNV infection (Daffis et al. *PLOS Pathogens* 3: e106 (2007)). To look for alleles associated with severe WNV disease, we compared mild WNV cases combined with asymptomatic infections to severe WNV disease cases. None of the SNPs associated with risk of disease were associated with disease severity. This suggests that genetic factors influencing the host immune responses underlying development of symptoms might differ from those influencing risk of severe neuroinvasive disease. Identification of candidate SNPs associated with WNV susceptibility and host response will help stratify risk, identify novel disease-related pathways, and discover new potential therapeutic targets.

## 866/W/Poster Board #524

**Functional SNPs in CD244 gene associated with rheumatoid arthritis in a Japanese population.** *A. Suzuki[1], R. Yamada[1, 2], Y. Kochi[1], Y. Okada[2], T. Sawada[3], K. Matsuda[4], Y. Kamatani[4], M. Mori[3], K. Shimane[1, 3], A. Takahashi[1], K. Yamamoto[1, 3].* 1) Ctr for Genomic Medicine, Kanagawa, RIKEN, Yokohama City, Japan; 2) Laboratory of Functional Genomics, Human Genome Center, Institute of Medical Science, University of Tokyo, Japan; 3) Department of Allergy and Rheumatology, Graduate School of Medicine, University of Tokyo, Japan; 4) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Japan.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. These studies also indicated an important factor regarding genetic factors of RA and autoimmune diseases; some of the RA-susceptible polymorphisms also increase the risks of other autoimmune diseases as reported for e.g., STAT4 (ref1) and FCRL3 (ref2) with RA and SLE. One of the mechanisms of the inflammation in autoimmune diseases associated with signal transduction via signaling lymphocytic activation molecule (SLAM). It was reported that SLAM family gene, e.g., Ly108 is also associated with systemic lupus erythematosus (SLE). We studied whether variants of the SLAM family gene in the chromosome 1q region are associated with susceptibility to RA. The association peak in the block was observed at two functional SNPs (rs3766379 and rs6682654) in CD244 in two independent RA cohorts from Japan (P= 3.23 x 10-8 and P=7.45 x 10-8). We found a Japanese cohort of systemic lupus erythematosus (SLE) that had the similar genotype distribution with RA cohorts. A correlation between CD244 expression and genotype was observed in lymphoblastoid cell lines and these disease-associated SNPs, rs3766379 and rs6682654 have been shown to increase their expression in luciferase and allele-specific transcript quantification assays. Furthermore, we indicated that rs6682654 locates on the binding site of USF-1 in CD244 gene and affect on the regulation of CD244 expression via USF-1. CD244 also expresses in NK cell marker positive cells in RA synovial tissues. We supposed that up-regulation of CD244 by transcription factors including USF-1 affect on RA and other autoimmune diseases, including SLE. Thus, CD244 is a novel genetic risk factor for RA and may have a role for autoimmunity in RA. 1) Remmers, E.F. et al. N Engl J Med 357, 977-86 (2007). 2) Kochi, Y. et al. ## 867/W/Poster Board #525

**Replication and trinucleotide repeat instability at the Myotonic dystrophy type 1: tissue-specificity and the contribution of *cis*-elements.** *J. Cleary[1,2], K. Hagerman[1,2], A. López Castel[1], S. Tomé[3], L. Foiry[3], I. Paradis[4], M. Dorschner[5], H. Sroka[6], D. Chitayat[6,7], J. Stamatoyannopoulos[8], R. Drouin[4], G. Gourdon[3], C. Pearson[1,2].* 1) Genetics & Genome Biology, Hospital for Sick Children, Toronto, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 3) Inserm U871, Hopital Necker-Enfants Malades, Paris, France; 4) Department of Pediatrics, Faculty of Medicine and Health Sciences, Université de Sherbrooke, Sherbrooke, Canada; 5) Department of Medicine, University of Washington, Seattle, WA, USA; 6) Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Canada; 7) Department of Pediatrics, Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 8) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Myotonic dystrophy type 1 (DM1), as well as other trinucleotide repeat diseases, are often characterized by complex patterns of inherited and ongoing tissue-specific instability and pathogenesis. However what regulates the tissue-specific and age-dependent patterns of repeat instability is unknown. Repeat instability is observed in proliferating and non-proliferating tissues suggesting contributions from both DNA repair and DNA replication. In DM1 patient cells, where instability is proliferation-dependent, treatment with drugs that alter replication fork progression affects the DM1 repeat expansions. An analysis of replication in the presence of active instability and in different tissues may yield clues to the unique molecular mechanisms of repeat instability. Replication initiation, replication direction and fork progression through the DM1 (CTG)n repeat was determined in DM1 patient cells and transgenic mouse tissues actively undergoing expansions. The replication profile was determined using quantitative competitive PCR of newly replicated DNA from both patient cells and mouse tissues, while the contribution of flanking *cis*-element was assessed via 2D gel, bisulfite and DNase hypersensitive site analysis.

Replication analysis reveals that the DM1 repeat tract is flanked by two replication origins, such that replication of the expanded repeat proceeds from the downstream origin. Both tissue-specific and age-dependent variations in replication and CpG methylation were observed from analysis of the DM1 transgenic mice. The replication profile orients the CAG repeats as the lagging strand template and positions flanking CTCF sites between the repeat tract and replication origin. Analysis of *cis*-elements revealed that the flanking CTCF binding sites contribute to replication fork pausing at the expanded DM1 repeat tract. Alteration at these flanking sites affected replication efficiency, pausing and repeat instability. These results coupled with the coincidence of replication origins, CTCF binding sites and DNase hypersensitive sites with disease-linked trinucleotide tracts suggest these *cis*-elements mark the DM1, and other repeat loci, for tissue-specific and age-dependent instability.

**Using ontology fingerprint derived gene network to infer polygenic model from GWA study.** *W. Zheng, T. Qin, L. Tsoi, A. Lawson.* Dept. Biostat, Bioinfo & Epid, Med Univ South Carolina, Charleston, SC.

Contrary to general believe that human diseases are caused by single genetic variant, more and more evidences show that many human diseases are caused by cumulative effect of many genetic variants. This polygenic model poses a significant challenge to current Genome-wide Association (GWA) study, as variants in a polygenetic model do not show strong association with the disease phenotype individually. Therefore, additional biological evidences are needed to identify polygenic model from genes that are marginally associated with disease phenotypes from GWA study. We have developed the concept of ontology fingerprints a list of ontology terms overrepresented in the PubMed abstracts linked to a gene or a disease along with their corresponding enrichment p-value, to characterize genes and diseases. We further have quantified the relationship between a gene and a disease by comparing their ontology fingerprints - the more similar the ontology fingerprint between a gene and a disease, the more likely the gene will play a role in the disease. Such quantified biological relevance has been applied to prioritize genes identified from GWA study to be associated with the plasma concentrations of HDL, LDL and TG. Here we report a new approach to derive novel gene networks by performing pairwise comparison of ontology fingerprints of human genes. In this network, genes are nodes and the similarity scores between genes are weighted edges. We further developed a Bayesian hierarchical model to use exiting pathway information to infer biologically relevant threshold for the weighted edges in the network. Applying the identified threshold and algorithms based on graph theory, we are able to identify network modules. While using this approach to analyze genes associated with LDL, HDL and TG as identified from a GWA study, we are able to identify network modules that show strong biological relevance to disease phenotype. One module contains APOE and LDLR, consistent with their polygenic effect on lipid concentration supported by previous study. Additional genes in the same module point to a potential multi-gene model that influences lipid concentration. Such network modules have significant implication for the genetic bases of the polygenic model. Our methodology provides a novel way to analyze GWA study to infer novel polygenic model that may contribute to human disease.

**Interaction between periodontitis and arthritis involves immunological functional interferences and shared genetic susceptibility, with the possible involvement of NRAMP1/SLC11A1.** *G.P. Garlet[1], A.P. Trombone[2], M. Claudino[1], G.F. Assis[1], C.E. Repeke[1], E.M. Silveira[1], P. Colavite[1], M.J. Avila-Campos[3], A.P. Campanelli[1], M. de Franco[4], P.C. Trevilatto[5], W. Martins Jr[6], J.S. Silva[2], C.R. Cardoso[7].* 1) Biological Sciences, School of Dentistry of Bauru, São Paulo University, Bauru, SP, Sao Paulo, Brazil; 2) Department of Biochemistry and Immunology, School of Medicine of Ribeirão Preto, São Paulo University - FMRP/USP; 3) Department of Microbiology, Institute of Biomedical Sciences - ICB/USP; 4) Laboratório de Imunogenética, Instituto Butantan, São Paulo, Brazil; 5) Center for Health and Biological Sciences, Pontifícia Universidade Católica do Paraná - PUCPR; 6) Department of Periodontics, Dentistry School of University of Ribeirão Preto - UNAERP; 7) 3 Department of Biological Sciences, Federal University of Triângulo Mineiro - UFTM;.

Periodontitis (PD) and arthritis (AR) share characteristics such as the chronic nature of the inflammatory reaction associated with bone resorption activity, and have been found to be clinically associated. However, the mechanisms underlying such association are unknown. Therefore, we examined the basis of A. actinomycetemcomitans(AA)-induced PD and pristane-induced AR interaction in genetically selected mice strains (AIRmin and AIRmax) presenting distinct NRAMP (SLC11A1) alleles, and also AR-associated NRAMP SNPs in PD patients. AIRmax strain (that present R NRAMP allele) was found to be susceptible to the development of both experimental AR and PD, while AIRmin strain (that present S NRAMP allele) was found to be resistant to AR development, and to develop PD at a low severity. The increased tissue destruction in AIRmax mice was associated with higher levels of TNF-alpha, IL-1beta, IL-17, and also of MMP13 and the osteoclastogenic factor RANKL. When AIRmin and AIRmax mice were submitted to both AR and PD induction, higher scores of PD (but not AR) severity were seen in AIRmax but not in AIRmin strain. Increased tissue destruction in AIRmax mice submitted to both PD and AR was associated with increased IL-1beta, IFN-gamma, IL-17, RANKL and MMP13 levels, while similar levels of IL-4 and IL-10 were verified. Such functional interference of AR in PD development was associated with alteration in the patterns of T cell subsets transcription factors expression in submandibular LNs, where T-bet and RORgamma were found to be upregulated, while GATA3 levels were unaltered, when compared to mice only submitted to PD induction. Complementarily, NRAMP 5'(GT)n (rs34448891) SNP 3/3 genotype, previously associated with RA, was found to be significantly more frequent (p=0.0540, OR= 2.046, CI=0.98/4.21) in PD susceptible patients (N=178) than in control group (N=343) when compared to the 2/3 genotype, while no differences were found in comparison with 2/2 genotype (p=0.2528, OR=1.308). Interestingly, both murine R NRAMP allele and human 3 NRAMP 5'(GT)n allele were found to be associated with increased NRAMP mRNA expression in macrophages; and also with increased (human and experimental) PD and (experimental) RA severity. Our results demonstrate that the interaction between experimental periodontitis and arthritis involves functional immunological interferences and shared genetic susceptibility, with the possible involvement of NRAMP1.

**Glucose homeostasis Genes and Spina Bifida Risk.** *K.S. Au[1], K.S. Weymouth[1], C.M. Davidson[1], A.C. Morrison[2], J.-I. Lin[2], J.M. Fletcher[3], K.K. Ostermaier[4], G.H. Tyerman[5], S. Doebel[6], H. Northrup[1,7].* 1) Dept Pediatrics, Univ Texas Med Sch, Houston, TX, USA; 2) Human Genetics Center, Univ Texas Sch Public Health, Houston, TX, USA; 3) Dept Psychology, Univ Houston, Houston, TX, USA; 4) Texas Children Hospital, Houston, TX, USA; 5) Shriners Hospital for Children, Los Angeles, CA, USA; 6) The Hospital for Sick Children, Univ Toronto, Toronto, ON, Canada; 7) Shriners Hospital for Children, Houston, TX, USA.

Neural tube defects (NTDs) are a leading cause of infant mortality and morbidity involving the central nervous system. Spina bifida (SB) is a common NTD with the defect occurring in the developing spinal cord resulting in various degree of lower extremities paralysis. Glucose imbalance and deficiency of folate during pregnancy are two major risk factors for NTDs. We identified three single nucleotide polymorphisms (SNPs) in three glucose metabolic pathway genes showing association with SB risk in an earlier report. The current validation study investigated an additional 140 SNPs on the same simplex patient family set plus 103 additional patient families. The total number of simplex family included in the study is 608. Reconstruction-combined transmission disequilibrium test (RC-TDT) results verified association of a synonymous SNP coding for Pro196 (p=0.009) in the glucose transporter 1 (*GLUT1*) gene to occurrence of SB. Strikingly, nine additional SNPs in glucose transporters 1 (*GLUT1*), two SNPs in glucose transporter 3 (*GLUT3*), one SNP in glucose transporter 8 (*GLUT8*), one SNP in hexokinase 1 (*HK1*), two SNPs in insulin receptor (*INSR*), two SNPs in leptin (*LEP*), and two SNPs in superoxide dismutase 1 (*SOD1*) gene loci showed significant association to SB with nominal p-values range from 0.0039 to 0.049. The results in the present study strongly support a critical role of glucose homeostasis maintaining genes as contributory to SB susceptibility. Many of these genes have been associated with diseases (including NTDs) due to diabetes or glucose imbalance. The current findings support the hypothesis that maintenance of glucose homeostasis during pregnancy as a vitally important for normal neural tube development and implicate specific genes in this process.

## 871/W/Poster Board #529

**Haplotype-level candidate gene association analysis of *DPYSL2* and *COMT* in a European schizophrenia sample.** *M.E.S. Bailey[1], P.C.D. Johnson[2], B.J. Morris[1,4], J.A. Pratt[3,4], R. Hunter[2,4,5], C.L. Winchester[1,3,4].* 1) Molecular Genetics, and Neuroscience and Molecular Pharmacology, FBLS, University of Glasgow, Glasgow, UK; 2) Robertson Centre for Biostatistics, University of Glasgow, Glasgow, UK; 3) SIPBS, University of Strathclyde, Glasgow, UK; 4) Psychiatric Research Institute of Neuroscience in Glasgow (PsyRING), Glasgow, UK; 5) NHS Greater Glasgow and Clyde, Glasgow, UK.

When a gene harbours multiple functional variants, haplotype analysis may reveal genetic associations invisible at the single SNP level, particularly where confounding interaction or haplotype evolution effects are operating. Single SNP studies can thus be misleading. We are conducting a haplotype-level association study of two candidate genes in schizophrenia, *COMT* and *DPYSL2*. Five SNP markers spanning *COMT* were chosen to test the hypothesis that it harbours multiple functional variants, in addition to the widely studied exon 4 coding SNP, rs4680 (p.V158M), that influence schizophrenia risk via effects on transcription or mRNA stability. Eleven SNPs were chosen spanning *DPYSL2*, which had emerged as a physiological candidate from a microarray study of gene expression in prefrontal cortex in a phencyclidine (PCP) rat model of schizophrenia. *DPYSL2* maps to chr.8p21, a region believed to harbour one or more schizophrenia genes. We used a UK sample of 500 DSM-IV-diagnosed SCZ patients and 500 ethnically similar normal controls. ABI TaqMan assays were used to genotype SNPs. Haplotypes were predicted and analysed for association using the R module, haplo.stats, and using Haploview v.4.1. Five SNPs encompassing a region in the 3' half of *DPYSL2* previously implicated in schizophrenia showed modest associations with SCZ in our sample (best $P = 0.021$ for rs13277175 under a G allele-dominant model; O.R. = 1.35 [1.045-1.752, 95% C.I.]). Preliminary analysis of *DPYSL2* haplotypes in the sample suggest that the haplotype containing all 5 associated risk alleles is rare in the population and larger sample sizes may be required to demonstrate any haplotype-level association, but further analysis is ongoing. A qRT-PCR study of transcript levels in SCZ patient and control post-mortem brain showed that transcript levels are associated with genotype at several of the associated SNPs. Only one *COMT* SNP showed association with SCZ (rs4680; p.V158M; $P = 0.011$; O.R. = 1.44 [1.085-1.911] under a model in which the ancestral 'V' allele confers risk in dominant fashion). In a preliminary analysis, *COMT* haplotypes centred around rs4680 and two other nearby SNPs in a single LD block did not show any evidence for association with SCZ. Our modestly sized study supports the candidacy of *DPYSL2* in schizophrenia, but does not support a hypothesis of multiple SNPs near exon 4 of *COMT* influencing schizophrenia risk via local effects on mRNA stability.

**Association between the SNAP25 gene and the extremes in intellectual performance; mental retardation and high IQ.** *G. Beunders[1,2], P. Rizzu[1,2], E.A. Sistermans[1], J.W.R. Twisk[3,5], W. van Mechelen[4,5], J.B. Deijen[6], P. Heutink[1,2], H. Meijers-Heijboer[1,2], D. Posthuma[1,2,7].* 1) Department of Clinical genetics, VU medical centre, Amsterdam, The Netherlands; 2) Neuroscience Campus Amsterdam, Department of Clinical Genetics, VU medical centre, Amsterdam The Netherlands; 3) Department of epidemiology and biostatistics, VU medical centre, Amsterdam, The Netherlands; 4) Department of Public and Occupational Health, VU medical centre, Amsterdam, The Netherlands; 5) EMGO institute, VU Medical centre, Amsterdam, The Netherlands; 6) Department of Clinical Neuropsychology, VU University, Amsterdam, The Netherlands; 7) Department of Biological Psychology, VU University, Amsterdam, The Netherlands.

*Introduction* Intelligence in the normal range is shown to be highly heritable. For high cognitive ability a recent twin study has shown a substantial heritability of 0.50 as well. Low intelligence, mental retardation, defined by an IQ below 70 and a deficit at two or more adaptive skills starting at a childhood age (American Psychiatric Association, DSM-IV 1994), is thought to have a heritable cause in about 50% of the cases. Genome wide and candidate gene association studies have identified some loci and genomic variants associated with variation in intelligence in the normal range. High IQ is thought to be caused by the same genomic variants, but until now there is no direct prove for this hypothesis. For mental retardation however, most genetic causes seem to be rare and monogenetic. *Aim* We set out to test whether the SNAP25-gene, which was recently linked to variation of intelligence in the normal range (Gosso et al., 2006), is also linked to variation in intelligence at both the lower (mental retardation) and the upper range (high IQ). *Methods* We genotyped two SNP's in SNAP 25 (rs363039 and rs363050), previously linked to variation in intelligence in the normal range (Gosso, et.al. 2006), in two samples by use of a Taqman assay. The first sample contained DNA of 644 children with mental retardation aged 4-16 that had been tested negative for fragile-X syndrome and had a normal karyotype. The second sample contained DNA of 360 participants of the Amsterdam growth and health study, which were recruited at age 13-14 from two secondary schools; all were following the highest level of education. *Results* Using a case-cohort association test, we found significant association of both SNP's with the extremes of intelligence. The previously identified increaser alleles (Gosso et al. 2006) had a significant ($p<0.05$) higher allele frequency in the high IQ sample compared to the mental retardation sample. *Conclusion* We found evidence for association of two non-coding SNP's (rs363039 and rs363050) in SNAP25 with variation in the lower and upper extremes of intelligence. This suggests that, at least for SNAP-25, the same genomic variants affect both variation in normal intelligence and mental retardation as well as high IQ, an often heard but hardly tested statement. *reference* M.F. Gosso, et al. (2006) The SNAP-25 gene is associated with cognitive ability: Evidence from a family based study in two independent Dutch cohorts. Mol Psychiatry 11: 878-886.

## 873/W/Poster Board #531

**SNP and expression analyses of candidate genes for orofacial clefts.** *J. Kim[1], M. Dunnwald[2], J.C. Murray[1,2].* 1) Department of Anatomy and Cell biology, University of Iowa, Iowa City, IA; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

Association studies based on single nucleotide polymorphism (SNP) have substantially advanced our understanding of the genetic basis of complex human diseases. However, it remains a challenge to establish a functional link between associated variants and disease traits. Variation in gene expression is important in mediating disease susceptibility, and the identification of polymorphic genetic variants that affect gene expression may contribute to a better understanding of disease etiology. In order to assess the relationship between sequence variants and gene expression, we analyzed SNPs in selected candidate genes for orofacial clefts, one of the most common birth defects with a complex etiology, and correlated these with transcript expression levels. A total of 145 human foreskin samples were genotyped for 34 SNPs in 10 candidate genes for clefting including *BMP4*, *FGFR1*, *FGFR2*, *FOXE1*, *IRF6*, *MSX1*, *PDGFC*, *SOX9*, *TFAP2*, and *TGFB3*. Quantitative real-time PCR (qRT-PCR) was performed to evaluate the expression levels of each gene at the mRNA level in the same tissue samples. Of the 10 genes, eight were highly expressed in the foreskin tissue and were included in the analysis to correlate DNA variations with gene expression levels. There were no SNP variants found that are associated with a twofold or greater difference in gene expression. One variant in *FGFR2* and two variants in *SOX9* exhibited less than a twofold, but statistically significant difference (one-way ANOVA, $p<0.05$). The results suggest that a combination of multiple SNPs may produce effects that would be difficult to determine by looking at one SNP at a time, and that larger sample sizes might identify more subtle effects. Further studies of the interactions among multiple polymorphisms are needed to elucidate the genetic basis of variation in gene expression. Interrogation of the effects of SNPs on gene expression may prove to be useful in unraveling the causes of complex phenotypes.

## 874/W/Poster Board #532

**Genetic and functional characterization of GRIP1 sequence variants in autism spectrum disorders.** *R. Mejias-Estevez[1], A. Adamczyk[1], V. Angonno[2], S. Yang[1], C.E. Schwartz[3], R. Stevenson[3], C. Skinner[3], M.D. Fallin[4], D. Valle[1], R.L. Huganir[2], T. Wang[1].* 1) Institute of Genetic Medicine and Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Greenwood Genetic Center, Greenwood, SC; 4) Department of Epidemiology, Johns Hopkins University School of Public Health, Baltimore, MD.

Abnormal synaptogenesis and imbalance between the excitatory (glutamatergic) and inhibitory (GABAergic) neurotransmission are implicated in autism spectrum disorders. Glutamate receptor interacting protein 1 (GRIP1) is a neuron-enriched scaffolding protein with seven PDZ domains. GRIP1 is abundantly expressed in both glutamatergic and GABAergic synapses, and plays an important role in receptor trafficking and synaptic organization. The PDZ4-6 domains of GRIP1 mediate a direct interaction with the AMPA glutamate receptor 2/3 (GluR2/3), GABAA receptor interacting protein-associated protein and gephyrin, key components of the postsynaptic complex at GABAergic synapses. A case-control study of a known SNP in the PDZ4-6 genomic region implicated GRIP1 gene in autism. By screening exon-containing regions of the GRIP1 gene in a large cohort of patients with autism (n=480) and a cohort of ethnically matched controls (n=480), we identified seven missense variants involving highly conserved amino acid residues. All seven were transmitted from parents and six were found only in the autism cohort. Four variants are located in domains PDZ4-6 and at least three have altered interactions with GluR2/3 based on coimmunoprecipitation and/or a yeast two-hybrid assay. Immunofluorescence and receptor trafficking assays on the variants are being conducted in primary neurons to delineate their roles in both glutamatergic and GABAergic synapses. A positive correlation of the severity in the behavioral phenotype was noted in a proband family with two affected brothers, one homozygous and one heterozygous for the M794R variant. These studies suggest that functional GRIP1 variants could have a pathogenic role in a small fraction of autism subjects by altering synaptic trafficking of glutamatergic and/or GABAergic receptors leading to an imbalance between the excitatory and inhibitory circuitries in specialized regions of the brain.

## 875/W/Poster Board #533

**Genes in Folate and Glucose metabolism Associate with attention-deficit/hyperactivity disorder risk in patients with Spina Bifida.** *A.C. Morrison[1], J.-I. Lin[1], K.S. Au[2], K.S. Weymouth[2], C.A. Martinez[2], P.T. Cirino[3], J.M. Fletcher[3], K.K. Ostermaier[4], S. Doebel[5], M. Dennis[5], H. Northrup[2,6].* 1) Human Genetics Center, Sch Public Health, Univ Texas, Houston, TX, USA; 2) Dept Pediatrics, Univ Texas Med Sch Houston, Houston, TX, USA; 3) Dept Psychology, Univ Houston, Houston, TX, USA; 4) Texas Children Hospital, Houston, TX, USA; 5) The Hospital for Sick Children, Univ Toronto, Toronto, ON, Canada; 6) Shriners Hospital for Children, Houston, TX, USA.

**Objective:** Spina bifida (SB) is a common NTD with the defect occurring in the developing spinal cord resulting in various degree of paralysis of the lower extremities. An approximately 6-fold increased incidence of attention-deficit/hyperactivity disorder (ADHD) subtypes has been associated with SB and shunted hydrocephalus. Previous studies indicate that single nucleotide polymorphisms (SNPs) in genes belonging to the glucose metabolic pathway and folate/homosysteine metabolism are associated with SB. This study examined whether SNPs in genes from these pathways were associated with presence of ADHD among SB patients. **Study Design:** The study included 253 unrelated simplex SB patient families. A total of 81 SB patients met the criteria for ADHD based on DSM-IV in Swanson, Nolan, and Pelham-IV (SNAP-IV) survey and 172 patients were determined not to have ADHD. We evaluated 32 SNPs in the methylene-tetrahydrofolate reductase (*MTHFR*) and the glucose transporter 1 (*GLUT1*) genes for an association with ADHD using the reconstruction-combined transmission disequilibrium test (RC-TDT). **Results:** Significant association was identified with three SNPs (rs2274976, rs3737965 and rs4846049) in *MTHFR* with ADHD with p-values of 0.0414, 0.0003 and 0.0475, respectively. Two SNPs (rs2229682 and rs1385129) in *GLUT1* also demonstrated a significant association with ADHD with p-values of 0.0433 and 0.0386, respectively. **Conclusion:** Increased risk of ADHD among patients with SB may be associated with transmission of specific SNPs alleles in *MTHFR* and *GLUT1*. This is the first study to show that genetic variation in genes from the glucose metabolic pathway and folate/homosysteine pathway may increase risk of attention problems and executive functions in children with SB.

**Evidence for interactive effects of smoking and asthma status on associations between *NOS1*, *NOS2A*, and *NOS3* genetic variants and $Fe_{NO}$ or eosinophil levels in the EGEA study.** *R. Nadif[1], F. Monier[1], M. Boussaha[2], N. Le Moual[1], R. Matran[3], J. Bousquet[1], I. Pin[4], M. Lathrop[5], F. Kauffmann[1], F. Demenais[2], E. Bouzigon[2].* 1) Inserm U780, Univ Paris-Sud, IFR69, Villejuif, France; 2) Inserm, U946, Paris, France; 3) Univ Lille Nord de France, CHU, Lille, France; 4) Inserm U823, Univ Joseph Fourier, Grenoble, France; 5) CEA, CNG, Evry, France.

Asthma is a complex and heterogeneous disorder, resulting from both genetic and environmental factors. Blood eosinophil count and exhaled nitric oxide ($Fe_{NO}$) are markers of inflammation in asthma. Nitric oxide is produced endogenously by nitric oxide synthases (NOS). We investigated associations of $Fe_{NO}$ level and eosinophil count with 37 tag SNPs belonging to three candidate genes: *NOS1* (n=25), *NOS2A* (n=5) and *NOS3* (n=7), in current asthmatics and non asthmatics, and whether smoking habits modify these associations. Association analyses were conducted using GEE regression-based method in 172 families (482 adults, 39.2 yrs, 47% current asthmatics) from the French Epidemiological study on the Genetics and Environment of Asthma. Overall, $Fe_{NO}$ levels were positively associated with asthma (geometric mean: 20.4 *vs.* 15.9 ppb, P<0.0001) and with eosinophil count (*r*=0.28, P<0.0001) and negatively associated with smoking (trend P<0.0001). In asthmatics, *NOS1* polymorphisms were associated with both a decreased $Fe_{NO}$ level and an increase of eosinophil count (P ranging from 0.02 to 0.003), while no association was found in non-asthmatics ($P_{Interaction} \leq 0.03$). Regarding $Fe_{NO}$ level, we also found a strong interactive effect between *NOS3* (rs743507) and current asthma status ($P_{Int}<0.0001$). In asthmatics, TT genotype increased $Fe_{NO}$ (29.8 vs. 19.3 ppb, P=0.002), whereas this genotype was associated with a decrease in $Fe_{NO}$ in non-asthmatics (10.8 *vs.* 15.6 ppb, P=0.01). We also detected an interaction between *NOS2A* polymorphisms and smoking influencing $Fe_{NO}$ levels ($P_{Int}$ = 0.002). Indeed, non-asthmatic smokers carrying AA genotype at rs3730013 had a decreased $Fe_{NO}$ level (8.8 *vs.* 15.1 ppb, P=0.002), whereas no association was found in non-smokers. In asthmatics, this latter polymorphism was also associated with an increase of eosinophil count (P=0.002). No interactive effect between smoking and *NOS1* or *NOS3* genes on $Fe_{NO}$ level or eosinophil count was observed. Our findings suggest that 1) associations of *NOS1* and *NOS3* with $Fe_{NO}$ level and eosinophil count differed according to current asthma status and 2) smoking modify the effect of *NOS2A* variants on FeNO level.

***ARMS2* A69S and *CFH* Y402H polymorphisms are not associated with choroidal neovascularization in highly myopic eyes of the Japanese population.** *H. Nakanishi[1,2], N. Gotoh[1,2], R. Yamada[3], K. Yamashiro[1], A. Otani[1], H. Hayashi[1,2], I. Nakata[1,2], A. Tsujikawa[1], N. Shimada[4], K. Ohno-Matsui[4], M. Mochizuki[4], M. Saito[5], K. Saito[5], T. Iida[5], F. Matsuda[2], N. Yoshimura[1].* 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 3) Human Genome Center, Institute of Medical Science, University of Tokyo, Tokyo, Japan; 4) Department of Ophthalmology and Visual Science, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 5) Department of Ophthalmology, Fukushima Medical University, Fukushima, Japan.

Choroidal neovascularization (CNV) is one of the most vision-threatening complications in high myopia. Clinical findings such as patchy chorioretinal atrophy and lacquer cracks are important predisposing signals for the development of CNV in highly myopic eyes. CNV is a complication which is observed in both high myopia and in age-related macular degeneration (AMD); this raises a hypothesis that the process involved in the development of AMD also contributes to the development of CNV in highly myopic patients. To examine this hypothesis, we studied genetic association of two major genetic determinants for AMD, namely, *ARMS2* and *CFH*, with the development of CNV in Japanese population. For this purpose, DNA samples of 569 high myopia patients (axial lengths > 26.00 mm or a refractive errors > -6.0 diopters) consisting of 281 patients with CNV (mean age ± standard deviation of 58.8 ± 13.6 years, ranged from 21 to 88 years; male : female, 22.8% : 77.2%) and 288 patients without CNV (55.1 ± 13.9 years, ranged from 21 to 88 years; male : female, 43.1% : 56.9%) were recruited. We compared genotype distribution of rs10490924 (A69S) of *ARMS2* and rs1061170 (Y402H) of *CFH* between these two groups using the Taqman technology. The differences in the genotype distributions for these two SNPs were tested with the Trend $\chi^2$ test. We failed to obtain significant difference in the genotype distribution of both SNPs between the two groups (*P*=0.49 for rs10490924 and *P*=0.38 for rs1061170). The P-values were not improved with adjustments for age and gender using logistic regression analysis (*P*= 0.50 for rs10490924 and *P*=0.78 for rs1061170). Although functional roles of *ARMS2* and *CFH* in the onset and progression of AMD, particularly CNV in the disease, are yet to be elucidated experimentally, genetic alteration of these two genes is not likely to contribute to the development of CNV in high myopia in Japanese.

## 878/W/Poster Board #536

**Common Variants in the Pregnane X Receptor Gene may contribute to the Genetic Susceptibility to Nonalcoholic Fatty Liver Disease.** *S. Sookoian[1,2], G. Castaño[2], A. Burgueño[1], T. Fernández Gianotti[1], M. Rosselli[1], C. Pirola[1].* 1) Laboratory of Clinical and Molecular Hepatology and Department of Molecular Genetics and Biology of Complex Diseases. Institute of Medical Research A Lanari-IDIM, University of Buenos Aires- National Council of Scientific and Technological Research. CONIC; 2) Department of Medicine and Surgery. Hospital Abel Zubizarreta. Ciudad Autónoma de Buenos Aires, Argentina.

Background: Nonalcoholic fatty liver disease (NAFLD), a disease characterized by fat accumulation in the liver, is an emerging epidemic disease affecting 10 to 40 percent of the general population in Western countries, and up to 80% of obese and diabetic individuals. While it is well known that environmental risk factors influence the development and progression of NAFLD, the contribution of the individual genetic variation to disease predisposition is still uncertain. Pregnane X receptor (PXR) is a member of the nuclear receptor superfamily, whose primary function is the regulation of an entire network of genes involved in the detoxification and elimination of xenobiotics from the body. Emerging evidence has also pointed to an equally important role of PXR as an endobiotic receptor by impacting on lipid homeostas.Objective: To explore the contribution of gene variants and derived haplotypes of the PXR to the severity of NAFLD. Methods: 290 individuals were evaluated in a case-control association study, including 188 NAFLD patients with different stages of disease severity and 102 healthy individuals. Four tag SNPs (rs12488820 C/T; rs2472671 C/T; rs2461823 A/G; rs1054191 A/G) encompassing 36 kb in chr.3 and representing 33 polymorphic sites (r2 >0.8) were genotyped. Besides, 4 additional SNPs (rs3814055, rs3814057, rs6785049 and rs7643645) were included because they showed previous evidence about functionality. Results: Genotypic tests for single SNP showed that rs7643645 and rs2461823 were significantly associated with disease severity by ordinal multinomial analysis (p=0.0011 and 0.038, respectively). A significant association was also observed under the additive model for both variants (p=0.00037 and 0.011, respectively). Consistent with the analysis of individual markers, we observed that the multimarker composed by the rs2461823/A-rs7643645/G was significantly associated with the disease severity (p=6.8X10$^{-5}$, beta 0.45). In addition, the rs7643645/G variant was significantly associated with ALT level (p= 0.025), a surrogate marker of severe liver injury. Finally, in univariate analysis the rs7643645/G was significantly associated with fatty liver disease (p value=0.039), odds ratio, 1.457; 95% confidence interval, 1.018-2.086. Conclusion: Our study suggests that PXR polymorphisms and related haplotypes may contribute to the disease severity in NAFLD by influencing the individual susceptibility to progress to more severe stages of the disease.

## 879/W/Poster Board #537

**Mitochondrial DNA polymorphisms in metabolic syndrome.** *M. Lu[1], R. Bai[3], L. Wong[3], S. Juo[1,2].* 1) Graduate Institutive Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Kaohsiung Medical Univerisity Memorial Hospital, Kaohsiung, Taiwan; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, USA.

Metabolic syndrome is characterized by hyperglycemia, dyslipidemia, hypertension and diabetes. Growing evidence indicated that mitochondrial dysfunction is involved in the development of type 2 diabetes mellitus and metabolic syndrome. We hypothesized that mtDNA variants may be involved in the development of metabolic syndrome. We proposed a case-control study to investigate the association between mtDNA polymorphisms and metabolic syndrome. A total of 537 cases and 1106 controls were recruited in our study. We selected 82 mtDNA SNPs and 18 Asian-specific haplogroups in the initial screening test (case n=141; control n=506). The initial screening showed that six mtSNPs (249delA, C3970T, A10398G, A12361G, G13928C, T12126C) and three haplogroups (D4, F and M10) were related to susceptibility to metabolic syndrome. Among these mtDNA polymorphisms, we selected the most significant genetic variant, mtSNP A10398G, for the validation test in another dataset. We found the G variant of mtSNP A10398G mildly increased the risk (OR=1.25, 95% C.I=1.00~1.57, p=0.05) for metabolic syndrome. However, the G variant was not found to be significantly related to any of the risk components of metabolic syndrome. Our results indicated that mtDNA polymorphisms may participate in the development of metabolic syndrome in the Chinese population.

**HFE variants do not contribute to the high prevalence of diabetes in the Jordanian population.** *A. Alkhateeb, A. Uzrail.* Dept Biology, Jordan Univ Science & Tech, Irbid, Jordan.

Diabetes mellitus has different etiologies and different frequencies across populations. Prevalence in the United States is around 8%. In Jordan, a recent estimate of diabetes prevalence was 17.1%, about twice that of the United States. Some studies showed that mutations in HFE gene, the gene mutated in hemochromatosis, might play a role in increasing the risk of developing diabetes. In this study, we sought to examine whether HFE variants might partially explain the increased risk of diabetes in the Jordanian population. For that purpose we genotyped 89 patients with type 2 diabetes and 204 controls for the two main variants in HFE gene, C282Y and H63D. We extracted DNA from all participating individuals, used polymerase chain reaction to amplify exons 2 and 4 of the HFE gene and restriction fragment length polymorphism method to genotype the variants. We did not find any C282Y variant in either patients or controls. H63D heterozygous in diabetics were 23.60% and in controls 22.55%. Allelic frequency of the mutant H63D allele was 11.80% in diabetics and 11.27% for controls. Genotype and allele frequencies were compared using Freeman-Halton extension of Fisher's exact test for a 2*3 contingency table and Chi squared test, respectively. We found no significant difference between the two groups. Our results suggest that HFE variants do not play a major role in the increased frequency of diabetes in the Jordanian population and, consequently, other factors might be involved.

## 881/W/Poster Board #539

**Detailed physiologic characterization of novel genetic loci implicated in fasting glucose homeostasis.** *E. Ingelsson[1], M-F. Hivert[2,3], I. Prokopenko[4,5], V. Lyssenko[6], C. Langenberg[7], J. Dupuis[8,9], N.J. Wareham[7], M. Walker[10], J.B. Meigs[2,3], R.M. Watanabe[11,12], M. McCarthy[4,5], L. Groop[6], J.C. Florez[3,13] on behalf of the MAGIC investigators.* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) General Medicine Division, Massachusetts General Hospital, Boston, USA; 3) Department of Medicine, Harvard Medical School, Boston, Massachusetts, USA; 4) Wellcome Trust Center for Human Genetics, Oxford, UK; 5) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK; 6) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, University Hospital Malmö, Malmö, Sweden; 7) MRC Epidemiology Unit, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, UK; 8) Department of Biostatistics, Boston University School of Public Health, Boston, Massachusetts, USA; 9) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, Massachusetts, USA; 10) Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK; 11) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California, USA; 12) Department of Physiology and Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, California, USA; 13) Diabetes Research Center (Diabetes Unit) and Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts, USA.

Quantitative genetic studies have indicated that genetic factors underlie a substantial component of both insulin sensitivity and insulin secretion. Recently, the Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) identified 9 novel genetic loci associated with fasting glucose (FG; in or near *ADCY5, MADD, ADRA2A, CRY2, FADS1, GLIS3, SLC2A2, PROX1* and *FAM148B*) and one novel locus associated with fasting insulin (*IGF1*). In the present study, we have genotyped the lead SNPs from these 10 loci as well as 7 additional loci previously associated with FG, in non-diabetic individuals from the general population assessed with 3- or 4-point oral glucose tolerance tests (OGTT; n=15,530), fasting proinsulin levels (n= 13,734), and/or euglycemic clamps (n=2,106). M/I from euglycemic clamps, Si from frequently-sampled intravenous glucose tolerance tests, and several OGTT-derived insulin sensitivity indices were used to reflect insulin sensitivity, whereas insulin response was approximated with the insulinogenic index (at 30 minutes).

Of the 17 examined loci, the FG-raising alleles at *MADD* and *FAM148B* were exclusively associated with higher proinsulin (~1.1 pmol/L per FG-raising allele at the *MADD* locus, $p=3.1*10^{-65}$ after adjusting for age, sex, fasting insulin and BMI), but not with the insulinogenic index, suggesting a defect in insulin synthesis or processing. The FG-raising alleles at *TCF7L2*, *SLC30A8* and *PROX1* were associated with higher fasting proinsulin as well as a lower insulinogenic index, indicating an effect on both insulin processing and secretion. The FG-raising alleles at 4 of the examined loci (*GCK*, *FADS1*, *DGKB*, *MTNR1B*) were associated with lower insulin response to glucose load, while 2 were associated with higher insulin response (*G6PC2* and *SLC2A2*). Finally, 3 of these loci previously associated with FG or fasting insulin were associated with lower insulin sensitivity measured with euglycemic clamps (*G6PC2*, *ADCY5*, and *TCF7L2*) or OGTT surrogate measures (*GCKR* and *IGF1*).

These loci have been suggested to affect FG levels through various biological functions, including signal transduction, cell proliferation and development, glucose-sensing and circadian regulation. Our findings extend the physiological knowledge about these loci and provide important mechanistic insights into their role in glucose and insulin regulation.

## 882/W/Poster Board #540

**Sex Hormone Binding Globulin (SHBG) $TAAAA_n$ polymorphism is associated with measures of fetal growth in a Hispanic cohort.** *C. Ackerman[1], M.G. Hayes[1], L.P. Lowe[2], H. Lee[1], R. Freathy[3], A.R. Dyer[2], B.E. Metzger[1], W.L. Lowe[1], M. Urbanek[1], HAPO Study Cooperative Research Group.* 1) Division of Endocrinology, Dept of Medicine, Northwestern University, Chicago, IL; 2) Dept of Preventive Medicine, Northwestern University, Chicago, IL; 3) Genetics of Complex Traits, Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, UK.

Prenatal exposure to testosterone has been implicated in fetal growth and subsequent insulin resistance in animal models. Furthermore, prenatal testosterone exposure in humans, from maternal or fetal sources, is linked to low birth weight, head circumference and length. SHBG is a glycoprotein that binds the sex hormones testosterone and estradiol and regulates their biological activity. Therefore, genetic variation in SHBG may impact birth outcome in humans by changing the amount of biologically active testosterone *in utero*. The $TAAAA_n$ repeat in the SHBG promoter affects transcription of the gene and serum SHBG levels. We used the multi-ethnic Hyperglycemia and Adverse Pregnancy Outcome (HAPO) cohort, comprised of pregnant mothers and their offspring, to evaluate the impact of genetic variation at the SHBG $TAAAA_n$ repeat on fetal growth. This cohort is ideal for these studies due large subject number and consistently assessed measures of fetal growth. We tested for association between fetal genotype and fetal traits (cord C-peptide, cord and 2-hour plasma glucose, birth weight, fat mass, head circumference, length, and skinfolds) in four ethnic groups (3518 Caucasian babies, 2129 Thai babies, 1237 Afro-Caribbean babies; and 792 Hispanic babies). Alleles were re-coded into a biallelic system and associations were assessed through linear regressions with single trait outcomes under an additive model and adjusted for covariates. SHBG A07 (7 TAAAA repeats) was strongly associated all measures of fetal growth and adiposity in the Hispanic population. For example, SHBG A07 was negatively associated with birth weight ($\beta$= -76.24gm, [95%CI: -120.5 to -31.98] per allele, *P*=0.0008), fatmass ($\beta$= -29.79, [95%CI: -47.74 to -11.84], *P*=0.001), head circumference ($\beta$= -0.22cm, [95%CI: -0.35 to -0.1], *P*=0.0006), length ($\beta$= -0.22cm, [95%CI: -0.41 to -0.04], *P*=0.02), and sum of skinfolds ($\beta$= -0.52mm, [95%CI: -0.86 to -0.19], *P*=0.002). These associations were not seen in the non-Hispanic populations. Our results indicate that genetic variation at the SHBG promoter $TAAAA_n$ repeat may be involved with fetal growth. The fact that all the associations with SHBG A07 were negative suggests a protective effect, perhaps preventing the offspring from excessive growth. Because these associations were not seen in non-Hispanic populations it is unlikely that the $TAAAA_n$ repeat is the causal variant, but is in linkage disequilibrium (LD) with the causal variant in the Hispanic population.

## 883/W/Poster Board #541

**Genetic risk factors for post-infectious irritable bowel syndrome (IBS) vs. sporadic IBS: the involvement of distinct pathways.** *A.-C. Villani[1], Y. Saito[2], M. Lemire[3], M. Thabane[4], J.J. Larson[2], E.J. Atkinson[2], J. Zimmerman[2], A.E. Almazar Elder[2], S.M. Collins[4], D. Franchimont[1,5], J.K. Marshall[4].* 1) McGill University, Montreal, QC, Canada; 2) Mayo Clinic, Rochester, MN, USA; 3) Ontario Institute for Cancer Reseach, Toronto, ON, Canada; 4) McMaster University, Hamilton, ON, Canada; 5) Erasme University Hospital, Brussels, Belgium.

Acute gastroenteritis (GE) is the strongest risk factor for development of irritable bowel syndrome (IBS), the most common and costly gastrointestinal disorder in Western society. In May 2000, over 2300 residents of Walkerton (Canada) developed GE from microbial contamination of the municipal water supply and a third of them subsequently developed post-infectious (PI)-IBS. We have previously identified *TLR9*, *IL6*, and *CDH1* regions as novel PI-IBS susceptibility loci in the unique and only known PI-IBS population cohort (Walkerton Health Study). We aimed to 1) defining whether these associations were independent from the known PI-IBS clinical predictors, 2) pursue functional experiments, and 3) evaluate whether these risk factors contributed to the development of IBS without an infectious onset since it's unknown whether sporadic IBS share a common disease trigger. Methods: The clinical predictors of IBS after acute GE were evaluated in the 1253 patients who provided DNA for the genetic analysis and variants at the 3 most significantly associated loci were integrated in the analyses. Quantitative RT-PCR, Elisa, and sequencing methods were used to assess gene-expression and protein level associations in monocytes derived from 32 healthy individuals. For the Mayo Clinic validation cohort, we compared 473 sporadic IBS cases to 464 healthy controls matched for age, gender, ethnicity and region. Associations between variants and traits were assessed using mixed effects logistic regression models and chi-square test. Results: The identified susceptibility variants in the *TLR9*, *IL6* and *CDH1* regions are independent risk factors for developing PI-IBS when compared to the previously identified clinical risk factors (i.e. younger age, female gender, bloody stools, abdominal cramps, weight loss). Carriers of the rs2069861 risk allele were associated with increased *IL6* mRNA expression ($p$=0.0366) and decreased, LPS-stimulated IL-6 production ($p$=0.0269). None of the *TLR9*, *IL6*, and *CDH1* functional and tagging variants were significantly associated with sporadic IBS. Conclusion: The 3 susceptibility loci are all independent risk factors for developing PI-IBS when controlling for previously reported PI-IBS clinical risk factors in the Walkerton population. This is the first study comparing genetic risk factors for PI-IBS and sporadic IBS. The results suggest that different pathways and distinct genetic risk factors contribute to PI-IBS and sporadic IBS susceptibility.

## 884/W/Poster Board #542

**Interaction between SNPs in the *ESR1* gene and estrogen exposure in age-related macular degeneration.** *J.A. Ayala Haedo[1], D.R. Velez[1], M. Polk[1], P.J. Gallins[1], P.L. Whitehead[1], A. Agarwal[4], E.A. Postel[5], S.G. Schwartz[2], J.L. Kovach[2], G. Wang[1], J.L. Haines[3], W.K. Scott[1], M.A. Pericak-Vance[1].* 1) Miami Institute of Human Genomics. University of Miami, Miller School of Medicine, Miami, FL; 2) Bascom Palmer Eye Institute. University of Miami, Miller School of Medicine, Miami, FL; 3) Center Human Genetics Research Medical Center, Vanderbilt University, Nashville, TN; 4) Vanderbilt Eye Institute, Vanderbilt University, Nashville, TN; 5) Duke University Eye Center. Duke University, Durham, NC.

Estrogen exposure is a strong protective factor for age-related macular degeneration (AMD). In addition, SNPs in estrogen receptor 1 (*ESR1*) correlate with estradiol levels and increase the risk for AMD. The purpose of our study was to assess association of AMD with SNPs in *ESR1* and their interactions with exogenous estrogen exposure. We genotyped 22 tagSNPs ($r^2$>0.60) in the *ESR1* gene using a Sequenom assay in 778 related and unrelated female subjects. Individuals were classified for AMD using a modified version of the Age related eye disease study (AREDS) classification, where grades 1 & 2 were considered controls (n=257) and grades 3, 4 and 5 were considered AMD cases (n=521). Estrogen exposure was determined through a series of questions that included hormonal replacement therapy (HRT) and oral contraceptive usage (OC) history. Binary outcome variables [yes (1)/ no (0)] were constructed for each category (OC and HRT). Association between AMD, tagSNPs and estrogen exposure through HRT and OC was examined using generalized estimating equations (GEE), adjusting for age and cigarette smoking. Significant interactions ($p<0.05$) between SNPs and estrogen exposure were examined by a stratified analysis of genotype by estrogen exposure. We found a protective effect of HRT (OR=0.67, 95% CI [0.45, 0.98], p=0.039) and OC (OR=0.60, 95% CI [0.41, 0.90], p=0.013) on AMD. No association was found with SNPs in *ESR1* and risk of AMD. There were no interactions detected with OC and *ESR1* SNPs. However, when considering all cases (grades 3-5, n=521) and controls (grades 1-2, n=257), a significant SNP/estrogen exposure (HRT) interaction ($p< 0.05$) was detected for RS3020375, RS9341052, RS2813543, RS2813544, RS827423, and RS2234693 . Of these SNPs, only the latter two are in strong linkage disequilibrium ($r^2$=0.78). Only RS2234693 has a putative functional effect, reportedly altering *ESR1* mRNA levels by eliminating transcription factor binding sites. The stratified analysis demonstrates that the protective effect of HRT is found only in carriers of at least one copy of the minor allele at SNPs, RS3020375, RS9341052, RS2813543, RS2234693, RS827423 and in carriers of two copies of the minor allele for RS2813544. These results suggest that the inverse association of AMD and HRT is dependent on *ESR1* SNP genotypes.

**Angiopoietin-like protein 4 (*ANGPTL4*) gene polymorphisms and risk of brain arteriovenous malformations (BAVM).** *B. Mikhak[1], S. Weinsheimer[1], L. Pawlikowska[1,2], P.-Y. Kwok[2,3], S. Sidney[4], C.E. McCulloch[5], W.L. Young[1,6], H. Kim[1,2,5].* 1) Center for Cerebrovascular Research, Department of Anesthesia and Perioperative Care, University of California, San Francisco (UCSF), San Francisco, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA; 3) Cardiovascular Research Institute, UCSF, San Francisco, CA; 4) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 5) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA; 6) Departments of Neurology and Neurosurgery, UCSF, San Francisco, CA.

**Background**: Brain arteriovenous malformations (BAVM) are high-flow vascular lesions with direct shunting of blood from the arterial to venous circulation and are an important cause of intracranial hemorrhage (ICH). The etiology of BAVMs is unknown, but abnormal angiogenesis is hypothesized to play a role. Angiopoietin-like protein 4 (*ANGPTL4*) has been implicated in lipid metabolism and in angiogenesis; it can show anti-angiogenic activity in tumorigenesis by inhibiting vascular permeability, tumor cell motility and invasiveness and pro-angiogenic activity during ischemia. Therefore, we investigated the association between common polymorphisms in *ANGPTL4* and risk of BAVM. **Methods**: We conducted a case-control study of 216 BAVM patients and 246 healthy controls among Caucasians. Using HapMap CEU data, minor allele frequency ≥5% and pairwise $r^2 > 0.8$, four haplotype-tagging single nucleotide polymorphisms (SNPs) in *ANGPTL4* captured variation over a 10kb region: rs2278236 *C/T* (intron 3), rs1044250 *C/T* (exon 5, Thr266Met), rs11672433 *G/A* (exon 6, Pro389Pro), and rs1808536 *A/G* (3' UTR). Allelic, genotypic, and haplotypic tests of associations were performed. **Results**: The minor allele (*A*) of rs11672433 was associated with an increased risk of BAVM (P=0.006) and the association persisted after Bonferroni correction for 4 tests (P=0.02). Carriers of the minor *A* allele were at higher risk for BAVM compared to non-carriers (Odds Ratio (OR)=1.56; 95% Confidence Interval (CI)=1.01-2.41; P=0.046). Risk of BAVM increased with increasing copy of the minor *A* allele after adjusting for age and gender (OR=1.49, 95% CI=1.03-2.15; P=0.03). No other SNPs were associated with BAVM (P>0.05). Five common haplotypes (frequency >1%) were inferred; overall haplotype distribution differed between BAVM patients and controls ($\chi^2$=12.2, df=4, P=0.02). Only 1 haplotype (AG<u>A</u>G) contained the minor *A* allele of rs11672433, and was associated with increased BAVM risk (p=0.01), consistent with single SNP analysis. **Conclusion**: In this population of Caucasians, we found an association between rs11672433 (synonymous Pro389Pro) and risk of BAVM. These results suggest that polymorphisms in the *ANGPTL4* gene may be involved in BAVM pathogenesis, and warrant further investigation.

## 886/W/Poster Board #544

**Crohn's Disease molecular interaction network identifies novel risk locus.** *G.A. Pirela[1], S. KaraMohamed[1], D. Nicolae[1,2,3], T.C. Gilliam[1].* 1) Human Genetics Department, The University of Chicago, Chicago, IL; 2) Statistics Department, The University of Chicago, Chicago, IL; 3) Medicine Department, The University of Chicago, Chicago, IL.

**Purpose -** Crohn's disease (CD) genome wide association studies (GWAS) along with a recent meta-analysis identified 22 potential risk loci. We employed this set of "seed genes" to generate CD-specific molecular interaction networks. We show that 18 of these genes map to a single network. Five network "candidate" genes, not previously reported, showed significant allelic association in the Wellcome Trust Case Control Consortium (WTCCC) data set. Furthermore, 4 of the associated genes showed similar association in the NIDDK-IBD data set.

**Methods -** We used Ingenuity Pathway Analysis (IPA) software to explore molecular and biological networks among 22 previously implicated CD candidate genes. These seed genes were used to interrogate the IPA molecular interaction database and networks were generated algorithmically by maximizing connectivity among seed genes. The software generates and rank-orders the minimum number of networks (up to 35 molecules each) required to include all seed genes. We treat the connecting genes as CD candidates and examine their allelic association to CD in the WTCCC and NIDDK-IBD data sets.

**Results and Conclusions -** Network core analysis with IPA identified a highly connected CD-network by maximizing connectivity among seed genes. The network harbors 18 seed genes and 17 interconnecting, or CD candidate genes. Association analysis of these candidate genes in large CD case-control data sets showed significant allelic association with 7 genes in the WTCCC data set; four of which also showed significant association in the NIDDK-IBD data set. For one of these genes, an upstream SNP was found to be significantly associated in both data sets. Further functional analysis of the core network revealed that 2 of the GWAS associated genes have well-established roles in inflammatory response and immunological disease. These findings further illustrate the power of the network approach for validating candidate gene predictions and for identifying novel risk loci. We discuss the concept of gene-mapping potential of a "threshold" number of authentic candidate genes required to elucidate a disease-related molecular interaction network.

## 887/W/Poster Board #545

**Scanning the Regulatory Landscape of Transcription Factor 7-Like 2 (*TCF7L2*).** *D. Savic, M. Nobrega.* Human Genetics, The University of Chicago, Chicago, IL.

Several genome-wide association studies (GWAS) have pointed to non-protein coding regions in the genome as harboring variants underlying common disease traits. One possibility is that these variants disrupt long-range cis-regulatory elements that control the tissue and temporal expression patterns of neighboring genes. However, given the paucity of efficient platforms for interrogating non-coding sequences for function and subsequently elucidating the effects of variation within these intervals, this makes the experimental follow-up of GWAS at present considerably difficult. Here we describe a strategy to systematically identify regulatory elements and functionally evaluate the impact of mutations within them. A 92.1-kb block of strong linkage disequilibrium (LD) within the *TCF7L2* locus has consistently shown associations to type 2 diabetes (T2D) in diverse human populations. Coding variations within *TCF7L2* were not identified, raising the possibility that regulatory variations in *TCF7L2* distant enhancers may underlie the increased risk to type 2 diabetes. Using a combination of bioinformatics, comparative genomics and mouse genetic engineering, we have obtained a comprehensive map of the regulatory landscape of *TCF7L2*. We have identified several tissue-specific enhancers in the region spanning the association LD block. These enhancers recapitulate the endogenous pattern of *TCF7L2* expression. Interestingly, several enhancers show expression in tissues with established roles in maintaining glucose homeostasis, including pancreas, stomach, brain and bones. Deep sequencing of these enhancers in various human populations, including diabetics and non-diabetics, is undergoing, aiming to identify potential causal variants within these enhancers. In vivo and in vitro studies are being carried out to infer the functional role of these enhancers and will be used to establish the consequences of variants within them. Our results strongly support the notion that distant cis-regulatory elements are often present in regions associated with common diseases, making this a priority target of investigation as a follow-up to GWAS.

## 888/W/Poster Board #546

**Examination of all type 2 diabetes GWAS loci reveals *HHEX* as a locus influencing pediatric BMI.** *J. Zhao[1], J.P. Bradfield[2], H. Zhang[2], K. Annaiah[2], K. Wang[2], C.E. Kim[2], J.T. Glessner[2], E.C. Frackelton[2], F.G. Otieno[2], K.A. Thomas[2], M. Garris[2], R.M. Chiavacci[2], M. Li[3], R.I. Berkowitz[4,5], H. Hakonarson[1,2,6], S.F.A. Grant[1,2,6].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 4) Behavioral Health Center and Department of Child and Adolescent Psychiatry, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Center for Weight and Eating Disorders, Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 6) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA.

A number of studies have found that body mass index (BMI) in early life influences the risk of developing type 2 diabetes (T2D) later in life. Utilizing data from an ongoing genome wide association study (GWAS) of pediatric BMI in our cohort, we investigated the association of pediatric BMI with 21 SNPs at 17 type 2 diabetes loci uncovered through GWAS, consisting of *ACDC*, *ADAMTS9*, *CDC123-CAMK1D*, *CDKAL1*, *CDKN2A/B*, *EXT2*, *HHEX*, *IGF2BP2*, the intragenic region on 11p12, *JAZF1*, *KCNQ1*, *MTNR1B*, *NOTCH2*, *SLC30A8*, *TCF7L2*, *THADA* and *TSPAN8-LGR5*. All subjects were consecutively recruited from the Greater Philadelphia area from 2006 to 2009 at the Children's Hospital of Philadelphia. BMI percentiles were defined using the standard Center for Disease control (CDC) growth chart z-scores. All subjects were biologically unrelated and were aged between 2 and 18 years old. All subjects were between -3 and +3 standard deviations of CDC corrected BMI i.e. outliers were excluded to avoid the consequences of potential measurement error or Mendelian causes of extreme obesity. We partitioned our cohort exactly in half such that we had a 'discovery' cohort (n=3592) and a 'replication' cohort (n=3592). Our data show that the minor allele of rs7923837 at the *HHEX* locus was associated with lower pediatric BMI in both the discovery ($P$=0.0013; survived correction for 21 tests) and replication ($P$=0.023) sets (combined $P$=1.01x10$^{-4}$). However, association was not detected with any other known type 2 diabetes loci uncovered to date through GWAS. One hypothesis could be that rs7923837 is primarily associated with birth weight, as reduced birth weight is often reported to be associated with BMI and type 2 diabetes later in life; although we agree with previous studies that *CDKAL1* is a birth weight associated gene, we have not observed significant association between *HHEX* and this trait. So in summary, our data show that the same genetic *HHEX* variant that is associated with type 2 diabetes from previous studies also influences pediatric BMI.

## 889/W/Poster Board #547

**Variants in the Regional Paralogs and Receptors of IL10 Gene and HIV-1 Susceptibility in African American Adolescents.** *S. Shrestha[1], H.W. Wiener[1], W. Song[1], A. Shendre[1], C.M. Wilson[1], R.A. Kaslow[1], B. Aissani[1], J. Tang[2].* 1) Dept Epidemiology, UAB, Birmingham, AL; 2) Dept Medicine, UAB, Birmingham, AL.

Cytokines in the interleukin-10 (IL10) gene family have broad immunomodulatory function and several SNPs in IL10 have been reported to influence HIV-1 pathogenesis or infection. While most genetic studies of IL10 have focused on its promoter region, we hypothesize that several genes in the IL10 family likely act in concert to modulate HIV susceptibility. We conducted a case-control study on 250 HIV-1 seropositive and 106 high-risk seronegative African American adolescents who were recruited into the Reaching for Excellence in Adolescent Care and Health (REACH) study in 13 US cities between 1996 and 1998 and followed until 2001. All subjects designated uninfected for this study had a history of either sexual intercourse or injection drug use, had negative HIV enzyme linked immunosorbent assay (HIV-ELISA) performed within 30 days of enrollment into the REACH study, and remained seronegative until the end of the study period. All infected subjects had a positive ELISA test, with a confirmatory Western blot performed before REACH enrollment. We screened 84 single nucleotide polymorphisms (SNPs) in the coding and UTR regions and haplotype tagging SNPs in introns of IL10 and five related genes, paralogs (IL19, IL20 and IL24), and receptors (IL10RA and IL10RB). In univariate (additive) model using logistic regression analysis, 8 SNPs in IL20, IL24, IL10RA and IL10RB resulted to be statistically significant (<0.0003-0.05). In the multivariate model, rs9610 (p=0.0005) in IL10RA 3'UTR, rs2981572 (p=0.02) in IL20 5'UTR, rs6517158 (p=0.003) and rs8178565 (p=0.01) both in IL10RB 3'UTR were independently associated with HIV-1 infection. Further, the haplotype analysis of these two SNPs in the IL10RB 3'UTR showed that one haplotype with 7% frequency in HIV-positives seemed very rare (0.5%) in HIV-negatives.Multiple studies have extensively examined the association between SNPs in the IL10 gene and HIV disease pathogenesis or infection, but the evidence for involvement remains inconclusive. Our study suggests that variants in several members of the IL10 gene family might influence susceptibility to HIV infection in African Americans. Involvement of the IL10 molecule in immunity to HIV infection could be modulated through more complex interactions among related genes. Investigation of the role of the IL10 gene family in HIV infection deserves a comprehensive systems biology approach.

## 890/W/Poster Board #548

**Impact of host APOBEC3 retroviral restriction family genes on HIV-1/AIDS.** *P. An[1], J.J. Goedert[2], G.D. Kirk[3], S. Donfield[4], S. Buchbinder[5], J. Phair[6], C.A. Winkler[1].* 1) Lab Genomic Diversity, SAIC-Frederick Inc, Frederick, MD; 2) Epidemiology Branch, National Cancer Institute, Bethesda, MD; 3) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 4) Rho, Inc., Chapel Hill, NC; 5) San Francisco Department of Public Health, San Francisco, CA; 6) Northwestern University, Chicago, IL.

Human APOBEC3 cytidine deaminases are intrinsic resistance factors to retroviral infection including HIV-1. APOBEC3 proteins restrict the replication of vif-deficient HIV-1 by cytidine deamination on single-stranded DNA or by RNA binding. APOBEC3 family proteins (APOBEC3A-H) were encoded by seven genes (*APOBEC3A-H*) arrayed in a 150 kb region on 22q13.2, with near identity of several exonic sequences among APOBEC3 genes posing great challenge for genotyping. APOBEC3 genes may have arisen from gene expansion, domain duplication, gene conversion and recombination. In vitro.studies have shown that APOBEC3 proteins vary in their ability in restricting HIV-1 replication, vif resistance and deamination target motifs. Previously we have reported that a structural variation in *APOBEC3G* and a deletion in *APOBEC3B* were associated with HIV-1 disease progression. At the present study, we seek to evaluate the in vivo effect and interaction of all seven APOBEC3 genes on host susceptibility to HIV- acquisition and disease progression. Genetic association study was performed in five well-characterized HIV-1 natural cohorts consisting of more than 3000 HIV-1 infected and exposed but uninfected individuals of European and African Americans. Guided by phylogenetic and sequence homology analyses, gene-specific SNPs were selected for genotyping and the genotype distribution were found to conform to Hardy-Weinberg equilibrium. The association analysis was done by a logistic regression for the comparison of HIV-1 infected and uninfected groups and by Cox proportional hazards model for the rate of AIDS progression. Linkage disequilibrium blocks were formed for each gene, in consistence with the gene duplication origin. Variation in *APOBEC3A* and *APOBEC3C* had no effect on either infection or progression in both populations. On the order hand, in addition to effects of *APOBEC3B* and *APOBEC3G*, two amino acid-changing SNPs in *APOBEC3F* were significantly associated with slower rate of progression to AIDS in European Americans and a trend of protection in African Americans. Our epidemiological results are consistent with the in vitro observation that APOBEC3B, APOBEC3G and APOBEC3F have strong anti-HIV effect. Our comprehensive analysis provides insights into the in vivo role of APOBEC3 proteins and their interplay in host innate defense against retroviral infection. **Association of KIR gene polymorphism with malaria severity in Thailand.** *K. Hirayasu[1,2,3], J. Ohashi[4], K. Kashiwase[3], M. Minemoto[3], I. Naka[4], H. Hananantachai[5], A. Ogawa[3], M. Takanashi[3], K. Tokunaga[1], J. Patarapotikul[5], T. Yabe[3].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) JSPS Research Fellow; 3) Tokyo Metropolitan Red Cross Blood Center, Tokyo, Japan; 4) Doctoral Program in Life System Medical Sciences, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Ibaraki, Japan; 5) Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand.

**[Purpose]** Malaria is one of the most important infectious diseases, affecting 300 million people and causing more than 1 million deaths annually worldwide. Despite extensive studies on the critical roles of NK cells in malaria, epidemiological study concerning NK receptor polymorphism and malaria severity has not been described yet. In this study, we examined a possible association of killer Immunoglobulin-like receptor (KIR) gene polymorphism with severity of Plasmodium falciparum malaria.

**[Methods]** Subjects enrolled in this study were 203 mild malaria, 165 non-cerebral severe malaria, and 109 cerebral malaria patients living in northwest Thailand near the border with Myanmar. KIR ligand (HLA-A3, HLA-A11, HLA-Bw4, HLA-C1, HLA-C2) and KIR genotypes were determined by PCR-SSO and PCR-SSP method. The carrier frequencies of the KIR-HLA receptor-ligand pairs were compared between malaria patient groups using the Fisher's exact test based on a 2 x 2 contingency table.

**[Results]** In our study population, detected KIR-HLA receptor-ligand pairs were as follows: KIR2DL1-HLA-C2, KIR2DL2-HLA-C1, KIR2DL3-HLA-C1, KIR3DL1-HLA-Bw4, and KIR3DL2-HLA-A3, -A11. Among these pairs, KIR2DL3-HLA-C1 was significantly associated with cerebral malaria compared with non-cerebral severe malaria (odds ratio (OR) 3.44, P=0.001), and mild malaria (OR 2.90, P=0.004).

**[Conclusion]** KIR-HLA receptor-ligand combinations have been previously shown to influence differences in NK cell functional responses among individuals. Therefore, our result suggests that individuals carrying KIR2DL3-HLAC1 show NK cell response susceptible to cerebral malaria.

**Variants in Toll-like receptor 2 (*TLR2*) associate with pulmonary tuberculosis in Caucasians and West Africans.** *W.K. Scott[1], D.R. Velez[1], W.F. Hulme[1], J.L. Myers[1], M.E. Stryjewski[2], E. Abbate[3], R. Estevan[3], S.G. Patillo[4], R. Olesen[5], C. Wejse[5,6], G. Sirugo[7,8], A. Tacconelli[7,8], J.R. Gilbert[1], C.D. Hamilton[4,9].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics and Miami Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Medicine, Centro de Educación Médica e Investigaciones Clínicas "Norberto Quirno" (CEMIC), Buenos Aires, Argentina; 3) Department of Medicine, Hospital F.J. Muñiz, Buenos Aires, Argentina; 4) Department of Medicine, Duke University Medical Center, Durham, NC; 5) Department of Infectious Diseases, Aarhus University Hospital, Skejby, Denmark; 6) Bandim Health Project, Danish Epidemiology Science Centre and Statens Serum Institute, Bissau, Guinea-Bissau; 7) Unità di Genetica Medica, Ospedale San Pietro FBF, Rome, Italy; 8) Dipartimento di Biopatologia e Diagnostica Per Immagini, Università di Tor Vergata, Rome, Italy; 9) Family Health International, Research Triangle Park, NC.

Tuberculosis (TB) is a global public health problem and a major cause of preventable death each year, with 8.8 million new cases of TB and 1.6 million deaths worldwide in 2005. Approximately ten percent of exposed individuals develop pulmonary or extrapulmonary TB, suggesting that host defense factors, assumed to be at least partly under genetic control, influence development of active disease. Polymorphisms in Toll-like receptors (TLRs) have been previously associated with regulation of TLR expression and development of active TB. In the present study 71 single nucleotide polymorphisms (SNPs) in *TLR1*, *TLR2*, *TLR4*, *TLR6*, and *TLR9* were examined in a case-control sample of TB cases, relatives, and close contact controls comprising 474 (295 cases and 179 controls) African-Americans, 381 (237 cases and 144 controls) Caucasians, and in a community-based case-control sample of 667 (321 cases and 346 controls) Africans from Guinea-Bissau. Association of SNPs with pulmonary TB was examined using generalized estimating equations and logistic regression. We also performed case-only tests of association for increased lung cavitation when data were available. Multiple statistically significant associations were observed across populations at *TLR9* and *TLR2*. The strongest evidence for association came at an insertion (I) /deletion (D) polymorphism (-196--174) in *TLR2* that strongly associated with TB in both Caucasians (II vs. ID&DD, OR=0.41 [95% CI 0.24-0.68], p=0.0007) and Africans (II vs. ID&DD, OR=0.70 [95% CI 0.51-0.95], p=0.023). Four SNPs in *TLR9* associated with TB in African-Americans with the strongest evidence for association coming from the additive model for rs352139 (OR=1.80[95% CI 1.29-2.50], p=0.001). One SNP in *TLR2* associated with increased cavitation in Caucasians (rs1816702, OR=3.00 [95% CI 1.27-7.13], p=0.013) and one SNP in *TLR1* associated with decreased cavitation in African-Americans (rs4624663, OR=0.40 [95% CI 0.17-0.96], p=0.040). Our preliminary findings in three independent population samples indicate that variations in *TLR2* and *TLR9* play important roles in both TB susceptibility and development of lung cavitation.

## 893/W/Poster Board #551

**Obesity and diabetes genes are associated with being born small for gestational age: Results from the Auckland Birthweight Collaborative study.** *A.R. Morgan[1,2], D.Y. Han[1,2], W.J. Wam[1,2], J. Thompson[3], P.N Black[4], L. Ferguson[1,2], E.A Mitchell[3].* 1) Discipline of Nutrition, FM & HS, The University of Auckland, Auckland, New Zealand; 2) Nutrigenomics New Zealand; 3) Department of Paediatrics, FM & HS, The University of Auckland, Auckland, New Zealand; 4) Department of Pharmacology & Clinical Pharmacology, FM & HS, The University of Auckland, Auckland, New Zealand.

Individuals born small for gestational age (SGA) are at increased risk of rapid postnatal weight gain, later obesity and diseases in adulthood such as type 2 diabetes, hypertension and cardiovascular diseases. Although several hypotheses have been proposed, the mechanism underlying this association remains unknown. In this study, we have tried to determine genetic factors that may have a role to play. It has previously been estimated that about 46% of the predisposition to be delivered SGA is due to genetic factors. The fact that SGA births tend both to cluster in families and to recur in successive generations further supports the role of genetics.

In this study we tested the association between small for gestational age and polymorphisms in genes that have previously been associated with obesity and/or diabetes. We investigated 65 single nucleotide polymorphisms (SNPs) in 43 genes in samples from the Auckland Birthweight Collaborative study - a longitudinal study that is currently in phase 5. Data have been collected at birth, 1, 3.5, 7 and most recently 11 years of age. Approximately half the children were born small for gestational age (SGA) and half were appropriate for gestational age (AGA). DNA samples were available for 561 European children and genotyping of these samples was undertaken using the Sequenom genotyping platform.

To date 32 SNPs have been genotyped and from our preliminary analysis a number of these are showing evidence of association with SGA. This includes significant p values (less than 0.05) for the novel findings of the genes FTO (fat mass and obesity associated), KCNJ11 (potassium inwardly-rectifying channel J11) and BDNF (brain-derived neurotrophic factor) being associated with SGA at the allelic and/or genotypic level. Full results of all 65 genetic variants analysed for their association with SGA will be presented at the conference.

## 894/W/Poster Board #552

**Interaction of WDR36 & STI1 Mutations are Involved in Polygenic Inheritance of Primary Open-Angle Glaucoma.** *T. Footz[1], S. Dubois[2], V. Raymond[2], M. Walter[1].* 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Ocular Genetics and Genomics, CHUL Research Center, Quebec City, Quebec, Canada.

Glaucoma is a common neurodegenerative disease characterized by progressive irreversible blindness and frequently presents with increased intraocular pressure. A variety of loci have been linked to inherited forms of the most common subtype, primary open-angle glaucoma (POAG), including the rRNA-processing gene WDR36. The occurrence of rare non-synonymous WDR36 sequence variants in normal control subjects supported the theory that the genetics of POAG is complex, where the normally late-onset disease would result from gene:gene and gene:environment interactions. We previously demonstrated that WDR36 mutations encode functional defects that affect cell growth when expressed in the homologous UTP21 gene in haploid yeast carrying a null mutation in a second gene, the co-chaperone STI1. POAG patients carrying WDR36 variants have recently been screened for mutations in STI1, whose gene product also has neurotrophic properties. Using our yeast system, we investigated the functional consequences of the POAG-exclusive STI1(K434R) variant, which was found in a doubly-heterozygous patient also possessing the WDR36(L25P) variant. We created yeast strains carrying the null mutation of STI1 and a deletion of UTP21 but with low-copy plasmids expressing human STI1 and yeast UTP21 under the control of the corresponding yeast gene promoters. Strains co-expressing the POAG-associated mutation D621G in yUTP21 (homologous to D658G in hWDR36) and the K434R variant in hSTI1 exhibited slower growth than the strains with only wild-type or single-mutant constructs, indicating that hSTI1(K434R) is functionally deficient and synthetically interacts with UTP21. Therefore, WDR36 and STI1 also appear to be co-modifier genes in humans which affect POAG susceptibility through polygenic modes of inheritance. Furthermore, we propose that the WDR36/UTP21-STI1 interaction has been conserved throughout evolution and participates in the regulation of ribosome assembly and/or stress responses that normally prevent glaucoma.

## 895/W/Poster Board #553

**FOXP2 and CNTNAP2 Influence Phonology, Motor Praxis, and Reading in Individuals with Dyslexia.** *B. Peter[1], Z. Brkanac[2], M. Matsushita[3], M. Lisowski[3], T. Vu[3], V.W. Berninger[4], E.M. Wijsman[3,5], W.H. Raskind[2,3].* 1) Speech & Hearing Sciences, University of Washington, Seattle, WA; 2) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 3) Department of Medicine, University of Washington School of Medicine, Seattle, WA; 4) Department of Educational Psychology, University of Washington, Seattle, WA; 5) Department of Biostatistics, University of Washington, Seattle, WA.

Mutations in the FOXP2 gene cause severe impairments in language comprehension and expression and concomitant apraxic speech deficits, but are rare among individuals with common forms of speech sound disorder (SSD) and language impairment (LI). Vernes et al. (2008) identified CNTNAP2 as a transcriptional target of FOXP2 and reported significant associations with a quantitative measure of nonsense-word repetition (NWR) and nine intronic CNTNAP2 SNPs in a sample of 184 family trios with common forms of LI. Because deficits in NWR are frequently reported for dyslexia (DYX), we hypothesized that CNTNAP2 might affect NWR performance in families with DYX. Also, because oral apraxia is often associated with oral reading fluency problems in DYX and FOXP2 mutations are associated with oral apraxia in LI, this gene may also influence motor praxis in both disorders. At issue is whether the apraxia affects both oral and finger motor planning. In the present study, we tested measures of NWR, oral and finger planning, and word reading for association with CNTNAP2, in a sample of 188 family trios ascertained through a child with DYX. Quantitative transmission disequlibrium testing was used. Two of the seven SNPs with significant association to NWR in Vernes et al.'s LI sample, rs2710102 and rs1922892, were associated with NWR in our DYX sample (p=.029). To extend the study to the FOXP2 gene, nine SNPs from FOXP2 were selected from the promoter and intronic regions and evaluated for associations with the same measures of interest. Strongest associations were found for rs7782412, located in the zinc finger region, for a finger succession task (p=.0076), word reading efficiency (p=.0074), word reading accuracy (p= .0351), and NWR (p=.0434). Two SNPs from the promoter region were associated with NWR (p=.0422) and finger succession (p=.0390), and two SNPs, rs10533005 and rs7785701, located between exons 1 and 3, were associated with oral praxis (p=.0196). These results suggest that CNTNAP2 affects NWR not only in LI but also in DYX, consistent with the facts that LI and DYX are frequently comorbid and share deficits in phonologic memory. The findings regarding the FOXP2 associations are consistent with the hypothesis that FOXP2 influences performance in motor planning tasks in individuals with DYX. This study shows the influence of CNTNAP2 and FOXP2 in a population (DYX) and for phenotypes (motor praxis) previously not evaluated for these genes.

## 896/W/Poster Board #554

**Association of Tumor Necrosis Factor-alpha Gene Polymorphisms with Overweight/Obesity in Korean Population.** *G. YU[1,2], SY. LEE[1,2], HK. SON[1,2], IS. CHUNG[1,2], JJ. LEE[1,2], MY. LEE[1,2], DH. SHIN[1,2].* 1) PREVENTIVE MEDICINE, KEIMYUNG UNIVERSITY SCHOOL OF MEDICINE, TAEGU, TAEGU, Korea; 2) INSTITUTE FOR MEDICAL GENOME RSEARCH KEIMYUNG UNIVERSITY , TAEGU, KOREA.

Obesity and excess weight are major risk factors for chronic diseases, including type II diabetes, cardiovascular diseases, gastrointestinal disorders and certain forms of cancer. Increased concentrations of tumor necrosis factor-alpha (TNF-alpha) might therefore play an important role in obesity-induced insulin resistance in humans. To this investigate the genetic association between TNF-alpha gene and the risk of overweight/obesity in Korean population, previously described three single nucleotide polymorphisms (SNPs;rs361525, rs1799274, rs1800630) in the TNF-alpha gene promoter region were analyzed with 123 control (body mass index, BMI 18 to less than 23) and 208 overweight/obesity (BMI more than 23) subjects. Among three SNPs, one SNP (rs361525) presented an association with overweight/obesity in the codominant model (p=0.0046).. In Haplotype analysis with three SNPs, one haplotype (ACC) presented protective effect with overweight/obesity (p=0.0052). There were significant differences in the clinical lipid biomarker and genotype among the groups compared to overweight/obesity and control subjects. Our results supported T carrier group of the rs1799724 in TNF-alpha gene were significantly associated with increasing TG. A carrier group of the rs1800630 in TNF-alpha gene were significantly associated with increasing TG and increasing LDL-C These result indicate that polymorphism of TNF-alpha gene may be associated with obesity and the clinical lipid biomarker in Korean population.

**Are reporter gene and gel shift assays useful in assessing regulatory SNP function? *In vivo* assays to probe -308 TNF polymorphism function.** *L.J. Abraham[1], M. Karimi[1], L.C. Goldie[1], M.N. Cruickshank[1], E.K. Moses[2].* 1) Biomedical Biomolec & Chem Sci, Univ of Western Australia, Crawley, Western Australia, Australia; 2) Department of Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX.

One of the greatest challenges facing genetics is the development of strategies to distinguish functional from nonfunctional variation. Two first-pass functional assays, the reporter gene assay and the electrophoretic mobility shift assay (EMSA), both have substantial limitations. The reporter gene assay was originally designed to define transcriptional elements that have a substantial impact on expression; the differences due to a regulatory SNP are likely to be much smaller. Small differences in reporter activity can be due to a range of confounding factors rather than a true reflection of differences. Also, as chromatin context is likely to be important, the transient transfection assay is not a completely appropriate model to assess the influence of small transcriptional differences due to SNPs. To avoid these limitations, we have developed a novel system, which permits the comparison of transcriptional reporter gene activities following site-specific genomic integration and have validated its use by comparing G-308A variation in TNF expression. The second assay commonly used is the EMSA, which is a very sensitive assay to detect differences in transcription factor binding activity. Allele-specific binding is generally a good indicator of the likelihood that a SNP is functionally relevant. However, we have developed more in vivo approaches using the -308 TNF polymorphism as a model, to assess the use of two assays that measure allelic differences in tissues of defined genotype. The first is a chromatin accessibility assay to measure the effect of putative regulatory polymorphisms on chromatin arrangement. This is a very good measure of whether a region containing a SNP is relevant in regulating a gene. The second approach involves assessing whether allele-specific differential factor binding occurs in vivo by use of chromatin immunoprecipitation (ChIP). Haplo-ChIP (Knight et al., 2003) is able to measure differential transcription of each haplotype but requires the use of heterozygous material. We have developed an alternative ChIP-based method that is SNPcentric (SNP-ChIP). Once the transcription factors that interact are identified, an assessment of differential interaction of the factor with the polymorphic site can be made in vivo. Using genotyped material, we show by SNP-ChIP, that in vivo transcription factor interactions occur exclusively with the -308G SNP of the TNF gene reaffirming functionality.

## 898/W/Poster Board #556

**Novel Candidate Genes in Polycystic Ovary Syndrome: Harnessing Expression Data.** *M.R Jones[1,2], R. Azziz[3,4], M.O. Goodarzi[1,3,4,5].* 1) Endocrinology, Diabetes & Metabolism, Cedars-Sinai Med Ctr, Los Angeles, CA; 2) Graduate Program in Biomedical Sciences and Translation Medicine, Cedars-Sinai Med Ctr, Los Angeles, CA; 3) Department of Obstetrics & Gynecology, Cedars-Sinai Med Ctr, Los Angeles, CA; 4) Center for Androgen Related Disorders, Cedars-Sinai Med Ctr, Los Angeles, CA; 5) Medical Genetics Institute, Cedars-Sinai Med Ctr, Los Angeles, CA.

Familial aggregation and twin studies have established a genetic etiology for polycystic ovary syndrome (PCOS); however, few susceptibility genes are widely agreed upon. A number of expression studies have been performed in PCOS tissues (e.g. ovary, adipose) with remarkably few transcripts reported as differentially expressed in more than one study. Those transcripts that have been reported by more than one study represent a diverse group of proteins and include DKK1, an inhibitor of Wnt signalling and cellular growth repressor, and DNAJB1, a chaperone under transcriptional regulation by insulin. These represent novel pathways and candidates for PCOS. We genotyped 335 White women with PCOS and 198 White female controls for three single nucleotide polymorphisms (SNPs) in DKK1 and four SNPs in DNAJB1. These SNPs capture the majority of variation across these genes in the HapMap database. Association with PCOS was tested by logistic regression; association with quantitative traits in cases was tested by ANCOVA, adjusting for age and BMI. A modified Bonferroni approach was used to correct for multiple testing, such that a P value $<0.009$ was set as significant. We found highly significant associations of DKK1 SNP rs1569198 with total testosterone (AA/AG: 79.0 (34.8) vs. GG: 68.0 (26.0) ng/dl; P=0.0035). DNAJB1 SNP rs3962158 was significantly associated with fasting insulin (CC: 13.0 (15.4) vs. CT/TT: 18.0 (20.7) uIU/mL; P=0.003), and homeostatic model assessment measures of insulin resistance (HOMA-IR; CC: 1.72 (1.96) vs. CT/TT: 2.34 (2.39); P=0.006) and beta-cell function (HOMA-%B; CC: 145.2 (99.2) vs. CT/TT: 177.2 (108.6); P=0.004) [Data are median (IQR)]. We have demonstrated a novel approach to the genetics of PCOS. In an attempt to select candidate genes without being hindered by insufficient knowledge of PCOS pathophysiology, we have used mRNA expression data reported from several tissues to identify novel candidates. These results suggest that variation in gene expression may be an important factor in identifying relevant PCOS pathways. Of particular interest as a candidate was DNAJB1 as it lies in a previously identified PCOS linkage region on Ch19p13.2. Replication of these results in independent cohorts is warranted, followed by functional studies to elucidate the role of these genes in PCOS.

## 899/W/Poster Board #557

**Promoter SNPs in 5q22.1 associated with susceptibility to glaucoma.** *K. Kim[1], Y. Yun[2], C. Kim[2], C. Kang[1].* 1) Dept Biological Sciencesl, KAIST, Daejeon, Korea; 2) Dept of Ophthalmology, Chungnam National Univ Hospital, Daejeon, Korea.

Glaucoma is the second leading cause for optic nerve degeneration and irreversible blindness worldwide. Especially primary open-angle glaucoma (POAG), which constitutes the majority of glaucoma in most populations, is a multi-factorial optic neuropathy with a strong hereditary component. In this case-control study, candidate gene approach was used in order to discover the genetic polymorphisms associated with susceptibility to glaucoma. Genomic DNA was obtained from 176 unrelated Korean patients of glaucoma (including 108 patients of POAG, 31 patients of angle-closure glaucoma, and 37 patients of the other types) and 202 unrelated control subjects free of any eye diseases. All study subjects were successfully genotyped for 134 single-nucleotide polymorphisms (SNPs) located in 32 candidate genes and their associations with susceptibility to glaucoma were tested statistically. Our candidate genes were located within the previously identified glaucoma-susceptibility loci and have been differentially expressed upon elevation of intraocular pressures. We found that three SNPs located in the promoter region of an open-reading frame in 5q22.1 were significantly associated with glaucoma susceptibility. Effects of the promoter SNPs on gene expression level were determined using a luciferase reporter assay. A risk haplotype of two adjacent SNPs reduced the gene expression level significantly. Our results suggest that these two promoter SNPs control gene transcription level and reduced expression levels of an open-reading frame in 5q22.1 increases glaucoma susceptibility. [supported by a grant of the Korea Healthcare technology R&D Project].

## 900/W/Poster Board #558

**Association of *RBP4* gene variants and serum HDL cholesterol levels in the Newfoundland population.** *J.L. Shea[1], J.C. Loredo-Osti[2], H.W. Zhang[1], G. Sun[1].* 1) Discipline of Genetics, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; 2) Dept of Math and Statistics, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Objective: Retinol binding protein 4 (RBP4) is a novel adipokine that likely contributes to systemic insulin resistance and dyslipidemia. The role of genetic variations in *RBP4* on phenotypes of glucose and lipid metabolism is not clear in humans. The purpose of this study was to examine five SNPs in the *RBP4* gene to determine their relationship with markers of insulin resistance and serum lipids in the CODING Study. Research Design and Methods: The CODING Study consists of 1851 subjects recruited from the genetically homogeneous population of Newfoundland and Labrador (NL), Canada. Serum glucose, insulin, HOMAIR, HOMA$\beta$, total cholesterol, high-density lipoprotein (HDL), low-density lipoprotein (LDL), and triglycerides were determined after a 12-hour fast. Five SNPs within the *RBP4* gene (rs3758539, G/A 5' flanking region; rs61461737, A/G intron; rs10882280, C/A intron; rs11187545, A/G intron; and rs12265684, C/G intron) were genotyped using TaqMan validated or functionally tested SNP genotyping assays. Results: We observed a significant association between rs11187545 (G allele) and higher HDL levels ($p = 0.016$; corrected $p = 0.050$, based on 10,000 permutations). Although serum HDL was also associated with rs61461737 and rs10882280, these did not survive correction for multiple testing (corrected $p = 0.096$ and $0.053$, respectively). An association was also evident between rs61461737 and triglyceride levels however this failed to remain significant after correction for multiple testing. We found no significant association between any variant sites and markers of insulin resistance. Conclusions: Our results suggest that genetic variations in *RBP4* may play a role in the differences in serum HDL levels in the NL population.

**Genome-wide Analysis of Gene-Gene Interaction.** *Y. Zhu[1], G. Peng[1], H. Dong[1], X. Zhou[2], M. Ward[3], M. Weisman[4], M. Brown[5], J. Reveille[2], M. Xiong[2].* 1) Laboratory of Theoretical Systems Biology, School of Life Science, Fudan University, Shanghai, 200433, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77225; 3) NIAMS, Bethesda, TX; 4) Cedars-Sinai Med Ctr, Los Angeles, CA; 5) Univ. of Queensland, Brisbane, Australia.

It is thought that complex genetic diseases are caused by multiple genes, primarily through nonlinear gene interactions and gene-environment interactions. Development of disease is thought to be a dynamic process of gene-gene and gene-environment interaction within a complex biological system which is organized into complicated interacting networks. Modern complex theory assumes that the complexity is attributed to the interactions among the components of the system, therefore, interaction has been considered as a sensible measure of complexity of the biological systems. We argue that interaction holds a key to dissecting the genetic architecture of complex diseases. Despite current enthusiasm for investigating gene-gene interactions, published results that document these interactions in humans are limited. Three issues(1) definition and measure of gene-gene interaction, (2) development of powerful statistics for testing gene-gene interaction, and (3) development of strategies and algorithms for genome-wide search of gene-gene interaction should be addressed are essential to the gene-gene interaction studies. In this report, we present a novel statistic for testing interaction between two linked loci. Its type 1 error rates are not appreciably different from the nominal levels. The statistic was applied to 35,206 SNPs in 501 pathways that were assembled from KEGG and BioCart pathway database, and investigated in a genomewide association study of susceptibility toankylosing spondylitis (AS). The AS dataset includes both UK/Australian and North American cohorts. In the North American cohort we have 762 cases and 1,616 controls. In UK/Australian dataset, we have 1,061 cases and 1,1117 controls. Illumina HumHap370 microarray platform was used to genotype 317,000 SNPs. We identified 392 interacted genes that were common in North American and UK/Australian datasets where each pair of interacted genes has at least one pair of interacted SNPs with P-values < 1.0x10-8. The maximum connected interaction network that was common in North American and UK/Australian studies includes 361 genes and 657 interactions.

### 902/W/Poster Board #560

**Searching susceptibility loci for nicotine dependence through a pathway-based association analysis.** *X.-Y. Lou[1], J.Z. Ma[2], T.J. Payne[3], G.-B. Chen[1], T. Niu[1], J. Wang[1], M.D. Li[1].* 1) Dept Psychiatry & NB Sci, Univ Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, University of Virginia, Charlottesville, VA; 3) ACT Center, University of Mississippi Medical Center, Jackson, MS.

Following our previous genome-wide linkage scans for nicotine dependence (ND) in the Mid-South Tobacco family cohort that includes 2,037 subjects from 602 nuclear families of either African-American (AA) or European-American (EA) origin, we selected 3,072 single nucleotide polymorphisms (SNPs) from the five linkage regions based on several criteria including minor allelic frequency, distance between SNPs, location of SNPs, LD among SNPs as well as annotation information and then used to search susceptibility genes for ND. We first conducted family-based association test for each SNP with ND, which was assessed by smoking quantity, Heaviness of Smoking Index and Fagerström Test for ND, for EA, AA, and the pooled sample, respectively. In consideration of various numbers of SNPs being genotyped within each gene and their varying LD structure, we evaluated the significance of each gene (P-value) by conducting empirically permutation testing within each gene, and then used the P-values of 436 annotated genes which are retrieved from the genotyped SNPs to identify pathways associated with ND by using gene set enrichment analysis (GSEA) and other bioinformatics approaches. Such analyses reveal several important pathways, such as those involved in neuron differentiation, neurite development, and neuron development, to be significantly associated with ND phenotypes (FDR < 0.001). In summary, this study implies that pathway-based association analysis offers a valuable approach to identify susceptibility genetic variants with subtle effects for ND through comparing the distribution of genes in the dataset with the null distribution in a pathway library. (This study is being supported by NIH grants DA-12844 and DA-025095.).

### 903/W/Poster Board #561

**Comprehensive Genome-wide Association Studies of Psoriasis.** *M. Xiong[1], L. Luo[1], G. Peng[2], H. Dong[1,2], X. Wu[2], H. S[2], Y. Zhu[2], Y. Xiao[3], X. Zhou[4], C. Amos[5], L. Jin[2], J. Reveille[4].* 1) Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX; 2) School of Life Science and Institute for Biomedical Sciences, Fudan University, Shanghai 200433, China; 3) Department of Computing and Information Technology, Fudan University, Shanghai 200433, China; 4) Division of Rheumatology, Medical School, University of Texas Health Science Center at Houston, Houston, TX 77030; 5) Department of Epidemiology, University of Texas, M. D. Anderson Cancer Center, Houston, TX 77030.

Despite their great success, the current GWAS can detect DNA variants that account for only a few percent of the genetic variance. This raised new questions about where and how we can find the remaining genetic variance. The current GWAS approaches have focused on single SNP analysis. However, common disease often arises from the joint action of multiple loci within a gene or joint action of multiple genes within pathways. If we only consider the most significant SNPs, the genetic variants that jointly have significant risk effects, but individually make only a small contribution, will be missed. Furthermore, the current statistics for GWAS have limited power to detect interactions among SNPs. Very few statistics exist for testing interactions among genes, where each contains a number of SNPs. We propose a novel analytical framework that will allow one to holistically unravel the complex genetic architecture of common diseases to gain insight into the biological processes and disease mechanism. Specifically, we develop novel concepts, statistical methods and algorithms for gene and pathway-based GWAS in which a gene or a pathway is taken as a basic unit of association analysis, genome-wide interaction analysis and genome-wide genetic studies of gene expressions, which lead to a network definition of complex disease. As a proof of concept, the developed new paradigm for GWAS was applied to two independent GWAS datasets and a whole genome-wide expression dataset of psoriasis. The preliminary results identify 50 significant loci in the MHC region, 40 significant genes on chromosome 6 and 5 significant non-MHC genes (e.g. LRP1B with P-value < 2.9E-6 by QT statistic, but the best SNP with P-value < 0.0004 by chi-square test) , 10 significant pathways such as Antigen processing and presentation (P-value < 4.5 E-11), Natural killer cell mediated cytotoxicity (P-value < 3.1 E-11), shared by GWAS, an interaction network with 626 interactions, and a comprehensive eQTL-expression network with 5 significant e-SNPs, 19 significant e-GENEs, 24 interacted ePSNPs, and 66 differentially expressed genes. These results were replicated in two independent studies.

### 904/W/Poster Board #562

**Regulation of tissue specific functions in susceptibility genes for schizophrenia.** *F. Macciardi[1, 2], E. Osimo[2], S.G. Potkin[1], J. Turner[1], F. Torri[2], J. Fallon[1], M. Vawter[1], B. Lerer[4], S. Gaudi[3].* 1) Dept of Psychiatry and Human Behavior, UCI, Irvine, CA, USA; 2) Dept of Science and Biomedical Technologies, University of Milano, Italy; 3) Istituto Superiore di Sanità, Roma, Italy; 4) Department of Psychiatry Hadassah - Hebrew University Medical Center Ein Karem, Jerusalem Israel.

It is increasingly clear that the complexity of the genome has little to do with the number and heterogeneity of its genes. Only 2% of the human genome codes for proteins, while 45% consists of Transposable Elements (TEs). The relative amount of TEs increases consistently with complexity (1) and the TEs domains of the regulatory genome (2, 3), and drives genome evolution (4), alters gene expression (5) and substantially contributes to the etiology and characteristics of complex diseases (6). The regulation of TE expression has been already associated with complex diseases; in particular cancer cells are characterized by high expression levels of LINE-1 (7), correlating transforming cancer cell to the reactivation of RT expression (8) that is barely present in differentiated non-pathological cells (9). Furthermore complex human diseases cannot be explained only by genetic factors and are likely to be the result of gene-environment interactions with the contribution of TEs. The detection of retroviral transcripts in the brains of schizophrenics suggests that activation or upregulation of distinct human endogenous retroviruses (HERVs) may play a role in the etiopathogenesis of neuropsychiatric diseases (10). Our aim is to investigate the functional relationship between TE and genes identified as "best" candidate from GWAS, validating them with exon-expression array and reconstructing their regulatory network with computational methods, and to propose a novel mechanism for gene dysregulation in schizophrenia, including differential methylation. We found preliminary evidence of alternative regulation of tissue specific gene expression in schizophrenic patients vs controls from genes that we identified as associated to schizophrenia from our GWAS and we present results for both tissue specific expression and alternative TSS in pivotal disease-related genes. ## 905/W/Poster Board #563

**Genetic Basis of Differential Transcriptional Aging and Cognitive Function.** *J.W. Kent[1], J. Charlesworth[1], J.E. Curran[1], M. Carless[1], T.D. Dyer[1], H.H.H. Göring[1], V.P. Diego[1], M.P. Johnson[1], M.C. Mahaney[1], L. Almasy[1], E.K. Moses[1], D.C. Glahn[2], J. Blangero[1], S. Williams-Blangero[1].* 1) Dept Genetics, SW Fndn Biomedical Research, San Antonio, TX; 2) Olin Neuropsychiatry Research Center, The Institute of Living and Dept of Psychiatry, Yale University, New Haven, CT.

Individual humans age at different rates, but the causes of heritable variation in biological aging are largely unknown. Our research group has previously examined genome-wide gene expression levels in lymphocytes from 1,240 Mexican Americans in the San Antonio Family Heart Study (SAFHS). Using these data, we have identified more than 600 gene expression phenotypes that are correlated with age at a 5% false discovery rate and exhibit polygenic genotype x age interaction (GxAI) at a nominal $p<0.05$. We searched OMIM for information on biological function for the top 25 of these by association with age; six (*LRRN3*, *FLNB*, *PLEKHG4*, *B3GAT1*, *PACSIN1*, *CAPN2*) are implicated in processes relevant to neurodegenerative disease including Alzheimer disease, Huntington disease, and spinocerebellar ataxia. Most show significant genetic and/or environmental correlation in bivariate analyses. We implemented a joint regression model in SOLAR that allows SNP genotype-specific regressions of phenotypes on age to test for equality of intercepts at mean age (association), equality of slopes (variance-type GxAI), and same sign for all slopes (correlation-type GxAI). We conducted genome-wide joint regression of the 6 expression phenotypes of interest on ~550K haplotype-tag SNPs in 858 SAFHS participants and ranked SNPs by likelihood ratio test (LRT) statistics. We performed network analyses (Ingenuity) on genes co-localized with a subset of SNPs with suggestive evidence (LRT > 20) of SNP-level GxAI. The largest network comprises 63 genes with known functional interactions, 34 of which are involved in neurological disorders, 18 in progressive motor neuropathy, and 21 in developmental disorders. Three hub genes in this network have known functional relationships with *PACSIN1* and *CAPN2*. Finally, we used our SNP subset in a joint regression analysis of a panel of cognitive phenotypes measured in 700 participants in the Genetics of Brain Structure and Function Study, including 458 former participants in SAFHS (~15y after they provided the gene expression data). Three SNPs showed suggestive evidence of GxAI effects on measures of processing speed, with the top hit in the thyrotropin-releasing hormone-degrading ectoenzyme gene *TRHDE*. Thus, our investigation of the genetic structure of differential transcriptional aging has revealed variants with possible prospective effects on cognitive function.

## 906/W/Poster Board #564

**Integrating Analysis of Genomic Variation and Transcriptional Profiling in Families with Childhood Atopic Dermatitis.** *A. Bauerfeind[1], J. Esparza-Gordillo[1,2], H. Schulz[1], K. Rohde[1], F. Ruschendorf[1], N. Hubner[1], Y.A. Lee[1,2].* 1) Max-Delbrück-Centrum, Berlin, Germany; 2) Pediatric Pneumology and Immunology, Charité, Berlin, Germany.

Atopic dermatitis (AD or eczema) is a common chronic inflammatory skin disorder with complex etiology. To identify genetic determinants of atopic dermatitis we have previously carried out a genome-wide association analysis for atopic dermatitis (1). As gene expression represents an important link between genetic variation and the phenotypic outcome that we diagnose as a clinical disorder, we performed gene expression profiling of more than 33,000 human genes in peripheral blood mononuclear cells representing key functional cells in the allergic immune response. Results were obtained in 236 individuals with atopic dermatitis including 47 nuclear families with affected children and 35 affected singletons in whom a genome-wide set of 440,794 SNPs have been genotyped. Heritability of expression traits was measured within a variance-component framework and the resulting distribution differ considerably from those under random conditions. On this evidence we identified cis and trans effects of genetic factors (eSNPs) on heritable gene expression traits. We found highly significant correlation with global gene expression levels measured in Epstein-Barr virus-transformed lymphoblastoid cell lines of children with asthma (2), another allergic disorder that is closely associated with atopic dermatitis. We identified expression quantitative trait loci that reflect genetic determinants of gene expression due to common genetic variation, but also found disease specific eQTLs, thus providing a functional annotation of genetic variants associated with allergic disease. (1 ) Esparza-Gordillo J et al. A common variant on chromosome 11q13 is associated with atopic dermatitis. Nat Genet 41[5], 596-601. 2009. (2) Dixon AL et al. A genome-wide association study of global gene expression. Nat Genet 39[10], 1202-1207. 2007.

## 907/W/Poster Board #565

**Deep MHC Haplotype Sequencing: An Integrated Approach to Common Disease.** *M.R. Hoehe[1], R. Horton[1], S. Schulz[1], S. Palczewski[1], H.v. Eberstein[2], S. Schreiber[2], T. Hübsch[1], E.-K. Suk[1].* 1) Vertebrate Genomics, Max-Planck-Institute for Molecular Genetics, Berlin, Germany; 2) University of Kiel, IKMB, Kiel, Germany.

**Purpose of project:** To sequence complete human major histocompatibility (MHC) haplotypes at the population level and in specific diseases. **Motivation:** The MHC has been recognized as the most important genetic region in relation to common diseases including inflammatory, infectious and autoimmune diseases as well as transplant medicine. Recent WGA studies confirmed associations between the MHC and numerous disease phenotypes of interest. To move from the regions of association to the causal variants, the complex nature of the MHC needs to be resolved. Copy-number variations, insertions, deletions and inversions, high levels of SNPs, differing degrees of recombination and LD extending over Megabases suggest that sequencing MHC haplotypes completely is the strategy of choice to capture and clinically harness the full variation content of the MHC. **Resources & technologies:** To this aim, we have established a unique 'Haploid Reference Resource' of 100 human fosmid libraries from a representative German population cohort (PopGen; 200 haploid genomes), and a SOLiD next generation sequencing (NGS) & MHC data analysis pipeline. **First results:** In the first phase of this project, presence and position of MHC haplotype-informative fosmids have been identified by high throughput SNP mapping (~2500 SNPs) of our fosmid libraries. SNP-based *in silico* assembly of the two MHC haplotypes of an individual showed that on average, 93,9% of the 4.6 MB mapped MHC was covered, and each haplotype was physically covered on average by 6,9 fosmids at any position. NGS of 10 BAC clones from the PGF MHC reference haplotype confirmed high quality performance of our SOLiD sequencing & data analysis pipeline (99,96% sequence identity). Entire fosmid pools (5000 and 15.000 fosmids per pool) have been sequenced to achieve an average 10x sequence coverage, which due to the physical redundancy of the libraries should allow a first assembly of MHC haplotype sequences. In addition, enrichment of distinct MHC fosmids is being tested with the HybSelect Oligo Array (Febit Inc.) and in-solution approaches, targeting complete 40 kb fosmids in the highly variable MHC regions, which is difficult to achieve with array-based enrichment technologies. To conclude, fosmid pool sequencing and sequencing of selectively enriched MHC fosmids are used as complementary approaches to generate complete MHC haplotypes at an unprecedented depth.

## 908/W/Poster Board #566

**Sequence variants of the CAST Gene are associated with Glaucoma related trait in a cohort of West Africans.** *Y. Chen[1], A. Adeyemo[2], G. Chen[2], A. Doumatey[2], H. Huang[2], J. Zhou[2], A. Amoah[3], K. Agyenim-Boateng[4], J. Oli[5], O. Fasanmade[6], C. Adebamowo[7], C. Rotimi[2].* 1) National Human Genome Ctr, Howard University, Washington, DC; 2) Center for Research on Genomics and Global Health, National Human Genome Research Institute, NIH, Bethesda, Maryland; 3) University of Ghana Medical School, Department of Medicine, Accra, Ghana; 4) University of Science and Technology, Department of Medicine, Kumasi, Ghana; 5) University of Nigeria Teaching Hospital, Department of Medicine, Enugu, Nigeria; 6) University of Lagos, College of Medicine, Endocrine and Metabolic Unit, Lagos, Nigeria; 7) University of Ibadan, College of Medicine, Ibadan, Nigeria.

Glaucoma is a chronic neurodegenerative disease of optic nerve characterized by degeneration of retinal ganglion cells and progressive loss of optic nerve axons, which is thought to be caused by Calpain induced apoptosis. Primary open-angle glaucoma (POAG), mainly caused by elevated intraocular pressure (IOP), is the most common adult form of glaucoma. Genetics play an important role in the pathogenesis of POAG with at least 20 genetic loci for POAG reported to date. In this study, we re-sequenced all the exons, their flanking regions and the promoter region of the CAST gene located in our linkage region on chromosome 5q in 48 West Africans (96 chromosomes). Identified SNPs were subsequently genotyped in a cohort of 630 West Africans with IOP measurements. The SNP rs9667 at exon 3 was significantly associated with elevated IOP with 30% of the cases (i.e., IOP ≥ 22mmHg) carrying the GG genotype compared to 18% of the controls (P=0.0024). A second SNP rs27524 in a different LD block was marginally associated with elevated IOP (P=0.0467). Considering that the CAST gene product, Calpastatin, is a highly specific activator of Calpains which plays a central role in glaucoma related retinal degeneration, we conclude that the CAST gene may play an important role in the pathological elevation of IOP, apoptosis of retinal ganglion cells and resulting retinal degeneration.

## 909/W/Poster Board #567

**Integrative genomics and eQTL mapping in primary cells for the identification of disease-associated regulatory variation.** *B.A. Raby, A. Murphy, J. Lasky-Su, B.J. Klanderman, R. Kelly, S. Mazza, B. Himes, V.J. Carey, S.T. Weiss.* Channing Lab, Brigham & Women's Hospital, Harvard Medical School, Boston, MA.

Early studies using immortalized cell lines suggest that eQTL mapping in human populations combining genome-wide SNP and expression data is technically feasible, and can be used to identify disease-associated variation. We have previously demonstrated similar success using primary (non-immortalized) peripheral blood CD4+ lymphocytes collected in a population of well-characterized asthmatic adolescents (n=199), having mapped 6,799 cis-acting regulatory SNP (rSNP) in 1,831 genes. Here we demonstrate that these results are enriched for disease-susceptibility variants. We first compared our results with the Catalog of Genome-Wide Association Studies (Hindorff LA, PNAS 2009) and found that the set of rSNP includes regulatory variants for 45 candidate genes previously associated with clinical traits, including 18 examples where the rSNP represents the variant demonstrating the most significant association in the disease-GWAS scan. Though the list of disease-associated genes was itself enriched for immune-related diseases (inflammatory bowel disease, connective tissue disease, type I diabetes, asthma), disease-associated rSNP were also observed for other phenotype classes, including cancer, neuropsychiatric disorders, and anthropomorphic measures. We next assessed whether the set of rSNP could be used to identify novel asthma-associated variants. We found that 420 of the 6,799 cis-acting rSNP (6.2%) were nominally associated with asthma affection status in 395 non-Hispanic white parent-child asthma trios. , including one previously reported asthma gene - ORMDL3. Other asthma-associated SNP include variants on chromosome 12q for which we have previously demonstrated association with asthma in four independent populations. These variants reside on a 176kb haplotype block and are strongly associated with the expression of the IL4-related gene TFCP2. We next tested the remaining subset of asthma-associated rSNP for replication of the asthma associations in a hospital-based cohort of adult non-Hispanic white asthmatics (n=429) and healthy controls (n=853). 11 SNP in 8 genes were significantly associated in this second population, suggesting generalizability of results. Together, these findings illustrate the potential of eQTL mapping in human populations for the identification of regulatory variants that contribute to complex trait pathogenesis. Grant support: NIH/NHLBI RHL086601.

**Identification of TSLP as a Susceptibility Gene for Chronic Rhinosinusitis.** *L. Mfuna Endam[1], Y. Bosse[2,3], A. Filali-Mouhim[1], Z. Allakhverdi[4], G. Delespesse[4], M.P. Platt[5], K.M. Stankovic[5], R. Metson[5], P. Boisvert[6], L.P. Boulet[2], M. Desrosiers[1,7].* 1) Departement of Otolaryngology, CHUM Hotel Dieu , Montreal, PQ, Canada; 2) Institut Universitaire de Cardiologie et de Pneumologie de Quebec, Quebec, PQ, Canada; 3) Laval University Hospital Research Center (CRCHUL), Quebec, PQ, Canada; 4) Laboratory on Allergy, CHUM Research Center, Notre-Dame Hospital, Montreal, PQ, Canada; 5) Departement of Otolaryngology, Massachusetts Eye and Ear Infirmary, Havard Medical School, Massachusetts, USA; 6) Departement of Otolaryngology, Saint-Francois d'Assise Hospital, Quebec, PQ, Canada; 7) Departement of Otolaryngology - Head and Neck Surgery, Montreal General Hospital, McGill University, Montreal, PQ, Canada.

Background: Chronic rhinosinusitis (CRS) is a common disease characterized by inflammation of the paranasal sinuses of uncertain etiology. A pooling-based genome wide association scan (pGWAS) performed on individuals with or without CRS has suggested the Thymic Stromal Lymphopoietin (TSLP) gene as a promising candidate for CRS. TSLP is released by epithelial cells in response to certain microbial products and has been implicated in asthma and atopic dermatitis. Objective: To explore whether single nucleotide polymorphisms (SNPs) in the TSLP gene are associated with CRS. Methods: A set of 13 SNPs selected to capture most of the genetic variability in the TSLP gene were genotyped on individual samples from a population of 206 patients with severe CRS and 196 postal-code matched controls. A replication was carry out in a larger independent case-control data set of CRS patients recruited from the same location (n=407) and a shared control group (n=260). Functional validation was carried out by measuring gene expression in nasal biopsies taken from patients with or without CRS as well as by comparing TSLP-mediated IL5 production in cell lines isolated from CRS patients with different genotypes. Results: Four SNPs in the TSLP gene were significantly associated with CRS (rs3806932, OR=0.62, p=0.0009; rs2289276, OR=0.62, p=0.0032; rs11466741, OR=0.62, p=0.0033; rs10455025, OR=0.67, p=0.0050). Three of these SNPs were replicated in the second population (rs3806932, OR=0.62, p=0.00006; rs2289276, OR=0.67, p=0.0022; rs11466741, OR=0.67, p=0.0024). There was a 3.2-fold change in the expression of TSLP in tissue of CRS patients compared to controls (p adjusted =0.000066). Genotype-specific cell line assays suggest a greater TSLP-mediated IL-5 secretion in individuals with the risk allele. Conclusions: Polymorphisms in the TSLP gene are associated with CRS. Greater TSLP expression in CRS patients coupled with genotype-specific activity of this cytokine may explain the genetic association. The potential implication of TSLP in the development of CRS corroborates previous observations that demonstrate the role of this cytokine with other inflammatory disorders. This discovery is an important step in the understanding of the disease process and provides a novel therapeutic target for this condition.

**Genomewide expression profiling suggests a role for granulocytes and B-cells in multiple sclerosis and reveals LILRA4 as a novel candidate gene for genetic studies.** *A.K. Kemppinen[1,2], E. Jakkula[1,3,4], V. Leppa[1,2,3], P. Tienari[5], K. Koivisto[6], J. Kaprio[7], I. Elovaara[8,9], T. Pirttila[10], M. Reunanen[11], A. Palotie[3,4,12], L. Peltonen[1,4,12], J. Saarela[1,3].* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki and National Institute for Health and Welfare, Helsinki 00290, Finland; 2) Helsinki Biomedical Graduate School, University of Helsinki, Helsinki, Finland; 3) Institute for Molecular Medicine Finland (FIMM), Finnish Genome Center and Department of Clinical Chemistry, University of Helsinki, Helsinki 00290, Finland; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA 02142, USA; 5) Department of Neurology, Helsinki University Central Hospital and Molecular Neurology Programme, Biomedicum, University of Helsinki, Helsinki, Finland; 6) Department of Neurology, Seinäjoki Central Hospital, Seinäjoki, Finland; 7) Department of Public Health, University of Helsinki, Helsinki, Finland; 8) Department of Neurology, Tampere University Hospital, Tampere, Finland; 9) Medical School, University of Tampere, Tampere, Finland; 10) Department of Neurology and Neuroscience, Kuopio University Hospital, Kuopio, Finland; 11) Department of Neurology, Oulu University Hospital, Oulu, Finland; 12) Wellcome Trust Sanger Institute, Cambridge, UK.

Multiple sclerosis (MS) is a chronic inflammatory disease, leading to demyelination and axonal loss in the central nervous system. Associations with variants in MHCII, *IL7R* and *IL2R* suggest that immunological genes play a central role in MS. We conducted genomewide expression profiling in peripheral blood mononuclear cells (PBMCs) in 12 Finnish MS patients and 15 healthy controls using Affymetrix HG U133 Plus 2.0 array. 926 probesets were differentially expressed in MS patients versus controls by ≥1.5-fold with Benjamini-Hochberg corrected nonparametric P-value≤0.05. Of the most strongly upregulated genes, *CLC*, *DEFA1A3* and *LTF* are known to be highly expressed in granulocytes, possibly reflecting higher levels of granulocytes in MS patients. Other highly upregulated genes (≥4 fold) were *CD24*, *CD200*, *EBF*, *FCRL1*, *FOSL2*, *G0S2*, *HBA1*/*HBA2*, *HBM*, *IGHD*, *IGHM*, *IL8*, *MS4A1* (*CD20*), *MS4A3*, *NR4A2*, *TCL1A* and *TCN1*. We selected five genes for replication by RT-PCR in 30 MS patients and 30 controls and replicated the upregulation of *DEFA1A3*, and downregulation of *LILRA4* and *TNFRSF25*. *IGHM* and *IL8* showed a trend for upregulation, but were not statistically significant. Pathway analysis on all ≥1.2-fold differentially expressed genes (Ingenuity Pathway Analysis) identified B-cell receptor signaling as the most strongly enriched pathway and in total 27 pathways, including IL-2, IL-4, IL-8 and IL-12 signaling, were enriched with a P-value≤$10^{-5}$. Finally, we genotyped tagging SNPs in the identified candidate genes *LILRA4*, *TNFRSF25* and *IL8* in 803 cases and 1171 controls. Although no significant associations were observed in the entire sample, a SNP in *LILRA4*, encoding for leukocyte immunoglobulin-like receptor subfamily A member 4 located at 19q13, showed suggestive evidence for association in meta-analysis of three geographically matched case-control subsets (P-value=0.002). However, we did not observe significant correlation between the associated allele and LILRA4 transcript levels in 42 Finnish MS patients. Genotyping of this SNP is currently ongoing in other Nordic populations and, of note, has not been genotyped or tagged in previous genomewide association studies. In conclusion, our results suggest a role for granulocytes and B-cells in MS pathogenesis and provide initial evidence for association of *LILRA4* with MS.

## 912/W/Poster Board #570

**Integrative Genomics: Environmental Influences on Expression Quantitative Trait Loci.** *K.G. Tantisira[1,2], A. Murphy[1], J. Lasky-Su[1], Q.L. Duan[1], S. Niu[1], C. Anderson[1], B. Klanderman[1], V. Carey[1], B.A. Raby[1,2], S.T. Weiss[1,3].* 1) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Pulmonary Division, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA.

Combining genome-wide association (GWAS) genotyping with genome-wide expression to identify regulatory variation in the form of expression quantitative trait loci (eQTL) has proven to be a powerful analytic strategy; many of the identified cis-acting eQTL explain a large proportion of the variability in expression. To date, eQTL studies have focused primarily on explaining variability related to basal expression characteristics. We hypothesized that integrative analysis of changes in cellular expression would identify eQTL that strongly influence the genomic response to environmental perturbation. We used immortalized B-cells and Illumina HumanHap550 genotyping data obtained from participants in the Childhood Asthma Management Program. Cells from 118 asthmatics were cultured and treated with $10^{-6}$M dexamethasone or sham, RNA isolated, and spotted on Illumina HumanRef8 v2 microarray BeadChips. Following background correction and normalization, the change in expression response related to environmental stimulation was quantified within each subject as $\log_2$(Dexamethasone) expression minus $\log_2$(Sham) expression. Cis-eQTL analysis, evaluating the region within 50 kb of a gene, was performed using the BioConductor package GGtools and a GLM analysis. There were 2755 cis-acting eQTL identified using a nominal p-value threshold of 0.01 and 355 using a p-value of 0.001. For the latter, the median heritability was 10.2% with an interquartile range of 9.5-11.6%. In addition, fourteen eQTL met criteria for multiple comparisons at an FDR of 0.1, with a median heritability of 16.8%. From the 355 eQTL meeting p<0.001 criteria, a large number of genes were immediately recognized as contributing to asthma pathogenesis and/or to corticosteroid modulation, including *ADRB2, CCL17, CFTR, IFNW1, IL17R, PDGFB,* and *TSLP*. Ontologic analyses, as well as analyses correlating the identified eQTL with clinical response to inhaled corticosteroids, are underway. We conclude that, in a fashion similar to basal expression, there are eQTL that contribute substantially to the expression response resulting from environmental exposures within a system.

**Genetical genomic analyses of the nuclear factor-κ B signal transduction network: Detection of emergent system-level properties relevant to the aging process.** *V.P. Diego[1], A. Vinson[2], P.B. Higgins[1], J.M. Peralta[1], J. Charlesworth[1], S.A. Cole[1], T.D. Dyer[1], J.E. Curran[1], M.P. Johnson[1], E.K. Moses[1], H.H.H. Göring[1], L. Almasy[1], A.G. Comuzzie[1], D.L. Rainwater[1], M.C. Mahaney[1], J.W. MacCluer[1], J. Blangero[1], S. Williams-Blangero[1].* 1) Dept Genetics, SW Foundation Biomed Res, San Antonio, TX; 2) Dept Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR.

A promising theory of aging holds that the physiological decline associated with aging is caused by the dysregulation of transcription factors that govern central physiological processes. One such transcription factor is nuclear factor kappa B (NF-κB). From work on NF-κB in relation to aging, it has become clear that the NF-κB signal transduction network (STN) plays a crucial role both in the normative senescence associated with aging, and in the associated pathophysiology of complex diseases such as cancer, neurological disorders, and the metabolic syndrome which includes type 2 diabetes, obesity, and cardiovascular disease. To better understand the role of the NF-κB STN in aging, we adopted a systems genetics approach to studying the transcriptional profiling data available for the San Antonio Family Heart Study. Ingenuity Pathways Analysis (IPA) was used to identify published gene/gene product interactions between NF-κB and the genes detected in our transcriptional profiling. The genes of interest were overlaid onto a global molecular network developed from the literature on reported connectivity recorded in the IPA knowledge base. Principal components factor analysis was performed on a candidate sub-network of 19 genes directly related to the NF-κB STN, and produced 6 orthogonal factors with eigenvalues greater than 1. Using a maximum likelihood variance components approach, we performed multipoint genome-wide scans of these factors. For factor 1comprised of genes involved in the alternative NF-κB signaling pathway (*RelB*, *TRAF5*, and *TRIF*)we found a LOD score of 3.23 at 62 centiMorgans (cM) on chromosome 15, and for factor 5comprised of the genes *Rel* and *TRADD*we found a LOD score of 3.25 on chromosome 17 at 136 cM. To better characterize these results, we performed interaction modeling of all suggestive and significant LOD scores. For factor 1, the putative quantitative trait locus (QTL) on chromosome 15 was found to have a significant epistatic interaction with another locus on chromosome 1 at 24 cM giving a LOD score of 3.58. For factor 1 again, the putative QTL on chromosome 15 was found to exhibit significant QTL × age interaction ($p = 0.005$). Modeling QTL × age interaction for factor 1 increased the LOD score on chromosome 15 to 4.11, and revealed that the QTL variance decreased with increasing age. We conclude that this systems genetics approach is a powerful method for the detection of novel QTLs and of systems-level emergent properties.

## 914/W/Poster Board #572

**Transcriptomic epidemiology of human apolipoprotein E variation.** *E. Drigalenko, D.L. Rainwater, J.E. Curran, M.P. Johnson, J.C. Charlesworth, T.D. Dyer, M. Carless, S.A. Cole, M.C. Mahaney, E.K. Moses, J. Blangero, H.H.H. Göring.* Dept. of Genetics, Southwest Foundation of Biomedical Research, San Antonio, Texas.

Apolipoprotein E (apoE) plays an essential role in the metabolism of several different lipoproteins. Genetic variation in the APOE gene is known to be associated with atherosclerosis, Alzheimer's disease and other diseases. We sought to characterize the relationships between apoE plasma concentrations and gene expression levels in lymphocytes, in an effort to identify genes that act either upstream or downstream of this risk factor for multiple common diseases. Apolipoprotein E levels were measured by immunoassay in blood samples collected after an overnight fast in randomly ascertained participants in the San Antonio Family Heart Study, which seeks to shed light on the genetic etiology of cardiovascular disease risk factors in Mexican Americans. Expression profiles were generated on lymphocyte samples from 1,240 study participants. After adjustment for the effects of sex and age and normalization, we performed bivariate variance components-based quantitative genetic analysis on apoE level and 19,648 autosomal transcripts whose expression levels were significantly detected in the lymphocyte samples. A likelihood ratio test was used to examine whether apoE level and transcript level were significantly genetically correlated. At a 0.05 FDR, we identified 114 transcripts, corresponding to 93 unique genes with NCBI gene IDs, whose expression level is significantly genetically correlated with apoE blood levels. Bayesian model selection methods were employed to derive a subset of transcripts which optimally predict apoE protein levels. We also used Ingenuity Pathways Analysis v. 7.5 to examine the relationship among the identified genes. Compared to the total set of transcripts found to be expressed in lymphocytes, several functional annotation categories are overrepresented, including cell proliferation (16 genes; p=7.8x10-4) and immune response (11 genes; p=2.1x10-3). Based on the genetic correlations among transcripts, we connected 31 of the 93 genes into a single network. We are currently using association analysis, based on genotypes generated with Illumina's HumanHap 550 BeadChip, as well as the genotypes underlying the three main apoE isoforms, to disentangle which genes act upstream of apoE and which act obligately downstream of apoE. Our results show that transcriptional profiles represent a valuable adjunct to traditional epidemiological approaches utilized in studies of classical disease risk-related phenotypes.

**Metabolic syndrome candidate genes identified by linkage, genome-wide association, expression and protein interactions.** *A.T. Kraja[1], D.C. Rao[2], S.C. Hunt[3], R. Kume[4], U. Broeckel[5], R.H. Myers[6], D.K. Arnett[7], M.A. Province[1].* 1) Div. of Statistical Genomics, Washington U. MO; 2) Div. of Statistics, Washington U. MO; 3) Cardiovascular Genetics Div., U. of Utah, UT; 4) GEMS Training Program Washington U. MO; 5) HMGC Laboratories, Med. College of Wisconsin; 6) Dep. of Neurology, Boston U., MA; 7) Dep. of Epidemiology U. Alabama at Birmingham, AL.

Metabolic syndrome (MetS), a complex infirmity of obesity, dyslipidemia, glucose intolerance and insulin resistance, and hypertension, has become a debilitating disease in the US and developed countries. While a few candidate gene polymorphisms have been previously reported in relation to MetS, an integrated strategy involving genome-wide and candidate genes studies, in multiple studies for discovering a network of metabolic syndrome genes has not been reported. In this work we investigate the contributions of genes to 4 quantitative latent factors underlying MetS (obesity-insulin, lipids-insulin, blood pressure and central obesity factors). We start with 123 MetS candidate genes identified from the literature. These candidate genes were found to interact with 846 genes based on protein x protein databases. The polymorphisms available in MetS candidate genes and in the interacting genes were tested for their significant main effects in The Hypertension Genetic Epidemiology Network Study (Caucasians, n=1,316, which already were genotyped for about 0.5M SNPs and African Americans, n=1,263, genotyped for about 1M SNPs using the Affymetrix platforms). Linkage results have been published from these two ethnicities for the four MetS latent factors. GWAs are now presented for each latent factor from HyperGEN Caucasians and African Americans. For example, polymorphisms in 90 SNPs of 49 genes were identified in Caucasians to be significantly associated with MetS. A meta-analysis between Caucasians and African Americans for each of the four latent factors of MetS was performed to identify overlaps of significant results between two ethnicities. Three SNPs, among the most significant SNPs in the HyperGEN Caucasians, were genotyped in the Longitudinal Utah Pedigree Study (n=1,126) for further validation. A comparison of the significant genes with the ones differentially expressed in the STRRIDE study (GSE1295, n=10) (a gene expression of exercise intervention in individuals with MetS) is being performed. We use the MetS candidate genes in model building as well as in classifying individuals' MetS status. The main focus of this work is to present the methodology for an integrated approach to discovery of clusters of genes with relatively small effects that contribute to the MetS development.

**The presence of cell-free male DNA in the plasma from non-pregnant women with scleroderma.** *A. Higashijima, K. Yamasaki, K. Miura, H. Masuzaki.* OB/GYN, Nagasaki University Hospital, Nagasaki, Nagasaki, Japan.

Object; Microchimerism, which has been suggested to occur by pregnancy, is the condition that low-level fetal (donor) cells maintain in mother (host). Recently, the condition of microcimerism is considered to play a role in the pathogenesis of scleroderma, suggesting that circulating fetal DNAs affect on immune reaction in mothers. However, how microchimerism affects on immune system remains unknown. In this study, to get further information between the microchimerism and the autoimmune diseases, we examined whether cell-free male DNA (donor) exist in the plasma from non-pregnant women (host) with scleroderma or not. Methods; Written informed consents were obtained from all non-pregnant women with autoimmune diseases, who were followed-up in Nagasaki university hospital. Peripheral blood was taken from non-pregnant women and cell-free DNA was extracted from 1.6 mL plasma. The SRY gene and the DYS 14 gene were selected as the markers of male DNAs of donor components, while the beta-globin gene was selected as the marker of total DNAs including both donor and host components. Quantitative real-time PCR analysis and regular PCR analysis were performed to detect the male sequences. When male DNA was detected in same non-pregnant woman two times separately, we decided that patient had a microchimerism. Results; Regular PCR could not detect the male sequences in all non-pregnant women examined. When the quantitative real-time PCR was performed, the DYS 14 sequence was detected in three out of 12 non-pregnant women with scleroderma, while not in women with autoimmune disease except for scleroderma. However, the quantitative real-time PCR using SRY probe could not detect the male sequences in same women with scleroderma. Conclusions; In this study, circulating male DNAs were detected in plasma from non-pregnant women with scleroderma, while not in other autoimmune diseases. The condition of microchimerism was detected by only the quantitative real-time PCR and the detection rate of it depends on the difference of TaqMan probes. Therefore, our results suggested that the level of microchimerism, which could be involved in the pathogenesis of scleroderma, is a very small amount.

## 917/W/Poster Board #575

**Gene set enrichment analysis of a genome-wide association study of fasting glucose in the Framingham Heart Study.** *A. Manning[1], L.A. Cupples[1], J. Dupuis[1], J.C. Florez[2,3,4], J.B. Meigs[4,5].* 1) School of Public Health, Boston University, Boston, MA; 2) Diabetes Research Center (Diabetes Unit) and Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Department of Medicine, Harvard Medical School, Boston, MA; 5) General Medicine Unit, Massachusetts General Hospital, Boston, MA.

**Introduction:** Gene Set Enrichment Analysis (GSEA) has been developed to detect multiple small changes in several genes belonging to a functional set where single-gene changes are too modest to achieve statistical significance. When applied to genetic association studies, the goal of GSEA is to find gene sets with a greater than expected number of low p-values for association between single nucleotide polymorphisms (SNPs) and a trait. We apply GSEA to a genome-wide association scan (GWAS) of glycemic traits in a family-based population cohort. **Methods:** Using genotypes from the Framingham Heart Study SNP Health Association Resource project, we selected imputed tag SNPs +/- 20 Kb of genes. Associations with fasting glucose were assessed using linear mixed effect models. Genes were annotated to gene sets using the Molecular Signatures Database. Kolmogorov-Smirnov Enrichment Scores and hypergeometric statistics were computed for each gene set to determine if it was enriched with low p-values. Because these test statistics assume independence between tests, we present the result of a simulation study which explores the effect of high linkage disequilibrium (LD) among the tagSNPs. To adjust for LD, the empirical enrichment of the top gene sets was assessed by comparing the proportion of tests in the gene set with p-values less than 0.001 to the null distribution of the proportion of p-values less than 0.001 obtained by performing association tests with 1000 unassociated traits. **Results:** For fasting glucose, the most significant associations from the GWAS were observed in the ABCB11 gene ($p<10^{-8}$), and thus every gene set containing this gene was observed to be enriched. The GSEA was repeated after removing ABCB11. Among the highest scoring gene sets (N Genes, Multinomial P, Enrichment Score, Empirical Enrichment P) are: chr11p11 (29, $8.44 \times 10^{-25}$, 0.71, 0.001), chr11q11 (43, 0.0005, 0.65, 0.03), RECEPTOR_ACTIVITY (352, $5.1 \times 10^{-9}$, 0.5, <0.001) and NAKAJIMA_MCSMBP_MAST (26, $2.1 \times 10^{-5}$, 0.65, 0.007). RECEPTOR_ACTIVITY describes molecular function defined as “Combining with an extracellular or intracellular messenger to initiate a change in cell activity.” NAKAJIMA_MCSMBP_MAST is a curated gene set of the “top 50 most-increased mast cell specific transcripts.” **Discussion:** A GSEA was performed with a continuous trait in a family sample. Several gene sets were enriched with low p-values, allowing plausible weak associations to be considered for replication.

## 918/W/Poster Board #576

**Influence of genetics, smoking, age and obesity on urine metabolomic profiles among healthy Korean adult men - the Healthy Twin Study.** *J. Lee[1], J. Sung[1], Y. Song[2], K. Lee[3], S. Cho[1], J. Lee[4], M. Lee[1].* 1) Department of Epidemiology, Seoul National University School of Public Health; 2) Department of Family Medicine, Samsung Medical Center, SungKyunKwan University School of Medicine; 3) Department of Family Medicine, Busan Paik Hospital, School of Medicine, Inje University; 4) Korea Institute of Science and Technology.

Providing personalized evidence for disease prevention/therapy is one of the important goals of the genome research. Findings from multidisciplinary rather than single “omics” research will be more informative to those purposes. Each metabolite level in human body is known to be determined by both environments and genes. However, studies exploring the overall associations between metabolomic and genetic profile, especially in general population, have been rare. We attempted to explore the associations between metabolomic profiles and alleged determinants such as genetic contributions, age, obesity and smoking. Among the participants in the Healthy Twin study(a total of 2,750 individuals), 104 adult men were selected, comprising 35 monozygotic twin(MZ) pairs, 7 dizygotic twin(DZ) pairs, and 6 families with MZ plus their brothers. Zygosity of twins was identified by forensic genotype markers. Collected 12-hour urine(7PM to 7AM) samples were analyzed by non-targeted, high-throughput metabolomic profiling methods (Gas Chromatography-Mass Spectrometry). 251 metabolites from 97 individuals were finally analyzed. Genetic influence was measured by the heritability(h2), and associations between metabolites determinants were estimated by linear regression. Associations with current smoking amount, age, body mass index(BMI), and waist-circumference were tested adjusting family relationship as random effects. Among 251 metabolites, 37 showed significant h2(>.3), and 12 indicated high genetic influence(h2>.5). Conversely, there were only 2 metabolites showing positive associations with smoking amount, while 8 were negatively associated. With age, however, 19 metabolites exhibited positive, and 4 showed negative associations. There were 4 and 3 metabolites with positive associations with BMI and waist-circumference, while 11 and 12 metabolites with negative associations.Although ours is non-targeted metabolomic profiling which cannot estimate the health significance of each metabolite, the patterns based on the proportion of metabolites associated with common risk factors revealed new findings. First, more metabolites were associated with genetics, aging, or obesity than with smoking. Second, more negative associations were observed with major determinants. Considering that most existing biomarkers have positive associations with exposure/effects, this abundance of negatively associated metabolites may require revision of conventional view on biomarkers of exposure.

## 919/W/Poster Board #577

**A new methodology for gene-mapping in complex disorders: pathway based analysis using logistic regression.** *G. Kalsi[1], M. Reimers[2], B.P. Riley[1], K.S. Kendler[1].* 1) Dept Psychiatry, Virginia Commonwealth Univ, Richmond, VA; 2) Dept Biostatistics, Virginia Commonwealth University, Richmond, VA.

For complex disorders such as alcohol dependence (AD), genetic factors contribute 40-60% of the variance in liability to AD. Although epidemiological and linkage findings do not support the existence of single genes of major effect in complex disorders, gene-finding efforts have largely focused on single gene studies. Consequently, gene-mapping studies have not replicated in other samples or have produced inconsistent findings. In contrast, functional studies in model organisms and humans provide considerable information about changes following alcohol exposure and about systems that may explain differences in response to alcohol and alcohol-related behavior. This information can be utilized in designing new tools for performing systems based investigations into complex disorders. In this study, we employed a logistic regression methodology to test the hypothesis that multiple alleles within a functional set have significantly higher than expected predictive value, even though none may have strong individual effects. We tested 1350 single nucleotide polymorphisms in 130 addiction candidate genes studied in a sample of 575 AD cases and 530 controls. The analysis produced empirical evidence indicating that AD is related to variation in genes participating in glutamate (P=0.05), GABA signaling (P=0.04) and in stress response pathways (NOR, P=0.02; CRH, P=0.01) but not with genes in several other systems implicated in other drugs of abuse. One concern about this study may be that the genes were a priori selected to be likely candidates for association with addictive behavior. We are currently following up our initial testing of the pathway based methodology with results from a genome-wide association study performed by the Genetics Association Information Network.

## 920/W/Poster Board #578

**A Disequilibrium Model for Detecting Genes Associated with the Aneuploidy of Cancer Cells.** *Y. Li[1], Z. Wang[2], R. Wu[2].* 1) Department of Statistics, West Virginia University, Morgantown, WV; 2) Department of Public Health Sciences, PSU College of Medicine, Hershey, PA.

Because of the occurrence of one or more extra or missing chromosomes, aneuploidy is thought to affect the metabolic control of cells and then cause cancer. Thus, it is interesting to predict the incidence of aneuploid cancer through genetic data. Here, we present a statistical model for estimating and testing the non-random associations between diploid loci and aneuploid loci. The model formulates a series of disequilibrium coefficients to characterize genes in the normal tissue that are associated with aneuploidy. We provide a procedure for testing these disequilibria individually or jointly within the EM framework. Simulation studies are performed to investigate the statistical properties of the model. Our model can be useful for unraveling the genetic architecture of cancer.

## 921/W/Poster Board #579

**Predictive modeling for Parkinson Disease.** *R.-H. Chung[1], T.L. Edwards[1], W.K. Scott[1], C. Almonte[1], A. Burt[1], E.H. Powell[1], G.W. Beecham[1], I. Konidari[1], M.A. Pericak-Vance[1], J.L. Haines[2], S. Zuchner[1], G. Wang[1], L. Wang[1], J.M. Vance[1], E.R. Martin[1].* 1) Miami Institute for Human Genomics, and Dr. John T Macdonald Foundation Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Parkinson disease (PD) is a neurodegenerative disorder with complex etiology. One of the goals of identifying susceptibility genes for PD is to improve predictive models for PD risk. To explore this possibility at our current knowledge state, both candidate-gene and GWAS approaches were used to create predictive models. We used two GWAS datasets: our recent GWAS (605 cases and 621 controls) and the CIDR GWAS dataset (891 cases and 863 controls). We randomly selected 200 cases and 200 controls from the combined dataset as the test dataset, while the remaining 1296 cases and 1284 controls were used as the training dataset. In the candidate-gene approach, SNPs in the 24 most strongly associated genes reported in the PDGene database were selected. These SNPs were first tested with BIMBAM, a Bayesian modeling method, to identify associated SNPs [Bayes factor (BF) > 5]. Then the Random Forest method was used to create a predictive model based on these SNPs. In the GWAS approach, SNPs with BF > 10 and in gene regions were selected across autosomes. These SNPs were also used in Random Forest analysis. The candidate gene approach identified 46 significant SNPs in nine genes. The resulting model from Random Forests had 59.6% sensitivity and 52% specificity for the training dataset. For the test dataset, the predictive model had 58.5% sensitivity and 57.5% specificity. In the GWAS approach, 600 SNPs in 405 genes were identified. The predictive model reached 81.65% sensitivity and 77.7% specificity for the training dataset. For the test dataset, the predictive model had 66% sensitivity and 50% specificity. The results suggest that the predictive models can have > 60% sensitivity in both candidate gene and GWAS approaches, while specificity ranges between 50% and 78%. The results also show the difficulty with over-fitting in the GWAS approach. Although the models may not yet be ideal to predict diseases for clinical practice or to enrich for high risk groups for preclinical imaging, these results are encouraging. Further, known environmental exposures associated with PD were not used in this experiment, but their incorporation should improve the results further, as they have stronger associations with PD than the genetic risk factors identified thus far. With more candidate genes to be discovered for PD and more powerful datasets being assembled, we expect that the sensitivity and specificity for PD prediction using genetic data and other factors will be increased.

## 922/W/Poster Board #580

**Joint Genetic Influences on Height and Bone Mineral Density.** *L.M. Yerges-Armstrong[1], J.R. Shaffer[2], K.A. Ryan[1], J. Liu[1], J.M. Bruder[3], M.A. Carless[4], T.D. Dyer[4], J. Blangero[4], C.M. Kammerer[2], B.D. Mitchell[1].* 1) Division of Endocrinology Diabetes and Nutrition, University of Maryland, Baltimore, MD; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) University of Texas Health Science Center, San Antonio, TX; 4) Southwest Foundation for Biomedical Research, San Antonio, TX.

Height and bone mineral density (BMD) are both under substantial genetic influence. Whether genes related to skeletal growth contribute jointly to variation in both of these traits is unknown. We evaluated whether common sets of genes may exert joint influence on both human stature and BMD in 685 Mexican Americans participating in the San Antonio Family Osteoporosis Study. Study participants were relatively healthy and comprised 41 distinct families. Study participants were ≥23 yrs old; BMD was measured by dual-energy x-ray absorptiometry.

We first estimated the overall degree of pleiotropy between height and BMD by using quantitative genetic methods to partition the phenotypic covariance between height and BMD into components attributable to genetic and environmental sources. Then, we estimated genetic correlation ($\rho_G$) which represents the proportion of covariance due to shared genetic factors with non-zero genetic correlations reflecting evidence for pleiotropy. Both height and BMD were highly heritable ($h^2$=0.55-0.85) in this population. Genetic correlations exhibiting evidence for pleiotropy were observed for height and whole body BMD ($\rho_G$=0.26) and height and hip BMD ($\rho_G$ =0.19-0.25), but not height and spine BMD. To identify possible pleiotropic loci, we genotyped 24 single nucleotide polymorphisms that have been reliably associated with variation in height, and tested their associations with BMD. In general, there was little evidence for association of any of these loci with height or BMD in this Mexican American population. SNP rs7560657 was nominally associated with height (p=0.03), but this SNP was not associated with whole body, hip or spine BMD. In fact, only one of the 24 loci showed a nominal association (p=0.01) with any BMD measure. Our data are consistent with joint genetic effects on height and BMD. However, none of the replicated height loci account for the shared genetic effects in our data. Given the very small effect sizes of these previously reported height loci, any effects on BMD may be small and undetectable with our sample size.

## 923/W/Poster Board #581

**Single Nucleotide Polymorphisms of Genes in Folate Metabolism Associate with Spina Bifida.** *H. Northrup[1,7], C.A. Martinez[1], M.R. O'Byrne[1], J.-I. Lin[2], A.C. Morrison[2], J.M. Fletcher[3], K.K. Ostermaier[4], G.H. Tyerman[5], S. Doebel[6], K.S. Au[1].* 1) Dept Peds/Div Med Gen, Univ Texas Med Sch-Houston, Houston, TX, USA; 2) Human Genetics Center, Sch Public Health, Univ Texas, Houston, TX, USA; 3) Dept Psychology, Univ Houston, Houston, TX, USA; 4) Texas Children Hospital, Houston, TX, USA; 5) Shriners Hospital for Children, Los Angeles, CA, USA; 6) The Hospital for Sick Children, Univ Toronto, Toronto, ON, Canada; 7) Shriners Hospital for Children, Houston, TX, USA.

**OBJECTIVE:** Neural tube defects (NTDs) are common birth defects with complex etiology involving both genetic and environmental factors on the developing neural tube. Spina bifida (SB) is one of the most common NTDs affecting 2 to 4 live births per 10,000 live births in the United States. Maternal deficiency in folate and diabetes are two major risk factors for NTDs. We tested single nucleotide polymorphisms (SNPs) in genes that regulate the folate/homocysteine metabolism to evaluate their contribution to SB susceptibility. **STUDY DESIGN:** A total of 608 unrelated simplex SB patient families were included in this study. We examined genotypes of 77 SNPs located in 13 folate metabolic pathway genes. Association was evaluated by the reconstruction-combined transmission disequilibrium test (RC-TDT). **RESULTS:** We found significant association in SNPs in the respective indicated genes: rs5742905 in cystathionine-beta-synthase (*CBS*), rs1643649 in dihydrofolate reductase (*DHFR*), rs2853533 in thymidylate synthetase (*TYMS*), rs327592 in 5-methyltetrahydrofolate-homocysteine methyltransferase reductase (*MTRR*) and rs3737965 in methylene-tetrahydrofolate-reductase (*MTHFR*) with p-values of: 0.015, 0.041, 0.021, and 0.007 respectively. We also observed significant interactions between the SNPs with a demonstrated association. **CONCLUSION:** Transmission of specific SNPs alleles in the *CBS*, *DHFR*, *MTHFR*,*MTRR* and *TYMS* confer increased susceptibility to SB. The presence of risk alleles with interactions between risk allele of genes may contribute to dys-regulated folate/homocysteine metabolism subsequently increasing SB susceptibility.

**Mutational screening and functional analyses in the zebrafish model of GIGYF2 as a candidate gene for Parkinson disease.** *I. Guella[1], A. Pistocchi[2], R. Asselta[1], V. Rimoldi[1], F. Sironi[3,4], L. Trotta[3,4], P. Primignani[3], M. Zini[4], A. Zecchinelli[4], D. Coviello[3], G. Pezzoli[4], L. Del Giacco[2], S. Duga[1], S. Goldwurm[4].* 1) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli studi di Milano, Milan, Italy; 2) Dipartimento di Biologia, Università degli studi di Milano, Milan, Italy; 3) Laboratorio di Genetica Medica, Fondazione IRCCS "Ospedale Maggiore Policlinico, Mangiagalli e Regina Elena", Milan, Italy; 4) Parkinson Institute, Istituti Clinici di Perfezionamento, Milan, Italy.

Parkinson disease (PD) is the second most common neurodegenerative disorder, with an age-associate prevalence of approximately 2% in the population above 65 years of age. Several loci (PARK1-15) for familial PD have been described, but for some of them the specific gene remains elusive. GIGYF2 (Grb10-Interacting GYF Protein-2) has been proposed as the PD susceptibility gene underlying the PARK11 locus after the identification of 7 different genetic variants in this gene in 123 Italian and 126 French familial PD cases, which were absent in 318 controls. Although GIGYF2 represents a good candidate gene for PD, being known to interact with the Grb10 protein and consequently to be potentially involved in insulin and insulin-like growth factor (IGF) signaling, several further studies did not confirm its association with the disease. However, the majority of these replication studies did not screen the whole gene and/or focused on sporadic PD patients, notwithstanding the fact that both the PARK 11 locus and the GIGYF2 gene were pointed out by studying familial PD. Moreover, a functional validation of GIGYF2 mutations is still lacking. In this frame, to elucidate the role of GIGYF2 in the pathogenesis of familial and sporadic PD, we performed a comprehensive mutational screening of the gene in a large Italian population of familial and sporadic PD patients and controls. Moreover, we analyzed the function of GIGYF2 in vivo, using the zebrafish model. Mutational screening of GIGYF2 was performed by a combination of high-resolution melting analysis and direct DNA sequencing. Exons containing previously reported mutations were analyzed in 552 cases (243 familial, 309 sporadic) and 552 controls. Thereafter, a subset of 184 familial PD cases and an equal number of controls were subjected to a full screening of all 27 coding exons. This analysis identified 8 different missense variations in a total of 9 individuals (4 PD patients and 5 controls). Abrogation of gigyf2 function in zebrafish embryos by morpholino oligonucleotide injection did not lead to a drastic loss of neurons in the diencephalic dopaminergic (DA) neuron clusters, neither caused a change in the expression levels of otp1 and prox1 genes, two of the major players in diencephalic DA neurons development, suggesting that gigyf2 is not required for proper DA neuron differentiation. These data, together with those recently reported by other groups, suggest that GIGYF2 is unlikely to be the PARK11 gene.

## 925/W/Poster Board #583

**Assessing the association between PAX6 polymorphism and high myopia.** *E. Hsi[1,2,3], C. Liang[4], Y. Pan[3], W. Chang[3], F. Lin[2], S. Juo[2,3,5].* 1) Dept Medicine, Kaohsiung Med Univ, Kaohsiung, Taiwan; 2) Dept Medical Research, Kaohsiung Med Univ Hospital, Kaohsiung, Taiwan; 3) Dept Med Genetics, Kaohsiung Med Univ, Kaohsiung, Taiwan; 4) Bright-Eyes Clinic, Kaohsiung, Taiwan; 5) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

**Purpose:** Pax-6 mutations are associated with a variety of human ocular diseases. In addition to the biological plausibility, a genome-wide linkage study revealed strong linkage of refractive error to the PAX6 locus. PAX6 has long been speculated as a potential gene involved in the development of myopia. Recently, studies on non-syndromic myopia have reported some significant susceptibility genes but most of the findings cannot be replicated. Therefore, replication of the genetic effect in large and independent samples is an important way to reduce the false positive finding. **Methods:** A total of 1083 cases and 1096 controls were included in the study. A case was defined as refraction ≤ -6 D and control ≥ -1.5 D. Four tagging single nucleotide polymorphisms (tSNPs) were genotyped. Statistical analyses included Hardy-Weinberg equilibrium (HWE) test, chi-squared test to evaluate the genotypic effect, linkage disequilibrium (LD) estimation, LD block construction and haplotype analysis. Subset analysis was also conducted for cases with highly myopic parents. The permutation was used for multiple test correction. **Results:** We only found a marginally significant result for SNP2 in the original definition for cases (≤ -6.0 D) and controls (≥ -1.5 D), the common genotype CC became significant when extreme myopia (≤ -11 D) was used to define a case. In addition, the frequency of the CC genotype increased with the severity of myopia in our population, which indicates a genetic dose effect. **Conclusions:** we conducted a large scale study to systematically evaluate the genetic effect of the PAX6 gene. We found a tagging polymorphism of PAX6 associated with extreme myopia but not high myopia among Chinese living in Taiwan.

## 926/W/Poster Board #584

**Assessing the association between *MAPK9* polymorphism and high myopia.** *C. Hu[1], E. Hsi[1,4], Y. Pan[2], S. Juo[2,3,4].* 1) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Center of Excellence for Environmental Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Departments of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Purpose: We investigate the association between high myopia and the MAPK9 gene. Methods: A total of 114 candidate genes were selected from our GWAS data. We conducted the pathway analysis to identify promising genes, and 114 candidate genes were entered into MetaCore software suite developed by GeneGo. We enrolled 967 high myopic individuals (≤-6 diopters) and 1087 controls (≥-1.5 diopters) . One SNP rs13190345 at MAPK9, associated in GWAS data, was genotyped initially. We further genotyped 12 tSNPs in a pilot sample of 170 cases and 200 controls. Hardy-Weinberg equilibrium was tested for each SNP, and genetic effects were evaluated by the chi-square test. Subset analyses were performed according to the family history and educational level. Results: Our pathway analysis showed that MAPK9 might relate to the development of myopia, which is involved in variety of cellular processes such as proliferation, differentiation, and transcriptional regulation. SNP rs13190345 at MAPK9 showed a borderline significance with myopia. Compared to the common homozygote CC, the rare allele carriers (TC and TT) appeared to have a dominant effect and was associated with myopia (OR = 0.72, p=0.057). Subset analysis on cases with a strong family history or higher educational level did not demonstrate significant results. We further genotyped 12 tSNPs to systematically assessed whether MAPK9 eliminate a susceptibility to myopia. No significant associations were seen with further tSNPs tests. Conclusions: From the borderline significance in rs13190345, it reveals that MAPK9 gene may play a moderate role in the development of myopia in the Taiwanese population. More subjects will be recruited in the near future to provide a more solid result.

## 927/W/Poster Board #585

**Analysis of 9p24 and 11p12-13 regions in Autism Spectrum Disorders: rs1340513 in the *JMJD2C* gene is associated with ASDs in the Finnish sample.** *K. Kantojärvi[1], P. Onkamo[2], R. Vanhala[3], R. Alen[4], M. Hedman[5], A. Sajantila[5], I. Järvelä[1,6].* 1) Dept Med Gen, Univ Helsinki, Helsinki, Finland; 2) Department of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland; 3) Hospital of Children and Adolescents, University of Helsinki, Helsinki, Finland; 4) Department of Child Neurology, Jyväskylä Central Hospital, Jyväskylä, Finland; 5) Department of Forensic Medicine, University of Helsinki, Finland; 6) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland.

Autism spectrum disorders often show obsessive repetitive symptoms characteristic to obsessive compulsive disorder (OCD). Aberrant glutamate function has been suggested as a risk for both autism spectrum disorders (ASDs) and obsessive compulsive disorders (OCD). Two independent studies for OCD have shown suggestive evidence for linkage in the chromosomal region of 9p24. Furthermore, several studies for OCD have detected association at SNPs covering the glutamatergic gene *SLC1A1* region. Interestingly, comprehensive autism family material analyzed by the Autism Genome Project Consortium (2007) reported linkage peaks at 9p24 and 11p12-13 containing glutamatergic genes *SLC1A1* and *SLC1A2*. In order to answer the question whether there is common molecular background for obsessive repetitive symptoms in ASDs and OCD we have analyzed ten single nucleotide polymorphisms (SNPs) at 9p24 and 11p12-p13 covering glutamate transporter genes *SLC1A1* and *SLC1A2* and their neighboring genes in one hundred seventy-five patients with autism spectrum disorders of Finnish origin. 139 of them had infantile autism and 36 Asperger syndrome. The control material consisted of 216 Finnish anonymous blood donors. The SNPs were analyzed using real-time-PCR or direct sequencing. The results were calculated using Fischer's exact test, Plink and logistic regression.

Interestingly, the strongest association was detected with rs1340513 in the *JMJD2C* gene at 9p24.1 (p=0.007; permuted p=0.011) that is the same SNP that showed significant association with infantile autism (p-value= 0.0007) in the Autism Genome Project Consortium (2007). In a recent study by Shugart et al., (2009) the strongest association was found at rs301443 (p-value = 0.000067) residing 7.5kb outside at the 3'end of the *SLC1A1* gene in over 1000 OCD-patients. This location suggests that the true associated SNP for OCD will reside at the 3' end of the *SLC1A1* gene closer to the *JMJD2C* gene. Thus, these data is in agreement with ours and encourages further analysis on the 3'end of the *SLC1A1* gene and it's 3'UTR area with bigger sample set. No association was detected at 11p12-p13 with ASD. In summary, our results further suggest a common locus for OCD and ASDs at 9p24. We speculate that the region is a special candidate region for obsessive repetitive symptoms.

**MC4R SNP is associated with BMI but not BMI response to resistance training in young females.** *F.E. Orkunoglu-Suer[1], H. Gordish-Dressman[1], P.M. Clarkson[2], P.D. Thompson[3], T.J. Angelopoulos[4], P.M. Gordon[5], N.M. Moyna[6], L.S. Pescatello[7], P.S. Visich[8], R.F. Zoeller[9], D.W. Moore[1], J.M. Devaney[1], E.P. Hoffman[1].* 1) Rsrch Cntr Genetics Med, Children's Natl Med Cntr, Washington, DC; 2) Dept of Kinesiology, U of Massachusetts, Amherst, MA; 3) Div of Cardiology, Henry Low Heart Cntr, Hartford Hospital, Hartford, CT, US; 4) Cntr for Lifestyle Med and Dept of Health Profes, U of Cntrl Florida, Orlando, FL; 5) Dept of Phys Med and Rehab, Sch of Med, U of Michigan, Ann Arbor, MI; 6) Sch of Health and Hum Perf, Dublin City University, Dublin 9, Ireland; 7) Dept of Kinesiology & Hum Perf Lab, University of Connecticut, Storrs, CT, US, 06269; 8) Hum Perf Lab, Cntrl Michigan University, Mount Pleasant, MI,; 9) Dept of Exer Sci and Health Promotion, Florida Atlantic University, Davie, FL.

**Background:** Recently, a genome wide association study (GWAS) that identified eight single nucleotide polymorphisms (SNPs) associated with body mass index (BMI) highlighted a possible neuronal influence on the development of obesity. We hypothesized that these SNPs will be validated with measures of BMI, and govern change in BMI in response to resistance training in young, college-aged individuals. **Methods:** We genotyped the following SNPs: NEGR1 (rs2815752), MTCH2 (rs10838738), TMEM18 (rs6548238), GNPDA2 (rs10938397), SH2B1 (rs7498665), MCR4 (rs17782313), FTO (rs9939609), and KCTD15 (rs11084753) in our cohort of young, healthy individuals, FAMUSS (Functional polymorphisms associated with human muscle size and strength) (n= 755). The individuals in our cohort underwent a 12-week resistance-training program on their non-dominant upper arm. Genotype/phenotype associations for BMI and subcutaneous fat levels before and after the exercise program were tested using an analysis of covariance model with age and weight as covariates. The percent variation in each phenotype attributable to genotype was determined using hierarchical models with a likelihood ratio test. **Results:** Females with a copy of the rare allele (C allele) for rs17782313 had significantly higher BMIs than TT females (CC/CT: n=174; 24.70 ± 0.33 kg/m2, TT; n=278; 23.41 ± 0.26 kg/m2, p=0.0025). This SNP accouted for 1.9% of overall variation in BMI in females and was statistically significant after correcting for multiple testing (p= 0.0071). Males with a copy of the rare allele (A allele) for rs9939609 lost a significant amount of subcutaneous fat with exercise (AT/AA; n=83; -798.35 ± 2624.30 mm3, TT; n=47; 9435.23 ± 3494.44 mm3, p=0.0190). This variant attributed 4.1% variation in phenotype but was not significant after correcting for multiple testing. We did not observe any effect of the other six loci on baseline subcutaneous fat levels, BMI, or change in BMI or subcutaneous fat following resistance training. **Conclusions:** This research supports and extends the original finding that there is an association between measures of obesity and variant near the MC4R gene in a healthy, young population. In addition seven other GWAS variants associated with BMI were not validated in our young population. There is no association between exercise and change in BMI with these GWAS SNPs.

## 929/W/Poster Board #587

**SCAN Database Promotes Gene Discovery and Elucidates Expression-level Replication Across Diabetes Studies: Pleiotropic Effects in Diabetes.** *J. Below[1], E. Gamazon[2], E. Kistner[3], D. Nicolae[2,4], N.J. Cox[1,2].* 1) Dept Human Genetics, Univ Chicago, Chicago, IL; 2) Dept Medicine, Univ Chicago, Chicago, IL; 3) Dept Health Studies, Univ Chicago, Chicago, IL; 4) Dept Statistics, Univ Chicago, Chicago, IL.

As in type 2 diabetes (T2D), the modest effect sizes of common susceptibility variants have impeded replication in many studies of common diseases. We demonstrate that the use of tools that incorporate information from expression quantitative trait loci (eQTLs) as an adjunct to physical linkage disequilibrium (LD) and known function of polymorphisms can identify relationships within phenotypes to prioritize SNPs and genes for additional study as well as novel relationships across phenotypes. The SCAN (SNP and Copy number variant ANnotation; http://www.scandb.org) database provides a novel approach to annotate genetic variation by aggregating large-scale published physical and functional information as well as multilocus LD and associations to gene expression level in the HapMap CEU and YRI lymphoblastoid cell lines at a user specified significance threshold. Using SCAN we have identified significant (pval < 0.001 by permutation) overlap in the list of genes whose expression is predicted (pval < 0.0001) by the most significant SNPs (pval < 0.001) implicated in the previously published independent T2D studies by the WTCCC, DGI, and FUSION, and the list similarly generated from SNPs associated with HbA1C level, a measure of diabetic control, in the GoKinD study of complications in type 1 diabetics (T1D). Among these genes showing significant pleiotropic effects are replicated T1D genes HLA-B, HLA-DRB1, and RNLS as well as genes implicated in other autoimmune diseases such as BST2, and genes associated with hypertension such as EDN1. In addition SCAN identified significant overlap (p <0.0001) between genes whose expression is predicted (as above) by SNPs associated with HbA1C level in the GoKinD study and SNPs associated with T1D in the curated NHGRI catalogue, including both novel and established T1D genes such as IL2RA. SCAN-generated gene lists provide novel information about replication and pleiotropy across diabetic phenotypes: the SNPs associated with the overlapping genes are not replicated between the studies and show no evidence of linkage disequilibrium ($r^2$<0.3).

## 930/W/Poster Board #588

**MAP2K3 Variation is Reproducibly Associated with Body Mass Index in Pima Indians.** *L. Bian, J. Mack, S. Kobes, W.C. Knowler, R.L. Hanson, C. Bogardus, L.J. Baier.* PECRB, NIDDK, NIH, Phoenix, AZ 85004.

To identify genetic variation that contributes to obesity in Pima Indians, a population with a high rate of obesity and type 2 diabetes, we completed a genome-wide association study using the Affymetrix 1million SNP chip. Several SNPs in the mitogen-activated protein kinase kinase 3 gene (MAP2K3) were associated with body mass index (BMI) in 1149 Pima Indians (P=2.7x10-7-0.003, adjusted for age, sex, and family membership). As an upstream kinase, MAP2K3 can induce activation of p38 MAPK, which may play a role in human adipogenesis through regulation of C/EBPβ and PPARγ. MAP2K3 was therefore directly analyzed as both a positional and biologic candidate gene for obesity in Pima Indians. Six tag SNPs (rs10468608, rs2363226, rs9901404, rs12602109, rs2230435, and rs8074866) selected from HapMap CEU and/or CHB populations by the criteria of minor allele frequency ≥0.05 and r2≥0.80, were genotyped in a population-based sample of 2789 full-heritage Pima Indians who had been longitudinally studied and had a BMI measurement from an exam when they were at non-diabetic status. The maximum BMI after the age of 15 years, from a non-diabetic exam, was used for association analyses. Five tag SNPs (all but rs8074866) were associated with BMI in the population-based study (P=0.0001-0.02, adjusted for age, sex, birth year, and family membership). Rs9901404 provided the strongest association, where the homozygous risk allele carriers (A, major allele) had a mean BMI of 36.7± 0.2 kg/m2 as compared with a BMI of 34.5± 0.5 kg/m2 for the homozygous non-risk allele carriers (G) (adjusted P=0.0001). To assess whether the association with BMI could be replicated in an independent group of subjects, rs9901404 was further genotyped in 2918 subjects from the same community, most of whom were of mixed heritage (on average ½ Pima Indian). The association with BMI reproduced in the mixed heritage replication sample in the same direction (adjusted P=0.01), and combining the full-heritage Pima Indian and mixed heritage subjects provided the strongest evidence for association (adjusted P=5.3x10-6). Preliminary functional studies using real time PCR of mRNA isolated from subcutaneous adipose tissue biopsies from 78 non-diabetic Pima Indians showed a positive correlation between MAP2K expression and BMI (adjusted P=0.0002). Taken together, our results suggest that common variation in MAP2K3 may contribute to obesity in Pima Indians by affecting MAP2K3 expression in human adipocytes.

**Epidemiologic Architecture for Genes Linked to Environment (EAGLE): Characterizing genome-wide association study variations associated with type 2 diabetes in the National Health and Nutrition Examination Surveys.** *K. Brown-Gentry, L. Dumitrescu, K. Spencer, J.A. Canter, D. Murdock, J.L. Haines, M.D. Ritchie, D.C. Crawford.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Type 2 diabetes (T2D) is a common, complex disease affecting 8.0 % of the US population. SNPs associated with T2D status are being discovered in large genome-wide association (GWA) studies in samples of European-descent, and associations from diverse cohorts are just now emerging. To characterize the growing list of GWA-identified variants, we, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study, are genotyping samples collected for the National Health and Nutrition Examination Surveys (NHANES), a cross-sectional survey of Americans representing at least three major groups: non-Hispanic **w**hites (n=3,974), non-Hispanic **b**lacks (n=1,334), and **M**exican-**A**mericans (n=1,877). To date, six SNPs previously associated with T2D have been genotyped in NHANES 1999-2002. In preceding GWA studies, these SNPs explained a relatively small proportion of the risk, with odds ratios ranging from 1.1 to 1.6. T2D status can be defined four different ways in NHANES 1999-2002, three based on the self-reported status ("Doctor told you had diabetes," "Taking diabetic pills to lower blood sugar," "Taking insulin now,") and one based on laboratory values (fasting glucose levels ≥ 200 mg/dL). Using logistic regression, SNPs were tested for an association with each of the four T2D status definitions among adults assuming an additive genetic model and adjusting for age, sex, and body mass index. Despite being under-powered, we were able to detect several associations at the p=0.05 level. In **W**, *TCF7L2* rs7903146 was associated with T2D based on fasting glucose levels (n=15 cases, 2242 controls; p=0.036; OR=2.18; 95% CI: 1.05-4.50) and self-reported medication usage (n=51 cases, 34 controls; p=0.026; OR= 2.39; 95% CI: 1.11-5.16). In **B**, *IGF2BP2* rs4402960 (p=0.047; OR=1.48; 95% CI=1.01-2.18) and *TCF7L2* rs7903146 (p=0.021; OR=0.619; 95% CI= 0.41-0.93) were both associated with self-reported T2D status (n=57 cases, 716 controls). For **MA** (25 cases, 1170 controls), *FTO* rs8050136 was associated with fasting glucose-defined T2D (p=0.04; OR=0.54; 95% CI=0.30-0.96). No associations were observed for *CDKN2B* rs10811661, *HHEX* rs1111875, and *PPARG* rs1801282 for any T2D case definition in any group, and none of the observed associations were consistent across T2D definitions or groups. Limitations of sample size and refined case definition make characterization of T2D GWA-identified variations challenging in large epidemiologic cohorts such as NHANES.

**A moderate association of the *MTNR1B* and *G6PC2* gene variants with fasting plasma glucose levels in Asian Sikhs.** *J.L. Hatfield[1], L. Been[1], S.K. Ralhan[2], G.S. Wander[2], N.K. Mehra[3], J.R. Singh[4], D.K. Sanghera[1].* 1) Pediatrics, University of Oklahoma HSC, Oklahoma City, OK; 2) Hero DMC Heart Institute, Ludhiana, Punjab, India; 3) All India Institute of Medical Sciences, New Delhi, India; 4) Guru Nanak Dev University, Amritsar, Punjab, India.

Increased fasting plasma glucose (FPG) levels are a hallmark sign of type 2 diabetes (T2D). Recent genome-wide association scans (GWAS) and meta-analyses have identified common SNPs in the *MTNR1B* (encoding melatonin receptor 1-B), and *G6PC2* encoding an islet-specific protein (glucose-6-phosphatase catalytic unit 2) that contribute to individual variation in FPG levels and T2D risk in Europeans. This investigation examines the role of three SNPs with T2D and associated sub-phenotypes in a case-control sample from our Sikh Diabetes Study (SDS). We genotyped two variants from *MTNR1B* including rs1387153, located near the 5' untranslated region, and an intronic variant (rs108309630) located in *MTNR1B*. We also genotyped an intronic variant (rs560887) from *G6PC2*. These SNPs were screened on 2,194 SDS subjects comprising 1,379 T2D cases and 815 normoglycemic (NG) controls. We analyzed the association of these variants with T2D using logistic regression. We also examined the impact of these variants on quantitative sub-phenotypes of T2D [FPG, 2 hour plasma glucose, fasting insulin, and homeostatic model assessment of insulin resistance (HOMA-IR)] using multiple linear regression analysis. None of these variants were associated with T2D in this sample. However, our study confirmed prior evidence of association of these three variants with FPG levels in NG controls and these associations remained significant after adjusting for the effects of age, sex, and BMI. With the exception of FPG, no other quantitative trait revealed any association with these SNPs. A variant near the 5'untranslated region of *MTNR1B* (rs1387153) was significantly associated with FPG levels (p=0.02) under an additive model. A gender-specific significant association (p=0.022) was also observed in rs10830963 in *MTNR1B* with FPG in NG males. The *G6PC2* variant (rs560887) also revealed an 'A' allele associated significant decrease in FPG levels ($\beta$= -0.094; p=0.021) under the dominant model in controls. These associations would not remain significant in multiple testing corrections. From these results it appears that genetic variation in these genes could be a strong modulator of FPG levels in this population and may lead to the development of T2D in Asian Indians. As the overall contribution of each of these variants for controlling FPG levels in this sample is <2%, it is likely that causal variants in these loci with larger effects remain unidentified.

## 933/W/Poster Board #591

**Replication and joint effect analyses of genetic variants from type 2 diabetes susceptible loci in a Chinese population.** *C. Hu[1,2], R. Zhang[1], C. Wang[1], J. Wang[2], X. Ma[1], K. Xiang[1,2], W. Jia[1,2].* 1) Shanghai Diabetes Inst, Shanghai, China; 2) Dept Endocrinology and Metabolism, Shanghai Jiao Tong University Affiliated Sixth People's Hospital.

**Objective**: Recent advance in genetic studies added the confirmed susceptible loci for type 2 diabetes to eighteen. In this study, we attempt to analyze the independent and joint effect of variants from these loci on type 2 diabetes and clinical phenotypes related to glucose metabolism. **Research Design and Methods**: Twenty-one single nucleotide polymorphisms (SNPs) from fourteen loci were successfully genotyped in 1,849 subjects with type 2 diabetes and 1,785 subjects with normal glucose regulation. We analyzed the allele and genotype distribution between the cases and controls of these SNPs as well as the joint effects of the susceptible loci on type 2 diabetes risk. **Results**: We confirmed the effects of SNPs from *PPARG*, *KCNJ11*, *CDKAL1*, *CDKN2A-CDKN2B*, *IDE-KIF11-HHEX*, *IGF2BP2* and *SLC30A8* on risk for type 2 diabetes, with odds ratios ranging from 1.114 to 1.406 (*P* value range from 0.0335 to 1.37E-12). But no significant association was detected between SNPs from *WFS1*, *FTO*, *JAZF1*, *TSPAN8-LGR5*, *THADA*, *ADAMTS9*, *NOTCH2-ADAM30* and type 2 diabetes. Analyses on the quantitative traits in the control subjects showed that *THADA* SNP rs7578597 was association with 2-h insulin during oral glucose tolerance tests (*P*=0.0005, empirical *P*=0.0090). The joint effect analysis of SNPs from eleven loci showed the individual carrying more risk alleles had a significantly higher risk for type 2 diabetes. And the type 2 diabetes patients with more risk allele tended to have earlier diagnostic ages (*P*=0.0006). **Conclusions**: Our findings suggested that genetic variants played important role in the susceptibility of type 2 diabetes in the Chinese.

## 934/W/Poster Board #592

**ENPP1 Variants associate with quantitative metabolic traits and T2D in Afro-Caribbean men from Tobago.** *T.S. Leak[1], I. Miljkovic[1], A.L. Patrick[2], V.W. Wheeler[2], C.H. Bunker[1], C.S. Nestlerode[1], J.M. Zmuda[1].* 1) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pennsylvania; 2) Tobago Health Studies Office, Scarborough, Tobago, Trinidad and Tobago.

The ectonucleotide pyrophosphatase/phosphodiesterase 1 (*ENPP1*) gene, also referred to as plasma cell membrane glycoprotein (PC-1), has been shown to be associated with type 2 diabetes (T2D) and quantitative metabolic traits in multiple ethnic groups. Using HapMap data, we identified 41 tag single nucleotide polymorphisms (SNPs), based on a threshold linkage disequilibrium score $r^2 \geq 0.80$ and minor allele frequency ≥5%. These SNPs were genotyped in 281 unrelated Afro-Caribbean cases with T2D defined based on the criteria of fasting serum glucose levels ≥126 mg/dl and 934 unrelated Afro-Caribbean controls without a known diabetes diagnosis from Tobago. We performed age- and body mass index (BMI)adjusted linear regression on genotypic (additive,dominant, recessive) models to test for association with quantitative metabolic traits fasting plasma glucose (FPG), fasting insulin and insulin resistance by homeostasis model assessment (HOMA-IR), while logistic regression was used to test for association with T2D alone. We identified four noncoding SNPs (rs6916495, rs858338, rs943004 and rs7749493) associated with increased FPG, fasting insulin and insulin resistance by HOMA-IR (all P = 0.020-0.050). Additionally, rs9373000 (P = 0.025 dominant model; P = 0.011 additive) located in the downstream region, and an intron 1 SNP (rs6569759: P = 0.015 recessive) showed compelling evidence of association with an increased risk for T2D. We conclude that *ENPP1* gene is associated with quantitative metabolic traits and T2D in this population of Afro-Caribbean men from Tobago. However, the extensively studied K121Q variant (rs1044498) did not reveal evidence of association. The consistent evidence of association suggests pleiotropic effects for this gene.

## 935/W/Poster Board #593

**Contribution of TNFSF15 but not IL23R to ulcerative colitis susceptibility in Koreans.** *K. Song[1], J. You[1], M. Park[1], S. Yang[2].* 1) Dept Biochem & Molec Biol, Univ Ulsan Col Medicine, Seoul, Korea; 2) Dept Internal Medicine, Univ Ulsan Col Medicine, Seoul, Korea.

Inflammatory bowel diseases are chronic intractable diseases that consist of Crohn's disease and ulcerative colitis. Of the two subtypes of IBD, the genetic contribution to disease risk has been documented more clearly for CD than for UC. Linkage and genome-wide association studies in Caucasian populations identified over 30 susceptibility loci to Crohn's disease (CD). Some of the CD candidate genes were shown to be shared with UC. Previously, we have shown that TNFSF15 and IL23R genes are associated with susceptibility to CD in Koreans. As the IL23R gene was reported to be associated with UC as well as CD in Caucasian samples, we tested the two CD susceptibility genes, TNFSF15 and IL23R, in Korean UC samples. We analyzed four IL23R SNPs and four TNFSF15 SNPs in 380 patients with UC and 380 healthy controls. Two TNFSF15 gene variants, rs3810936 and rs7848647, showed marginal associations with UC; odds ratio (OR) for rs3810936 was 1.447 (95% CI = 1.024-2.044, P = 0.036) and OR for rs7848647 was 1.451 (95% CI = 1.059-1.990, P = 0.021). The contribution of TNFSF15 variants in Korean UC patients overall is much lower than in comparison with studies of CD (for rs3810936 aOR = 2.81, 95 % CI = 1.94-4.07, P = 4.4 x 10-8, for rs7848647 aOR = 3.49, 95 % CI = 2.42-5.03, P = 2.2 x 10-11 respectively). Our results of no association of IL23R with UC in Koreans do not support the previous Caucasian reports of shared association of the IL23R gene between CD and UC.

## 936/W/Poster Board #594

**Replication of markers from recent inflammatory bowel disease genome wide association scans in a Lithuanian cohort.** *J. Sventoraityte[1], A. Zvirbliene[1], L. Kupcinskas[1], G. Kiudelis[1], S. Schreiber[2], A. Franke[2].* 1) Dept. Gastroenterology, Kaunas University of Medicine, Kaunas, Lithuania; 2) Institute for Clinical Molecular Biology, Christian-Albrechts University, Kiel, Germany.

**INTRODUCTION.** Inflammatory bowel disease (IBD), a chronic inflammatory disorder affecting the intestinal mucosa, most commonly presents as either one of the two subtypes, ulcerative colitis (UC) or Crohn disease (CD). The genetic variations conferring susceptibility to IBD has increased substantially over the past few years after the introduction of genome-wide association scans (GWAS). Although several susceptibilty loci have been replicated, some of the associations have been reported to be unique for certain ethnicities. **AIM.** To perform a comprehensive association analysis of genetic markers reported by the two previous GWAS studies [1,2] to further characterize the CD and UC associations in a Lithuanian case-control sample set. To our knowledge, this is the first case-control study using an Eastern-European panel of IBD patients and healthy controls. **MATERIAL AND METHODS.** A set of 43 SNPs from three different categories were selected: (1) the 6 SNPs reported by Rioux *et al.*; (2) the 12 'non-converging' CD SNPs from Parkes *et al.* and (3) 25 SNPs - markers 'converging' between CD and nonautoimmune disease cases of the same study. They were genotyped in a cohort of 152 UC (mean age: 41.80±17.07) and 73 CD (mean age: 35.72±15.38) patients plus 249 unrelated healthy controls (mean age: 43.30±12.39) using ligation-based SNPlex genotyping (Applied Biosystems, USA) technology. The SNPs were quality-controlled for: genotyping success rate (>90%), allele frequency (>1% in healthy controls), deviation from Hardy-Weinberg equilibrium (pHWE>0.01 in the control sample). Assessment of all SNPs and single-marker association analyses were performed using the software program Haploview 4.0. **RESULTS.** Single-marker analyses revealed marginal associations between IBD and genetic variants from category (2) and (3): CD and rs17419032 (1q32.1; p=$4.96x10^{-2}$) and rs9993022 (4q13.1; p=$4.78x10^{-2}$); UC and rs10883365 (*NKX2-3*; p=$2.67x10^{-2}$), rs17419032 (1q32.1; p=$3.44x10^{-2}$), rs12529198 (*LYRM4*; p=$3.22x10^{-2}$, OR=0.37 (95%C.I.:0.15-0.93)) and rs9895062 (*STX8*; p=$9.64x10^{-3}$, OR=0.34 (95%C.I.:0.16-0.78)). **CONCLUSION.** We replicated genetic associations for CD with 4q13.1, UC with *NKX2-3*, *LYRM4*, *STX8*, both subtypes with 1q32.1. However, the lack of non-replication for the other loci is probably due to the small sample size and the lack of statistical power. **REFERENCES.** 1. Rioux, J.D. *et al.* Nat. Genet.39,596-604 (2007). 2. Parkes, M. *et al.* Nat. Genet.39,830-832 (2007).

**Positive association of genetic variants in the upstream region of *NKX2-3* with Crohn's disease in Japanese patients.** *K. Yamazaki[1], A. Takahashi[2], M. Takazoe[3], N. Kamatani[2], Y. Nakamura[4, 5], A. Hata[6], M. Kubo[1].* 1) Lab for Genotyping Development, RIKEN, Center for Genomic Medicine, Yokohama, Japan; 2) Laboratory for Statistical Analysis, RIKEN, Center for Genomic Medicine, Yokohama, Japan; 3) Department of Medicine, Division of Gastroenterology, Social Insurance Chuo General Hospital, Tokyo, Japan; 4) Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Japan; 5) Center for Genomic Medicine, Yokohama, Japan; 6) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan.

A number of genome-wide association (GWA) studies have been performed as a robust means of identifying susceptibility loci for Crohn's disease (CD). The loci detected after the completion of the HapMap project are quite concordant among these studies, suggesting that the results are reliable. Recently, the Wellcome Trust Case Control Consortium (WTCCC) reported the primary scanning of 17,000 individuals for seven diseases, including CD, and a subsequent study has validated these susceptible genetic variants in independent UK sample sets. To study the possible association of the variants reported by WTCCC with CD in a Japanese population, a total of 484 patients with Crohn's disease and 470 healthy controls were examined. Seventeen genetic variants at eight newly identified loci, including *IRGM*, *NKX2-3* and *PTPN2*, were genotyped using the TaqMan assay or the invader assay. We detected positive association signal presumably common to different ethnic groups for rs10883365 in the upstream region of *NKX2-3* (p = 0.019 under the genotypic model, p = 0.0065 under the allelic model, p = 0.019 under the recessive model, p = 0.036 under the dominant model). In addition to rs10883365 , marginal associations for two SNPs were detected in Japanese population; rs6887695 near *IL12B* and rs10761659 on 10q21. Further genotype-phenotype analysis found a significant association between rs6887695 and pure ileal CD patients. Our results indicate that the three loci are possible candidates for conferring susceptibility to Crohn's disease in people of different ethnicities.

**Transferability and Fine-Mapping of Genome-wide Associated Loci for Adult Height across Human Populations.** *D. Shriner[1], A. Adeyemo[1], N. Gerry[2], A. Herbert[3], G. Chen[1], A. Doumatey[1], H. Huang[1], J. Zhou[1], M. Christman[2], C. Rotimi[1].* 1) National Institutes of Health, Bethesda, MD; 2) Coriell Institute for Medical Research, Camden, NJ; 3) Boston University School of Medicine, Boston, MA.

Human height is the prototypical polygenic quantitative trait. Recently, several genetic variants influencing adult height were identified, primarily in individuals of East Asian (Chinese Han or Korean) or European ancestry. Here, we examined 152 previously identified genetic variants influencing adult height for replication in a sample of 1,016 unrelated African Americans. In a well-powered replication analysis, nine genetic associations originally identified in individuals of East Asian or European ancestry replicated ($p$-values $\leq 0.05$ under an additive genetic model with directionally consistent effects) in our African American sample. Association $z$-scores, scaled for differences in sample sizes, were an average of 7.4-fold smaller in magnitude in our African American sample compared to the original East Asian or European samples. Power analysis indicated that our sample size was sufficient to overcome most differences in allele frequencies as well as most differences in linkage disequilibrium patterns. Effect size estimates were directionally consistent for 90% of associations with replication $p$-values $\leq 0.05$. In contrast, directional consistency was observed for 57% of associations with replication $p$-values $> 0.05$, consistent with the null hypothesis of sampling variability ($p = 0.23$). Our findings suggest that most previously reported associations for adult height are likely to be population-specific. Only one association transferred across all three groups, implying substantial heterogeneity across human populations among genetic variants explaining heritability for adult height. Using differences in linkage disequilibrium patterns between HapMap CEU or CHB reference data and our African American sample, we fine-mapped eight independent height loci, improving both the localization and the annotation of these transferable associations.

## 939/W/Poster Board #597

**Common variants in the *MEIS1*, *BTBD9*, and *MAP2K5/LBXCOR1* gene regions are major risk factors for Restless Legs Syndrome and Periodic Leg Movements during Sleep.** *L. Xiong[1], M.-P. Dubé[2], C. Gaspar[1], Y. Feroz Zada[2], G. Asselin[2], A. Levchenko[1], P. Thibodeau[1], J.-B. Rivière[1], J. St-Onge[1], G. Turecki[3], A. Desautels[1,4], J.Y. Montplaisir[4], G.A. Rouleau[1].* 1) Center of Excellence in Neuromics, CHUM Research Center, University of Montreal, Montréal, QC, Canada; 2) Research Centre, Montreal Heart Institute, University of Montreal, Montréal, QC, Canada; 3) Research Center, Douglas Hospital, McGill University, Montréal, QC, Canada; 4) Centre d'étude du sommeil, Hôpitall du Sacré-Cœur de Montréal and Centre de recherche en sciences neurologiques, Université de Montréal, QC, Canada.

Restless legs syndrome (RLS) and periodic leg movements during sleep (PLMS) are two largely overlapping common neurological phenotypes. Family and twin studies have indicated a significant genetic contribution to RLS. Recently, genome-wide association studies (GWAS) have identified three genomic regions associated with RLS or PLMS, i.e., the *MEIS1* gene, the *BTBD9* gene, and the overlapped regions between the *MAP2K5* and *LBXCOR1* genes on chromosomes 2p, 6p, and 15q, respectively. We carried out confirmation studies of 14 selected associated markers from these three regions in an enlarged French-Canadian (FC) case-control sample (281 cases and 803 controls). We also performed family-based association and linkage analyses in 116 pedigrees with RLS. The case-control samples showed significant association with all markers tested. Two markers (rs12469063 and rs2300478) from the *MEIS1* gene showed significant association, with P values of $4.97 \times 10^{-8}$ (allelic OR: 1.78; 95% CI: 1.45-2.19) and $3.24 \times 10^{-7}$ (allelic OR: 1.71; 95% CI: 1.40-2.09), respectively. The OR of the homozygous GG genotype for marker rs12469063 was 3.46 (95% CI: 2.12-5.60) when compared to the wild-type AA genotype. Among the five SNPs in the *BTBD9* region, only rs3923809 showed significant association with RLS (P = 0.0008; allelic OR: 1.46; 95% CI: 1.16-1.82), with the homozygous OR of AA versus GG being 2.28 (95% CI: 1.21-4.62). All seven markers from the *MAP2K5/LBXCOR1* region showed significant association with RLS, with ORs of 1.40-1.50, and with higher OR for the homozygous genotype of the risk allele for each marker (OR: 1.79-1.90), withe the exception of rs4489954. The concordant significant associations for the RLS, PLMS, and RLS/PLMS phenotypes in the FC case-control sample at these three loci respectively confirmed the highly correlated phenotypes and indicate shared pathways. Family-based analyses also showed excessive transmission of the associated alleles to the affected individuals and excessive allele-sharing among the affected siblings at the *MEIS1* and *MAP2K5/LBXCOR1* loci. The estimated population attributable fraction (PAF) of the risk alleles in the FC population was 18% at the *MEIS1* locus, 25% at the *BTBD9* locus, and 25% for the *MAKP2K5/LBXCOR1* locus. The joint PAF was estimated as 54%. Therefore, common variants in the *MEIS1*, *BTBD9*, and *MAP2K5/LBXCOR1* regions are major risk factors for both sporadic and familial RLS.

## 940/W/Poster Board #598

**Replication of association of *ZBTB38* variants with height and subsequent fine mapping in independent adult and adolescent Caucasian populations.** *A.E. Duncan[1], C.A. Olsson[2,3,4], G.C. Patton[2,3], S.B. Harrap[1], J.A. Ellis[1,2].* 1) Department of Physiology, University of Melbourne, Melbourne, Australia; 2) Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Australia; 3) Department of Paediatrics, University of Melbourne, Melbourne, Australia; 4) Department of Psychology, University of Melbourne, Melbourne, Australia.

Adult height is a polygenic trait with heritability estimated to be around 80%. Recent genome-wide association (GWA) studies of adult height have implicated numerous genes. SNPs in one such gene, *ZBTB38* (zinc finger and BTB domain containing 38) located on chromosome 3q23, were identified by three separate, simultaneously published, GWA studies. ZBTB38 appears to bind methylated DNA and repress transcription, although its exact function has yet to be determined. Here, we report on the replication and finer-scale mapping of the association of *ZBTB38* SNPs with height in two independent Australian Caucasian populations, the Victorian Family Heart Study (VFHS, 2876 family-based adult samples) and the Victorian Adolescent Health Cohort Study (VAHCS, 1001 unrelated samples with height measured at eight separate time points from age 15 years to adulthood). SNPs studied included those most strongly implicated by previous GWA studies (rs6440003, rs6763931 and rs724016), those in linkage disequilibrium ($r^2 \geq 0.5$) with these SNPs in the Caucasian population based on HapMap data, and those in close physical proximity based on dbSNP data. SNPs were genotyped using the Sequenom MassARRAY platform and stringent QC was applied to the data. Results for a total of 38 SNPs were analysed using PLINK or SOLAR, adjusting for age and sex. In the VFHS, SNP rs6763931 (chr3: 142585523, intron 4) was the most significantly associated with height ($p = 4.5 \times 10^{-6}$) when testing for total evidence of association. In the VAHCS, rs6440003 (chr3: 142576899, intron 3) was the most significantly associated ($p = 2.4 \times 10^{-7}$), although this SNP is in strong LD with rs6763931 ($r^2 = 0.99$ in the VFHS). The association with height was consistent across the adolescent time points of the VAHCS, suggesting that this gene has an effect on growth that occurs prior to age 15 years. The functionality of the associated SNPs is unknown. However there was some evidence that haplotypes of SNPs were more strongly associated with height than individual SNPs, suggesting that these haplotypes could be better tagging other functional SNPs in the region than single SNPs alone. In conclusion, we have replicated the GWA studies' findings of association of SNPs around *ZBTB38* in two independent populations. The effect of this gene on growth appears to occur at an early age. The functional variant(s) are yet to be identified.

## 941/W/Poster Board #599

**_ITGAM_ is more strongly associated to discoid lupus erythematosus than systemic disease in Finnish patients.** *T.M. Järvinen[1,2,3,4], A. Hellquist[4], S. Koskenmies[5], J. Panelius[5], T. Hasan[6], H. Julkunen[7], J. Kere[2,3,4], U. Saarialho-Kere[1,8].* 1) Department of Dermatology, University of Helsinki, Helsinki, Finland; 2) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 3) Folkhälsan Institute of Genetics, Helsinki, Finland; 4) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 5) Department of Dermatology, Helsinki University Central Hospital, Helsinki, Finland; 6) Department of Dermatology, University of Tampere and Tampere University Hospital, Tampere, Finland; 7) Peijas Hospital, Helsinki University Central Hospital, Vantaa, Finland; 8) Section of Dermatology and Department of of Clinical Science and Education, Karolinska Institutet at Stockholm Söder Hospital, Stockholm, Sweden.

Lupus erythematosus (LE) is a heterogeneous autoimmune disease with abnormal immune responses including production of autoantibodies and immune complexes. We have recruited a population-based cohort representing different subphenotypes of LE: 177 discoid (DLE), 42 subacute cutaneous (SCLE), 275 systemic (SLE) patients and 356 control individuals from Finland. To test whether these different subphenotypes possess similar genetic predisposition, 47 SNPs in 16 genes with strongest evidence of susceptibility for SLE implicated in previous genome-wide association studies were investigated. The samples were genotyped using the Sequenom iPLEX Gold chemistry and association analyses were performed with HaploView 4.0. As a novel finding, *ITGAM* marker rs1143679 showed strongly increased risk for DLE ($p=4.7 \times 10^{-11}$, OR=3.2 [95% CI=2.2-4.6]) compared to SLE ($p=8.3 \times 10^{-6}$, OR=2.1 [95% CI=1.5-3.0]). Also other markers in *ITGAM* were significantly associated to DLE (p-value range from $10^{-11}$ to $10^{-4}$, OR-range from 1.6 to 3.1). Interestingly, a modest association between *ITGAM* and SLE patients with malar and/or discoid lesions was observed (p=0.05). In addition, *BLK/C8orf13* gene region on chromosome 8p was associated more strongly to DLE ($p=2.0 \times 10^{-4}$, OR=1.7 [95% CI=1.3-2.3]) than SLE ($p=1.5 \times 10^{-3}$, OR=1.5 [95% CI=1.2-2.0]). A known SLE susceptibility gene *STAT4* showed significant association to SLE ($p=1.1 \times 10^{-6}$, OR=1.9 [95% CI=1.5-2.5]), whereas only moderate association was observed in DLE ($p= 4.4 \times 10^{-2}$, OR=1.4 [95% CI=1.0-1.9]). We conclude that different subphenotypes of LE share much the same genetic predisposition. The observed association between skin manifestations and *ITGAM* may implicate that abnormal function of this protein is a hallmark of more severe disease progression towards SLE in patients with cutaneous LE. Furthermore, *ITGAM* is involved in inflammation and complement system, both showing defects in LE patients. We are currently replicating these results in Swedish patients with LE or primary Sjögren Syndrome and positive for Ro/SSA antibody.

## 942/W/Poster Board #600

**A common variant in BMP2 modulates severity of the iron burden in HFE p.C282Y homozygous patients: a follow-up study.** *G. LeGac[1], J. Milet[2], V. Scotet[1], I. Gourlaouen[1], C. Thèze[1], J. Mosser[3], C. Bourgain[4], Y. Deugnier[5].* 1) Inserm U613, EFS-Bretagne, Centre Hospitalier Universitaire; Brest, France; 2) IRD - UR010; Paris, France; 3) Medical Genomics Unit, Pontchaillou Hospital and CNRS, UMPR6061, IFR 140, Université Rennes, France; 4) Inserm U535 and Univ. Paris-SUD; Villejuif, France; 5) Center of Clinal Investigation (CIC INSERM 0203) and Service des Maladies du Foie; Rennes, France.

It is now generally admitted that penetrance of the common HFE p.C282Y/p.C282Y genotype is incomplete, and identification of modifier genes is the concern of a growing number of research projects. We recently identified a significant association between pretherapeutic serum ferritin level and the common rs235756 single nucleotide polymorphism (SNP) of the BMP2 gene region. Our results further suggested an interactive effect between the BMP2 rs235756 SNP and the rs16827043 SNP in HJV, with a small additive effect of the rs4901474 SNP in BMP4. The present study has been designed as a replication study in an independent cohort of 450 HFE p.C282Y homozygous patients from a nearby French region (Brittany). Information on individual alcohol consumption and amount of iron removed by phlebotomy being available for a substantial part of this cohort, additional analyses were conducted. Although we failed to replicate results of the initial study, we argue that, altogether, our results help to consider genes involved in regulation of hepcidin synthesis as potential modifiers of the p.C282Y/pC282Y genotype expression and especially BMP2.

## 943/W/Poster Board #601

**Fine-mapping the _MAPT_ H1 haplotype clade in Parkinson's disease.** *I. Mata[1], A. Samii[2], S. Factor[3], D. Higgins[4], A. Griffith[5], J. Roberts[6], H. Kim[2], P. Agarwal[5], D. Yearout[1], C. Hutter[7], K. Edwards[8], D. Kay[9], H. Payami[9], C. Zabetian[1,2].* 1) Dept Neuroscience, VA Puget Sound Healthcare Sys, Seattle, WA; 2) Dept of Neurology,University of Washington, Seattle, WA; 3) Dept. of Neurology, Emory University School of Medicine, Atlanta, GA; 4) Parkinson's Disease and Movement Disorder Clinic, Albany Medical Center, Albany, NY; 5) Booth Gardner Parkinson's Care Center, Evergreen Hospital Medical Center, Kirkland, WA; 6) VA Puget Sound Health Care System, Virginia Mason Medical Center , Seattle, WA; 7) Fred Hutchinson Cancer Research Center, Seattle, WA; 8) Dept. of Epidemiology, University of Washington, Seattle, WA; 9) Division of Genetic Disorders, Wadsworth Center, New York State Department of Health, Albany, NY.

Background: An inversion polymorphism of ~900kb on chromosome 17q21, which includes the microtubule associated protein tau (*MAPT*) gene defines two haplotype clades, H1 and H2. The H1 clade has consistently been demonstrated to associate with Parkinson's disease (PD) and the tauopathies. While putative functional risk variants within H1 have been nominated for the tauopathies, none have been identified for PD. Methods: We fine-mapped the H1 clade in a large case-control sample of white individuals from the NeuroGenetics Research Consortium using a two-tiered approach. In Tier 1 (n=692 cases and 692 controls), we genotyped a comprehensive set of 87 tagging single nucleotide polymorphisms (tagSNPs) selected from the International HapMap Project CEU panel. SNPs associated with PD under an additive model ($\alpha=0.05$) in Tier 1 were then validated in Tier 2 (n=1,277 cases and 1,422 controls). For comparison with the literature, we genotyped three additional SNPs reported to associate with the tauopathies in both Tiers 1 and 2. To account for the effect of the H1 versus H2 clade, analyses were restricted to individuals of the H1/H1 diplotype. Results: As expected, there was a significant excess of the H1/H1 diplotype within the Tier 1 (p=2.2 x 10-3), Tier 2 (p=8.9 x 10-5), and combined PD groups (p=7.2 x 10-7). Among H1/H1 individuals in Tier 1, nine tagSNPs (six within *MAPT*) were marginally associated with PD, with p values ranging between 0.01-0.05. However, none of these nine tagSNPs was replicated in Tier 2 after adjustment for age and sex. Finally, none of three tauopathy-related SNPs was associated with PD in Tier 1 or Tier 2. Conclusions: Our data suggest that the MAPT variants that convey disease risk are distinct between PD and the tauopathies. However, the identification of the true risk allele(s) for PD remains to be determined. We are now seeking to address the problem using deep resequencing of the *MAPT* region as an alternate strategy to discovery potential risk variants of low frequency.

## 944/W/Poster Board #602

**A population specific susceptibility and genotype risk to Crohn's disease and ulcerative colitis.** *S. Nakagome[1], Y. Takeyama[2], S. Mano[3], S. Sakisaka[2], T. Matsui[4], S. Kawamura[1], H. Oota[1].* 1) Department of Integrated Biosciences, University of Tokyo, Kashiwa, Chiba, Japan; 2) Department of Gastroenterology and Medicine, Fukuoka University Faculty of Medicine, Fukuoka, Japan; 3) Graduate School of Natural Sciences, Nagoya City University, Nagoya, Japan; 4) Department of Gastroenterology, Fukuoka University Chikushi Hospital, Fukuoka, Japan.

Inflammatory bowel disease (IBD) is a chronic inflammation in the digestive tract. The Crohn's disease (CD) and the ulcerative colitis (UC) are named generically as IBD. IBD is common in Europe, but not in East Asia. However, the prevalence rate of CD is increasing in East Asian in the last 20 years. Recent genome-wide association studies (GWAS) have identified more than 30 CD-associated genomic loci in Europeans. Risk alleles in some loci (*IL23R*, *NKX2-3*, and *MST1*) are reported to be associated also with UC in Europeans. Regarding these loci, however, no clear association has been shown in East Asians, except *TNFSF15*. Furthermore, little is known whether the IBD-causative alleles identified in Europeans work dominantly or recessively in any population. To clarify whether there is any population-specific susceptibility and genotype risk, we conducted genotyping for 212 IBD patients and 168 controls from Kyushu, Japan, of the seven loci (*NOD2*, *IL23R*, *ATG16L1*, *TNFSF15*, 5q31, *IRGM*, 10q21) that are shown associated with CD in Europeans by multiple studies. We confirmed that *TNFSF15* is associated with CD also in Japanese. We found that this gene is also associated with UC, which has not been reported for Europeans. By the modified genotype relative risk (mGRR) test we showed that the risk variant of TNFSF15 works dominantly in CD whereas it works recessively in UC. These results suggest that susceptibility and genotype risk to multifactorial diseases, such as IBD, differs among populations.

## 945/W/Poster Board #603

**Association between a functional polymorphism of *ITPKC* gene and Kawasaki disease: a replication study.** *Y. Onouchi[1], K. Ozaki[1], H. Suzuki[2], M. Terai[3], Y. Suzuki[4], A. Hata[4], Y. Nakamura[5,6], T. Tanaka[1].* 1) Lab. Cardiovascular Diseases, Center for Genomic Medicine RIKEN, Yokohama, Japan; 2) Dept. Pediatrics, Wakayama Medical Univ., Wakayama, Japan; 3) Dept. Pediatrics, Tokyo Women's Medical Univ. Yachiyo Medical Center, Yachiyo, Japan; 4) Dept. Public Health, Graduate School of Medicine, Chiba Univ., Chiba, Japan; 5) Lab. Molecular Medicine, Human Genome Center, Institute of Medical Science, the Univ. of Tokyo, Tokyo, Japan; 6) Director, Center for Genomic Medicine RIKEN, Yokohama, Japan.

Kawasaki disease (KD) is an acute systemic vasculitis syndrome of infants and young children. Recently we reported that a single nucleotide polymorphism (SNP) located in intron 1 of inositol 1,4,5-trisphosphate 3-kinase C (*ITPKC*) gene was associated with KD and the risk for formation of coronary artery lesions (CALs) both in Japanese and Caucasian populations. The SNP (rs28493229) was also associated with the risk for unresponsiveness to intravenous immunoglobulin (IVIG) therapy in Caucasian KD patients. However, the findings have not been replicated to date and the association between the SNP and unresponsiveness to IVIG therapy has not been investigated in the Japanese KD patients yet. We recruited 282 Japanese KD patients and 373 ethnically matched controls independent from those in the original report and performed an association study. In this new case-control panel, the C allele of rs28493229 was significantly associated with KD again (OR = 1.60, 95%CI 1.15 - 2.21, $P$ = 0.0047 in dominant model). When combined with the data in the original report (637 KD patients vs. 1034 controls; OR = 1.89, 95%CI 1.53 - 2.33, $P = 2.2 \times 10^{-9}$ in dominant model) using the Mantel-Haenszel method, the pooled OR was 1.80 (1.51 - 2.14) and the $P$ value was $5.5 \times 10^{-11}$. In addition, among the KD patients who received a single dose of 2g/kg or 1g/kg daily for 2 days of IVIG in the acute phase (n = 122), the C allele was significantly overrepresented in patients subgroup who responded poorly to the therapy (n = 34, OR = 2.76, 95%CI 1.23 - 6.23, $P$ = 0.013 in dominant model) and was marginally associated with CALs formation (n = 14, OR = 2.94, 95%CI 0.92 - 9.39, $P$ = 0.059 in dominant model). These data indicated that the C allele of rs28493229 truly confers susceptibility to KD and has the potential to be a tool for personalized medicine predicting patients who will experience severe clinical course and treating them with alternative or additional therapy before they are destined to develop CALs.

## 946/W/Poster Board #604

**Association analyses between 9 loci and metabolic traits in Chinese Han population.** *Y. Liu[1,3], DZ. Zhou[2], D. Zhang[2], Z. Zhang[2], L. He[1,2,3].* 1) Institutes Of Biomedical Scien, Fudan university, Shanghai, China; 2) Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, China; 3) Bio-X Center, Shanghai Jiao Tong University, Shanghai, China.

Aims/hypothesis: Recently, genome-wide association studies had been performed in the genetics studies of plasma lipid level, and identified several common variants associated with LDL-C, HDL-C and triglycerides, including some new polymorphisms. The aim of this study was to replicate these associations in Han Chinese individuals. Methods: In the present study, nine SNPs in nine loci were genotyped in a Chinese Han population (n= 3,953), the associations of these SNPs with metabolic traits were assessed by linear regression adjusted for age, gender, diabetes status and body mass index. Results: Four variants (rs780094, p=4.43×10-11 ;rs17145738, p=4.28×10-7; rs439401, p=3.47×10-5;, rs326, p=1.51×10-6;) show strong evidence for association with TG after multiple testing, four variants (rs3764261, p=4.67×10-14; rs1800588, p=1.93×10-7; rs17145738, p= 1.90×10-4; rs326, p=1.14×10-3;) show strong evidence for association with HDL-C after multiple testing, two variants (rs3764261, p=6.24×10-7; rs12654264, p=1.57×10-6;) show strong evidence for association with total cholesterol after multiple testing, one variants (rs12654264 p=1.92×10-5) show strong evidence for association with LDL-C after multiple testing. Conclusions: Our findings indicate that these variants associated with metabolic traits in Europeans may also play a role in Chinese Han population.

## 947/W/Poster Board #605

**Variants in the TNFAIP3 locus form Three Risk Haplotypes Associated with SLE in Koreans.** *J.S. Bates[1], C.J. Lessard[1,2], S.C. Bae[3], Y.W. Song[4], B.P. Tsao[5], L.J. Battiest[1], T. Nguyen[1], J. Rodgers[1], A. Adler[1], K.M. Kaufman[1,2], J.A. Kelly[1], J.B. Harley[1,2], C. Gray-McGuire[1], K.L. Moser[1], P.M. Gaffney[1].* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK, OK; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Hanyang University, Seoul, Republic of Korea; 4) Seoul National University, Seoul, Republic of Korea; 5) University of California- Los Angeles, Los Angeles, CA.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by acute and chronic inflammation in multiple tissues and often leads to organ malfunction and failure. Variants in tumor necrosis factor alpha interacting protein 3 (TNFAIP3) have recently been associated with SLE and rheumatoid arthritis risk in Europeans. TNFAIP3 encodes A20, a zinc-finger protein with dual ubiquitin and de-ubiquitin properties required for efficient termination of the NF-κB signaling axis. Variants in TNFAIP3 (n = 22) were assessed for association with SLE in Koreans using 821 cases and 1008 controls in PLINK. Genotyping was performed using the Illumina GoldenGate chemistry. Association of SLE risk with the TNFAIP3 locus in Koreans was observed in 13 variants ($OR$ = 1.78-2.32, $P < 1 \times 10^{-4}$). Eight haplotypes (MHF > 0.5%) in the TNFAIP3 locus were formed with greater than 95% confidence per individual using DECIPHER in SAGE from 20 observed variants and evaluated for SLE risk using the LOGISTIC procedure in SAS. Three risk haplotypes explained 98.8% of SLE risk in the TNFAIP3 locus and each contained a primary risk block marked by minor alleles from rs5029937, rs5029939, rs2230926, rs610604, rs7752903, rs9494894, rs7749323, and rs6932056. The most strongly associated risk haplotype was further marked by the minor allele at rs9494883 ($OR$ = 3.35, $P = 3.4 \times 10^{-7}$). The second most strongly associated haplotype was further marked by the major allele at rs10499194 and the minor allele at rs10499197 ($OR$ = 2.27, $P = 8.9 \times 10^{-3}$). The third risk haplotype, further marked by the minor allele at rs10499194, was independent from the major frequency non-risk haplotype ($OR$ = 1.80, P = 0.005) and the most strongly associated risk haplotype ($OR$ = 0.54, $P$ = 0.04). Our results suggest variants in TNFAIP3 form three risk haplotypes associated with SLE risk in Koreans and that two risk haplotypes are independent of one another, suggesting multiple causal variants in the TNFAIP3 locus may exist.

## 948/W/Poster Board #606

**The Protein Kinase C Alpha (PRKCA) gene is associated with multiple sclerosis in the Italian population.** *R. Asselta[1], E.M. Paraboschi[1], G. Soldà[1], C. Dall'Osso[1], D. Gemmati[2], P. Zamboni[3], M.D. Benedetti[4], S. D'Alfonso[5], S. Duga[1].* 1) Dipartimento di Biologia e Genetica per le Scienze Mediche, Università degli Studi di Milano, Milano, Italia; 2) Center Hemostasis and Thrombosis, University of Ferrara, Ferrara, Italy; 3) Vascular Diseases Center, University of Ferrara, Ferrara, Italy; 4) Department of Neurological and Vision Sciences, Section of Clinical Neurology, University of Verona, Verona, Italy; 5) Department of Medical Sciences and IRCAD, Eastern Piedmont University, Novara, Italy.

Multiple sclerosis (MS) is a chronic neurological disorder characterized by multicentric inflammation, demyelination, and axonal damage. The Protein Kinase C Alpha (PRKCA) gene was found to be associated with MS in Finnish, Canadian, and UK populations, in which specific risk haplotypes were identified. Moreover, PRKCA transcript levels were shown to be higher in CD4- mononuclear cells of MS patients carrying the risk haplotypes, suggesting a contribution of PRKCA regulatory mechanisms in the pathogenesis of MS. In this study, we analyzed the role of PRKCA in MS susceptibility in a cohort of 358 cases and 662 controls from continental Italy. An association analysis was performed genotyping 3 microsatellites and 20 single nucleotide polymorphisms (SNPs) covering the whole gene. A significant association with 2 microsatellites, mapping respectively in the promoter region and in intron 2, was found (P=0.032 and P=0.027). The 5' regulatory region of the PRKCA gene was hence further investigated by sequencing the first 424 bp of the promoter and the entire exon 1 in all MS cases and controls. However, no genetic variants specific for MS cases were identified. Analysis of individual SNPs did not show any evidence for association; however, a haplotype of 7 SNPs, spanning a genomic region of 43 kb of PRKCA intron 3, resulted strongly associated with the disease status (P= 7.4*10-4; OR=1.54, 95% CI=1.22-1.95). This haplotype, which partially overlaps the risk haplotypes observed both in Finns and Canadians, includes an alternative exon characterizing a shorter PRKCA protein isoform. Since no information were available on the tissue distribution of this isoform, its expression pattern was analyzed and compared to the expression profile of PRKCA in a panel of 20 human tissues by RT-PCR: the shorter isoform showed a more marked tissue-specific expression. The possible differential expression of the 2 transcripts between MS patients and controls is currently underway by qRT-PCR on RNA extracted from peripheral blood mononuclear cells. In conclusion, our study provides a strong replication evidence that haplotypes characterizing PRKCA increase the risk of MS; a metanalysis including all studies investigating the role of PRKCA as a MS susceptibility gene reported so far showed the considerable OR of 1.52 (95% CI=1.36-1.69; P=2.2*10-14).

## 949/W/Poster Board #607

**Influence of the HLA-DRB1*15 allele on Multiple Sclerosis in a Colombian population.** *M.C. Lattig[1], C. Perea[1], J.M. Gonzalez[2], H. Groot[1], D. Vela-Duarte[3], J. Toro[2,3].* 1) Laboratorio de Genetica Humana, Universidad de los Andes, Bogota - Colombia; 2) Facultad de Medicina, Universidad de los Andes, Bogota - Colombia; 3) Grupo Esclerosis Multiple Fundacion Santa Fe Bogota - Colombia.

Multiple Sclerosis (MS [MIM 126200]), a demyelinating disease of the central nervous system, varies in prevalence depending on the geographic region where the disease is encountered. A low MS prevalence has been reported in tropical regions of the world. In Bogota - Colombia, an area of defined low risk for the disease, an MS prevalence rate of 4,41/100,000 was previously reported by our group. Genetic factors including (HLA) class II genes such as (HLA)-DRB1*15 play a role in the susceptibility to multiple sclerosis, especially in Northern European populations. To determine the contribution of the (HLA)-DRB1*15 allele in the Colombian population we performed a case-control study involving 53 MS patients collected following the McDonald criteria and 51 matched controls observing that the allele was present in similar frequencies among patients and controls [odds ratio (OR) = 1.47; 95% CI = 0.59 - 3.70; p = 0.49]. The clinical course and symptoms of MS vary considerably between patients. Among the affected individuals we analyzed, the HLA DR15 contribution to various clinical phenotypes showed no evidence that the allele has an influence on the clinical course of MS. In summary, the contribution of the (HLA)-DRB1*15 allele appears to be less significant in the low risk zone known to have a high admixture component such as Bogota - Colombia.

## 950/W/Poster Board #608

**Association between insulin-like growth factor 2 gene polymorphism and normal tension glaucoma in the Japanese population.** *F. Mabuchi[1], Y. Sakurada[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: Previous study reported that the insulin-like growth factor 2 (*IGF2*) gene polymorphism (rs680) was associated with primary open angle glaucoma (POAG) in the Chinese population. However, there have been no studies in the other ethnic populations. POAG is clinically classified into high tension glaucoma, in which elevated intraocular pressure is a major feature, and normal tension glaucoma (NTG), in which the intraocular pressures are consistently within the statistically normal population range. POAG is a complex and genetically heterogeneous disease characterized by the progressive apoptotic death of retinal ganglion cell, and apoptosis-related genes like *IGF2* seem to possibly be associated with POAG, especially NTG. We thus assessed whether the *IGF2* gene polymorphism was associated with NTG in the Japanese population. Methods: One hundred Japanese patients with NTG and 100 control subjects were analyzed for the *IGF2* gene polymorphism (rs680) using an allele specific primer PCR technique, and the genotype and allele frequencies were compared between the NTG patients and control subjects. The mean age at the time of blood sampling was 63.7 ± 13.5 years (mean ± SD) in patients with NTG and 65.5 ± 11.5 years in the control subjects. Results: No significant difference was observed (P = 0.98, Chi-square test) regarding the *IGF2* genotype between the NTG patients (GG: 36%, GA: 42%, AA: 22%) and the control subjects (GG: 37%, GA: 42%, AA: 21%). Additionally, there was no significant difference (P = 0.89, Fisher's exact test) in the frequencies of the *IGF2* alleles between the NTG patients (G allele: 57%, A allele: 43%) and the control subjects (G allele: 58%, A allele: 42%). Conclusion: The *IGF2* gene polymorphism was not found to be associated with NTG in the Japanese population. Further studies in the different ethnic populations are desirable to elucidate the relationship between the *IGF2* gene and POAG, especially NTG.

Serum metabolite concentrations provide a direct readout of biological processes in the human body, and are associated with disorders such as cardiovascular and metabolic diseases. We have previously identified frequent genetic polymorphisms with large effects sizes that alter an individual's metabolic capacities (Gieger et al., PLoS Genetics, 2008). We argue that knowledge of these "genetically determined metabotypes" in the human population is key to identifying the contributions and interaction of genetic and environmental factors in the etiology of complex diseases. Here we present a genome-wide association study with 163 metabolic traits, covering a biologically relevant panel of amino acids, sugars, acylcarnitines, and phospholipids, using 1809 participants from the KORA population, which we replicated in the TwinsUK cohort with 422 participants. Most often, the genetic variant is located in or near enzyme or solute carrier coding genes, where the associating metabolic traits match the proteins' function, many of these polymorphisms being located in rate limiting steps of important enzymatic reactions. For several loci, an association with clinical endpoints has previously been reported, such as *SLC22A4* with Crohn's disease, *FADS1* with hyperactivity and cholesterol/triglyceride levels, and *ACADS* with susceptibility to ethylmalonic aciduria. Here we report association of these loci with different metabolic phenotypes and show that these allow deriving new functional information about the underlying pathophysiology. In summary, this study allowed us to draw a systemic perspective of the genetic variation that is found in human metabolism. In contrast to most GWAS with clinical endpoints, it appears that for metabolic traits most of the associations are linked to genetic variants in genes with a matching metabolic function. Our study shows the exciting potential of Metabolomics to unravel the genetics of complex traits and polygenic disorders.

## 952/W/Poster Board #610

**Genome-wide transcriptomic and genomic analyses of Ashkenazi Parkinson's disease patients.** *A. Orr-Urtreger[1,3], A. Bar-Shira[1], E. Kenny[4], I. Pe'er[4], N. Giladi[2,3], M. Kedmi[1].* 1) Genetic Institute, Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel; 2) Movement Disorders Unit, Parkinson Center, Department of Neurology, Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel; 3) Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel; 4) Department of Computer Sciences Columbia University, New-York, USA.

Parkinson's disease (PD) is a complex disorder. Aging, environmental variables and multiple genetic factors are involved in its pathogenesis. However, a surprisingly high proportion of disease-associated mutations were detected in about a third of Ashkenazi patients in the *LRRK2* and *GBA* genes, rendering this population valuable for genetic studies aimed to understand PD pathogenesis in the world population-at-large. In order to define novel genes, genomic regions and cellular pathways associated with PD, combined genome-wide analyses of transcription, SNPs and CNVs were performed. RNA (n=118) and DNA (n=428) samples from peripheral blood leukocyte (PBL) of patients and controls were tested. Four study groups were analyzed: Ashkenazi patients with either *LRRK2* G2019S or *GBA* mutations, patients without these mutations and age- and sex-matched controls. Analysis of Affymetrix Exon 1.0 Array "core data" (21,980 genes and 232,448 exons) revealed 173 differentially expressed exons between all PD patient and controls ($P<0.01$ and Fold Change>1.5). These exons were incorporated into 80 genes; some of which showed alternative splicing. When comparing only two experimental groups, non-carrier PD-patients and controls, 206 differentially expressed exons ($P<0.01$ and Fold Change>1.5) were detected, that incorporated into 114 genes. Analysis of the genome-wide Affymetrix SNP6.0 Arrays demonstrated high quality data, with call rates above 97.8% and Identity-by-Descent of up to 4% sharing in the study population. This analysis confirmed *LRRK2* and *GBA* as two major loci associated with PD in Ashkenazi Jews, and further identified novel candidate PD-associated SNPs on chromosomes 14 and 20. The CNV analysis demonstrated 4715 gain and loss events in patients and 1880 in controls, revealing an increased CNV burden in PD patients, as measured by the number of CNVs in each individual ($P$=0.023). Additionally, 33 novel CNVs were shared by two or more individuals, 13 of them by patients only. Together, our results demonstrate the importance of the Ashkenazi PD-patients population for studying the complex genetic basis of PD. Results from the expression studies support PBL as a relevant surrogate tissue to identify transcriptional changes involved in PD pathogenesis, and the SNP and CNV data will hopefully help identify genes and genetic pathways associated with PD.

## 953/W/Poster Board #611

**GWAS of systemic lupus erythematosus on a Chinese population in Hong Kong.** *W. Yang, Y.L. Lau, Chinese Consortium on SLE Genetics.* Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, Hong Kong.

SLE is a prototype autoimmune disease with strong genetic involvement and population differences in both clinical manifestations and genetic susceptibilities. In this study, we have genotyped 600 SLE patients of Chinese ethnicity residing in Hong Kong using Illumina 550K Beadchip, and analyzed the data against 900 controls matched with ethnicity and geography. We have analyzed the data using Plink and Eigenstrat to correct for potential subpopulation structures. About 50 SNPs were selected for replication based on their P value, gene ontology, relationship to expression of nearby genes, multiple independent alleles in a region, etc, using the remaining samples from Hong Kong as well as two other Chinese cohorts collected in Shanghai and Hefei, China, together with a cohort from Bangkok, Thailand. Our data confirmed association of some known susceptibility genes identified in the previous studies on populations of European ancestry, but also pointed out some differences in terms of effect sizes, allele frequency differences, and independently contributing alleles in genes such as STAT4, ITGAM, Bank1, BLK, TNFAIP3, and TNFSF4. We also report some novel findings that are different from previous Caucasian studies. The newly-discovered susceptibility genes for our Asian populations may reflect genes and alleles that are either population-specific in terms of disease association, or different effect sizes between different populations, explaining differences in the study power between our study and the previous ones. Our data concludes that due to the extreme heterogeneity of the disease, the high prevalence and more severe clinical manifestations of the disease in Asians, many more new susceptibility genes are going to be discovered despite previous efforts focusing on the Caucasian populations.

## 954/W/Poster Board #612

**Discovery of Genes Controlling Mono- and Polygenic Diseases in Mice: Genome-Wide Association Analysis of Serum-transfer Induced Arthritis.** *V.A. Adarichev[1,2], E. Kudryavtseva[1], T.S. Forde[1].* 1) Dept Medicine, Division of Rheumatology, Albert Einstein College Med, Bronx, NY; 2) Dept Microbiology & Immunology, Albert Einstein College Med, Bronx, NY.

Genome-wide association (GWA) analysis was proven to be an effective tool in human genetics, but GWA in mice is not developed yet hindered by the lack of efficient algorithm for SNP association analysis and by arbitrary small number of inbred murine strains characterized for susceptibility to complex diseases.

Using information about several million SNPs in more than 70 inbred murine strains, we propose a two-phase GWA analysis. First, 100k SNP set covering the entire mouse genome was used. On a second phase, all available SNPs within the regions that were found positive after the first GWA phase were tested. Computations were based on a single gene model, hence, independent statistical test for every polymorphic genome position was performed using linear regression model for genotype-phenotype association. Raw $p$-values were corrected for multiple comparisons generating genome-wide $q$-values.

To address the efficiency of GWA gene discovery in inbred murine strains, we performed statistical modeling using coat color trait. Tyrosinase encoding gene was identified as a single major genome-wide peak when more than 45 strains were used. Two SNPs within tyrosinase gene were strongly associated with coat color ($p < 4.4\times10^{-16}$, genome-wide $q < 1.1\times10^{-10}$). Signal-to-noise ratio for the major peak was $10^9$ to 1; locus size was smaller than 1,500 bp.

The two-phase GWA analysis was applied for murine serum-transfer induced arthritis. Analysis successfully confirmed two human rheumatoid arthritis loci previously found near hemolytic complement component *C5* and phosphatidylinositol-phosphate kinase *Pip4k2c* encoding genes. Both genes showed highly significant association with clinical score of murine arthritis: $p < 4\times10^{-10}$ and $p < 8.2\times10^{-11}$, respectively. Novel genetic loci containing *Serpine type 2* ($p < 10^{-9}$), fibrillin *Fbn2* ($p < 10^{-8}$), nuclear factor of activated T cells *Nfatc4* ($p < 10^{-7}$), and *Nfkb1* ($p < 10^{-7}$) were also found to be significantly associated with the effector inflammatory phase of murine arthritis.

The novel approach opens an avenue for discovery genes associated with common pathologies in a short period of time avoiding long and expensive genetic linkage studies.

**Genome-wide association study of degenerative disc disease (DDD).** *P.Y.P. Kao[1], D. Chan[1], K.S.E. Cheah[1], K.M.C. Cheung[2], D.W.H. Ho[1], J. Karppinen[5], J.C.Y. Leong[2], K.D.K. Luk[2], S.P. Yip[6], Y.Q. Song[1, 2], P.C. Sham[3, 4].* 1) Dept. of Biochemistry, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong, Hong Kong, China; 2) Dept. of Orthopaedics & Traumatology, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong, China; 3) Dept. of Psychiatry, Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong, China; 4) Genome Research Centre, University of Hong Kong, Hong Kong, China; 5) Dept. of Rehabilitation, University of Oulu, Oulu, Finland; 6) Dept. of Health Technology and Informatics, Hong Kong Polytechnic University, Hong Kong, China.

Low back pain is a common problem, where 70-85% of people experienced back pain in their life. There are a number of causes for LBP and the most important one is degenerative disc disease (DDD). The etiology of DDD is complex. Both environmental and genetic factors are possible contributing factors. Familial aggregation and similar degeneration patterns observed in twins suggested that genetic factors play an important role in DDD. Genetic variants related to DDD were already suggested in several candidate gene studies. To decipher the genetic component of DDD, we have initiated a whole-genome case-control association study for DDD using Affymetrix Mapping 500K microarray. Volunteers of Southern Chinese origin, aged from 18 - 65 years, were recruited and underwent blood sampling and magnetic resonance imaging (MRI) of the spine with consent. DDD status was graded according to Schneiderman's classification to give a DDD score. MRIs were analyzed by two experienced physicians (K.M.C.C., J.K.) blinded to the results of genetic analysis and clinical history. Scores of each of the five lumbar intervertebral discs were summed. An age-adjustment procedure for the DDD score was carried out using a standardization process to give age-adjusted DDD score (AADS). In this procedure, each sample's DDD score was standardized with the mean and standard deviation calculated from individuals having ages below and above a specified bandwidth. Cases and controls were selected from samples having the highest and lowest, respectively, AADSs. From these criteria, 200 cases and controls, respectively, were selected. DNA was extracted from whole blood and quality was checked to be conforming to the quality threshold for genotyping with 500K array set. Genotypes were called with BRLMM algorithm. Analysis was carried out using Plink, and Haploview was used for visualization of the data. Quality control was performed with Plink. Samples and markers with bad qualities were excluded. Relationships between individuals were checked by means and variances of the identity-by-state (IBS) to ensure there are no close relatives. The filtered samples and markers were corrected for hidden population structure with Eigenstrat. 318,747 SNPs remained after per-SNP QC filtering. After a further correction of hidden population substructure by Eigenstrat, markers with p-values of order 10-5 could be detected.

## 956/W/Poster Board #614

**Bone Density GWAS in Premenopausal White Women and Replication in Other Cohorts.** *D.L. Koller, S. Ichikawa, D. Lai, L. Curry, S.L. Hui, M. Peacock, T. Foroud, M.J. Econs.* Departments of Medical & Molecular Genetics and Medicine, Indiana Univ Sch Medicine, Indianapolis, IN.

Several genomewide association studies (GWAS) have been performed to identify genes contributing to bone mineral density (BMD), typically in samples of elderly women and men. In order identify genes contributing to peak BMD we completed a GWAS in a sample of 1,552 premenopausal white women aged 20-45 years from 762 sibships. BMD was measured at the lumbar spine and femoral neck by DXA. Genotyping was performed by the Center for Inherited Disease Research using the Illumina 610Quad. SNPs and samples with call rates below 95%, SNPs with deviation from Hardy-Weinberg equilibrium (p<0.00001), or minor allele frequency below 1% were removed, as were samples with evidence of population stratification. The final dataset consisted of 547,971 SNPs and 1,524 women. Age and weight-adjusted BMD values were tested for association with each SNP using PLINK, with p-values determined empirically via permutation. The top 50 SNPs for both peak femoral neck and lumbar spine BMD were genotyped in a sample of 669 black premenopausal women and 1,092 white men. Associations with $p<1.5 \times 10^{-5}$ for femoral neck or lumbar spine BMD were selected for replication genotyping. A SNP located 180 kb 3' of SOX6 was associated with lumbar spine BMD (rs10832519, $p=1.5 \times 10^{-5}$) and replicated in the sample of white men (p=0.01). This gene has been demonstrated to have a role in bone formation. SNPs in CATSPERB on chromosome 14 provided evidence of association with femoral neck BMD (rs1298989, $p= 2.7 \times 10^{-5}$; rs1285635, $p=3.0 \times 10^{-5}$) which was replicated in the black women (rs1298989, p=0.006; rs1285635, p=0.003). We also detected association with rs1826601 on chromosome 16 ($p=1.1 \times 10^{-5}$) near the 5' terminus of ADAMTS18. Association with SNPs in this gene has been previously reported in a GWAS and replicated by Xiong et al (AJHG 84:388-398, 2009). We conclude that a GWAS for peak BMD in a sample of premenopausal women replicates several genes previously identified, and that several of these findings replicate in black women or white men.

## 957/W/Poster Board #615

**Genome-wide association study of migraine with aura in a large international consortium sample identifies first SNP and CNV associations affecting migraine susceptibility.** *V. Anttila[1,2], K. Alakurtti[1], M. Kallela[3], G. Terwindt[4], U. Todt[5], T. Freilinger[6], V. Artto[3], M. Inouye[1], K. Kristiansson[1], S. Calafato[1], A. van den Maagdenberg[4], L. Peltonen[1,2,7,8], M. Wessman[2,9], J.-A. Zwart[10], M. Daly[7], D. Nyholt[11], M. Dichgans[6], C. Kubisch[5], R. Frants[4], A. Palotie[1,2,7], International Headache Genetics Consortium.* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, UK; 2) Institute for Molecular Medicine Finland and Center of Excellence for Complex Disease Genetics, University of Helsinki, Helsinki, Finland; 3) Dept. of Neurology, Helsinki University Central Hospital, Helsinki, Finland; 4) Leiden University Medical Center, University of Leiden, Leiden, the Netherlands; 5) Institute of Human Genetics, University Hospital Cologne, Cologne, Germany; 6) Klinikum Groβhadern, Ludwig-Maximilians-Universität, Munich, Germany; 7) Broad Institute at Harvard and MIT, Cambridge, MA, USA; 8) National Institute for Health and Welfare, Helsinki, Finland; 9) Folkhälsan Research Center, Helsinki, Finland; 10) Norwegian National Headache Centre, Department of Neurology and Clinical Neurophysiology, St Olavs Hospital, Trondheim, Norway; 11) Queensland Institute for Medical Research, Brisbane, Australia.

Here we present the results of the first genome-wide association (GWA) study in migraine. Despite a well-established genetic component for migraine and numerous studies, no variants or genes influencing migraine susceptibility have been convincingly identified. Given the recent successes by large-scale multinational collaborations in tackling complex diseases, we formed the International Headache Genetics Consortium comprised of seven top-tier migraine centres. In this study, we have performed a genome-wide analysis of 2,900 cases and 11,000 controls, roughly equally distributed between Finland, Germany and the Netherlands. All cases have extensive phenotype information available and diagnosis has been verified by a migraine specialist. For genotyping, we used the Illumina 610k and 550k GWA chip platforms, and obtained population-matched controls from other studies (Health2000 and the Helsinki Birth Cohort from Finland [www.nationalbiobanks.fi], the ERGO study from the Netherlands [www.epib.nl/ergo.htm], and KORA [www.helmholtz-muenchen.de/kora/], PopGen [www.popgen.de] and HNR [www.recall-studie.uni-essen.de] studies from Germany) genotyped on the same chips. Association analyses were performed using PLINK and Haploview for SNPs and PennCNV, QuantiSNP and CNVtools for CNV discovery and copy number assignment. We report the results of genome-wide SNP analyses, including both population-specific and population-agnostic genes, and several associating copy number variants. Specifically, we have identified several SNP associations (on chromosomes 4q, 10q and 17p), with a high degree of overlap with previous linkage findings, as well as CNV associations with similar overlap. Furthermore, we demonstrate that the previously published trait component approach has greater power to resolve the association signal at these loci. In this presentation we detail the first statistically robust and consistent genetic associations in migraine genetics, and the first step to quantify the contributions of CNVs to the genetic background of migraine.

**Background**: Handedness, a consistent asymmetry in skill or preferential use between the hands, is a moderately heritable trait which is related to the lateralization of language functions within the brain. The prevalence of left-handedness (~10% in the general population) is increased in a number of psychiatric, neurologic, and learning disorders suggesting that cerebral asymmetry may play a role in these disorders. Previous linkage and association studies have had only limited success. However these studies have used unselected samples resulting in low numbers of cases and low power. Here we present the results of a meta-analysis of 12 genome wide association studies, comprising 23,443 samples (2350 cases, 21093 controls). **Methods**: Writing hand was used to classify participants as left- or right-handers, and sex and year of birth were used as covariates. All samples were derived from European descent populations. We tested for trait associations under an additive model for a total of ~2.5 million common HapMap SNPs (directly genotyped and imputed). Weighted Z-score based meta-analysis was conducted using METAL with weights defined by effective sample size. **Results**: We observed a number of signals approaching genome-wide significance ($5x10^{-8}$) all of which were novel. Promising results were found on chromosome 5 ($p = 2.455e^{-07}$) and 13 ($p = 6.149e^{-07}$), in regions that encompasses *SLIT3* (which plays a role in the axon-guidance-pathways which guide motor neuronal development during fetal development), *MAB21L1* (involved in cerebellum development) and *NBEA* (which encodes a neuron-specific multidomain protein implicated in membrane trafficking that is predominantly expressed in the brain and during development). **Conclusions**: No evidence of association was found for any the traditional asymmetry candidate genes (*NODAL*, *LEFTY*). Large-scale replication efforts are currently underway. These results vastly extend the number of loci implicated in the development of handedness and lateralization in general.

## 959/W/Poster Board #617

**Heterogeneity in autism spectrum disorders (ASD): linkage analysis of four ASD subsets defined by ADI-R clustering.** *Z. Talebizadeh[1], E. Moore[1], V.W. Hu[2].* 1) Children's Mercy Hospital and University of Missouri-Kansas City MO; 2) Biochemistry and Molecular Biology, The George Washington University Medical Center, Washington, DC.

Autism is a genetically heterogeneous neurodevelopmental disorder which belongs to a group of conditions known as autism spectrum disorders (ASD). Recently a new ASD phenotypic sub-classification was reported by Hu et al. (2009) using ADI-R data, a gold standard autism diagnostic assessment tool. The objective of our current study was to determine the impact of this new ASD subject stratification on genome-wide linkage analysis. According to this classification, four reasonably distinct phenotypic subgroups were identified: (1) severe language impairment, (2) milder symptoms across all domains, (3) notable savant skills, and (4) intermediate phenotype. The genotyping data derived from the Affymetrix 10K SNP array for 426 families was downloaded from the Autism Genetic Research Exchange (AGRE) website. The AGRE SNP data files were sorted into separate files for each of the four ADI-R phenotypic sub-categories. Four group-related main lists were prepared by selecting families having at least one autistic sibling belonging to group 1, 2, 3, or 4. In multiplex families, affected members of each family may belong to different sub-categories reflecting intra-family heterogeneity. Therefore, once families were sorted based on these initial subject sub-categories, for increasing specificity the intra-family heterogeneity was further adjusted by removing affected siblings that were not in the same phenotypic subgroup. To assess gender affect, further analysis was done based on the affected individual's gender. Non parametric linkage (NPL) was calculated using MERLIN linkage analysis software. When the combined (non-subtyped) samples were analyzed, a suggestive linkage was found for 426 AGRE families for the following chromosomal bands: 3q25 (LOD=1.6, P=0.003), 4q22 (LOD=2.02, p=0.001), 5p13 (LOD=2.04, p= 0.001), 5q35 (LOD=2.7, P=0.0002), and 10q23 (LOD=2.84, P=0.0002). However, when analysis was performed based on the ADI-R subtypes, new group-specific suggestive linked regions were detected while the family sample size was smaller in each group compared with no grouping (e.g., n=496 no grouping; n=253 group 1; n=203 group 2; n=173 group 3; and n= 138 group 4). Our linkage analysis results indicate that application of such a phenotypic sub-classification method will improve the detection power in genome-wide linkage study by reducing heterogeneity in ASD study subjects.

## 960/W/Poster Board #618

**The nonsynonymous ATBF1 variant S72A is associated with Atrial Fibrillation.** *M. Müller[1], M.F. Sinner[2], S. Lindhof[3], S. Perz[4], H.E. Wichmann[1,5], T. Meitinger[3,6], A. Pfeufer[3,6].* 1) Institute of Epidemiology, Helmholtz Center Munich, Munich, Germany; 2) Department of Medicine I, Klinikum Grosshadern, Munich, Germany; 3) Institute of Human Genetics, Helmholtz Center Munich, Germany; 4) Institute of Medical Informatics, Helmholtz Center Munich, Germany; 5) Institute of Informatics, Biometry and Epidemiology, Ludwig-Maximilians-Universität, Munich, Germany; 6) Institute of Human Genetics, Technical University Munich, Germany.

Atrial fibrillation (AF) is the most common sustained arrhythmia in man with a population prevalence of about 1 percent. A recent genome-wide association study has identified association with AF in the 16q22 locus near the ATBF1 (ZFHX3) gene, encoding a zinc finger transcription factor. In order to further characterize this association we intended to investigate the presence of independent association signals in the locus. We analyzed 2,145 AF cases from the German Kompetenznetzwerk Vorhoflimmern (AFNET) and 4,073 controls from the population based KORA S4 study in a LD-based SNP-tagging replication approach. We confirmed association at the AFBF1 gene. The strongest association was with rs9302644 (C>G, MAF= 0.19) in intron 1 of the gene with the rare G allele predisposing to AF under an additive model. (OR= 1.48, (1.35 - 1.62), p= 1.1e-16). In a multivariable regression model we found independent association with rs9302644 (OR = 1.28, (1.10-1.50), p= 1.5E-03), rs2106261 OR = (1.20, (1.02-1.41), p= 2.4E-02) and rs7193297 (OR = 1.23, (1.12-1.35), p= 2.1E-05). While rs9302644 and rs2106261 are significantly correlated (r2 = 0.416) neither of them is correlated to rs7193297 (r2 < 0.01). rs7193297 is the nonsynonymous coding variant ATBF1 p.S72A (MAF= 0.23). Overall we could identify two novel common variants in ATBF1 that were independently associated with AF. One of them is a nonsynonymous coding variant which may greatly facilitate the funcitonal investigation of how ATBF1 influences predisposition to AF.

## 961/W/Poster Board #619

**Genetic variation in insulin-like growth factor 1 receptor (IGF1R) and metabolic syndrome-related phenotypes: Maximizing data from Genome-wide association studies.** *C. Pirola, T. Fernandez Gianotti, C. Gemma, A. Burgueño, S. Sookoian.* Department of Molecular Genetics and Biology of Complex Diseases. Institute of Medical Research A. Lanari-IDIM, University of Buenos Aires-National Council of Scientific and Technological Research (CONICET). Ciudad Autónoma de Buenos Aires, Argentina.

Background: The application of stringent statistical thresholds in genome-wide association studies (GWAS) may dismiss SNPs in genes that are biologically meaningful in the pathogenesis of a disease. A first stage of in silico exploratory assessment of GWAS data may be considered for the identification either of new or candidate loci in the genetic susceptibility of metabolic syndrome (MS)-related phenotypes, and then for further replication stages. Aims and Research design: We perform a two-stage study to explore the role of gene variants and derived haplotypes in MS-related phenotypes. The selection of putative variants was performed by a first stage of in silico analysis of the open data of the GWAS on genes involved in common human diseases, granted by the Diabetes Genetics Initiative-DGI and the Welcome Trust Case Control Consortium-WTCCC, available at public websites. The complete dataset encompass a total of 3000 individuals in the DGI study (1464 patients with T2D and 1467 controls) and 7000 individuals in the WTCCC (T2D and hypertension, 2000 patients for each disease, and 3000 control samples). Among the more promising variants, IGF1R ones with modest significant P values for association with MS-related phenotypes in both datasets (close to $10^{-3}$-$10^{-4}$) were selected for further replication in our population. Altogether, 1094 men of self-reported European ancestry were included in a population-based study. Then, in the second stage of the analysis, a total of six SNPs in the IGF1R were genotyped in our sample: rs11247362 C/T, rs10902606 G/C, rs1317459 C/G, rs11854132 A/G, rs2684761 A/G and rs2715416 G/C. Association was tested by PLINK software.Results: Genotypes of rs2684761 showed significant association with insulin resistance (as measured by HOMA-IR, OR per G allele: 1.13, 95%CI: 1.02-1.25, p<0.026) and HOMA-IR as a continuous trait p<0.011, and fasting serum insulin p<0.011. The association with HOMA-IR was even stronger with the haplotype TCGGGG (P<0.003).Interestingly, a significant association of the rs2684761 with arterial hypertension was observed: OR 1.14 per G allele, 95% CI 1.01-1.28, P<0.034, after adjusting by age and HOMA-IR. As expected, by ordinal multinomial analysis, the cumulative number of metabolic syndrome components was associated with the rs2684761 G variant ($chi^2$: 7.4, p<0.026). Conclusions: Our study suggests a putative role of the IGF1R variants in the individual susceptibility to the MS-related phenotypes.

## 962/W/Poster Board #620

**Genomewide association meta-analysis of >120,000 individuals reveals 39 loci that influence body weight.** *C.J. Willer[1], S.I. Berndt[2], C.M. Lindgren[3,4], J.C. Randall[3], G. Ingelsson[16], the GIANT Consortium.* 1) Dept Biostatistics and Center for Statistical Genetics, Univ Michigan, Ann Arbor, MI, 48109. USA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), National Institutes of Health (NIH), Bethesda, Maryland, USA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK; 4) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford OX3 7LJ, UK; 5) deCODE Genetics, Reykjavik, Iceland; 6) Department of Epidemiology University of North Carolina at Chapel Hill Chapel Hill,NC 27516-3997, USA; 7) Carolina Center for Genome Sciences University of North Carolina at Chapel Hill Chapel Hill, NC 27516, USA; 8) MRC Epidemiology Unit, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge CB2 0QQ, UK; 9) Division of Genetics, Children's Hospital, Boston, MA 02115, USA; 10) Institute of Epidemiology,University of Regensburg, Germany; Institute of Epidemiology, Helmholtz Zentrum München, Germany; 11) Wellcome Trust Sanger Institute, Hinxton, Cambridge CB10 1SA, UK; 12) Broad Institute at MIT and Harvard, Boston MA 02115, USA; 13) Departments of Genetics and Pediatrics, Harvard Medical School, Boston, MA 02115, USA; 14) Division of Endocrinology, Children's Hospital, Boston, MA 02115, USA; 15) Department of Gastroenterology, Massachusetts General Hospital and Harvard Medical School, Boston MA. 02114, USA; 16) Dept. of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

Body shape, size, and composition are influenced by multiple genes and environmental factors, including secular trends. Furthermore, different measures of body size and shape may have different sensitivity to the influences of individual genetic loci, and may therefore facilitate the discovery of novel genetic associations. Body weight, a commonly measured phenotype, integrates both height and body shape. We conducted a genomewide association scan meta-analysis for body weight of >120,000 individuals from 48 separate cohorts, examining ~2.8 million directly genotyped or imputed SNPs. Overall, 39 unique loci reached genomewide significance ($p < 5x10^{-8}$), highlighting the polygenic nature of body weight regulation.

The three strongest signals were observed near *FTO* ($p \approx 10^{-47}$), *MC4R* ($p \approx 10^{-25}$), and *TMEM18* ($p \approx 10^{-21}$), three loci previously associated with body mass index (BMI) and other measures of obesity. Other prominent loci in the list include *ZBTB38* ($p \approx 10^{-18}$), *HMGA2* ($p \approx 10^{-16}$), and *GDF5* ($p \approx 10^{-10}$), all loci with common variants strongly associated with human height. Still, not all the loci previously associated with height and/or BMI showed association with body weight (e.g. *MTCH2* $p \approx 10^{-3}$ for weight and $10^{-10}$ for BMI), and conversely, 7 loci that did not reach genomewide significance in parallel analyses of BMI, waist circumference, waist-hip ratio and height, did reach genomewide significance for body weight (e.g. *MTIF1* $p \approx 10^{-10}$, *CADM2* $p \approx 10^{-9}$ , and *HNF4G* $p \approx 10^{-8}$). Although not genomewide significant, an additional 46 loci had p-values < $1x10^{-6}$, and efforts to replicate these may reveal many new associated loci.

By using body weight as a phenotype, we have augmented the catalog of loci implicated in the regulation of body shape and size. The loci include genes that are likely to act in the brain to regulate appetite and energy balance, and genes that are likely to influence overall growth -- consistent with the observed overlap of many of our findings with previous genetic studies of height and BMI. We expect that, over the next few years, continued progress will be made in the identification of loci and variants that influence body shape and size. Furthermore, we expect this progress will be enhanced by the examination of multiple quantitative summaries of body size, shape and composition.

## 963/W/Poster Board #621

**Genome wide search for genes controlling risk to non-syndromic oral clefts in a consortium case-parent trio study.** *T.H. Beaty[1], J.B. Hetmanski[1], K.Y. Liang[1], I. Ruczinski[1], R.A. Redett[2], A.F. Scott[2], M.L. Marazita[3], J.C. Murray[4], R.G. Munger[5], A. Wilcox[6], R.T. Lie[7], Y.H. Wu-Chou[8], H. Wang[9], X. Ye[10], V. Yeow[11], S.S. Chong[12], S.H. Jee[13], B. Shi[14], K. Christensen[15], GENEVA. Consortium[16].* 1) School of Public Health, Johns Hopkins Univ, Baltimore, MD; 2) School of Medicine, Johns Hopkins Univ., Baltimore MD; 3) School of Dental Medicine, University of Pttsburgh, Pittsburgh PA; 4) Children's Hospital, School of Medicine, University of Iowa, Iowa City, IA; 5) Dept. of Nutrition and Food Sciences, Utah State Univ. Logan UT; 6) Epidemiology Branch, NIEHS/NIH, Durham NC; 7) University of Bergen, Bergen Norway; 8) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 9) Peking University Health Sciences Center, Beijing, China; 10) School of Stomatology, Wuhan University, Wuhan, China; 11) KK Women's and Children's Hospital, Singapore, Singapore; 12) School of Medicine, National University of Singapore, Singapore; 13) Yonsei University, Seoul, Korea; 14) West China School of Stomatology, Sichuan University, Chengdu, China; 15) University of Southern Denmark, Odense, Denmark; 16) NIDCR/NHGRI.

As part of an international consortium, we assembled a collection of 2463 case-parent trios from 9 countries in the first genome wide association study (GWAS) of oral clefts utilizing a family-based study design. These trios included both major cleft phenotypes [cleft lip with/without cleft palate: CL/P; and cleft palate: CP], and incorporated information on recognized environmental risk factors. Oral clefts are thought to be influenced by several different genes and by different environmental risk factors (including maternal smoking, alcohol consumption and vitamin supplementation). Thus, this consortium was designed to conduct a genome-wide search for genes important in the etiology of oral clefts where both environmental risk factors and parent-of-origin effects could be considered. Probands were drawn from 13 recruitment sites in 9 countries and were all diagnosed as having either an isolated, non-syndromic CL/P (n=1920) or CP (n=563). Review and approval for this study was obtained from IRBs at each participating institution, and informed consent was obtained from all participants (including parental consent for minor children). Forty-five percent of these trios are of European ancestry and 51.9% are of Asian ancestry. DNA was obtained from the case child and both parents and genotyped at the Center of Inherited Disease Research (CIDR) for 589,945 single nucleotide polymorphic (SNP) markers on the Illumina 610Q chip. Using 580,307 autosomal SNPs in a transmission disequilibrium test (TDT), we scanned the genome for evidence of linkage and association in CL/P trios and CP trios separately. We first focused on chromosome 8 to confirm evidence that a region of 8q24 influences risk to CL/P as reported by a case-control GWAS from Germany (Birnbaum et al. 2009 NAT GENET 41:473). Our preliminary analysis confirmed strong evidence of linkage and association in a 270 kb region of 8q24 among CL/P trios, but not CP trios. Testing for heterogeneity between European and Asian derived trios showed much stronger evidence of linkage and association in the European derived families. This region of chromosome 8q24 appears to be a "gene desert", approximately 300 kb from a region reported to be associated with prostate and other cancers.

## 964/W/Poster Board #622

**A genome-wide survey of SNPs and CNVs for association to body mass index in 1,931 individuals from African-derived populations.** *C.W.K. Chiang[1,2,3], S.J. Kang[4], B. Tayo[5], C. Palmer[2,3], G. Lettre[6], J.L. Butler[2,3], R. Hackett[3], C. Guiducci[3], T. Nguyen[2,3], A. Adeyemo[7], C. Rotimi[7], A. Luke[5], H.N. Lyon[2,3], R. Cooper[5], J.N. Hirschhorn[1,2,3], X. Zhu[4].* 1) Department of Genetics, Harvard Med School, Boston, MA; 2) Children's Hospital Boston, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) Case Western Reserve University, Cleveland, OH; 5) Stritch School of Medicine, Loyola University Chicago, Chicago, IL; 6) University of Montreal, Montreal, Canada; 7) Howard University, Washington, District of Columbia.

Genome-wide association studies (GWAS) in large cohorts have identified numerous loci associated with central and overall obesity. However, most studies were conducted in European-derived populations, and it is not known whether the identified loci generally replicate in populations with recent African ancestry. Lack of replication could reflect genetic, environmental or phenotypic heterogeneity, or the different recombination history in African-derived populations. To begin to identify genetic variants associated with obesity in populations with recent African ancestry, we conducted a comprehensive GWAS in 743 African Americans and 1188 Nigerians using the Affymetrix 6.0 platform and surveyed SNPs as well as common and rare copy number variants (CNVs). Additionally, we devised a method using a mixed reference panel to impute genotypes at over 2 million HapMap SNPs in our African-American cohort, and showed that this method achieved > 95% accuracy in imputation calls, comparable to imputation of non-admixed population using a single reference panel. After applying quality controls and correcting for genetic ancestry, we observed no associations that reached genome-wide significance for any SNPs or common CNVs. There was a nominal association of the lean individuals with heavier burden of longer ($P = 0.004$) and total ($P = 0.001$) rare CNVs (population frequency < 5%). We also attempted to replicate in additional African-American cohorts the top independent SNPs from this GWAS and the best SNPs at known loci. There were no strong consistent associations, with the best evidence of replication coming from SNPs near a previously known gene, MC4R. It does not appear that there are common variants with large effects on BMI that are unique to African ancestry population. Replication of further SNP associations with suggestive evidence will be done in additional well-powered cohorts, and meta-analysis with other GWA in African-derived populations, should detect valid associations in African-derived populations.

## 965/W/Poster Board #623

**Genome-wide profile of copy number variants for Hirschsprung disease.** *C.S. Tang[1], M.M. Garcia-Barceló[2], S.S. Cherny[1], P.C. Sham[1], P.K.H. Tam[2].* 1) Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR; 2) Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong, HKSAR.

Hirschsprung disease (HSCR, aganglionic megacolon) is a developmental disorder characterised by the absence of the enteric ganglia along the intestinal tract. In addition to the major implicating gene *RET*, common polymorphisms, rare mutations and chromosomal abnormalities have been found to be associated with HSCR. The most common associated chromosomal abnormality is trisomy 21 (Down syndrome). Other chromosomal aberrations including 13q chromosomal deletions were also reported, which pinpointed the region for the discovery of disease susceptibility loci, such as *EDNRB*. To characterize the copy number variants for HSCR, we analyzed 139 HSCR patients and 333 controls previously genotyped by Affymetrix 500k SNP arrays using Birdsuite. For HSCR patients, we identified 92 duplications and 60 deletions of at least 100kb. The total burden for rare and singleton CNVs increased for cases when compared to controls, both for the number of CNVs per individual ($p = 0.0008$) and the number of overlapping genes ($p < 0.0004$). In particular, long singleton duplications and deletions were identified for HSCR patients. Focusing on highly confident structural variations revealed three duplications ranging from 1.8 to 10Mb, spanning 8p21, 15q11-13 and 16p12. Two nonoverlapping deletions (14.9 & 29.7Mb) with both breakpoints residing in 11q23 were also shown. As previously reported, a 16Mb deletion overlapping with *EDNRB* was found on one HSCR patient. Together with other shorter variants, this finding could account for a sustainable proportion of susceptibilty to HSCR.

## 966/W/Poster Board #624

**Meta-analysis of six large type 1 diabetes cohorts identifies multiple loci.** *J.P. Bradfield[1], H.Q. Qu[2], K. Wang[1], H. Zhang[1], P.M. Sleiman[1], C.E. Kim[1], K. Annaiah[1], J.T. Glessner[1], K. Thomas[1], E.C. Frackelton[1], R. Chiavacci[1], M. Imielinski[1], D.S. Monos[3,4], S.F.A. Grant[1,3,5], C. Polychronakos[2], H. Hakonarson[1,3,5].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania; 2) Departments of Pediatrics and Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 4) Department of Pathology and Laboratory Medicine, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania; 5) Division of Human Genetics, Abramson Research Center, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania.

Type 1 diabetes is an autoimmune disease leading to the destruction of the pancreatic islets. The prevalence of T1D in the United States in individuals below the age of 20 is 1.7 per 1000. Genome wide association studies (GWAs) have been particularly valuable in identifying the genetic susceptibility loci underlying type 1 diabetes with over 40 associations described in the last two years. One inherent limitation of GWAs is the large sample sizes required to detect loci of modest effect. Meta-analyses are the most efficient and economical way to assemble such large cohorts. In an effort to find more loci, we analyzed the largest combined T1D cohort to date, totaling 10,000 cases and 17,500 controls, comprising ~14,000 samples (~3,500 cases, ~10,500 controls) genotyped on Affymetrix 500K chips (Gokind, WTCCC) and ~13,500 samples (~6,500 cases, ~7,000 controls) genotyped on Illumina 550K chips (McGill, CHOP, DCCT-EDIC, T1DGC). Power calculations based on these sample sizes indicate we have greater than 80% power to detect a variant with relative risk of 1.13 and above assuming a minor allele frequency of 20%. Methodologically, we initially imputed all datasets up to the 2 million CEU Hapmap SNPs using Mach 1.0 so that platform independent comparisons could be made. To control for population stratification, we used SNPs common to both platforms as input into a Multi-Dimensional Scaling(MDS) algorithm. The results of the MDS analysis were then used as covariates in a logistic regression. Summary stats were then computed on the combined cohort at all 2 million SNPs. The results of this, the largest T1D meta-analysis to date, will be presented at the meeting.

## 967/W/Poster Board #625

**Predictive model for type 2 diabetes mellitus using Korean community based on chort.** *J. Lee[1], B. Keam[2], M. Park[3], J. Heo[3], J. Lee[1].* 1) Division ofStructural and Genomics, Korea Centers for Disease Control and Prevention, Seoul, Korea; 2) Division of BioBank for Health Sciences, Korea Centers for Disease Control and Prevention, Seoul, Korea; 3) Division of B-medical Informatics, Korea Centers for Disease Control and Prevention, Seoul, Korea.

Recent genetic association studies have provided convincing evidence that several novel loci and single nucleotide polymorphisms (SNPs) are associated with the risk of type 2 diabetes mellitus (T2DM). The aims of this study were to compare misclassification rates of different models. We surveyed and had second follow-up 10,038 individuals from the Korean Genome and Epidemiology Study (KoGES). And then we also genotyped 500,568 SNPs using SNP array(Affymetrix). We selected 1,745 individuals with T2DM and 1,857 controls from the Korean Genome and Epidemiology Study (KoGES). We also considered their past-history of Type 2 diabetes. There were 1,745 cases of diabetes during 8 years of follow-up. For selection of significant SNPs, it was tested their associations of SNPs(additive model) using PLINK. SNPs were analyzed for significant association with T2DM using statistical tree QUEST algorithm. We tested these models using the complete KoGES cohort and computed the T2DM misclassification rates for each models. The misclassification rates of the statistical tree QUEST algorithms were estimated in 512 cases(with T2DM) and 568 controls. The dataset was then divided randomly into the training set (70% of the observations) and the test set (30% of the observations). In model, we analyzed misclassification rate of QUEST and optimized the model using 10-folds cross validation pruning method. The rate of misclassification was 0.41 in test data using 10-fold CV pruning method. We identified CDKAL1(rs7767391), ADAM12(rs11244960) and PEX19(rs2820421) SNPs that were significantly associated with Type 2 diabetes. Their SNPs are major risk factors related T2DM. If CDKAL1(rs7767391) and PEX19(rs2820421) had minor genotype, they were predicted diabetes. Alternative, if CDKAL1(rs7767391) was not minor genotype and then ADAM12(rs11244960) was hetero genotype, they were predicted diabetes. We have developed predictive models for T2DM using genotype data. However, the misclassification rates are relatively high. To improve the performance of these models, further studies using large sample sizes are warranted, and a better strategy to integrate the genotype data classifiers for the quantification of SNPs needs to be developed.

## 968/W/Poster Board #626

**A Genome-Wide Association Study of Diabetic Nephropathy in African Americans.** *C.W. McDonough[1,2], N.D. Palmer[2], M.A. Bostrom[2], P.J. Hicks[2], L. Lu[3], J. Divers[3], C.D. Langefeld[3], B.I. Freedman[4], D.W. Bowden[1,2,4].* 1) Program in Molecular Medicine and Translation Science, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 2) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 3) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC, USA; 4) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, USA.

African Americans (AA) have a 3.6-fold increased risk of developing end-stage renal disease (ESRD) compared to Caucasian Americans. Diabetes-associated nephropathy is the most common cause of ESRD, accounting for approximately 45% of cases in the U.S. The incidence of ESRD continues to increase. Multiple studies have concluded that there is a genetic component to ESRD in the general population and in AAs. In order to identify genes associated with type 2 diabetic nephropathy (DN), we performed a genome-wide association study (GWAS) in 966 AA type 2 diabetic (T2DM)-ESRD cases and 1,031 AA non-diabetic, non-nephropathy controls using the Affymetrix Genome-Wide Human SNP Array v6.0. The top 577 SNPs were genotyped in a replication set of 709 AA T2DM-ESRD cases and 693 AA controls. Those SNPs that replicated were then genotyped in 1,246 AA T2DM non-nephropathy DNAs in order to determine association with diabetes or diabetic nephropathy/ESRD. Admixture adjusted analysis has identified four candidate genes for T2DM-ESRD to date. SNP rs3775043 in *UNC5C*, unc-5 homolog (*C. elegans*), was associated in the GWAS under a dominant model (P=1.82E-05). This SNP replicated (dominant P=0.028), and had a combined GWAS-replication dominant p-value of 2.89E-06. SNP rs3775043 was not associated with T2DM alone. One SNP upstream of ribosomal protein S12 (*RPS12*), rs9493454, was associated in the GWAS, replication and combined set (additive P= 0.0009, 0.009, and 1.53E-05 respectively). rs9493454 was not associated with T2DM alone. SNP rs773506, upstream of the *AUH* gene, AU RNA binding protein/enoyl-Coenzyme A hydratase, had dominant p-values in the GWAS, replication set and combined set of P=0.0004, 0.01, and 1.73E-05 respectively, and was not associated with T2DM. Lastly, *LIMK2*, LIM domain kinase 2, SNPs rs2106294 and rs4820043 showed nominal association in the GWAS (additive P=0.027 and 0.024 respectively). These SNPs remained associated in the replication and combined analyses (rs2106294 dominant P=0.003 and 6.63E-06 respectively, rs4820043 dominant P=0.003 and 6.59E-06 respectively). Again, these SNPs were not associated in the T2DM non-nephropathy analysis. Genotype frequencies for each SNP were also significantly different when T2DM alone and DN samples were compared, suggesting they are DN genes. While these results need further replication to achieve genome wide significance, these four genes are strong candidates to play a role in the development of DN in AAs.

## 969/W/Poster Board #627

**A Genome-wide Association Study in 1997 African Americans Reveals Candidate Susceptibility Loci for Type 2 Diabetes.** *N.D. Palmer[1,2], C.W. McDonough[2,3], S.C. Smith[3], C.D. Langefeld[4], J. Divers[4], L. Liu[4], B.I. Freedman[5], D.W. Bowden[1,2].* 1) Biochemistry, Wake Forest University, Winston-Salem, N.C; 2) Center for Human Genomics, Wake Forest University, Winston-Salem, N.C; 3) Molecular Medicine and Translation Science, Wake Forest University, Winston-Salem, N.C; 4) Public Health Sciences, Wake Forest University, Winston-Salem, N.C; 5) Nephrology, Wake Forest University, Winston-Salem, N.C.

The prevalence of diabetes in the U.S. is on the rise with African Americans disproportionately affected by the disease. To identify type 2 diabetes (T2D) susceptibility variants, we analyzed genome wide association data (Affy6.0) from 966 African American T2D cases and 1031 controls. All subjects were recruited from the southeastern U.S. and case subjects were concordant for diabetes and diabetic nephropathy. Principal components analysis was used to correct for population stratification. PC1, which explained 22% of the variance, was highly correlated with African ancestry as determined from ancestry informative markers (AIMs) data, PC2 accounted for 3% and the remaining ≤2% each. Genotype analysis of the autosomal SNPs (>832K), adjusted for age at recruitment, gender, PC1 and PC2, resulted in a genomic inflation factor value of <1.046 and revealed several signals of association. Within the GWAS, we examined the impact of known T2D-susceptibility loci (the majority of which were identified from European-derived populations). With the exception of *TCF7L2*, these T2D-susceptibility loci do not appear to explain individual variation in T2D risk in African Americans. Replication of the top 577 SNPs from the GWAS was completed in an independent collection of African American T2D cases (*n*=709) and controls (*n*=693) recruited under identical ascertainment criteria. To distinguish between loci for diabetes and diabetic nephropathy, loci nominally associated in the replication were genotyped on a sample of 1246 T2D-only cases for validation. Among the top associations seen after admixture adjustment in the overall analysis (GWAS+Rep+Val) were SNPs in *TCF7L2* ($P_{ADD}$=6.11x$10^{-9}$) and intergenic regions on chr10 and chr14 ($P_{ADD}$=8.81x$10^{-5}$ and $P_{DOM}$=7.88x$10^{-5}$, respectively). In addition, these SNPs have been typed on an additional 640 controls with comprehensive metabolic phenotypes derived from the Frequently Sampled Intravenous Glucose Tolerance Test (FSIGT) with MINMOD analysis. SNPs which have been validated for association with T2D are now the focus of fine-mapping efforts to identify putative causal variants. In parallel, top hits from imputation, which include a hit on chr19 in a zinc finger gene ($P_{ADD}$=1.55x$10^{-16}$), are being tested. This study highlights the complexity of T2D and likely implicates ethnic-specific variants in the etiology of the disease.

## 970/W/Poster Board #628

**Analysis of gene-environment interactions with smoking on a genome-wide basis reveals a genetic network and a new pathway in the development of rheumatoid arthritis.** *L. Padyukov[1], B. Ding[2], H. Källberg[2], M. Seielstad[3], L. Klareskog[1], L. Alfredsson[2].* 1) Rheumatology Unit, Karolinska Inst, Stockholm, Sweden; 2) Department for Environmental Medicine, Karolinska Inst, Stockholm, Sweden; 3) The Genome Institute of Singapore, Singapore.

The search for the etiology of complex diseases is hampered by the involvement of multiple genetic and environmental factors. By examining the effect of a known environmental risk factor (smoking) in a genome-wide scan of 3000 Swedish rheumatoid arthritis patients and matched controls, we uncover multiple potential gene-environment interactions. Importantly, the genetic risk factors identified in this way are not apparent in the conventional genome-wide scan of main-effects, due to their modest risk ratios. This genome-wide interaction analysis with smoking and conservative correction for multiple comparisons revealed a set of genetic variants with an unexpected feature. While protective in the absence of smoking, these variants in combination with smoking increased the risk of RA dramatically. In order to enhance the validity for detection of potential mechanisms we used the corresponding genes in a pathway analysis by IPA software. The network of genes is pointing towards involvement of the Wnt/beta-catenin signaling pathway in the development of rheumatoid arthritis. In this study we introduce the notion of genome-wide interaction study (GWIS) that could be employed in investigating any complex disease for which at least one environmental or genetic risk factor is known. Genome-wide interaction analysis is an efficient way for the detection of new candidate genes and we successfully applied this strategy to rheumatoid arthritis.

## 971/W/Poster Board #629

**The Gene, Environment Association Studies (GENEVA) Consortium.** *M.C. Cornelis[1], A. Agrawal[2], J.W. Cole[3], N.N Hansel[4], T. Beaty[4], S. Bennett[5], K. Doheny[4], E.L. Harris[6], J.H. Kang[1], C.C. Laurie[5], H. Ling[4], T.A. Manolio[7], D.B. Mirel[8], E. Pugh[4], J. Udren[5], X.J. Wang[9], K. Williams[5] for the GENEVA Consortium.* 1) Harvard School of Public Health, Boston, MA; 2) Washington University School of Medicine, Saint Louis, MO; 3) University of Maryland School of Medicine, Baltimore, MD; 4) Johns Hopkins University, Baltimore, MD; 5) University of Washington, Seattle, WA; 6) National Institute of Dental and Craniofacial Research, Bethesda, MD; 7) National Human Genome Research Institute, Bethesda, MD; 8) Broad Institute of Massachusetts Institute of Technology and Harvard; 9) University of Pittsburgh, Pittsburgh, PA.

Genome-wide association studies (GWAS) have emerged as a powerful tool for identifying genetic loci related to complex disease and traits. The role of environment and its potential to interact with genes, however, has not been adequately addressed at a genome-wide level. Formation of networks of collaborative GWAS involving different study samples and multiple phenotypes is a powerful approach for addressing the many challenges in analysis and interpretation common across different GWAS. The Gene, Environment Association Studies (GENEVA) consortium was established in 2007 by the NHGRI to identify genetic variants related to common, complex disease or traits; to identify variations in gene-trait associations related to environmental exposures; and to ensure the rapid sharing of data to the general scientific community. This consortium consists of several NIH-based organizations and extramural participants including a coordinating center, 2 genotyping centers and a growing list of study investigators. GWAS completed or in progress target type 2 diabetes, oral clefts, alcohol addiction, lung cancer, chronic obstructive pulmonary disease, birth weight/maternal glycemia, premature birth, dental caries, blood pressure, prostate cancer, venous thrombosis, ischemic stroke, and glaucoma. A key feature which distinguishes GENEVA from other existing consortia is the availability of common and detailed environmental exposure information from multiple studies which allow analysis of additional traits (smoking behavior, anthropometric measures, substance use, lifestyle and dietary intake behavior) common to many studies and explicit tests for gene-environment interactions. Facilitated by its unique infrastructure to promote collaboration among groups, GENEVA has established a unified framework for sample submission and genotyping, data quality control and assurance, as well as independent and cross-study analysis and interpretation. Data from each study are shared with the scientific community through NIH's dbGaP. By maximizing knowledge obtained through collaborative GWAS which incorporate environmental exposure information, GENEVA will enhance our understanding of both disease etiology and identify opportunities for prevention.

**Meta-analysis of Genome-Wide Association Scans Identifies CARD11 as a Determinant of Bone Strength in Caucasian Women: The Genetic Factors For Osteoporosis (GEFOS) Consortium.**
*Y. HSU[1,2,10,11], AG. Uitterlinden[3,11], SG. Wilson[4,5,6,11], S. Demissie[7,10], MC. Zillikens[3], SJ. Brown[5], K. Estrada[3], RI. Price[5], N. Soranzo[8], HA. Pols[3], J. van Meurs[3], JB. Richards[6,9], LA. Cupples[7,10], TD. Spector[6], DP. Kiel[2,10], F. Rivadeneira[3,11], D. Karasik[2,10,11], GEFOS Consortium.* 1) Molecular and Integrative Phys, Harvard School of Public Health, Boston, MA., USA; 2) Hebrew Seniorlife, Boston, MA., USA; 3) Erasmus MC, Rotterdam, 3015GE, The Netherlands; 4) The University of Western Australia, Crawley, Australia; 5) Sir Charles Gairdner Hospital, Perth, Australia; 6) King's College London, London, UK; 7) Boston Univ. SPH, Boston, MA, USA; 8) Wellcome Trust Sanger Institute, Wellcome Hinxton, UK; 9) McGill University, Montreal, Canada; 10) The Framingham Study, Framingham, MA, USA; 11) These authors contributed equally.

GWA, an approach with hypothesis-free association testing of genetic determinants, has proved successful identifying at least 20 BMD loci. Hip geometry has been shown an important predictor of fracture. We performed meta-analysis of ~2.5 million imputed SNPs from three large GWA studies (including 9,021 Caucasian men and women) in relation to proximal femoral geometry phenotypes. We analyzed femoral neck length (FNL), neck-shaft angle (NSA), neck width (Wid), and section modulus (Z) estimated by hip structure analysis (HSA) algorithms from DXA scans. In each cohort sex-specific and sex- combined association analyses were performed under an additive model adjusted for age, age$^2$, height, BMI (and estrogen history in FOS women). The genomic inflation factor $\lambda_{GC}$ ranged from 0.977 to 1.025 across different traits and cohorts. A z statistic-based fixed-effect meta-analysis weighted by effective sample sizes across studies (METAL) was run on GWA results from the Rotterdam Study (RS, n=4,102; Illumina550), Framingham Osteoporosis Study (FOS, n=3,409; Affymetrix 550), TwinsUK Study (TUK, n=1,510 women; Illumina317) with 2,543,686 SNPs imputed from the HapMap CEU reference panel. The genome-wide significance (GWS) threshold was set at $p<5x10^{-8}$. Despite some GWS signals in isolated studies, the sex-combined meta-analysis identified no GWS loci. In contrast, several sex-specific associations were found with diverse traits for SNPs mapping to chromosome 1p13.3 (Wid, women), 5q13.1 (NSA, men), and 7p22 (Z, women), 12q21.2 (NSA, women), of which the notable association was between Z and variants in a novel gene CARD11 in women ($p=4.80x10^{-8}$); CARD11 was not previously associated with BMD. Other well-known candidate genes for bone strength were also identified (p-values: $3.8x10^{-6}$ to $2.0x10^{-10}$) including EXT1, PTH2R, TNFRSF11B, and TSHB. In conclusion, we showed at GWS level that genetic variation in CARD11 influences bone strength in Caucasian women. CARD11, which plays a role in NF-kappaB activation, may be a potential factor acting through the OPG-RANK-RANKL signaling pathway which is already known to be influential on bone strength. Further replication in additional independent samples is underway to maximize power as well as to determine the relation with hip fractures.

## 973/W/Poster Board #631

**Population-based cohorts can help validate genetic associations with asthma.**
*H.N. Lyon[1,2], J.L. Butler[1], C. Palmer[1,3], J. Reibman[4], M. Liu[4], G. O'Connor[5], J.N. Hirschhorn[1,3,6].* 1) Div Gen, Boston Children's Hosp, Boston, MA; 2) Dept of Pediatrics, Harvard Med School, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) Depts of Med and Environmental Med, NYU School of Med, NY; 5) Div Pulmonary Critical Care Med, Boston Univ School of Med, Boston, MA; 6) Dept Genetics, Harvard Med School, Boston, MA.

Asthma is a common disease with strong hereditary influences. Genome-wide association (GWA) studies in cohorts of people with asthma and controls highlight genetic variants that are predictors of disease. Large consortia will soon be available for studies of asthma, but GWA data exist for much larger sets of population-based cohorts with asthma and related phenotypes. We hypothesized that population-based cohorts could provide valuable GWA data to replicate or discover new genetic associations with asthma. Methods: We used data from the SHARe database which consists of SNP (single nucleotide polymorphism) genotypes across the genome in 3 generations of individuals from the Framingham Heart Study (FHS) and information on physician diagnosed asthma. We imputed genotypes at 2.2 million SNPs using the HapMap CEU reference panel. These SNPs were tested for association with asthma by comparing allele frequencies for 975 people with asthma and 3576 control individuals; smokers and people with lung diseases excluded. We used logistic regression and applied genomic control to correct for inflation of test statistics from relatedness within the 3 generation cohort. We validated previously reported variants for association with asthma and also found novel asthma SNPs for replication in further cohorts. To examine the utility of population- based data on related phenotypes, we also tested SNPs reported to influence eosinophil counts for association with atopy (allergen-specific IgE) within an asthma cohort from NY City. Results: We found that of 9 loci previously reported as associated with asthma, 8 SNP associations were validated in the FHS cohorts, and 6 had P-values below 0.05. We also examined the top novel signals for association. Although none reached genome-wide significance, the top ten loci highlighted several interesting candidate genes, including variants near TRPV1/TRPV3 (thermosensitive airway nocireceptor), RNASE3 (eosinophil cationic protein) and ALOX5AP (regulator in the leukotriene biosynthetic pathway). Genomic controlled P-values were $1.3x10^{-5}$, $1.3x10^{-6}$, and $2x10^{-5}$ respectively. Replication in asthma case-control cohorts is ongoing. Finally, we found a strong association between a SH2B3 eosinophil associated variant and atopy in an asthma case-control cohort from NY City (P<0.0006). Conclusion: Asthma and related phenotypes available in population-based cohorts are useful complements to case-control asthma association studies.

Age-related macular degeneration (AMD) is the leading cause of late onset blindness and arises from retinal damage associated with accumulation of drusen and subsequent atrophy or neovascularization that leads to loss of central vision. Prior studies have identified several loci explaining roughly half of the overall heritability of AMD, most of which are in the alternative complement pathway. We performed a genome-wide association study (GWAS) of 1000 cases of advanced AMD and 1709 controls, who were all Caucasian and unrelated, using the Affymetrix 6.0 platform (906,000 genotyped single nucleotide polymorphisms(SNPs)and 946,000 genotyped copy number variations(CNVs), to identify additional genetic variants and other pathways contributing to the development of this complex disease. We also conducted several stages of replication of our more significant findings (P < 10-4) using 4013 cases and 1915 controls from five additional independent Caucasian samples with similar phenotypes. Previously associated loci were confirmed to be strongly related to AMD including CFH rs1061170 - 3.84E-56; CFH rs1410996 - 3.52E-48; ARMS2/HTRA1 rs10490924 - 1.32E-60; CFB/C2 rs641153 - 1.07E-07; CFI rs10033900 - 1.26E-05; and C3 rs2230199 - 8.48E-04. Our most significant novel finding is an association with a common functional variant of a gene involved in the lipid metabolism pathway (P = 2.6 x 10-8), and we found this gene to be expressed in the retina. The association shows a consistent effect for both advanced dry and wet AMD and implicates a novel biologic pathway for this disease. We also conducted the first comprehensive analysis of CNVs in AMD. No new CNVs were shown to have genome-wide association to AMD. A previously reported common deletion variant at CFHR1 was associated with advanced AMD in our discovery cohort (P=1 x 10-19), but this observation was due to strong linkage disequilibrium to the two previously reported CFH locus SNPs. The deletion variant showed no association when conditioning on the CFH SNPs, yet both CFH SNPs remained strongly associated with AMD conditional on the deletion variant and the other SNP. The novel association to a gene in the lipid metabolism pathway adds to our previously published prediction algorithm for AMD which includes multiple genetic loci and environmental factors. This result further provides new information about the mechanisms associated with AMD and may provide new avenues for prevention and treatment.

**Quantitative trait loci for CD4:CD8 lymphocyte ratio in the general population associate with risk of type 1 diabetes.** *M.A.R. Ferreira[1], M. Mangino[2], M.J. Wright[1], D.R. Nyholt[1], S. Gordon[1], M. Campbell[1], B.P. McEvoy[1], A. Henders[1], D.M. Evans[1,3], J.S. Lanchbury[2], N. Soranzo[2], T.D. Spector[2], I.H. Frazer[4], G. Montgomery[1], N.G. Martin[1].* 1) Queensland Institute of Medical Research, Brisbane, Australia; 2) Twin Research and Genetic Epidemiology Department, King's College London St Thomas' Hospital, London SE1 7EH, UK; 3) Current address: MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol BS8 2BN, UK; 4) The University of Queensland Diamantina Institute for Cancer, Immunology and Metabolic Medicine, Princess Alexandra Hospital, Brisbane, QLD 4102, Australia.

Through a whole-genome association study of lymphocyte levels in the general population, we identified variants in the major histocompatibility complex explaining 7% of the variation in CD4:CD8 ratio, with both class I and II genes independently regulating T cell numbers. Class II variants also associated with type-1 diabetes, suggesting that genetically determined variation in T cell numbers may influence immune-related diseases.

## 976/W/Poster Board #634

**Admixture mapping to identify risk genes for preterm premature rupture of membranes in African-American women.** *L.N. Pearson[1], J.P. Kusanovic[2], R. Romero[2], M.D. Shriver[1], J.F. Strauss 3rd[3].* 1) Department of Anthropology, Pennsylvania State University, University Park, PA; 2) Perinatology Research Branch of the Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health in Bethesda, Maryland and Wayne State University, Detroit MI; 3) School of Medicine, Virginia Commonwealth University, Richmond, VA.

Preterm delivery is a complex disorder that is a leading contributor to infant mortality in the United States, particularly among African-American women, who are at increased risk. It is evident that risk of preterm delivery is not limited to social and environmental factors, suggesting a role for genetic influences. We are using genome-wide admixture mapping to identify gene regions that affect the risk of preterm delivery, specifically preterm premature rupture of membranes (PPROM), in African-American women using an admixture mapping approach. PPROM is characterized by spontaneous rupture of fetal membranes prior to 37 weeks gestation and constitutes 30% of preterm deliveries. This methodology has revealed novel candidate genes for future studies of PPROM in African-American women.

Self-reported African-American women were recruited at Hutzel Hospital (Detroit), the Hospital of the University of Pennsylvania (Philadelphia) and MCV Hospitals (Richmond) (n = 536). DNA from 275 women with confirmed PPROM and 261 women with normal pregnancy outcomes were genotyped on a genome-wide panel of 1,509 ancestry informative markers (AIMs), single nucleotide polymorphisms (SNPs) with large allele frequency differences between European and West African parental populations. This panel is specifically designed for admixture mapping, a method that exploits linkage disequilibrium created by recent admixture to identify risk regions associated with genetic ancestry, in African-American populations. We used ADMIXMAP, an admixture mapping statistical package, to control for admixture stratification and to test for associations between PPROM and ancestry across the genome. Ancestry estimates and phenotype-ancestry associations were generated using prior allele frequencies from three parental populations, West African, European, and East Asian. The average African contribution to genetic ancestry in the combined sample is 80%. Regions on eight chromosomes were identified as significantly contributing to risk of PPROM in the African-American sample, five associated with West African ancestry (Chromosomes 2, 3, 5, 8 and 11) and three with European ancestry (chromosomes 3, 13 and 21). Several of these loci overlie genes involved in matrix metabolism that are candidate PPROM genes.

## 977/W/Poster Board #635

**Combining Genome Wide linkage and association reveals new candidate gene loci for Celiac Disease.** *A. Torinsson Naluai[1], M. Östensson[2], A.H. Gudjonsdottir[3], H. Ascher[3,4], S. Nilsson[2], J. Wahlström[1].* 1) Medical and Clinical Genetics, Inst. of Biomedicine, Gothenburg, Sweden; 2) Inst. of Mathematical sciences, Chalmers university of Technology, Gothenburg, Sweden; 3) Sahlgrenska University hospital, Gothenburg, Sweden; 4) The Nordic School of Public Health, Gothenburg, Sweden.

The GWASes published so far, including the one on Celiac Disease (CD) are based on a comparison between affected cases and healthy controls. The results provide disease gene variants, which are relatively common in the population and with a small effect on disease risk. If there are gene variants influencing these diseases with large effects they are most likely to be rare in the population. Rare variants are often located on different haplotype backgrounds due to separate founder mutations both within but most certainly between populations. Apart from massive parallell sequencing, there are two ways to detect associations due to rare variants; one way is to stratify the material in some way which selects for those specific individuals that carry the rare variant, e.g. by subphenotype or by an isolated ethnic population. Also, one can use families and combine both genetic linkage and association. The first GWAS in CD, like other diseases, revealed only a small percentage of the genetic variance responsible for CD. Rare variants with a larger effect could not be detected due to limitations of the case-control design. Family-based study designs from the earlier microsatellite linkage scans (including our own) do not have the same limitations. Linkage scans, on the other hand, can not generally pick up common variation underlying the disease. So why then, were the linkage scans not successful? The answer is partly that they were unable to extract all the genetic information from the families. It has been suggested that all these scans should be re-run with today's technology. As far as we know, we are the first to perform a GWAS in families taking advantage of a test using both family linkage information as well as a population based association test. Doing this, we will be able to extract all available information under our linkage peak on chromosome 5. Since we have the strongest linkage of the populations tested so far we also have the best chance of identifying the disease risk variants in this region. Second, we will get complete linkage information across all chromosomes. Third, we will be able to detect new disease variants by combining the linkage and association signals. A selection of 50 CD families have been genotyped using the Illumina 660w-quad chip. The results from the analysis will be presented.

**Testing association with a Reference Control Population: evaluation of case-control matching strategies.** *M.-C. Babron[1,2], H. Perdry[3,4], R. Kazma[1,3], S. Heath[5,6], G.M. Lathrop[5,6], E. Genin[1,2].* 1) INSERM UMR-S946, Paris, France; 2) Univ Paris-Diderot, Paris, France; 3) Univ Paris-Sud, Le Kremlin-Bicêtre, France; 4) INSERM UMR-S535, Villejuif, France; 5) Centre National de Génotypage, CEA, Evry, France; 6) Fondation Jean Dausset/CEPH, Paris, France.

Genome-wide association studies, involving the genotyping of hundreds of thousands of markers in thousands of subjects, are increasingly used to evidence genetic risk factors involved in multifactorial diseases. An attractive idea to minimise cost and work load is to gather a common Reference Control Panel (RCP). Each centre only needs to collect and genotype its own sample of patients, and compare them to the RCP. However, controls must be carefully selected to avoid false positives due to population stratification.

Here, we focus on local studies where cases originate from one country and compare two control matching designs: global matching where the set of cases is compared to a set of controls, and individual matching where each case is compared to one or two genetically matched controls. We investigated three selection schemes: selection at-random, selection based on the IBS, and selection based on the Principal Components Analysis.

From the RCP set up by the Centre National de Génotypage, that includes 6,000 controls from 13 European countries, genotyped on an Illumina 317K chip, we simulated samples of 600 French cases, based on their genotypes for chosen disease susceptibility SNPs, under an additive model (GRR= 1.5). We then selected up to 1,200 controls among the remaining individuals. The chosen disease susceptibility SNPs represent the different stratification characteristics observed across the European populations (no stratification, North-South and East-West clines, ...).

Selection at-random or based on IBS does not perform well. Overall, selecting controls on the basis of the results of Principal Components Analysis is better, both in terms of Type I error and power to detect association. However, even that approach does not correct well when the SNP under study exhibits important stratification.

## 979/W/Poster Board #637

**Multiple genome-wide association studies reveal variants with large effects on biochemical traits measured in blood serum.** *B. Benyamin, A. McRae, M. Ferreira, S. Gordon, R. Middelberg, B. McEvoy, G. Zhu, A. Henders, M. Campbell, L. Wallace, D. Nyholt, N. Martin, G. Montgomery, J. Whitfield, P. Visscher.* Queensland Institute of Medical Research, 300 Herston Road, Brisbane 4029, Australia.

Hundreds of genetic variants associated with complex traits have been identified via genome-wide association studies (GWAS). The individual effects of these variants are typically small and together only explains a small proportion of the heritability. One exception to this general finding appears to be quantitative biochemical traits measured in blood serum. Using GWAS in multiple cohorts, we found genetic variant(s) with large effect influencing variation in serum transferrin levels (a marker for iron overload- and deficiency-related diseases) and serum bilirubin levels (a marker for cardiovascular diseases). Three variants in TF plus the known C282Y mutation in HFE explained ~40% of genetic variation in serum transferrin. Similarly, we also confirm variants within UGT1A1 explaining ~30% of genetic variation in serum bilirubin levels. These results strongly support the hypothesis that genetic architecture of some traits may be simpler than that of disease.

## 980/W/Poster Board #638

**Genome-wide association study of lipid related phenotypes in the Avon Longitudinal Study of Parents and Children (ALSPAC).** *C.R. Boustred[1], N. Timpson[1], B. Glaser[1], D.M Evans[1], P. Deloukas[2], A. Hingorani[5], N. Sattar[3], L. Peltonen[2], J.E. Deanfield[4], G. Davey-Smith[1].* 1) Medical Research Council Centre for Causal Analysis in Translational Epidemiology and Department of Social Medicine, University of Bristol, Bristol, UK; 2) Human Genetics Group, The Sanger Centre, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 3) British Heart Foundation Glasgow Cardiovascular Research Centre, University of Glasgow, Glasgow, UK; 4) Great Ormond Street Hospital, 30 Guilford St, London, UK; 5) Department of Epidemiology and Public Health, University College London, London, UK.

Genome-wide association studies (GWAS) in population based birth cohorts enable detailed investigation of common genetic variation that is associated with complex human disease. Applying the GWAS strategy to population-based cohorts avoids problems of bias associated with case-control GWAS as well as the traditional problems associated with candidate gene studies. We report GWAS results for three lipid fractions, high-density lipoprotein (HDL), low-density lipoprotein (LDL) and triglycerides measured in the ALSPAC study. We have used direct genotyping (Illumina 300K chip) and indirect genotype imputation (MACH) to replicate previously reported associations for the first time in children (n = 1400, average age 9.55yrs) as well as to identify previously unreported associations. Replicated associations include the CEPT gene region on chromosome 16 (rs3764261, p = 2.41E-23) and its association with circulating HDL levels, and the CELSR2, PSRC1, SORT1 region on chromosome 1 and its association with circulating LDL levels (rs646776, p = 1.69E-06). Replicated results through genotype imputation include LIPC (15q21, rs4775041, p = 3.58E-06) associated with HDL, APOE (19q13, rs445925, p=2.71x10-19) and the PCSK9 gene region associated with LDL and ZNF259 (11q23, rs964184, p=1.86x10-06) associated with triglycerides. This work provided replication for the first time in a child cohort and substantiates their association with lipid concentrations from an early age. We also report 11 genetic loci that show novel associations with altered circulating lipid levels in children (p < 1 x 10-5). Of the eleven newly identified loci, two SNPs rs2039973 and rs1538833 (10q23 within ~140kb of each other near PPP1R3C and TNKS2) were associated with HDL cholesterol, three with LDL cholesterol, rs1569247 (7p12 near FLJ45974), rs8601 (12p2 in PLEKHA5) and rs5923437 (Xq21 near CHM and DACH2). Novel SNPs associated with triglycerides include, rs2293851 (8p24.1 gene desert), rs9291033 (3q28 in C3ORF59), rs1129055 (3q13.3 in CD86), rs614394 (11q13 near CCND1), rs7553212 (1q41 in ESRRG) and rs2387308 (10p15 in ADARB2). Abnormal variations in HDL, LDL and triglyceride levels are known to alter risk for coronary vascular disease (CVD) and stroke. Evidence suggests that the CVD process starts in childhood. Therefore the genetic variants identified here may be influencing blood lipid concentrations at an early age, resulting in an altered CVD risk later in life.

## 981/W/Poster Board #639

**Genome-Wide Association Study of Type 2 Diabetes and population-based quantitative traits in Asian populations.** *Y.S. Cho, M.J. Go, Y.J. Kim, J.H. Oh, J.Y. Heo, M.H. Lee, H. Min, J.-Y. Lee, B.-G. Han, H.-L. Kim.* Center for Genome Science, Korea National Institute of Health, Seoul, Korea.

Recent advances in genotyping technologies and analytic methods greatly contribute to investigating the entire genome in a large population in order to search for genetic factors controlling complex diseases and traits via genome-wide association study (GWAS). Many GWASs, however, have been accomplished primarily in samples of West European descent to date. Thus, it is not clear if the same or different loci play a role in Asian populations. To conduct GWAS aiming for exploring the genetic basis of lifestyle-related complex diseases such as T2D prevalent in Korea and complex traits with significant public health impact, we initiated the Korea Association Resource (KARE) project in 2007. In this project, almost all of the participants (n= 10,038) aged 40 to 69 in Ansung (n=5,018) and Ansan (n=5,020) cohorts, established as a part of the Korean Genome Epidemiology Study (KoGES) since 2001, were genotyped using the Affymetrix SNP Array 5.0. Using genotyping information and epidemiological data, we analyzed associations between common genetic variants and T2D as well as population-based quantitative traits. So far 11 SNPs showing strong evidence of association with given traits (SBP, pulse rate, WHR, BMI, height, and bone density) were identified and replicated in the independent population. Our results revealed both similarities and intriguing differences in the genes contributing to trait variation in Asian and European populations. In addition to carrying out GWAS, we were able to construct the genomic database for Korean genetic variations. This whole genome-wide SNP information from 10,038 participants in Korean population-based cohorts will facilitate research on the area of genomic science.

## 982/W/Poster Board #640

**Genome-wide association study of four anthropometric traits in a cohort of 1,798 Filipino women from the Cebu Longitudinal Health and Nutrition Survey.** *D.C. Croteau-Chonka[1], A.F. Marvelle[1], E.M. Lange[1,2], N. Lee[3], L.S. Adair[4], L.A. Lange[1], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 3) Office of Population Studies, University of San Carlos, Cebu City, Philippines; 4) Department of Nutrition, University of North Carolina, Chapel Hill, NC.

Genome-wide association (GWA) studies in a variety of population contexts enhance our understanding of the contribution of common genetic variants to human phenotypes. We performed a GWA study for four anthropometric traits ($log_{10}$-transformed body mass index [BMI], weight, waist circumference [WC], and average height) in a cohort of 1,798 unrelated adult Filipino women from the Cebu Longitudinal Health and Nutrition Survey (CLHNS). The associations were adjusted for age, $age^2$, assets, $log_{10}$-transformed income, number of pregnancies, menopausal status, and five principal components of population substructure. We replicated 10 of 84 genome-wide significant SNP-trait associations previously reported in European populations ($p < 5 \times 10^{-8}$) for three of our traits (CLHNS $p < 0.05$, same direction of additive effect): both BMI and weight with *BDNF*, *MC4R*, and *FTO*; BMI alone with *KCTD15*; and height with *EFEMP1*, *ZBTB38*, and *TBX2*. We also replicated three loci with suggestive evidence of association ($p < 10^{-4}$) with either height (*HIST1H1PS2*, *C14orf145*) or BMI (*OTOL1*) in a Korean population. An inter-population difference in local linkage disequilibrium narrowed one of the putative association regions. The CLHNS association signal at *BDNF* is 61% smaller in genomic size (115 kb vs. 294 kb) than the signal described in European populations, and still includes a proposed functional non-synonymous amino acid substitution variant. The strongest SNP not previously reported with our four traits was located nearby the gene *KCNE4*, and was highly associated with both BMI and WC ($p < 5 \times 10^{-6}$). *KCNE4* codes for the potassium voltage-gated channel, Isk-related family, member 4 protein, which acts as an inhibitory subunit to *KCNQ1* (potassium voltage-gated channel, subfamily Q, member 1). *KCNQ1* is expressed in adipose tissue and has been associated with type 2 diabetes in European and Asian populations. Our study also identified two regions (near *RPS24-POLR3A* and *USP13*) containing SNPs that significantly interact with total daily caloric intake to influence WC (tail area-based genome-wide false discovery rate of $q < 0.1$). Replication of these findings and the biological relevance of the nearby genes to their associated traits remain to be determined. Our results are further suggestive evidence for the utility of both non-European populations and differing environmental backgrounds in determining the genetic underpinnings of complex human traits.

## 983/W/Poster Board #641

**The Tobacco and Genetics Consortium: Genome-wide meta-analyses for smoking behavior among 74,035 individuals.** *J. Dackor, H. Furberg, Tobacco and Genetics Consortium.* Department of Genetics, University of North Carolina, Chapel Hill, NC.

Substantial evidence supports that cigarette smoking behavior has genetic determinants. Genome-wide association studies (GWAS) entail an unbiased search of the human genome and have yielded numerous, unsuspected and robust associations for a variety of complex traits. We conducted meta-analyses for smoking behavior using genotype and smoking data from existing GWAS of other traits (e.g., diabetes, cancer, heart disease). Our sample is comprised of 74,035 individuals from 16 different studies in the U.S. and Europe. We examined associations between ~2.5 million imputed markers and four smoking phenotypes, including smoking initiation (ever vs. never smokers), age at onset of smoking, average number of cigarettes smoked per day (CPD) and smoking cessation (current vs. former smokers). We partnered with two other smoking GWAS consortia to provide independent validation for our top 15 loci, resulting in a total sample size of >150,000 individuals. We confirmed the genome-wide significant association between the nicotinic receptor cluster on chromosome 15q25.1 and average CPD (rs1051730 p=5.19 x 10-73), In addition, we identified other genome-wide significant loci associated with average CPD, Ever vs. Never smoking, and Current vs. Former smoking status. No SNPs met genome-wide significance for age at onset of smoking. Findings from this meta-analysis shed light on novel biological pathways involved in multiple smoking phenotypes, potentially identifying novel susceptibility genes and new targets for smoking cessation treatment development.

## 984/W/Poster Board #642

**A Genome-wide Approach For The Identification of Shared Susceptibility Loci.** *D. Ellinghaus[1], M. Nothnagel[2], S. Schreiber[1,3], A. Franke[1].* 1) DFG, Excellence Cluster Inflammation at Interfaces, Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 2) PopGen Biobank, Christian-Albrechts-University, Kiel, Germany; 3) First Medical Department, University Clinic S.-H., Campus Kiel, Germany.

Historically, medical indications have been defined anatomic along organ structures. However, recent genetic discoveries indicate that an organ-based definition of disease may not be appropriate as discovered disease genes are often causative for several diseases. Hence, a novel definition of diseases along etiologically relevant pathways may improve our future ability to develop effective therapies. Genome-wide association studies (GWAS) and subsequent meta-analysis projects have been successful in identifying novel genetic susceptibility factors for several autoimmune and inflammatory diseases. Although many examples exist that different disorders share common genetic risk loci (e.g. IL23R in Crohn's disease, ulcerative colitis and psoriasis; NOD2 in Crohn's disease and sarcoidosis), systematic and genome-wide approaches are scarce. We therefore started a joint genome-wide analysis of various immune-related diseases to detect and characterize new disease susceptibility alleles that are relevant for more than one of these diseases. We have recently completed GWAS for various complex diseases. More than 5000 controls and 7000 cases for 11 distinct diseases were genotyped on Affymetrix 6.0 [1000k] or Illumina 550k arrays. Standard and uniform quality thresholds were applied to all data sets before and after imputation with MACH leaving >1.7 Mio. SNPs for inclusion in the analyses. Subsequent case-control analyses were carried out using MACH2DAT. Replication genotyping will be carried out using TaqMan/SNPlex genotyping technology. Different and complementary analysis strategies are currently developed to identify common disease loci and to prioritize associated loci for follow-up studies. Selected SNPs are then subjected to a replication phase using large and independent case-control collections. The project takes a systematic, genome-wide approach by studying an overlay of GWAS data sets from different diseases in clinically relevant combinations. A large-scale replication of the identified loci as well as subsequent resequencing of replicated disease loci will identify the broad spectrum of variation and will yield lists of potentially causative variants. Association analysis results for both the individual analyses and the combined analyses will be made publicly available through a UCSC custom track. The current status of the project will be presented at the conference.

## 985/W/Poster Board #643

**Genomewide association study of age of onset of asthma in the Childhood Asthma Management Program.** *E. Forno[1,2,5], J. Lasky-Su[1], C. Ramsey[4], J. Brehm[1,3,5], B. Klanderman[1], J. Ziniti[1], S.T. Weiss[1,5], J.C. Celedon[1,3,5].* 1) Channing Laboratory, Boston, MA; 2) Division of Pediatric Pulmonology, University of Miami, Miami, FL; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 4) Division of Pulmonary and Critical Care Medicine, University of Manitoba, Canada; 5) Harvard Medical School, Boston, MA.

Asthma, a chronic obstructive airway disease, is a major public health problem with known heritability. An earlier age of onset of asthma is associated with increased disease severity in childhood. We performed a genome-wide association study of the age of onset of asthma in 573 affected children in the Childhood Asthma Management Program (CAMP) trial. Participants were 5-12 years of age at enrollment in the trial, and their reported age of onset of asthma ranged from 6 months to 12 years. Genome-wide SNP genotyping was performed by Illumina, Inc. (San Diego, CA) on the HumanHap550v3 BeadChip for CAMP subjects and their parents. After stringent quality-control filters, 512,296 SNPs remained for analysis. In order to control for population stratification, Eigenstrat was used to identify the main eigenvectors describing the population substructure, and these were used as covariates in the analysis. Testing for association between the SNP panel and age of onset of asthma in index children was performed by survival analysis in R via PLINK, using an additive model adjusted for age at enrollment, gender, environmental tobacco exposure during infancy, and the eigenvectors. Two SNPs, one on chromosome (chr.) 11q24 and one on chr. 17p12, were associated with age of onset of asthma after a Bonferroni correction for genomewide significance ($P < 9.8 \times 10^{-8}$). In addition, 12 SNPs among those with the lowest P values had evidence for a biologically plausible role on asthma from prior studies in animal models and/or human studies. Replication studies in independent cohorts are ongoing.

## 986/W/Poster Board #644

**Interim analysis from a genome-wide association study of childhood obesity identifies *FTO* as strongly associated with the trait.** *S.F.A. Grant[1,2,3], J.P. Bradfield[1], J. Zhao[2], H. Zhang[1], K. Annaiah[1], C.E. Kim[1], J.T. Glessner[1], E.C. Frackelton[1], F.G. Otieno[1], K.A. Thomas[1], M. Garris[1], R.M. Chiavacci[1], K. Wang[1], M. Li[4], R.I. Berkowitz[5,6], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 5) Behavioral Health Center and Department of Child and Adolescent Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA; 6) Center for Weight and Eating Disorders, Department of Psychiatry, University of Pennsylvania, Philadelphia, PA.

The prevalence of obesity in children and adults in the United States has increased dramatically over the past decade. A number of genetic determinants of adult obesity have already been established through genome wide association (GWA) studies. Although we are still in the midst of recruiting cases and controls for a GWA study of childhood obesity, we elected to carry out an interim analysis of the subjects that have already been genome wide genotyped to date. As such, we generated a data freeze of genome wide SNP genotyping data from 1,285 Caucasian obese children (BMI≥95th percentile) and 6,169 Caucasian controls (BMI<95th percentile) produced on the Illumina Infinium II HumanHap550 or 610S BeadChip platform. All subjects were consecutively recruited from the Greater Philadelphia area from 2006 to 2009 at the Children's Hospital of Philadelphia. BMI≥95th percentile was defined using the Center for Disease control (CDC) z-score= 1.645. All subjects were biologically unrelated and were aged between 2 and 18 years old. All subjects were between -3 and +3 standard deviations of CDC corrected BMI i.e. outliers were excluded to avoid the consequences of potential measurement error or Mendelian causes of extreme obesity. Six common variants (most notably rs9930333) in strong linkage disequilibrium in the *FTO* gene on chromosome 16q12 attained genome-wide significance for childhood obesity association (*P*-value range $6.81 \times 10^{-9}$ to $5.84 \times 10^{-11}$; odds ratio range 1.297-1.338). As such, variants in the *FTO* gene confer a similar magnitude of risk for obesity in children as to what has already been described in their adult counterparts. We did not observe association to any other chromosomal regions at the genome wide significance level, including to other loci previously described from adult obesity studies. Once our GWA study is complete, we will have the opportunity to search for novel variants in the genome that are associated specifically with childhood obesity.

## 987/W/Poster Board #645

**Evidence for significant allele frequency variation as a function of age within and across GWAS control datasets detected using PLINK and MAP.** *T.H. Hamza, D.M. Kay, H. Payami.* Wadsworth Center, New York State Department of Health, Albany, NY.

Background: Hidden age effects in association studies can lead to both false positive signals and missing true associations, therefore, identifying SNPs whose frequencies vary by age could help investigators guard against spurious results. We tested (1) age related allele frequency variation in reference and control populations from three GWAS datasets, and (2) compared allele frequencies over age between datasets. Methods: We used three publicly available GWAS: Intragen population genetics database (Intragen) (914 control subjects, 317,503 SNPs), GWAS in Familial Parkinson Disease (CIDR) (895 control subjects, 344,301 SNPs), and Population Reference Sample (POPRES) (3189 control subjects, 457,297 SNPs), genotyped on Illumina HapMap 300v1.1, Illumina Human CNV370-DUO and Affymetrix 500k respectively. SNPs with MAF <5%, HWE p≤0.00001, and call rates <95% were excluded. We used PLINK to test age-SNP association, treating age as a quantitative trait, and adjusting for population clusters. QQ-plot was used to examine the extent to which the observed distribution of the test statistic followed the expected distribution. We then used frequency moving average plots (MAP) to visualize allele frequency distribution across the age spectrum within each dataset, as well as to test differences between datasets, and to measure the degree of differences by a moving average odds ratios (the MAP method is in press in Genetic Epidemiology). Results: 198 SNPs in Intragen, 5 in CIDR and 1 in POPRES reached $p \leq 10^{-5}$ for association with age. None of these SNPs achieved a $p \leq 10^{-5}$ in all three studies. Comparing intragen and CIDR, both of which used Illumina, 3 SNPs achieved $p \leq 10^{-3}$ in both data sets. Visual inspection by MAPs showed that the pattern of the allele frequency change for all three SNPs was in the same direction in both data sets. We then compared the frequency distribution of these 3 SNPs between pairs of datasets (intragen vs. CIDR vs. POPRES), and found significant differences (p<0.001) that generated odds ratios as large as 2.0 (95% CI: 1.5-2.5). Conclusions: (1) There can be significant allele frequency variation as a function of age within a dataset which if undetected could skew the association results. (2) Control datasets can differ considerably; therefore caution should be taken when borrowing controls. Visual inspection of data using MAP can help detect and control for these anomalies.

## 988/W/Poster Board #646

**Combination of Case-Control and Family-based Asthma Genome-wide Association Results Using Probands from a Single Population.** *B.E. Himes[1,2,3,4], J. Lasky-Su[2], A.J. Murphy[2], G.M. Hunninghake[2], B. Klanderman[2], R. Lazarus[2], J.C. Celedón[2], B.A. Raby[2], E.K. Silverman[2], S.T. Weiss[2,4].* 1) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 2) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Children's Hospital Informatics Program, Boston, MA; 4) Partners Center for Personalized Genetic Medicine, Boston, MA.

Asthma is a chronic inflammatory airway disease with well-established heritability that affects over 300 million people around the world. The Childhood Asthma Management Program (CAMP) was a clinical trial of asthma treatment that gathered genome-wide genotype data for family-based genomic studies of a subset of 422 Caucasian CAMP probands and their parents. In addition to using a family-based approach for the study of asthma, we increased our ability to detect associations by comparing CAMP probands to Caucasian controls that are publicly available through the Illumina ICONdb resource. After stringent quality-control filters were applied and genomic ancestry matching (GEM) was used to control for population stratification, data for 516,617 single nucleotide polymorphisms (SNPs) in 359 CAMP cases and 846 Illumina controls was used for case-control association analysis. The 5604 SNPs with case-control Cochran-Armitage trend test association p-values less than 0.01 were compared to those SNPs that had family-based FBAT additive model association p-values less than 0.05 in families. Both of these criteria were met by 1726 SNPs. A subset of 1377 of the 1726 SNPs was successfully genotyped in an Illumina 1536 GoldenGate assay in an independent population, the Genetics of Asthma in Costa Rica. Of the 1377 SNPs, 78 had 1-sided p-values less than 0.05 with effects in the same direction as CAMP. Replication of these results is ongoing in another independent population of Partners HealthCare patients recruited through the Informatics for Integrating Biology & the Bedside (i2b2) National Center for Biomedical Computing and the Crimson Project. Replication results in this third population will provide further evidence for the efficacy of screening SNPs based on both case-control and family-based analyses and of the validity of association of the 78 SNPs to asthma.

**Genome-wide association study of serum lipoprotein(a) concentration identifies multiple associated SNPs in addition to the kringle repeat.**
*S.M. Hosseini[1,2], E. Shen[3], D. Waggott[3], A.P. Boright[4], L. Sun[1,5], S.B. Bull[3,5], S.M. Marcovina[6], J.D. Brunzell[6,7], A.D. Paterson[1,2,5], the DCCT/EDIC Research Group.* 1) Genetics & Genome Biology Program, The Hospital for Sick Children, Toronto, ON, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 3) Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Prosserman Centre for Health Research, Toronto, ON, Canada; 4) Department of Medicine and University Health Network, University of Toronto, Toronto, ON, Canada; 5) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 6) Northwest Research Laboratory, Seattle, WA, USA; 7) Division of Metabolism, Endocrinology and Nutrition, Department of Medicine, University of Washington School of Medicine, Seattle, WA, USA.

**Background:** Lipoprotein (a) (Lp(a)) is an established independent risk factor for cardiovascular and cerebrovascular diseases. Serum level of Lp(a) is highly heritable. Based on linkage studies, most of the genetic effect is due to the *LPA* locus encoding for apolipoprotein(a), the unique structural protein of Lp(a). About half of the genetic effect is thought to be attributable to a VNTR, coding for kringle IV-2 (KIV-2) domain of apolipoprotein(a). The remainder of the effect at *LPA* locus is attributed to additional sequence variations, which are not fully understood. Genome-wide linkage studies have been inconsistent in detecting loci other than the main *LPA* locus.

**Methods:** A genome-wide association study was performed for serum Lp(a) level in 1236 white individuals with type 1 diabetes from the Diabetes Control and Complications Trial (DCCT) who were genotyped using the Illumina 1M chip. 841,342 SNPs with a minor allele frequency >1% were subjected to analysis. The number of KIV-2 repeats was determined in a multiplex qPCR reaction using two TaqMan® probes matching different regions of the repeat element. A series of analyses were performed: we tested for association between each SNP and serum Lp(a) level; SNPs in the *LPA* region (*LPA* gene and 0.5Mb on each side) were then evaluated for association with KIV-2 copy number; we finally fine-mapped the effect of SNPs on Lp(a), after adjusting for KIV-2, using forward selection in a linear regression framework.

**Results:** Significant evidence for association with serum Lp(a) levels was observed for a group of SNPs in the *LPA* region (57 SNPs with a $p<5\times10^{-8}$). KIV-2 copy number variation alone explained about 20% of variation in serum Lp(a) level ($p=4\times10^{-64}$). After adjusting for the effect of KIV-2 copy number variation, 54 SNPs from *LPA* region retained genome-wide significant ($p<5\times10^{-8}$) evidence of association with serum Lp(a) level. Using forward selection, 13 SNPs at the *LPA* locus showed evidence of association with Lp(a) in multivariate analysis (five of which had p-values $<5\times10^{-8}$).

**Conclusion:** We identify multiple SNPs in the *LPA* region that contribute to serum Lp(a) level independent of kringle copy number in the DCCT study population. Conditional genome-wide analysis after adjusting for the main effects at the *LPA* locus is underway to discover potential trans genetic effects.

## 990/W/Poster Board #648

**Meta-analysis of 28,141 individuals identifies common variants within five new loci that influence uric acid concentrations.**

Elevated serum uric acid levels cause gout and are a risk factor for cardiovascular disease and diabetes. To investigate the polygenetic basis of serum uric acid levels, we conducted a meta-analysis of genome-wide association scans from 14 studies totalling 28,141 participants of European descent, resulting in identification of 954 SNPs distributed across nine loci that exceeded the threshold of genome-wide significance, five of which are novel. Overall, the common variants associated with serum uric acid levels fall in the following nine regions: *SLC2A9* ($p=5.2 \times 10^{-201}$), *ABCG2* ($p=3.1 \times 10^{-26}$), *SLC17A1* ($p=3.0 \times 10^{-14}$), *SLC22A11* ($p=6.7 \times 10^{-14}$), *SLC22A12* ($p=2.0 \times 10^{-9}$), *SLC16A9* ($p=1.1 \times 10^{-8}$), *GCKR* ($p=1.4 \times 10^{-9}$), *LRRC16A* ($p=8.5 \times 10^{-9}$) and near *PDZK1* ($p=2.68 \times 10^{-9}$). Identified variants were analyzed for gender differences. We found that the minor allele for rs734553 in *SLC2A9* has greater influence in lowering uric acid levels in women and the minor allele of rs2231142 in *ABCG2* elevates uric acid levels more strongly in men compared to women. To further characterize the identified variants, we have analyzed their association with a panel of metabolites. rs12356193 within *SLC16A9*, was associated with DL-carnitine ($p=4.0 \times 10^{-26}$) and propionyl-L-carnitine ($p=5.0 \times 10^{-8}$) concentrations, which in turn were associated with serum UA levels ($p=1.4 \times 10^{-57}$ and $p=8.1 \times 10^{-54}$, respectively), forming a triangle between SNP, metabolites and UA levels. Taken together, these associations highlight additional pathways that are important in the regulation of serum uric acid levels and point towards novel potential targets for pharmacological intervention to prevent or treat hyperuricemia. In addition, these findings strongly support the hypothesis that transport proteins are key in regulating serum uric acid levels.

**Fine scale analysis and gene dicovery for age related macular degeneration.** *L. Kopplin[1], R.P. Igo[2], Y. Wang[2], T.A. Sivakumaran[2], S.A. Hagstrom[4], N.S. Peachey[4, 5], P.J. Francis[6], M.L. Klein[6], J.P. SanGiovanni[7], E.Y. Chew[7], D.V. Leontiev[2], G. Jun[2], L. Tian[2], T. Joshi[2], Q. Xi[2], A.K. Henning[8], K.E. Lee[9], R. Klein[9], B.E.K. Klein[9], S.K. Iyengar[1,2,3].* 1) Department of Genetics, Case Western Reserve University, Cleveland, OH; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Department of Ophthalmology, Case Western Reserve University, Cleveland, OH; 4) Cole Eye Institute, Cleveland Clinic Foundation, Cleveland, OH; 5) Louis Stokes Veteran Affairs Medical Center, Cleveland, OH; 6) Casey Eye Institute, Oregon Health & Science University, Portland, OR; 7) Division of Epidemiology and Clinical Applications, National Eye Institute, Bethesda, Maryland; 8) The EMMES Corporation, Rockville, Maryland; 9) Department of Ophthalmology and Visual Science, University of Wisconsin School of Medicine and Public Health, Madison, WI.

Age-related macular degeneration (AMD) is the leading cause of blindness in the elderly in the developed world. To identify novel genetic risk factors for AMD, we completed genome-wide association studies in two discovery cohorts followed by replication in 1940 cases and 1955 controls. Testing the full spectrum of disease severity, we examined 361,556 SNPs for association with a 15-step AMD severity scale in 294 individuals from 34 extended pedigrees from the Family Age Related Maculopathy Study and examined 186,807 SNPs for association with case-control status in 586 subjects collected as part of the Age Related Eye Disease Study. We followed up initial findings in five case-control replication cohorts. Strong evidence for association was observed with SNPs at the CFH and ARMS2 loci, with the best findings at rs3753395 (OR = 0.35, $p = 3.7 \times 10^{-64}$) and rs10490924 (OR = 2.79, $p = 2.0 \times 10^{-60}$), respectively. We also observed a protective effect at the C2/BF region, with our strongest result at a previously unreported marker ($p = 9.99 \times 10^{-16}$). Finally, we report the identification of a novel protective locus on chromosome 3 which implicates a pathway previously underappreciated for its potential in contributing to AMD pathogenesis. In summary, we have confirmed existing genes and after conditional analysis have identified novel loci involved in AMD pathogenesis.

Genome-wide scans of nucleotide variation in human subjects are providing an increasing number of replicated associations with complex disease traits. Most of the variants detected have small effects and, collectively, they account for a small fraction of the total genetic variance. Very large sample sizes are required to validate initial findings and to increase the number of new findings. In this situation, even small sources of bias and noise can cause spurious results or obscure real effects. The need for careful attention to data quality has been appreciated for some time in this field, and a number of strategies for quality control and quality assurance (QA/QC) have been developed. We have extended these methods to include some new approaches, which are illustrated here with examples from the “Gene Environment Association Studies” (GENEVA) program. Some key results: (1) Using probe intensities on the X and Y chromosomes, sex chromosome aberrations (e.g. XXY, XX/XO mosaics) can be detected that might otherwise be considered gender misidentification. (2) Using a measure of allelic imbalance, we detect contaminated samples and autosomal aberrations (in cell lines and blood samples) that may affect genotype calling accuracy. (3) We construct SNP filters based on duplicate concordance measures and suggest duplicate sample sizes appropriate to distinguish among SNPs with different error rates. (4) We have detected significant effects of numerous experimental factors on missing call rate, including tissue type, tissue collection date, DNA extraction method and date, study site, plate, well and genotyping batch. (5) Relatedness is inferred from IBD estimates with consideration of the variance of expected values. Poor quality samples can be detected as those with high relatedness connectivity. (6) We demonstrate sensitivity of principal components to SNP selection. (7) Hardy-Weinberg equilibrium test p-values plotted against minor allele frequency reveal distinct genotyping artifacts.

## 993/W/Poster Board #651

**Identification of 6 Loci for BMI in the Korean Population.** *H. Lee, J. Kim, J. Lee.* Genome Research Center, ASAN institute of life science, Seoul, Korea.

Obesity results from a greater intake of calories than the body requires. This is a serious public health problem which is associated with increase of risk such as type 2 diabetes mellitus, hypertension, dyslipidemia, cardiovascular diseases, sleep apnea and certain cancers. To find out loci associated with obesity in Asians, genome-wide association studies (GWAS) for body mass index (BMI), which is highly heritable and broadly used to diagnose obesity, has been conducted in the Korean population (n= 8842) using Affymetrix 500K SNP chip. In our study, we identified 4 novel BMI loci (FAM124B, RGS12, NFE2L3 and TNR) ($P < 0.00001$) as well as two previously reported BMI loci, FTO and MC4R in Koreans. Our study provides new candidate genes for BMI in Asians, and suggests that FTO and MC4R may be worldwide obesity-risk genes.

## 994/W/Poster Board #652

**A common variant on chromosome 11q13 is associated with atopic dermatitis.** *Y.A. Lee[1,2], J. Esparza-Gordillo[1,2], S. Weidinger[3,4], R. Fölster-Holst[5], A. Bauerfeind[1], F. Rüschendorf[1], K. Rohde[1], I. Marenholz[1,2], F. Schulz[1,2], T. Kerscher[1,2], N. Hübner[1], S. Schreiber[6,7], A. Franke[6], S. Heath[8], N. Novak[9], E. Rodriguez[3,4], T. Illig[10], M. Lee-Kirsch[11], M. Macek[12], A. Rüther[6].* 1) Max-Delbrück-Centrum, Berlin, Germany; 2) Pediatric Pneumology and Immunology, Charité, Berlin, Germany; 3) Department of Dermatology and Allergy, Technische Universität München, Munich, Germany; 4) Division of Environmental Dermatology and Allergy, Helmholtz Zentrum Munich and ZAUM-Center for Allergy and Environment, Technische Universität München, Munich, Germany; 5) Clinic for Dermatology, Venerology and Allergology, University Hospital Schleswig-Holstein, Kiel, Germany; 6) Institute for Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 7) POPGEN Biobank Project, Christian-Albrechts-University, Kiel, Germany; 8) Centre National de Génotypage, Evry, France; 9) Department of Dermatology and Allergy, University of Bonn, Bonn, Germany; 10) Department of Epidemiology, Helmholtz Zentrum Munich, Germany; 11) Klinik fur Kinder- und Jugendmedizin, Technical University Dresden, Dresden, Germany; 12) Department of Biology and Medical Genetics, Charles University Prague - 2. Medical School and Faculty, Hospital Motol, Prague, Czech Republic.

Atopic dermatitis (AD or eczema) is a chronic inflammatory skin disorder and a major manifestation of allergic disease. In the industrialized countries, the prevalence of AD is approximately 15 % with a steady increase over the past decades. Genetic and environmental factors interact to determine disease susceptibility, and family and twin studies indicate that the genetic contribution is substantial. The molecular mechanisms underlying eczema are not fully understood. To identify genetic variants contributing to AD, we conducted a genome-wide association study in 939 individuals with AD and 975 controls as well as 270 complete nuclear families with 2 affected siblings. SNPs consistently associated with AD in both discovery sets were then investigated in two additional independent replication sets totalling 2637 cases and 3957 controls. Highly significant association was found with a common sequence variant on chromosome 11q13.5 (Pcombined = 7.6 x 10-10) in all 4 study groups. Approximately 13% of individuals of European origin are homozygous for the risk allele, and their risk of developing AD is 1.47 times that of noncarriers. Notably, the same AD risk allele reported here has recently been identified as a susceptibility factor for Crohn’s disease. Crohn’s disease is a complex chronic inflammatory bowel disorder sharing many pathophysiological characteristics with AD such as recurrent inflammation of the epithelial barrier, defective cutaneous/mucosal barrier function, and deficient innate immune responses against bacterial infections. Our data suggest that rs7927894[A] confers susceptibility to AD and Crohn’s disease jointly which may contribute to the higher incidence of AD observed among Crohn’s patients. LD analysis in Hapmap showed that rs7927894 is located in a 200 kb LD block containing C11orf30. C11orf30 encodes the nuclear protein EMSY which has been implicated in chromatin modification, DNA repair, and transcriptional regulation. Finally, we provide a list of additional candidate genes. Further replication in independent cohorts, fine mapping and functional studies will be required to gain a better understanding of the physiological mechanisms underlying this common allergic disorder.

Sondergaard[11], H. Harbo[12], I.-L. Mero[12], P. De Jager[13], D. Hafler[13], M.J. Daly[4,10], A. Palotie[1,14], J. Saarela[1,2], L. Peltonen[1,2,14].* 1) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 2) Institute for Molecular Medicine Finland, Helsinki, Finland; 3) Helsinki Biomedical Graduate School, University of Helsinki, Finland; 4) The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Dept. of Neurology, Helsinki Univ. Central Hospital, Helsinki, Finland; 6) Central Hospital of Seinajoki, Seinajoki, Finland; 7) Dept. of Neurology, Tampere Univ. Central Hospital, Tampere, Finland; 8) Oulu University Central Hospital, Oulu, Finland; 9) Dept. of Neurology, Kuopio University Central Hospital, Kuopio, Finland; 10) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 11) Danish Multiple Sclerosis Research Center, Copenhagen University Hospital, Copenhagen, Denmark; 12) Department of Neurology, Faculty Division Ullevål Universtity Hospital, University of Oslo, Oslo, Norway; 13) Dept. of Neurology, Brigham & Women's Hospital, Boston, MA, USA; 14) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Prevalence of multiple sclerosis (MS) in the Southern Ostrobotnia (SO) sub-isolate region of Finland is 2-fold compared to other populations of Northern European descent. We used genealogical information up to 15 generations back to construct 2 SO megapedigrees. We hypothesize that one or more variants predisposing to MS may be regionally enriched and these pedigrees can be used to identify new, potentially rare MS alleles in GWA. We studied if variants in extended regions of homozygosity might affect MS susceptibility in this megapedigree. 68 MS cases from SO were genotyped using the Illumina 317K chip and 136 IBS matched population controls were selected from a control set of Finnish GWA data. We identified 2 tentative regions (>50 SNPs, >500kb): 1q42.12, 2q24.3. In 1q 16% of the MS (n=11, 9 same allele) and 8% of the controls (n=11, 10 same) and in 2q 40% of MS (n=27, 25 same) and 20% of controls (n=27, all the same) were homozygous. To test if we could identify a shared associated haplotype in this special sample, we performed a 5 SNP sliding window scan over linked regions. One haplotype flanking the C7-FLJ40243 locus on 5p12-14 showed tentative association (p <10-4). The association was replicated in an independent sample from the SO region (p<10-5). Finally to complete the GWA scan in SO we performed single SNP association analysis. Twenty eight loci with liberal p <10-4 were selected for replication in an independent Finnish set of 753 cases and 1029 controls. This identified 2 associated SNPs outside the HLA-region: rs1364194 (p=0.0046) and rs744166 in STAT3 gene (p= 0.0012). The 2 loci were further replicated in 6 GWA meta-analysis study sets (UK, CH, NL and 3 US) and in Nordic (DK, NO) samples (4638 cases, 10279 controls). Analysis of the replication sets using Cochran-Mantel-Haenszel population stratified analysis confirmed the association for STAT3 (p 2.65x10-10). The rs744166 T-allele underrepresented in MS cases tags one haplotype in CEU, CHB and JPT Hapmap populations (>56%) which is less common in YRI (7%). This might indicate positive selection of the "protective" haplotype outside Africa. Using the strength of special population structure, we identified 4 tentative susceptibility regions, 2 confirmed so far. Both genes are relevant biological candidates for MS: C7 is a rate limiting component of the innate immune system and STAT3. In previous studies mice with a knock-out of STAT3 in CD4+ T cells were resistant to EAE.

## 996/W/Poster Board #654

**Genome-wide association study of asthma identifies RAD50-IL13 and HLA-DR/DQ regions.** *X. Li, T.D. Howard, S. Zheng, E.R. Bleecker, D.A. Meyers.* Center for Human Genomics, Wake Forest University School of Medicine, Winston Salem, NC.

Asthma is a heterogeneous and complex disease with strong genetic susceptibility. Genome-wide association study (GWAS) is a powerful tool to study association of genetic markers with disease. To date, few GWAS of asthma have been performed. We performed a GWAS of asthma in a difficult-to-treat asthma population to identify novel genes and confirm previously identified genes involved in asthma.

A GWAS was performed with 292,443 SNPs to test for association with asthma in 473 TENOR cases and 1,892 Illumina general population controls. Asthma-related quantitative traits (total serum IgE, FEV1, FVC, and FEV1/FVC) were also tested for association with the SNPs on identified candidate regions in 473 TENOR cases and 363 controls without a history of asthma to confirm GWAS results. Imputation was performed in identified candidate regions for analysis with denser SNP coverage.

Multiple SNPs in the RAD50-IL13 region on chromosome 5q31.1 were strongly associated with asthma and peaked at rs2244012 in intron 2 of *RAD50* (P = 3.04E-07; Bonferroni adjusted P = 0.089). Several SNPs in *RAD50* and *IL13* were also associated with quantitative traits (P ≤ 0.05). The HLA-DR/DQ region on chromosome 6p21.3 showed consistent association with asthma and peaked at rs1063355 in the 3' UTR of *HLA-DQB1* (P = 9.55E-06). Imputation identified several significant SNPs in the TH2 locus control region (LCR) 3' of *RAD50*. Imputation also identified a more significant SNP, rs3998159 (P = 1.45E-06), between *HLA-DQB1* and *HLA-DQA2*.

Our GWAS confirmed the important role of TH2 cytokine and antigen presentation genes in asthma at a genome-wide level. Furthermore, our findings will stimulate more comprehensive research on these two regions due to their functional importance and structural complexity.

## 997/W/Poster Board #655

**Genome-wide meta-analysis of 38,455 subjects for smoking related traits.** *Z. Liu[1], F. Tozzi[2], V. Mooser[3], L. Cardon[3], C. Francks[4], J. Marchini[1].* 1) Dept Statistics, Oxford Univ, Oxford, United Kingdom; 2) Genetics Division, Drug Discovery, GlaxoSmithKline Research and Development, 37135 Verona, Italy; 3) Genetics Division, GlaxoSmithKline, King of Prussia, PA 19406, USA; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford OX3 7BN, UK.

Smoking is a leading global cause of disease and mortality. The nicotine present in tobacco acts on nicotinic acetylcholine receptors in the brain to release dopamine and other neurotransmitters that sustain addiction. Smoking and Nicotine Dependence are multifactorial, partly heritable traits. We have performed a genomewide meta-analytic association study of smoking-related traits in a total sample of 38,455 individuals drawn from 21 disease, population, and control cohorts (The arc Epidemiology Unit Rheumatoid Arthritis cohort, The Bright Study, The Cambridge GEM Consortium, The GEMS Study, The Bergen COPD case control collection, The GSK/IOP/CAMH bipolar cohort, The GSK/MPI depression cohort, The UK IBD Genetics Consortium, The KORA Study, The KORCULA Study, The LOLIPOP Study, The Medstar Cohort, The Northern Sweden Population Health Study, The ORCADES Study, The PennCATH cohort, The Popgen Biobank Study, The PsyCoLaus cohort, The SardNIA study, The Study of Health in Pomerania, The VIS Study and The WTCCC-CAD cohort). We used imputation based on the CEU HapMap haplotype to combine datasets from different genotyping chips. We attempted replication of associated regions within the TAG and ENGAGE smoking meta-analysis datasets, which are large, independent datasets that have been analysed concurrently with our own. For the cigarettes per day (CPD) phenotype (N=14,952) our analysis confirmed an effect in the chromosome 15 nicotine receptor cluster (P=2.5x10-18 in our own analysis and P=5.19 x 10-73 across all 3 meta-analyses at rs1051730). These results act as a clear positive control for our meta-analysis. A fine mapping analysis of the region suggests other more significantly associated novel variants. Of the 15 regions for the CPD that we took forward for in-silico replication in the TAG and ENGAGE datasets two regions, on chromosomes 8 and 12 (P<10-5), show some evidence of replication in the other studies (P<0.01). Analysis of the smoking initiation phenotype (Ever/Current vs Never smoking status) did not uncover any associations that we could replicate. While confirming that the CHRNA5/A3 region is likely to harbor the strongest common effect on smoking-related traits in the genome, our analysis has identified novel potential loci that await further investigation.

**Modeling genes for astigmatism.** *M.C. Lopes, A. Toby, T.D. Spector, C.J. Hammond.* Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

Astigmatism is a complex trait which is influenced by numerous genetic and environmental factors. Recent large twin studies of refractive error have found a high heritability of approximately 60% where the dominant effects explained most of the phenotypical variance. Here we report the first genome-wide association study on astigmatism for 2341 twin UK subjects (1172 DZ), with 318 232 SNPs based on polygenic models. A follow up candidate gene study including fine-mapping analysis was performed after imputing SNPs for the candidate regions. Replication analysis as well as meta-analysis was conducted for 1749 independent twin UK subjects using 537 179 SNPs. We identified significant SNP association ($P<1.05x10^{-5}$) with astigmatism in genes AC011592.5 (SNP rs2727385), DACH1 (SNP rs7328290) and COL13A1 (SNP rs2642609). None of these top hits were replicated. However, after completing the meta-analysis the rs2642609 SNP attained genome-wide significance ($1.14x10^{-5}$). This SNP is upstream of gene COL13A1 and is in a LD block interrupted by recombination hot-spots. Eight informative imputed SNPs in high LD ($r^2>0.8$) with the lead SNP rs2642609 have been identified and will be genotyped. A subset of these will be used for a haplotype study to characterize the common haplotypes associated with astigmatism. COL13A1 is a type of connective tissue, the organization of which affects the refraction of the cornea and then the astigmatism. This study provides new insights into astigmatism disease and advances an understanding of refractive error disease, which affects a considerable part of the world population.

**The POCEMON (Point-Of-Care MONitoring and Diagnostics for Autoimmune Diseases) project: building a Lab-On-Chip centered on Rheumatoid Arthritis and Multiple Sclerosis.** *S. Lupoli[1,2], C. Cosentino[2], V. Tieran[2], F. Taddeo[2], S. Atkinson[3], A. Barton[4], A.G. Wilson[3], D. Plant[4], J.R. Maxwell[3], E. Graudens[5], I. Chumakov[5], F. Kalatzis[6], F. Macciardi[2].* 1) INSPE, HsR Scientific Institute, Milan, Italy; 2) University of Milan, Milan, Italy; 3) University of Sheffield, Sheffield, UK; 4) arc Epidemiology Unit, University of Manchester, Manchester, UK; 5) Pharnext S.A., Paris, France; 6) Unit of Medical Technology and Intelligent Information Systems, University of Ioannina, Ioannina, Greece.

POCEMON is a large-scale integrated project founded from the European Commission (FP7-ICT-2007-216088). The aims of the project are to develop an integrated diagnostic platform mainly dedicated to Rheumatoid Arthritis (RA) and Multiple Sclerosis (MS) in a first stage by combining Lab-On-Chip technology, DNA microarray genotyping, microelectronics, mobile devices, intelligent algorithms and wireless communications. MS and RA are two progressive autoimmune diseases and are causes of disability in young adults. Considering the social relevance of MS and RA, it is extremely important to improve the timing and confidence of the diagnosis. According to this vision the POCEMON project can be a real milestone for the improvement of life style of many patients. In a first (discovery) phase, we are performing a case/control whole genome association study, mostly centered to identify HLA (Human Leukocyte Antigens) and other potentially relevant susceptibility genes for the two diseases. For the discovery phase of RA, we are using a homogeneous North-European population (with 800 cases and 800 controls). The discovery is then followed by a confirmatory phase, where the "best" SNPs are evaluated in a second independent sample (2000 cases affected by RA or MS respectively and relative controls), from three separate cohorts. The genotyping phase for RA, using Illumina HumanCNV-370, is concluded. Plink 1.06 is used for QC of genotyping data and Eigenstrat 3 is used for adjusting population structure in genetic association. The analysis is ongoing. Initial findings pointed to several susceptibility genes across the genome involved in the disorder other than confirming a role of HLA.

## 1000/W/Poster Board #658

**GWAS in patients with non-syndromic cleft lip with or without cleft palate (NSCL/P) of European descent.** *E. Mangold[1], S. Birnbaum[1], K.U. Ludwig[2], C. Baluardo[3], H. Reutter[1], S. Herms[2], N.A. de Assis[1], M. Ferrian[3], C. Lauster[4], B. Braumann[5], R.H. Reich[6], A. Hemprich[7], R.P. Steegers-Theunissen[8], F.-J. Kramer[9], T.F. Wienker[10], P.A. Mossey[11], P. Hoffmann[1,2], M. Rubini[3], M. Knapp[10], M.M. Nöthen[1,2].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany; 3) Department of Experimental and Diagnostic Medicine, Medical Genetics Unit, University of Ferrara, Ferrara, Italy; 4) Department of Cleft Lip and Cleft Palate Surgery, Humboldt University of Berlin, Berlin, Germany; 5) Department of Orthodontics, University of Cologne, Cologne, Germany; 6) Department of Oral and Maxillo-Facial-Plastic Surgery, University of Bonn, Bonn, Germany; 7) Department of Oral and Maxillo-Facial Surgery, University of Leipzig, Leipzig, Germany; 8) University Medical Center, Rotterdam, The Netherlands; 9) Department of Oral and Maxillofacial Surgery, University of Göttingen, Göttingen, Germany; 10) Institute of Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 11) Orthodontic Unit, Dental Hospital & School, University of Dundee, Dundee, UK.

Non-syndromic orofacial clefts are considered to have a multifactorial etiology with a strong genetic background. The most frequent form is the non-syndromic cleft lip with or without cleft palate (NSCL/P). We conducted a two-step genome-wide association study involving NSCL/P-patients and controls of Central European origin in order to identify novel susceptibility loci for NSCL/P. The first step of our study involved 224 NSCL/P-patients and 383 controls. A 640-kb region at chromosome 8q24.21 was found to contain multiple markers with strongly significant evidence for association with the cleft phenotype, including three markers which reached genome-wide significance. The 640-kb cleft-associated region was saturated with 146 SNP markers and analyzed in our entire NSCL/P sample of 462 unrelated patients and 954 controls. In the entire sample, the most significant SNP (rs987525) had a P value of 3.34 ×10-24. The OR was 2.57 (95% CI: 2.02-3.26) for the heterozygous genotype and 6.05 (95% CI: 3.88-9.43) for the homozygous genotype. The calculated PAR for this marker is 0.41, suggesting that this is a key susceptibility locus for NSCL/P (Birnbaum et al., Nature Genetics 41, 473-477). Interestingly, we found no evidence of any interaction between the 8q24.21 locus and IRF6, the only generally accepted NSCL/P gene to date. In the second step of our GWAS we extended the sample to 399 patients and 1318 controls. 110 SNPs not mapping to the 8q24.21 region with P values below 10-4 were found. We investigated 47 of the best SNPs in an independent replication sample of 793 triads and found genome-wide significant association in the combined sample for two loci and suggestive evidence for association for three additional loci. Our extension of the GWAS adds two new loci to the list of confirmed NSCL/P susceptibility loci and suggests three loci for independent replication.

**Variational Bayes algorithms for accurate multiple locus and multiple factor genome-wide association (GWA) analysis.** *J. Mezey, B. Logsdon, C. Gao, G. Hoffman, A. Brisbin, L. Omberg.* Biological Statistics (BSCB), Cornell Univ, Ithaca, NY.

Genome-wide association (GWA) studies have successfully identified loci that explain a small percentage of heritable variation in disease susceptibility and other complex aspects of human physiology. GWA algorithms that account for multiple loci and non-genetic factors could be used to explain missing heritability, by discovering associations hidden from standard GWA analysis. Making use of variational Bayes approximate inference techniques, we have developed a class of algorithms that provide a novel solution to the computational constraints and accuracy concerns associated with most multiple locus / multiple factor GWA algorithms. These variational Bayes algorithms simultaneously assess all genetic markers in a GWA study and have excellent scaling properties, such that an analysis of a thousand individuals, genotyped at one million markers, can be run on a desktop in a matter of hours. By analyzing simulated data, we demonstrate these algorithms can reliably identify associations that are too weak to be found by single-marker testing approaches, when using a highly conservative control of false positives. We use these algorithms to identify new locus associations with gene expression, replicated in multiple populations of HapMap, and to identify associations with major heritable disease phenotypes.

## 1002/W/Poster Board #660

**Genome Wide Association Study of Acute Rejection and Chronic Allograft Nephropathy in Kidney Transplant Donors and Recipients.** *S.L. Musone[1], W. Lin[2], E. Wan[1], M. Akana[1], J. Chen[1], C. Ha[1], S. Horvath[2], D. Salomon[3], P.Y. Kwok[1].* 1) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 2) Dept. of Biostatistics, University of California Los Angeles, Los Angeles, CA; 3) The Scripps Research Institute, La Jolla, CA.

Purpose: Acute rejection (AR) and chronic allograft nephropathy (CAN) are two important phenotypes contributing to kidney transplant dysfunction and failure. We hypothesize that these forms of allograft rejection are complex traits with genetic signatures that can be identified through a genome-wide association study of single nucleotide polymorphisms (SNPs). Methods: SNPs were genotyped using high-throughput SNP arrays. After rigorous quality control, we have performed logistic regression analysis with multidimensional scaling (MDS) values as covariates to adjust for population structure in 353 recipients versus 114 AR recipients or 72 displaying CAN at a minimum of 1 year post-transplant. We have done the same analysis in 336 donors of well functioning transplants versus 102 AR or 71 CAN subjects. Results: Different regions of the genome reach significance in each of the 4 comparisons, indicating diverse etiologies between AR and CAN as well as contribution by donor and recipient to these outcomes. Significant loci are being validated in an independent cohort with outcome defined in an identical manner.

**Decorrelating genetic association statistics for complex phenotypes: the PCPD method.** *G. Nelson[1], S. Hendrickson[2], S. O'Brien[2].* 1) BRP/LGD-NCI, SAIC Frederick, Frederick, MD; 2) Laboratory of Genomic Diversity, CCR, NCI-Frederick, Frederick MD.

Complex epidemiological phenotypes such as response to HIV are measured by multiple clinical variables collected on study individuals. While this gives more information per subject for association analysis, the interpretation is difficult, since these variables in general are non-independent; when a genetic factor shows significant association with several disease outcomes, is this confirmatory or does it simply reflect the correlation of these measures? In addition this non-independence complicates the problem of correcting for multiple comparisons. We present a general method for decorrelating association statistics using a principal components transformation. Traditionally, biometric measurements on individuals are transformed to independent variables by the principal components method, but this approach is not directly applicable to many of the common epidemiological statistics. On the other hand the population association statistics (e.g. relative hazards or odds ratios) are comparable measures. To quantify the intrinsic correlation of these measures on different outcomes, we consider a population of permutations of the genetic association in question, and for the set of disease measures, compute the principle components over the permuted data (PCPD). Applying this principle component transformation to the actual association data yields a set of uncorrelated association measures. The independent of the measures allows calculating an overall statistical significance, thus the additional information contained in multiple disease measures translates directly to increased power to detect disease associations.

## 1004/W/Poster Board #662

**Genome-wide association study of restless legs syndrome in Korean population.** *M. park, J. Lee, B. Keam, J. Heo, J. Lee.* Center for Genome Science, National Institute of Health, Korea Centers for Disease Control and Prevention, Seoul, Korea.

Background: The restless legs syndrome (RLS) is a common neurologic disorder characterized by an irresistible urge to move the legs. RLS affects near up to one in ten of the adult population and around one-third of patients experience symptoms more than twice weekly causing moderate to severe distress. Despite the high prevalence and social impact of depressive disorder, a little is known about the genetic contribution to the pathogenesis of RLS. The present study was purpose to investigate for sequence variants contributing of RLS in the Korean population. Methods: We conducted a genome-wide association study using 3,265 subjects recruited from a community-based epidemiological study. We used the currently accepted diagnostic criteria according to the National Institutes of Health consensus statement. A total 154 RLS cases and 3,111 controls were genotyped on a single platform using the Affymetrix Genome-Wide Human SNP array 500K chip. Of the SNPs assayed on the chip, 320,942 SNPs were analyzed that showed: 1) a call rate more than 95.0% in cases or controls; and 2) a minor allele frequency (MAF) $\geq$ 1% in the population; and 3) a significant distortion from Hardy-Weinberg equilibrium in the controls ($p \geq 0.05$). Results: In a genome-wide association study, we found 10 SNPs that were significantly associated with RLS. Ten SNPs in genes, PTPRD, ALG14, CPXM2, PAMR1, PELI2, ZFP161, LIMCH1 C2orf40, and C1orf168, exhibited a significant association with significance level of p<10-4. Among these SNPs, SNP (rs1556521) in PTPRD (protein tyrosine phosphatase receptor type delta) on chromosomes 9p showed significant association (p-value= 8.54x10-5), and this association with PTPRD was also confirmed in prior independent case-control study conducted in German, Czech and Canadian population. Conclusion: We have discovered a several SNPs associated with susceptibility to RLS. Further biologic and functional investigations are warranted to confirm these associations.

## 1005/W/Poster Board #663

**Age- and gender-specific genetic variations associated with serum C-reactive protein levels in 8,837 Koreans.** *J.W. Park[1], M.A. Jhun[1], J.Y. Lee[2], T. Park[3], S.H. Jee[4], S. Cho[5], J. Sung[5], J.E. Lee[6], N.H. Cho[7], C. Shin[8], B.G. Han[2], H.L. Kim[9].* 1) Dept Medical Genetics, Hallym Univ, Chuncheon, Korea; 2) Center for Genome Science, Korea Nat'l Institute for Health, Seoul, Korea; 3) Dept Statistics, Seoul Nat'l Univ, Seoul, Korea; 4) Institute for Health Promotion, Yonsei Univ, Seoul, Korea; 5) Dept Epidemiology, Seoul Nat'l Univ, Seoul, Korea; 6) DNA Link, Seoul, Korea; 7) Dept Preventive Medicine, Ajou Univ, Suwon, Korea; 8) Dept Internal Medicine, Korea Univ Ansan Hospital, Ansan, Korea; 9) Korea Nat'l Institute for Health, Seoul, Korea.

Elevated C-reactive protein (CRP) level is considered to be a predictor of a variety of aging-related diseases such as cardiovascular disease. Serum CRP levels vary by age, gender, and ethnicity; and moreover, correlate with adiposity and various biological characteristics. We conducted a genome-wide association study (GWAS) among 8,837 unrelated Koreans to identify age- and gender-specific genetic variants associated with serum CRP level. We initially analyzed the association of serum CRP with 65 variables including environmental and clinical variables to identify possible confounding variables. We analyzed natural log transformed CRP using 352,228 single nucleotide polymorphism (SNP) markers under three genetic models (*i.e.* additive, dominant, and recessive) and three multiple linear regression models stratified by age and sex with adjustments for residence and body mass index (model 1); model 1 plus additional adjustments for nine biochemical variables (model 2); and model 2 plus additional adjustments for five lifestyle variables (model 3). Nine SNPs of the six genes showed the genome-wide level of significance in one of age-gender groups. Among them, SNPs in the GRAMD3 (the lowest $p=2.44 \times 10^{-7}$), EPHA7 ($p=1.43 \times 10^{-7}$), and PIK3R1 ($p=2.8 \times 10^{-7}$) genes were identified in women aged 39-49 years, and ULK4 gene ($p=3.2 \times 10^{-8}$) were identified in women aged 60-70 years; while SNPs of CRP ($p=7.62 \times 10^{-8}$) and KIAA0182 ($p=1.89 \times 10^{-8}$) were significantly associated with CRP level in men aged 39-49 and 50-60 years, respectively. While the results must be confirmed in future studies, the genetic variations observed here might explain, in part, the serum CRP variation with age and gender.

## 1006/W/Poster Board #664

**The Genetic Architecture of Alopecia Areata.** *L. Petukhova[1], A. Lee[3], J. Freudenberg[3], M. Hordinsky[4], D. Norris[5], V. Price[6], M. Duvic[7], P.K. Gregersen[3], A.M. Christiano[1,2].* 1) Dept of Dermatology, Columbia Univ, New York, NY; 2) Dept of Genetics & Development, Columbia Univ, New York, NY; 3) The Feinstein Institute for Medical Research, North Shore LIJHS, Manhasset, NY; 4) Dept of Dermatology, Univ of Minnesota, Minneapolis, MN; 5) Dept of Dermatology, Univ of Colorado, Denver, CO; 6) Dept of Dermatology, UCSF, San Francisco, CA; 7) Dept of Dermatology, MD Anderson Cancer Center, Houston, TX.

Alopecia Areata (AA) [MIM 104000] is one of the most prevalent and least well understood of the autoimmune diseases. In AA, autoimmunity is acquired against the hair follicle, which causes non-scarring hair loss that is associated with the accumulation of an immune infiltrate around the affected hair follicle. While the pathogenesis of AA remains unknown, we hypothesize that the genetic architecture of AA will be composed of genes expressed in cells of the immune system, as well as genes expressed in the hair follicle that elicit the immune response. We expect that immune response genes are vulnerable to positive selection, which could increase allele frequencies, creating common variants in the population. Alternatively, it is not likely that hair follicle genes would be subject to strong selective forces, so we expect that these alleles will remain at much lower frequencies in the population. Because genome-wide association studies (GWAS) identify common variants, we thus anticipate that the immune component of AA genetic architecture will be particularly amenable to detection with this method. We therefore undertook a GWAS in a discovery sample of 256 unrelated cases and 1152 controls, and replicated in an independent sample of 834 cases and 1260 controls, all of Northern European descent as determined by ancestry informative markers. Joint analysis of the datasets identified 40 SNPs that are associated with AA (p<5x10-7), approximately half of which fall within the HLA region on chromosome 6p. The remaining SNPs cluster in four main regions, implicating immune genes involved in the activation and/or regulation of signaling pathways in T-cells and NK cells. This insight allows us for the first time to place AA within the context of shared genetics and common pathways among autoimmune diseases, and promises to elucidate the underpinnings of disease pathogenesis and illuminate novel therapeutic avenues for the treatment of AA.

## 1007/W/Poster Board #665

**Analysis of GWAS data reveals another locus for Nicotine Dependence.** *J.P. Rice[1], S. Saccone[1], N. Saccone[1], W. Howells[1], A. Goate[1], R. Grucza[1], L. Chen[1], S. Hartz[1], B. Porjesz[2], H. Edenberg[3], T. Foroud[3], J. Nurnberger[3], J. Kramer[4], E. Johnson[5], K. Doheny[6], E. Pugh[6], C. Laurie[7], L. Bierut[1], COGA, SAGE.* 1) Dept Psychiatry, Washington Univ, St Louis, MO; 2) SUNY Downstate Medical Center, Brooklyn NY; 3) Indiana University School of Medicine, Indianapolis, IN; 4) University of Iowa, Iowa City, IA; 5) Research Triangle Institute Research Triangle Park, NC; 6) CIDR Genotyping Lab and JHU SNP Center Johns Hopkins School of Medicine Baltimore, MD; 7) Department of Biostatistics, University of Washington, Seattle WA.

The SAGE addiction project, one of the GENEVA (Gene-Environment Association) GWAS studies, consists of data from three studies (alcohol dependence, cocaine dependence and nicotine dependence). Cases had to have had a diagnosis of alcohol dependence, and controls had neither a diagnosis of alcohol dependence nor cocaine dependence. Genotyping was performed on the Illumina 1M chip at CIDR and data were cleaned following stringent GENEVA standards. We performed logistic regression analysis for the phenotype of nicotine dependence with case-control status defined using a threshold of 4 on the FTND scale, a commonly used scale in tobacco research, where controls had to have ever smoked cigarettes in their lifetime. Covariates consisted of gender, age (coded in four quartiles), ethnicity, co-morbid alcohol dependence with and without cocaine dependence, and SNP genotype coded additively with one degree of freedom. There were 1294 cases and 2071 controls used in analysis. We first analyzed 1,341 SNPs present on the Illumina chip in a set of 56 candidate genes previously identified by a panel of experts (Saccone et al, Hum Mol Genet 2007; 16:36-49). SNPs in the beta nicotinic receptor (CHRNB3) on chromosome 8 were highly significant (p=2.4 x 10-8, OR = 1.54). We next analyzed the full set of GWAS SNPs, and the SNPs in CHRNB3 were the most significant, with the QQ-plot indicating their GWAS significance. Odds ratios were similar for African Americans and European Americans as well as for those with and without a co-morbid diagnosis. This signal was much stronger than that of the alpha5 region of chromosome 15, a highly replicated finding in several studies of nicotine dependence and lung cancer. However, the lung cancer studies, which analyzed cigarettes per day (CPD) as a quantitative phenotype, did not report GWAS significance for CHRNB3. Accordingly, we analyzed CPD and found a significance of 0.001. Interestingly, we found highly significant evidence for interactions with gender and age on chromosome 8, but only with gender for the region on chromosome 15. For CHRNB3, there was a greater SNP effect in males and in those over age 45. The use of CPD, rather than the FTND, may explain why CHRNB3 was not GWAS significant in these other studies. Nicotine dependence represents a major source of health morbidity and mortality, and the identification of risk alleles may lead to therapeutic targets for smoking cessation.

## 1008/W/Poster Board #666

**Common variants at ten loci influence glycated hemoglobin levels via glycemic and non-glycemic pathways.** *S. Sanna[1], N. Soranzo[2,3], E. Wheeler[2], C. Gieger[4], D. Radke[5], J. Dupuis[6], E. Stolerman[7], N. Bouatia-Naji[8], C. Langenberg[9], I. Prokopenko[10,11], M.S. Sandhu[12,13], W.H.L. Kao[14], N.J. Wareham[9], J.C. Florez[7,15,16], M. Uda[1,18], I. Barroso[2,18], J.B. Meigs[17,18] on behalf of MAGIC.* 1) Istituto di Neurogenetica e Neurofarmacologia del CNR, Monserrato, Cagliari, Italy; 2) Human Medical Genetics, Wellcome Trust Sanger Institute, Genome Campus, Hinxton, UK; 3) Department of Twin Research and Genetic Epidemiology, King's College London, UK; 4) Institute of Epidemiology, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany; 5) Institute for Community Medicine, Ernst Moritz Arndt University Greifswald, Greifswald, Germany; 6) Department of Biostatistics, Boston University School of Public Health, Boston, USA; 7) Center for Human Genetic Research, and Diabetes Research Center (Diabetes Unit), Massachusetts General Hospital, Boston, USA; 8) CNRS-UMR-8090, Institut Pasteur de Lille and Lille 2 University, Lille, France; 9) MRC Epidemiology Unit, Cambridge, UK; 10) WTCHG, Oxford, UK; 11) OCDEM, Oxford, UK; 12) Department of Public Health and Primary Care, Strangeways Research Laboratory, University of Cambridge, Cambridge, UK; 13) Department of Internal Medicine, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 14) Department of Epidemiology and Medicine, Johns Hopkins University, Baltimore, USA; 15) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 16) Department of Medicine, Harvard Medical School, Boston, USA; 17) General Medicine Division, Massachusetts General Hospital, Boston, USA; 18) These authors contributed equally.

Glycated hemoglobin ($HbA_{1C}$) results from the non-enzymatic glycation of hemoglobin molecules carried in erythrocytes, an essentially irreversible reaction whose rate is directly dependent on ambient blood glucose levels. The level of $HbA_{1C}$ reflects the mean blood glucose concentration over the preceding 2-3 months, the average life span of a human erythrocyte. While ambient blood glucose explains ~90% of the variability of $HbA_{1C}$, the relative influence of other factors independent of systemic glycemia, including increased red blood cell turnover, hemoglobinopathies, defects of glucose transport into erythrocytes, or alterations in intracellular glucose metabolism trait, is largely unknown. Though the estimated heritability of $HbA_{1C}$ in populations of European ancestry is relatively high (~47%), the genetic factors thus far identified (*HK1*, *GCK*, *G6PC2*, *SLC30A8*) only account for ~1.5% of the variance. To identify novel loci influencing $HbA_{1C}$ levels, we conducted a meta-analysis of ~2.5M directly genotyped or imputed autosomal SNPs from 10 GWAS (Stage 1 cohorts), totaling 14,898 non-diabetic adults of European descent. By following up the top 20 independent signals in 30,233 additional samples (Stage 2 cohorts) we identified two novel loci and replicated the association at *HK1* ($p=1.5x10^{-50}$), *GCK* ($p=8.8x10^{-20}$), and *G6PC2* ($p=9.3x10^{-18}$). Combining all available data from the Stage 1 and Stage 2 cohorts (45,131 individuals) five additional loci reached genome-wide significance ($p<5x10^{-8}$), including *MTNR1B* ($p=8.3x10^{-11}$), a locus recently associated with fasting glucose and type 2 diabetes risk. Of the ten association signals, five are in or near genes known to regulate systemic glycemia, and two are near genes involved in iron homeostasis. Genes in the remaining loci require further characterization, but may affect $HbA_{1C}$ levels through red blood cell skeletal organization or membrane stability. Measurement of $HbA_{1C}$ has universal significance in the diagnosis and clinical care of diabetes as a time-integrated index of glycemic control and a highly reliable biomarker of diabetes-specific and cardiovascular disease complications. The apparent distinction between loci influencing $HbA_{1C}$ levels via glycemic and non-glycemic pathways highlighted in this study, thus raises important considerations in the clinical interpretation of $HbA_{1C}$ levels.

## 1009/W/Poster Board #667

**Identification of Systemic Lupus Erythematosus Susceptibility loci by Pooling-based Genomewide Association Scan and Replication Studies.** *T. Tahira[1], K. Masumoto[1], A. Yoshinaga[1], Y. Okazaki[1], Y. Kochi[2], K. Yamamoto[3], T. Horiuchi[4], K. Hayashi[1].* 1) Division of Genome Analysis, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Laboratory for Autoimmune Diseases, Center for Genomic Medicine, RIKEN, Tokyo, Japan; 3) Department of Allergy and Rheumatology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Department of Medicine and Biosystemic Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Systemic lupus erythematosus (SLE) is an autoimmune disease in which multiple genetic and environmental factors are involved. To identify the genetic background of SLE susceptibility in Japanese, we performed two-stage pooling-based association study, that is, array-based hybridization analysis followed by SSCP analysis, of case pools (sizes 264 and183) and control pools (sizes 426 and 253). Each of the pooled samples was hybridized to six Affymetrix 500K array sets. The disease association was evaluated by silhouette score (calculated by Genepool 0.8.1, http://genepool.tgen-.org/) and interpreted by a sliding-window statistics of median rank in seven different window sizes. SNPs of highest scores in the top 30 regions for each window size, that covers 68 genomic regions were re-examined by quantitative SSCP (http://qsnp.gen.kyushu-u.ac.jp/placeSSCP/), and the associations (estimated $P < 10^{-4}$) for SNPs in 14 regions were confirmed. The association of these SNPs was further verified by individual genotyping using TaqMan assay. We genotyped additional samples (128 cases and 368 controls) and found consistent association in 5 regions. We then examined additional samples (606 cases and 940 controls) as further replication, and significant associations were confirmed for all that were examined (combined values in allelic test: ZPBP-IKZF1, $P = 7.7 \times 10^{-14}$, OR =1.50; PRDM1-ATG5, $P = 5.1 \times 10^{-10}$, OR = 1.4; HLA-G, $P = 3.6 \times 10^{-8}$, OR = 1.34). These three SNPs were all located outside the genic regions and regulatory roles are suspected. Interestingly, the SNP in ZPBP-IKZF1 is in strong linkage disequilibrium with one of the risk variant of Crohn's disease, indicating that this region is shared genetic risk factor for these two autoimmune diseases. This study showed pooling-based GWAS that combines microarray and quantitative SSCP analyses are cost-efficient and effective method in the search for disease related regions.

**Genome-Wide Association Study of Body Mass Index and Follow-up Candidate Genotyping in African Americans: the IRAS Family Study.** *M. Talbert[1, 2], M. Wing[1, 3], N. Allred[1], J. Ziegler[4], C. Langefeld[4], L. Wagenknect[4], K. Taylor[5], J. Norris[6], T. Haritunians[7], M. Bryer-Ash[8], D. Bowden[1, 3, 9].* 1) Center for Human Genomics, Wake Forest University School of Medicine, Winston Salem, NC; 2) Program in Molecular Medicine and Translational Sciences, Wake Forest University School of Medicine, Winston Salem, NC; 3) Program in Molecular Genetics, Wake Forest University School of Medicine, Winston Salem, NC; 4) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston Salem, NC; 5) Medical Genetics Institute, Department of Cardiology, Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, CA; 6) University of Colorado Health Sciences Center, Denver, CO; 7) Departments of Human Genetics, University of California, Los Angeles, CA; 8) Section of Endocrinology and Diabetes, Program for Adult Metabolic Health, Univ of Oklahoma Health Sciences Center, Oklahoma City, OK; 9) Departments of Biochemistry and Internal Medicine, Wake Forest University School of Medicine, Winston Salem, NC.

Obesity's highest prevalence is among ethnic minorities, but little is known about its genetic components in these groups. The Insulin Resistance Atherosclerosis Family Study (IRASFS) has examined 581 African Americans (AAs) from Los Angeles, CA for adiposity traits, including Body Mass Index (BMI;Mean BMI=30.0 kg/m2,Age=42.9,Female %=59.2). A GWAS using the Affymetrix 6.0 platform was performed in a subset of 254 IRASFS AAs (Mean BMI=30.1 kg/m2,Age=45.2,Female %=57.5). Analysis of the GWAS SNPs using the additive model of PLINK on residual BMI (after adjustment for age and gender) revealed a number of genic SNPs among the top 20 associated variants. Among the BMI candidate genes were CYP19A1 (Aromatase, mediates estrogen synthesis from androgens) and the proximal GLDN (Gliomedin,helps form nodes of Ranvier along myelinated axons), TMEFF2 (Tomoregulin,a cell survival and noted neurotrophic factor), and PEPD (Prolidase,metabolizes iminodipeptides containing C-terminal prolines). Genotyping of the most significant BMI-associated genic GWAS SNPs, as well as nearby GWAS-typed SNPs of MAF>5% and P-values<1x10-4, was completed in a replication set (the untyped IRASFS AAs;n= 330). The follow-up genotyping analysis utilized the variance component method of SOLAR, adjusting for age and gender. An intronic SNP in CYP19A1 was associated with BMI (rs7168331;P=5.1x10-7) in the initial GWAS. In the follow-up, rs7168331 of CYP19A1 and rs12148477 of GLDN were associated in the total IRASFS AA cohort (P-values=6x10-4 and .007), but only rs7168331 was associated in both the IRASFS AA GWAS (P=6 x10-4) and Replication (P=0.026) subsets using SOLAR. In the GWAS, TMEFF2 intronic SNPs were associated with BMI (rs4644972,rs2356953,rs4644972;P-values range from 1.1x10-7 to 3.6x10-6). In the follow-up, TMEFF2 SNPs rs7597998 and rs2356953 were associated in the combined IRASFS AAs (P=1.0x10-4 and 2.5x10-5), the GWAS (.007 and 5.7x10-4), and Replication (5.0x10-5 and 2.0x10-3) subsets. Finally, in the GWAS, an intronic SNP of PEPD was associated with BMI (rs4362488;P=3.4x10-6). In the follow-up, PEPD SNPs rs9676705 and rs11084731 showed only trending association with BMI in the combined IRASFS AA cohort (P=.065 and .088). That many of the associated genes have physiologic links to adiposity strongly supports the significance of these findings in AAs. Additional genotyping of tagSNPs in LD blocks of observed association in both the IRASFS AAs and additional populations is ongoing.

## 1011/W/Poster Board #669

**Genome-wide association study of percent body fat.** *B. Tayo[1], S. Kang[2], A. Luke[1], A. Adeyemo[3], C. Rotimi[3], X. Zhu[2], R. Cooper[1].* 1) Loyola University Chicago, Maywood, IL; 2) Case Western Reserve University, Cleveland, OH; 3) NIH Intramural Center for Genomics and Health Disparities, Bethesda, MD.

With the advent of genome-wide association studies, many common genetic variants have been identified to associate with obesity and some of its related traits. However, the identified variants collectively explain only a small fraction of the heritability of these traits, suggesting that some other genetic variants with stronger effect sizes remain to be identified. To identify additional variants accounting for yet unexplained fraction of genetic variation in obesity-related traits, we performed genome-wide association analysis of percent body fat using 823347 single nucleotide polymorphisms (SNPs) from the autosomal chromosomes in a sample of 660 unrelated adult African Americans from Maywood, Illinois who were genotyped on Affymetrix 6.0 platform. Residuals from linear regression of percent body fat on sex, age and body mass index served as phenotype in the fitted additive genetic model for each SNP. After applying genomic control to account for possible inflation in association estimates, we observed 7 SNPs with $P < 1.0 \times 10^{-5}$. We tested these SNPs in another sample of 205 unrelated adult Nigerians both separately and in meta-analysis with the Maywood samples. One of the SNPs, rs1431719 which is located on the CHRM3 gene had $P = 0.0001321$ for the same reference allele and with an effect size in the same direction in the Nigeria samples. Likewise, in the meta-analysis of both Maywood and Nigeria data, rs1431719 attained *p-value* of $6.17 \times 10^{-8}$ after applying genomic control. While additional replication is required, this report however presents evidence of possible association of rs1431719 with body fat in these African-origin populations.

## 1012/W/Poster Board #670

**PARK2 and SVOPL loci are associated with successful aging in the Amish.** *D.R. Velez[1], J.R. Gilbert[1], J.L. Myers[1], L. Jiang[2], A.C. Davis[2], P.J. Gallins[1], I. Konidari[1], L. Caywood[1], M. Creason[1], D. Fuzzel[1], C. Knebusch[2], R. Laux[2], M.L. Slifer[1], C.E. Jackson[3], M.A. Pericak-Vance[1], J.L. Haines[2], W.K. Scott[1].* 1) Miami Institute for Human Genomics, University of Miami, USA; 2) Center for Human Genetic Research, Vanderbilt University, USA; 3) Scott & White, Temple, TX.

Successful aging (SA) is defined as living to older age with high physical function, preserved cognition, and continued social engagement. Identification of both disease-causing and health-promoting polymorphisms and their interactions with the environment has the potential to greatly improve the health of older adults, the most rapidly growing segment of the U.S. population. Several domains underlying SA have evidence of heritability: longevity, grip strength, lower extremity function, and retention of cognitive ability. In the present study we examined 263 cognitively intact Amish individuals age ≥80 all of whom are part of a single 11-generation pedigree. These individuals were included in a genome-wide association study (GWAS) using the Affymetrix Genome-Wide Human SNP Array 6.0. 74 individuals met criteria for SA (cognitively intact, not depressed, satisfied with life, little self-reported limitation in activities of daily living or musculoskeletal function, in the top 1/3 of the sample on a lower-extremity physical function test) and were compared to the other 189 individuals in a case-control analysis. We also analyzed association with grip strength as an independent marker of musculoskeletal function. After data cleaning, 630,439 autosomal SNPs were analyzed for association with SA using the MQLS method and for association with grip strength using the GRAMMAR-GC method implemented in GenABEL. Both methods use pairwise kinship coefficients to adjust for correlations among related individuals. Chromosome 6q25-q27 (including the FRA6E fragile site and PARK2 locus) contained several SNPs strongly associated with SA (min p = 2 x 10-6) and analyses of grip strength, produced a genome-wide significant result (p = 1 x 10-7) in the SVOPL gene on chromosome 7q34. The associations of genes in the chromosome 6 region are of particular note because PARK2 has been associated with several other aging-related phenotypes including Parkinson's disease, general neuron degeneration, and several forms of cancer. Although the role of SVOPL in aging is unknown, the adjacent gene transcriptional intermediary factor alpha 1 (TRIM24) has been associated with several cancers. Both PARK2 and TRIM24 have been described as tumor suppressor genes, consistent with the theory that preserved DNA repair and tumor suppression activity are essential mechanisms for cancer-free longevity and successful aging.

## 1013/W/Poster Board #671

**A novel efficient genome-wide association study design: Application to glaucoma and age-related macular degeneration.** *K. Wang[1], T.E. Scheetz[2], A.J. Grundstad[3], J.S. Beck[4,5], T.L. Casavant[3], T.A. Braun[6], J.C. Folk[2], J.H. Fingert[2], E.M. Stone[2,5], V.C. Sheffield[4,5].* 1) Dept of Biostatistics, Univ Iowa, Iowa City, IA; 2) Dept of Ophthalmology and Visual Sci, Univ Iowa, Iowa City, IA; 3) Cntr Bioinformatics Comput Biology, Univ Iowa, Iowa City, IA; 4) Dept of Pediatrics, Univ Iowa, Iowa City, IA; 5) Howard Hughes Medical Institute; 6) Dept Biomedical Engineering, Univ Iowa, Iowa City, IA.

Primary open angle glaucoma (POAG) and age-related macular degeneration (AMD) are the two leading causes of irreversible blindness in developed countries. Common genetic variants leading to increased risk of AMD have been identified. Although genetic mutations leading to Mendelian forms of open-angle glaucoma have been identified, genome-wide association studies (GWASs) identifying loci involved in POAG have been lacking. We conducted a GWAS on POAG and AMD with a novel efficient study design. This experiment design maximizes the power to detect disease-associated risk alleles by utilizing both cohorts for discovery: the AMD cohort is the control for the POAG cohort, and vice versa. Allele frequencies in Caucasian populations as determined by the HapMap project are used to infer whether a significant SNP is associated with POAG or AMD. This study involves 400 POAG patients and 400 AMD patients using the Affymetrix 500 K SNP array and the Mapping 5.0 array. Two novel POAG associated loci have been identified. Previously reported AMD associations with CFH gene and ARMS2 gene are confirmed.

## 1014/W/Poster Board #672

**Identification of susceptibility genes/loci of Kawasaki disease in Han-Chinese through genome-wide association study.** *N. Wang[1], F.J. Tsai[2], C.H. Chen[1], L.C. Chang[1], Y.T. Chen[1,3], J.Y. Wu[1].* 1) IBMS, Academia Sinica, Taipei, Taiwan; 2) Col Chinese Medicine, China Medical University, Taichung, Taiwan; 3) Dept Pediatrics, Duke Uni Medical Ctr, Durham, NC.

Kawasaki disease is an acute systemic vasculitis with unidentified etiology, mainly affecting infants and children under 5 years old. The Northeast Asia countries, including Japan, Korea and Taiwan, are found to have the highest incidence rate when compared to other parts of the world. Therefore, a genetic susceptibility of the disease is suggested, although no genes or markers have been consensually confirmed with such role. We carried out a Genome-Wide Association Study with the purpose to identify genes and/or markers that dictate the genetic susceptibility of Kawasaki disease in the Han Chinese population residing in Taiwan. A total of 250 Kawasaki patients and 446 controls have been genotyped with Affymetrix Genome-Wide Human SNP Array 6.0. After filtering with quality control measures, a total of 51 SNPs were found to be significantly associated with P values less than 10-7. Analysis on the location of these SNPs identified 12 loci that contain more than two significantly associated SNPs in vicinity. A candidate gene previously reported to be associated with cardiovascular abnormalities in Kawasaki disease was found in one of these loci. We report here one of the first GWAS studies on Kawasaki based on the Han-Chinese patients and present novel loci in addition to a known candidate, as the putative susceptibility genes of Kawasaki disease.

## 1015/W/Poster Board #673

**Genome Wide Association Study (GWAS) of CT-derived measures of abdominal fat in African Americans of the Insulin Resistance Atherosclerosis Family Study (IRASFS).** *M.R. Wing[1], M.E. Talbert[1], M. Bryer-Ash[2], J.M. Norris[3], Y-D.I. Chen[4], L.E. Wagenknecht[5], D.W. Bowden[1].* 1) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Section of Endocrinology and Diabetes, University of Oklahoma Health Science Center, Oklahoma City, OK; 3) Department of Epidemiology, University of Colorado Health Sciences Center, Denver, CO; 4) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC.

Excess visceral adipose tissue (VAT), when compared to subcutaneous fat, causes an increased risk for disease (i.e. diabetes), emphasizing the importance of identifying genes associated with VAT and visceral to subcutaneous ratio (VSR). A GWAS focused on adiposity traits was performed in 254 African American (AA) subjects (mean VAT=96.2;mean VSR= 0.32;mean age=45;58% female) from the IRASFS. The Affymetrix 6.0 platform was used for genotyping. Preliminary analysis using a linear regression on residuals adjusting for familial correlation, age, gender, and BMI under the additive model revealed several genic hits among the top 20 associated SNPs for abdominal CT-derived measures (L4/L5 slice) of VAT and VSR. SNPs associated with VAT were in the genes *FETUB* (which regulates the insulin receptor and hepatocyte growth factor receptor), *PTPRD* (which promotes neurite growth and regulates neurons axon guidance), and *STAT3* (a transcriptional activator stimulated by cytokines and growth factors). VSR associated SNPs were in *MYO18B* (which regulates muscle specific genes and intracellular trafficking), *PDSS2* (second subunit of the enzyme that synthesizes Q10 ubiquinone), and *IQGAP1* (which regulates cell morphology and motility). High scoring SNPs and other GWAS variants (MAF>5% and P≤1E-4) in these genes associated with VAT and VSR were subsequently genotyped in additional cohort samples (n=330). Analysis was completed using the variance component approach in SOLAR, adjusting for age, gender, and BMI. SNPs associated in the GWAS with VAT in *FETUB* (rs1047115, rs7999;P<7E-5) and *PTPRD* (rs10977342;P=2.2E-5) were trending or associated in both the replication subset (P≤0.05) and in the total IRASFS AA cohort (P<2.5E-4). The *STAT3* SNP associated in the GWAS (rs3785898;P=1E-5) was only associated in the combined population (P=1E-3). The variants within *MYO18B*, *PDSS2*, and *IQGAP1* were associated with VSR in the GWAS (P<4.4E-4), but were only associated or trending in the total IRASFS AA (P<0.06). Interestingly, the SNPs within these genes were also associated with VAT in the GWAS (P<2.0E-3) and trending or associated in the combined population (1.7E-3<P<0.08). However, only SNPs within *PDSS2* (rs12215105) and *MYO18B* (rs6004901) also showed trends with VAT in the replication subset (P<0.086). Our results illustrate novel VAT and VSR genic hits in African Americans that are functionally relevant. Genotyping of tagSNPs in LD blocks within these genes is currently underway.

## 1016/W/Poster Board #674

**Treatment-refractory schizophrenia in Han Chinese.** *J.Y. Wu[1], C.J. Hong[2], H.H. Wang[1], Y.J. Liou[2], C.H. Chen[1], Y.T. Chen[1].* 1) Institue of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Taipei Veterans General Hospital.

This genome-wide association (GWA) study aims to identify genes susceptible to treatment refractory schizophrenics (TRS). A total of 418 TRS patients, who showed refractory symptoms for at least two separated 6-week treatments (equivalent to 600mg Chlorpromazine) or who received treatment of Clozapinethe, were recruited from major psychiatric centers in Taiwan. The patients and 446 controls have been genotyped with Affymetrix Genome-Wide Human SNP Array 6.0. More than 20 SNPs showed highly significant signals ($p < 5 \times 10\text{-}8$) in association analysis. Genes located nearby those SNPs and expressed predominantly in the brain and central nervous system were identified. Those genes were found to be involved in neuronal cell-adhesion, neuronal cell surface interaction, adenylate cyclase regulation, circadian regulation, glutamate receptor, cation channel (sodium or calcium), neuromodulator, etc. Most of those genes were not previously reported to be associated with schizophrenia. We report here the first GWAS studies on schizophrenia based on the Han-Chinese patients and present novel loci as the putative susceptibility genes of schizophrenia.

## 1017/W/Poster Board #675

**Genome-wide association study of hematocrit, hemoglobin, and red blood cell indexes.** *J.-P. Lin[1], S. Ganesh[2], CHARGE Consortium.* 1) Office of Biostatistics Research/Devision of Cardiovascular Sciences/National Heart, Lung, and Blood Institute; 2) Nationl Human Genome Research Institute.

Hematocrit, hemoglobin, erythrocyte count, mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration are widely reviewed in clinical practice and have a heritability of 40-90%. Hematocrit, hemoglobin and red cell indices are associated with a variety of co-morbid-conditions especially vascular diseases and mortality. We performed a genome-wide association study with 2.5 million genotyped and imputed autosomal SNPs in up to 24,807 subjects of European ancestry from six cohort studies within the CHARGE Consortium to identify loci associated with each of the six traits. We identified associations across the six correlated traits on 22 distinct chromosomal locations (p=1.3E-8 to p=1E-57), confirming several known loci like HBS1L-MYB,6q23.3 (p=1E-57), HFE,6p22.1 (p=1.4E-27) and TMPRSS6,22q12.3 (p=1.1E-30); and identifying many novel ones. Among them, several genes are related to iron homeostasis, erythropoiesis, red blood cell membrane structure and have been reported to be associated with blood pressure and coronary heart disease. This large GWAS provides substantial insight into the genetic architecture of red blood cell traits in the general population revealing promising molecular links between these traits, especially hematocrit, and vascular diseases.

## 1018/W/Poster Board #676

**Genome Wide Association Study of Non-Diabetic End Stage Renal Disease in African Americans using Pooled DNA.** *M.A. Bostrom[1,4,5], L. Lu[2], J. Chou[2], P.J. Hicks[1], J. Xu[4,5], C.D. Langefeld[2], B.I. Freedman[3], D.W. Bowden[1,4,5].* 1) Dept Biochemistry, Wake Forest Univ, Winston-Salem, NC; 2) Biostatistical Sciences, Wake Forest Univ, Winston-Salem, NC; 3) Internal Medicine/Nephrology, Wake Forest Univ, Winston-Salem, NC; 4) Center for Human Genomics, Wake Forest Univ, Winston-Salem, NC; 5) Center for Diabetes Research, Wake Forest Univ, Winston-Salem, NC.

African Americans have increased susceptibility to non-diabetic (hypertensive) end stage renal disease (ESRD) and previous studies have demonstrated a genetic component to the disease in this population. To identify genes associated with non-diabetic ESRD in African Americans, we performed a genome wide association study (GWAS) on 1000 African American non-diabetic ESRD cases and controls. Sample DNA was genotyped as pools for the GWAS and significant associations were confirmed with individual genotyping. DNA from 500 case and 500 control samples was quantified using gel electrophoresis and spectrophotometric analysis. Each DNA sample was normalized to a concentration of 50ng/μl. Samples were pooled to create 10 case pools and 10 control pools with each pool containing 50 samples. DNA pools were genotyped in duplicate on the Illumina HumanHap550-Duo BeadChip. Channel intensities were extracted from the Bead Studio data and channel means were normalized. Allele frequencies were calculated from the normalized channel intensities. A t-test was used to compare allele frequencies from case and control pools. Fourteen SNPs had p-values less than $1.0\times10^{-5}$. To confirm association, twenty-five of the most significantly associated SNPs were individually genotyped on 662 AA non-diabetic ESRD cases and 740 controls. Five SNPs were significantly associated after correction for multiple testing ($p < 0.002$). Three of these SNPs, rs9610448 ($p = 8.0\times10^{-8}$, odds ratio (OR) =0.64, confidence interval (CI) = 0.54-0.75; additive model), rs4821467 ($p = 1.13\times10^{-10}$, OR=1.66, CI= 1.42-1.94, additive model) and rs713753 ($p = 1.9\times10^{-13}$, OR=.41, CI=.32-.52, dominant model) are located on chromosome 22 near MYH9 gene which has been shown previously to be associated with non-diabetic ESRD. The remaining SNPs (rs4733947 and rs4658749) are located on chromosome 8 in the TACC1 gene ($p = 1.9\times10^{-5}$, OR=0.67, CI=0.56-0.8, additive model) and on chromosome 1 in the KIF26B gene ($p = 4.5\times10^{-4}$, OR=0.73, CI=0.62-.86, additive model). We have performed the first GWAS for non-diabetic ESRD in an African American population using pooled DNA samples. Through individual genotyping we have confirmed association at five SNPs, rs9610448, rs4821467, rs713753, rs4733947, and rs4658749. Additional populations will be needed for replication studies. In addition, by using other normalization methods and individual genotyping, we are identifying additional SNPs associated with non-diabetic ESRD.

## 1019/W/Poster Board #677

**Genomewide Association Study of Generalized Vitiligo in a European Founder Population Identifies *SMOC2*, in the Vicinity of *IDDM8*.** *S. Birlea, P. Fain, R. Spritz.* Human Medical Genetics Program, Univ Colorado Denver, Aurora, CO.

Generalized vitiligo is a disorder in which patchy loss of skin and hair pigmentation results from autoimmune loss of melanocytes in skin and hair. We previously characterized an isolated founder population in Romania with greatly elevated prevalence of generalized vitiligo (2.9%) as well as other autoimmune diseases, including autoimmune thyroid disease, rheumatoid arthritis, and type 1 diabetes mellitus. Here, we describe a genome-wide association (GWA) study of 310,598 SNPs in 32 distantly related villagers with generalized vitiligo and 50 healthy controls from surrounding villages. After data-cleaning and correction for relatedness among cases, vitiligo was significantly associated with SNPs in a 30-kb LD block on chromosome 6q27, in the immediate vicinity of a linkage region (*IDDM8*) previously identified for type 1 diabetes mellitus and rheumatoid arthritis, autoimmune diseases that are epidemiologically associated with generalized vitiligo in this founder population. The region of association contains only one gene, *SMOC2*, within which SNP rs13208776 attained genome-wide significance for association with generalized vitiligo ($P = 3.13\text{E-}08$) at odds ratio 7.45 (95% CI = 3.56 - 15.53) for the high-risk allele and population attributable risk 28.00. *SMOC2* encodes a modular extracellular calcium-binding glycoprotein of unknown function. Our findings indicate that *SMOC2* is a novel risk locus for generalized vitiligo and perhaps other autoimmune diseases.

## 1020/W/Poster Board #678

**Genomewide Association Study of Generalized Vitiligo.** *Y. Jin, S. Birlea, S. Riccardi, P. Holland, K. Gowan, P. Fain, R. Spritz, the VitGene Generalized Vitiligo Consortium.* Human Medical Genetics Program, Univ Colorado Denver, Aurora, CO.

Generalized vitiligo is a common autoimmune disease, in which patches of depigmented skin and hair result from loss of melanocytes from the involved regions. Generalized vitiligo is the 4th or 5th most frequent autoimmune disease, and the consequent white patches can result in significant psychosocial trauma, particularly in patients from highly pigmented ethnic groups. About 20-30% of vitiligo patients develop other autoimmune diseases, most often autoimmune thyroid disease, psoriasis, adult-onset type 1 diabetes, rheumatoid arthritis, pernicious anemia, lupus, and Addison's disease. We have carried out a genomewide association (GWA) study of generalized vitiligo. We initially genotyped 610,000 SNPs in 1509 unrelated Caucasian (CEU) generalized vitiligo patients from the USA, Canada, and UK, and compared the results with a dataset of 3505 CEU controls obtained from dbGaP. We first specifically analyzed data for several candidate genes that have previously been implicated in generalized vitiligo. We observed exceedingly significant association with numerous SNPs in the MHC, including several that are associated with autoimmune susceptibility. We also observed highly significant association with rs2476601 in *PTPN22* and a SNP that tags rs231775 in *CTLA4*, both SNPs that are thought to be causally related to autoimmune disease susceptibility. Data for *NLRP1*, which has been associated with generalized vitiligo in multiplex families, were equivocal. We next analyzed the data genomewide to prioritize SNPs for replication testing. We are currently conducting a replication study of several hundred SNPs that were highly ranked in the genomewide screen, genotyping these SNPs in over 250 CEU trios and over 250 CEU multiplex families, together comprising ~1000 trios, as well as an additional 750 unrelated CEU generalized vitiligo cases versus controls. We anticipate that the results of these analyses will identify novel loci that are associated with genetic susceptibility to generalized vitiligo, including susceptibility loci shared with other autoimmune diseases.

## 1021/W/Poster Board #679

**Joint analysis of genome-wide association studies of multiple related phenotypes.** *K.I. Morley[1,2], J.C. Barrett[1], UK IBD Genetics Consortium and Wellcome Trust Case Control Consortium.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, School of Population Health, The University of Melbourne, Melbourne, Australia.

Genome-wide association (GWA) studies of autoimmune disorders have identified over 50 associated genomic regions, many of which appear to be involved in pathogenesis of more than one condition and suggest the presence of common disease mechanisms. One example of this is Crohn's disease (CD) and ulcerative colitis (UC); GWA studies have identified numerous genomic regions associated with these diseases, many of which are shared between the two disorders. Finding shared genes is, however, complicated by the fact that a risk allele for one autoimmune disorder may be protective against another (e.g. the protective allele of PTPN22 in CD confers risk for type 1 diabetes). We report two efforts to identify shared genes for autoimmune disorders using data on CD, rheumatoid arthritis, type 1 diabetes, and UC from the Wellcome Trust Case Control Consortium. First we have conducted a large-scale joint GWA study of CD and UC, using 4,176 cases (1,748 CD, 2,428 UC) and 5,539 controls. This simple approach, when applied to closely related traits replicates previous findings of genes associated with both CD and UC such as IL23R and TNFSF15, some of those associated with more numerous autoimmune disorders such as PTPN2, as well as highlighting potentially novel associations that require further investigation. Second, in order to search for loci with allelic heterogeneity among diseases, we have implemented tests that pool information from multiple SNPs in a gene- or locus-centric approach.

## 1022/W/Poster Board #680

**Genome-wide association study of Invasive Pneumococcal Disease.** *A. Rautanen[1], T. Mills[1], I. Prokopenko[1], D. Crook[2], TN. Williams[3], A. Scott[3], SJ. Chapman[1], AV. Hill[1].* 1) WTCHG, University of Oxford, Oxford, United Kingdom; 2) Department of Microbiology, John Radcliffe Hospital, Oxford, United Kingdom; 3) Kenya Medical Research Institute/Wellcome Trust Programme, Centre for Geographic Medicine Research, Coast, Kilifi District Hospital, Kilifi, Kenya.

Infection with *Streptococcus pneumonia* is a major global problem and a common cause of death even in Western Countries. Colonisation of the nasopharynx by pneumococcus is widespread, yet only a minority of patients develop invasive disease, which is defined by the isolation of pneumococcus in a normally sterile site. Current understanding of the host genetic factors which influence the development of Invasive Pneumococcal Disease (IPD) is limited. Earlier studies have identified several susceptibility genes for IPD, but only a minority of these have been replicated. No genome-wide association studies for IPD have been reported to our knowledge.

We have conducted a genome-wide association study of 400 severe IPD cases and 1,300 publicly available controls from the UK. This is one of the largest collections of DNA samples from patients with IPD available worldwide. The genotyping of both cases and controls was performed using the Affymetrix 6.0 SNP chip, which consists of nearly 1 million SNPs. Following stringent QC criteria and association analysis, 4 loci showed association at $p<5x10^{-6}$, and a further 19 loci at $p<5x10^{-5}$. Three highly significant association signals in 1q32, 6p21 and 7q11 are located in genes that are directly involved in immune function. Others, such as those encoding for transmembrane ion channels might be involved in immune-related processes. Follow-up replication of the tagSNPs, capturing common variation within the most interesting loci, is ongoing in the sample set that consists of Kenyan children with pneumococcal bacteraemia, a severe manifestation of IPD, and healthy Kenyan children as controls. Investigation of the selected loci in the sample of African descent may allow us to define the boundaries of the IPD susceptibility loci with greater precision due to lower LD observed in Africans.

Furthering knowledge of the pathogenesis of invasive pneumococcal infection by identifying new susceptibility genes is extremely important, given the current limited understanding of the genetic basis of invasive bacterial infection and the huge global burden of the disease. The identification of functional genetic variants that predispose individuals to IPD is likely to have major implications for the study of other infectious and inflammatory disease processes as well.

## 1023/W/Poster Board #681

**Whole-genome association studies of severe malaria.** *K. Small, Malaria Genomic Epidemiology Network.* WTCHG, Oxford Univ, Oxford, United Kingdom.

Malaria kills approximately a million children each year, but a much larger number survive despite repeated infections. Human genetic factors have been estimated to determine 25% of severe malaria risk, of which known genetic variants account for a small fraction. The Malaria Genomic Epidemiology Network (partner institutions listed at www. malariagen.net) was established to carry out multicenter studies investigating the genetic basis of resistance to malaria. We present the results of genome-wide association studies of severe malaria in West and East Africa and discuss the implications for further genome-wide association studies in Africa.

## 1024/W/Poster Board #682

**Genome-wide association study identifies novel loci associated with endometriosis in a Caucasian population.** *H. Albertsen, K. Ward, G. Frech, P. Farrington, S. Dintelman.* Juneau Biosciences, LLC, Salt Lake City, UT.

Endometriosis is a complex condition of uncertain etiology in which endometrial glands, stroma, and/or tissue normally confined to the inner lining of the uterus is found outside the uterus, most often in the pelvic area. Endometriosis is further characterized by inflammation, cysts, and scarring at affected sites, as well as by pelvic pain, dysmenorrhea, and infertility. Endometriosis affects up to 10% of reproductive-age women. Using a large population-based genealogy database, we have demonstrated a significantly elevated kinship coefficient between endometriosis patients compared to matched population control sets. Family studies have also determined the relative risk of developing endometriosis among first-degree relatives to be 4-8 fold higher than the risk in the general population. Genetic association studies have cumulatively tested association between endometriosis and over 50 genes from numerous pathways, including cytokine signaling and cellular differentiation and regulation. To further elucidate the genetic underpinning of endometriosis, we undertook a genome-wide association study that involved 588 endometriosis patients and 1534 controls. Genotyping was performed using the Affymetrix 6.0 GeneChip. Of the 906,600 SNPs present on the 6.0 chip, 673,708 SNPs remained after filtering. Participants were initially evaluated for ethnicity using principal components analysis as implemented in the Eigenstrat package and subsequently analyzed for association using the Armitage Trend test as implemented in the PLINK package. In all, a total of 90 SNPs were identified with p-Trend values less than $10^{-4}$. We identified 12 autosomal SNPs with p-values between $9.40x10^{-6}$ and $1.56x10^{-8}$ and odds ratios between 0.23 and 1.86. The genes most closely located to these SNPs include *FSTL5*, *ZNF366*, *HLA-G*, *TBL2*, *FOXP2*, *SNX16*, *MPDZ*, *PAPPA* and *KCTD12*. The results presented here strengthen the evidence for a genetic component in endometriosis. As our case population expands, we expect these findings to strengthen further.

## 1025/W/Poster Board #683

**Association of the Protocadherin gene cluster on chromosome 5q31 with extreme obesity in the NHLBI Family Heart Study (FamHS).** *I.B. Borecki[1], M.F. Feitosa[1], R.H. Myers[2], J.B. Wilk[2], Q. Zhang[1], S. Ketkar[1], D.M. Becker[3], L.C. Becker[3].* 1) Division of Statistical Genomics, Washington University School of Medicine, St Louis, MO; 2) Department of Neurology, Boston University, Boston, MA; 3) Division of General Internal Medicine, The Johns Hopkins University School of Medicine.

The prevalence of obesity is increasing in the United States, particularly extreme obesity with its profound morbidities. We sought associations of common variants with extreme obesity (E_OB: BMI≥35.0 kg/m$^2$; N = 63) versus controls (18<BMI<27.0 kg/m$^2$; N=421) in the FamHS. Genotypes were assessed using the Illumina HumMap550 chip, and we imputed up to ~2.5 million SNPs based on HapMap Release 22 CEU phased haplotypes. Logistic regression, adjusting for age, sex, and field center effects that account for population stratification, was carried out, assuming additive SNP effects. The strongest association meeting genomewide significance occurred within the protocadherin (PCDH) gene cluster on 5q31 (p = 1.72e-08), in a broad region of linkage disequilibrium. In all, 48 SNPs in a vicinity spanning ~110 kb, showed evidence of association (P<1e-06); the minimum pairwise LD was D'=1 ($R^2$=0.75). For the SNP with strongest association, the minor allele was associated with an increased risk of E_OB (OR=4.43, CI:2.517.85, for each copy of the risk allele). Referring to the broader cohort of 1,000 subjects from which this sample of cases and controls was selected, the mean BMI was 27.5, 29.7, and 35.6 kg/m$^2$ for genotypes with 0, 1, and 2 copies of the risk allele, respectively, and the SNP accounts for 2.2% of BMI variability. We attempted to validate these associations in an independent sample of 1,251 Caucasian subjects from the Genetic Study of Aspirin Responsiveness (GeneSTAR) study. We tested all 48 PCHD SNPs for association with either E_OB (N=163) or Obesity (N=403; OB: defined as BMI ≥ 30.0 kg/m$^2$). While only 3/48 SNPs replicated for E_OB (p<0.01), virtually the entire region replicates with the OB trait with 37/48 SNPs significant at nominal levels; 9 additional SNPs within the focal LD region also were significant in the GeneSTAR data alone. This is a complex region including several closely-linked members of the protocadherin family, with overlapping reading frames, and with strong LD throughout, thus additional dissection of the region and the signal is needed. The protocadherins are members of the cadherin superfamily. While cadherins have a known role in cell adhesion, evidence suggests protocadherins are highly expressed in the central nervous system, and are involved in the modulation of synaptic transmission and the generation of specific synaptic connections, suggestive of a neuronal pathway influencing obesity.

## 1026/W/Poster Board #684

**Genetic variants in the RELN gene are associated with otosclerosis in populations of European origin.** *G. Van Camp[1], I. Schrauwen[1], M. Ealy[2], M.J. Huentelman[3], M. Thys[1], N. Homer[3,4], K. Vanderstraeten[1], E. Fransen[1], J.J. Corneveaux[3], D.W. Craig[3], M. Claustres[5], C.W.R.J. Cremers[6], I. Dhooge[7], P. Van de Heyning[8], R. Vincent[9], E. Offeciers[10], R.J.H. Smith[2].* 1) Dept Medical Genetics, Univ Antwerp, Antwerp, Belgium; 2) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology, University of Iowa, 200 Hawkins Drive, Iowa City, IA 52242, USA; 3) Neurogenomics division, Translational Genomics Research Institue (TGen) Phoenix, Arizona 85004, USA; 4) Department of Computer Science, University of California, Los Angeles CA 90095-7088, USA; 5) Université Montpellier 1, Faculté de Médecine et CHU, Laboratoire de Genetique Moleculaire, IURC, Montpellier, F-34000 France; 6) Department of Otorhinolaryngology, Donders Centre for Brain, Cognition and Behaviour, University Medical Center St.-Radboud, Philips van Leydenlaan 15, 6500 HB Nijmegen, The Netherlands; 7) Department of Otorhinolaryngology, University Hospital of Ghent, De Pintelaan 185, 9000 Ghent, Belgium; 8) Department of ORL, University Hospital of Antwerp, Wilrijkstraat 10, 2650 Edegem, Belgium; 9) Jean Causse Ear Clinic, Traverse de Béziers, 34440 Colombiers, France; 10) University Department of Otolaryngology, St.-Augustinus Hospital Antwerp, Oosterveldlaan 24, 2610 Antwerp, Belgium.

Otosclerosis is a common form of hearing loss characterized by abnormal bone remodelling in the otic capsule. The etiology of the disease is largely unknown, and both environmental and genetic factors have been implicated. To identify genetic factors involved in otosclerosis, we used a case-control discovery group (604 samples) to complete the first genome-wide association (GWA) study on otosclerosis with 555,000 single nucleotide polymorphisms (SNPs) utilizing pooled DNA samples. By individual genotyping of the top 250 SNPs in a stepwise strategy, we identified two highly associated SNPs on chr7q22.1 and chr11q13.1 that replicated in two additional independent populations (replication set 1: 784 and replication set 2: 935 samples). In addition, this study also highlights the success of pooling DNA samples as the first screening step in a GWA setup, as approximately 85% of top highly ranked SNPs identified by pooling were validated as true differences between cases and controls by individual genotyping of the discovery group. We then genotyped 79 tagSNPs to fine map the genomic regions defined by the associated SNPs. The region with the strongest association signal (pcombined=$6.23x10^{-10}$; OR:1.52), is on chromosome 7q22.1 and is located in the gene Reelin (RELN), a gene known for its role in neuronal migration. Furthermore, evidence for allelic heterogeneity was found in this region. We confirmed expression of RELN in the inner ear and in stapes footplate specimens. Subsequently, we genotyped several SNPs in this region in 4 additional small European populations (1141 samples total), which replicated again in the same direction when combining all 4 populations (pcombined= $4.25x10^{-6}$). In conclusion, we provide evidence that implicate RELN in the pathogenesis of otosclerosis. These results point towards a possible new function for RELN in bone metabolism.

## 1027/W/Poster Board #685

**A genome-wide association study in sarcoidosis reveals a new risk locus at 6p12.1.** *S. Hofmann[1], A. Fischer[1], A. Till[1], H. Schaarschmidt[1], A. Franke[1], M. Nothnagel[2], J. Müller-Quernheim[3], M. Schürmann[4], S. Schreiber[1].* 1) Inst Clinical Molec Biol, Kiel, Germany; 2) Institute of Medical Informatics and Statistics, Kiel, Germany; 3) Department of Pneumology; University of Freiburg, Freiburg, Germany; 4) Institute of Human Genetics, University of Lübeck, Lübeck, Germany.

Sarcoidosis is a complex systemic inflammatory disease with a strong genetic component. To identify sarcoidosis susceptibility loci, we genotyped 116,204 SNPs in 381 sarcoidosis patients and 392 control individuals of German ancestry. We followed up the 25 most strongly associated SNPs in 1,582 sarcoidosis cases and 1,783 controls. Our results provide strong support for the association of one locus on chromosome 6p12.1 and sarcoidosis (nominal $P$ value = $2.64x10^{-4}$ in the GWAS, and $P$ = $1.17x10^{-3}$ in the validation panel). Extensive fine mapping of the novel locus and expression studies of the corresponding genes points to yet unidentified variants in the *XXX*[*] gen as the most likely risk factor. Genetic and functional association of the gene with several kinds of cancer has been shown. Moreover, the gen is a key member of a pathway that has been implicated to play a role in chronic lung fibrosis and immune system communication. Our results extend the list of genetic loci implicated in sarcoidosis susceptibility and suggest a further promising target for study in related complex immune disorders. -------------------------------------------------- [*]anonymized, the gene name and corresponding SNPs will be presented at the meeting.

## 1028/W/Poster Board #686

**A combined genome-wide association scan and proteomics approach for the identification of genetic modifiers of pseudoexfoliation syndrome.** *K. Burdon[1], S. Sharma[1], P. Danoy[2], P. Leo[2], A. Hewitt[1], T. Chataway[3], M. Brown[2], D. Mackey[4], J. Craig[1], Wellcome Trust Case Control Consortium.* 1) Dept Ophthalmology, Flinders Univ, Bedford Park, SA, Australia; 2) Musculoskeletal Genetics Group, UQ Diamantina Institute, The University of Queensland, QLD, Australia; 3) Department of Human Physiology, Proteomics Laboratory, Flinders University, Adelaide, SA, Australia; 4) Centre for Eye Research Australia, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, Australia.

Pseudoexfoliation (PEX) syndrome is an age-related disorder characterized by accumulation of fibrillar extracellular deposits in the anterior structures of the eye. It is the most common identified cause of glaucoma and may lead to severe visual impairment or blindness. Recently, common coding variants in the *LOXL1* gene were associated with PEX in a genome-wide scan conducted in Iceland. This genetic association has now been replicated worldwide. Although a strong association between *LOXL1* and PEX is observed in Australia, the prevalence of the disease is significantly lower at around 5% in those aged over 80 years, compared to approximately 40% in Iceland. The *LOXL1* risk allele frequencies are very similar between the countries. Therefore the penetrance appears to be lower in Australia. Thus we hypothesised that there are additional factors that modify the risk of PEX. We have undertaken a genome-wide association scan on 243 PEX cases from Australia and 1436 individuals from the 1950 British Birth Cohort from the Wellcome Trust Case-Control Consortium as well as 62 Australian control samples. Australian samples were typed on either the Illumina HumanHap 370 or 610 arrays and the WTCCC controls on the 550 array. Analysis was conducted on the subset of SNPs common to all three arrays. After quality control screening, 329422 SNPs were analysed in 243 cases and 1496 controls. Three SNPs around the *LOXL1* gene survived Bonferonni correction for multiple testing with the most significantly associated SNP being rs2165421, p= 1.6x10-20. This confirms that the *LOXL1* gene is the most highly associated gene in the Australian population, as well as in Scandinavia where it was first reported. Multiple other SNPs also survived correction for multiple testing and clusters of highly associated SNPs are observed in many functional candidate genes. These are undergoing further investigation to confirm the results. In parallel with the genetic study, we have undertaken a proteomics approach to dissect the molecular pathology of PEX. PEX material isolated at the time of cataract surgery was chemically cleaved and subjected to mass spectrometry. Multiple novel proteins were identified in the material and are currently undergoing validation by immunohistochemistry. The genome-wide association results will be presented in relation to the mass spectroscopy results and those proteins previously reported to be found in PEX material, or differentially expressed in the disease.

## 1029/W/Poster Board #687

**A PRELIMINARY COMPARISON OF THE DISTAL GUT MICROBIOME IN HIV-INFECTED AND HEALTHY SUBJECTS.** *L.M. Bull[1], B. Youmans[2], Y. Shang[2], S.K. Highlander[2], J.F. Petrosino[2], K.C. Worley[1], L. Armitige[3], R.A. Gibbs[1].* 1) Human Genome Sequencing Ctr, Baylor College Med, Houston, TX; 2) Department of Molecular Virology and Microbiology, Baylor College Med, Houston, TX; 3) Department of Infectious Disease, Internal Med, University of Texas-Health Science Center-Houston, Houston, TX.

Metagenomics has begun to revolutionize our perception of health and disease. Within the last decade the requisite role of the GI tract in acute HIV infection has become increasingly evident and potentially implicates the importance of the microbiome in maintaining homeostasis. To examine the relationship between HIV infection and the distal colon's microbiome, we evaluated the difference in microbial community structure and diversity in HAART-naïve HIV infected patients (CD4 cell count <100 cells/ml) and compared their microbiomes to HIV-negative healthy controls. All subjects were matched by sex, race and age. 16S rDNA from fecal samples was amplified and sequenced using standard Sanger methods (1536 clones, 3072 reads per subject), and the taxonomic groups were compared. We found that in all samples, the predominant bacterial classes were the Clostridia (Phylum Firmicutes) and Bacteroidetes (Phylum Bacteroidetes), and to a lesser extent Actinobacteria (Phylum Actinobacteria). There was greater variation in the number of minor groups found in the control, including representatives from Betaproteobacteria and Erysipelotrichidae, which were not identified in the HIV-infected cases. We also found that in both case groups there was an average reduction of the Bacteroidetes to half of the community membership representation that was observed in the controls and a substantial increase in Clostridia and Bacilli when compared to the controls. Most significantly, there was a clear trend in the differences between the subjects. Group A had a slightly more advanced disease and almost a log greater HIV viral load (average 5.26 log10 copies/ml) than Group B (average 4.32 log10 copies/ml). While both case groups showed drastic changes at the phylum level compared to the controls, Group A also showed both a greater reduction in Bacteroidetes and a greater increase in Firmicutes than Group B, doubling the membership of Bacilli in comparison to Group B. Similarly there was greater variation in the number of minor class groups found in Group B compared to Group A, although there was less variation than found in the controls. This suggests that the shift in the GI microbial structure maybe correlated with HIV viral load in a dose-dependent manner. This is the first study to examine the relationship between HIV infection and the human distal colon's microbiome, and the first to report a possible association between HIV viral load and key microbial community membership.

## 1030/W/Poster Board #688

**Dairy intake associates with the IGF2 rs680 polymorphism to height variation in Greek children. The GENDAI study.** *GV. Dedoussis, E. Louizou, C. Papoutsakis, KP. Skenderi, M. Yannakoulia.* Dietetics-Nutrition, Harokopio University, Athens, Greece.

Objective: Height is a classic polygenic trait with a number of genes underlying its variation. We evaluated the prospect of gene to diet interactions in a children cohort for the IGF2 rs680 polymorphism and height variation. Methods: We screened 795 peri-adolescent children (424 females) aged 10-11 years old from the (Gene and Diet Attica Investigation; GENDAI) paediatric cohort for the IGF2 rs680 polymorphism. Results: Children homozygous for common allele (GG) were taller (148.9 ± 7.9 cm) comparing to those with the A allele (148.1 ± 7.9 cm), after adjusting for age, sex, and dairy intake ($\beta$±SE: 2.1± 0.95, p=0.026). A trend for interaction for the Igfrs680xdairy intake is also revealed (p=0.09). Stratification by IGF2 rs680 genotype revealed a positive association between dairy products intake and height only in A allele carriers, adjusted for the same confounders (standardized $\beta$=0.111, p=0.014). When dairy intake was classified, based on the median value, into two equal groups of low (1.9 ± 0.7 servings/day) and high dairy products intake (4.4 ± 1.5 servings/day), it was found that in A allele children high dairy eaters were significantly taller (p=0.05) compared with low dairy eaters (148.8 ± 7.9 cm vs 147.4 ± 7.7 cm respectively, adjusted for age and sex). Conclusion: A higher consumption of dairy products associated with increased height depending on the rs680 IGF2 genotype. Thus, exploring height variants and elucidating possible interactions with environmental factors like diet could help us to design effective strategies for the prevention of height associated diseases.

## 1031/W/Poster Board #689

**Interaction between maternal smoking and TNF, GSTP1, ADRB2 variants in childhood wheezing.** *F. Nyberg[1, 2], S. Panasevich[1], C. Lindgren[3], J. Kere[4, 5, 6], M. Wickman[1, 7, 8], G. Pershagen[1, 9], E. Melen[1, 10].* 1) Institute of Environmental Medicine, Karolinska Institute, Stockholm, Sweden; 2) Epidemiology, AstraZeneca R&D, Molndal, Sweden; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 4) Clinical Research Centre, Karolinska University Hospital, Huddinge, Sweden; 5) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 6) Department of Biosciences at Novum, Karolinska Institute, Huddinge, Sweden; 7) Sachs Children's Hospital, Stockholm, Sweden; 8) Centre for Allergy Research, Karolinska Institute, Stockholm, Sweden; 9) Department of Community Medicine, Karolinska University Hospital, Stockholm, Sweden; 10) Astrid Lindgren Children's Hospital, Karolinska University Hospital, Stockholm, Sweden.

**Background:** Children exposed to tobacco smoke early in life have higher risk of wheeze. Individual susceptibility may depend on genetic factors. We studied gene-environment interactions between single nucleotide polymorphisms (SNPs) in the *tumor necrosis factor* (*TNF*), *glutathione S transferase P1* (*GSTP1*), $\beta$*2-adrenoreceptor* (*ADRB2*) genes and tobacco smoke exposure in relation to asthma, childhood wheeze and sensitisation.

**Methods:** In the Swedish prospective birth cohort BAMSE (n=4089), data on tobacco smoke exposure and clinical outcomes up to age four were collected by questionnaires, specific IgE measurements and medical examinations. Early tobacco smoke exposure was defined as maternal smoking during pregnancy and/or shortly after childbirth. We investigated 5 *TNF*, 6 *GSTP1*, and 3 *ADRB2* SNPs in 982 selected wheezers and non-wheezers.

**Results:** Significant interaction with tobacco smoke exposure was found for 3 *TNF* SNPs (-857C/T, Intron 1, Intron 3) with respect to early wheeze (up to 2 years of age). For example, the odds ratio (OR) for developing early wheeze related to early tobacco smoke exposure in children with wild type CC homozygote genotype of the *TNF* -857 SNP was 2.3 (95%CI 1.5-3.6), while no risk related to tobacco smoke exposure was seen in carriers of the rare T allele. A clear dose-response was observed, with an OR of 1.2 (95%CI 1.1-1.5) per each additional pack per week smoked by the mother during pregnancy, in children with the common CC genotype. Suggestive interaction was also seen for 3 *GSTP1* SNPs (Intron 5, Intron 6 and Ile105Val) with respect to transient wheeze, but not for *ADRB2* and wheeze. No interactions were suggested for allergic sensitisation.

**Conclusions:** Our results suggest that the risk of early childhood wheeze associated with tobacco smoke exposure may be modified by TNF and GSTP1 polymorphisms.

## 1032/W/Poster Board #690

**Association between *FTO* polymorphism, adiposity peak and adiposity rebound in the Northern Finland Birth Cohort 1966.** *U. Sovio[1], N.J. Timpson[2,3], N.M. Warrington[4], L. Briollais[5], D. Mook-Kanamori[6], M. Kaakinen[7], A.J. Bennett[2], J. Molitor[1], M.I. McCarthy[2], M.-R. Jarvelin[1,7,8].* 1) Imperial College London, UK; 2) University of Oxford, UK; 3) MRC CAiTE Centre, Bristol University, UK; 4) The University of Western Australia, Australia; 5) Mount Sinai Hospital, Canada; 6) Erasmus Medical Center, the Netherlands; 7) University of Oulu, Finland; 8) National Public Health Institute, Finland.

A common variant in the fat mass and obesity related gene (*FTO*) has a strong effect on adult body-mass index (BMI) but its association with BMI development throughout childhood is less well studied. Early age of adiposity rebound (AR), i.e. the point where BMI reaches its minimum in childhood, is associated with higher level of cardiovascular disease risk factors such as obesity, hypertension and diabetes in adulthood. The association between timing of infant adiposity peak (AP) and these risk factors is unclear. This study investigated the association between the *FTO* SNP rs9939609 and both age and BMI at AP and AR using longitudinal data from the Northern Finland Birth Cohort 1966. AP and AR were derived from random effects models fitted at >0-1.5 years and >1.5-13 years (N=2,782 infants and N=3,413 children with minimum 3 measurements per age window). Additionally, correlations between derived parameters and BMI at age 31 were studied. Mean age at AP was 8.8 months and at AR was 5.7 years, and mean BMI at AP was 18.0 kg/m$^2$ and at AR was 15.4 kg/m$^2$. Age at AP correlated weakly with BMI at AP (r=0.04) and at AR (r=0.18) but not at 31 (r=0.02). Age at AR had a weak inverse correlation with BMI at AP (r=-0.05), and a modest inverse correlation with BMI at AR (r=-0.50) and at 31 (r=-0.44). BMI at AP and BMI at AR predicted adult BMI (r=0.20 and r=0.45, respectively). The *FTO* risk allele associated with slightly later AP (3 days per allele, p=0.0002) but it did not associate with BMI at AP (p=0.67). The risk allele associated with earlier AR (1.4 months per allele, p<0.0001) and with higher BMI at AR (0.12 kg/m$^2$ per allele, p<0.0001). The *FTO* effect on BMI increased gradually throughout childhood. This study shows the *FTO* effect is apparent by the time children reach AR.

## 1033/W/Poster Board #691

**Response to microRNA therapy in a model of the commonest human blood cancer.** *N. Zanesi, A. Bottoni, M. Kaou, R. Visone, A. Burch, C. Taccioli, M. Fabbri, S. Costinean, A. Efanov, E. Gaudio, Y. Pekarsky, A. Cimmino, C. Croce.* The Ohio State University, Columbus, OH.

Background: Chronic lymphocytic leukemia (CLL) is the most frequent hematopoietic cancer in adults in the Western world. Previously, we generated transgenic mice over-expressing the TCL1 oncogene in B cells. These mice develop a disease very similar to human CLL. Recent studies showed that CLL harbors also alterations in the microRNAs genes miR-15a and miR-16-1 that are frequently deleted and/or down-regulated in CLL patients. Both microRNAs negatively regulate Bcl2, an anti-apoptotic protein over-expressed in human as well as mouse CLL B cells. Therefore, miR-15 and -16 are natural antisense Bcl2 interactors that could be used for therapy of Bcl2-overexpressing malignancies. Since mouse CLL cells, like in humans, are mostly resting CD5+ B cells, in a previous study we did transplantation experiments of mouse malignant lymphocytes into syngeneic mice in order to expand CLLs in vivo. Purpose: We exploited the in vivo transplants to verify the potential ability of miRs 15/16 to delay or stop mouse CLL. Experimental Design: Ex vivo treatments of CLL cells with miRs 15/16 were performed as follows. White cells with expanded CD5+/IgM+ populations (70 to 95%) were isolated from the enlarged spleen of two syngeneic mice previously transplanted with CLL # 450 and 504 and incubated in vitro in 10% FBS in RPMI medium 1640 in three different conditions: a) regular medium, b) transfected with pSR-GFP-Neo expression lentiviral vector containing both miRNAs (TWEEN-miR15/16), and c) transfected with control empty lentiviral vector. After 2-3 days incubation, fifteen million cells were injected intraperitoneally into new syngeneic mice to monitor the evolution of the disease over time. Results: Eight mice were used as controls (injected with untreated or empty virus-treated cells) and eight more animals were injected with miR-treated cells. After at least 10 months from CLL cells injection, seven control mice were dead (87%) while only one miR-treated mouse died (13%; Fisher's exact test, $p = 0.01$). These findings show a significant delay in the disease due to miR-treatment. Conclusions: This is the first study showing an inhibitory effect of specific microRNAs on CLL phenotype with a therapeutic potential. These promising results from the ex vivo experiments encourage us to try now a direct in vivo approach to demonstrate the tumor suppressor effect of miR 15/16 in the TCL1 mouse model of CLL. Supported by the Sidney Kimmel Foundation for Cancer Research.

## 1034/W/Poster Board #692

**Gorham Stout Syndrome of the skull base.** *E. Prera, N. Lüblinghoff, W. Maier, R. Laszig, R. Birkenhäger.* Otorhinolaryngology H&N Surg, University Medical Center Freiburg, D-79106 Freiburg, Killianstr. 5, Germany.

Background: The Gorham Stout Syndrome (GSS) is exceedingly rare; as fewer as 150 cases have been described worldwide, 31 of which involve the facial skeleton and skull. GSS is characterised as a benign but aggressive angiomatosis of the bone with predilection sites of the shoulder and pelvic girdle. Alterations in the MMP2 and TNFRSF11A genes are potentially involved in the Gorham Stout Syndrome. Case History: A 40-year-old male patient presented himself in 2000 with a right-sided hearing loss and tinnitus for about nine month. He also developed dysphonia and dysphagia followed by headache and neck pain with nausea and emesis. The CT scan showed a pronounced osseous destruction of the skull base. The tip of the right petrous bone was destroyed reaching the semicircular canals. On the left side the inner auditory canal, the jugular foramen and the carotid canal were partly differentiated. The histological finding of an open biopsy showed an unspecific inflammation. Therapy was radiation with 40 Gy. In 2004 the clinical examination proved a now bilateral close to deafness hearing loss. The CT scan showed progression of the osteolytic lesions at the posterior and middle skull base, the petrous bone with complete destruction of the left inner ear. The nystagmography revealed a vestibular failure on the right side with spontaneous nystagmus to the left side. The radiological picture and reanalysing the biopsy (angiomatosis of the bone) supported the suspicion of a GSS. As a differential diagnosis a Schwannoma was considered. Methods: For the background of the patient history we performed direct sequencing of the encoding exons, intron-transitions and the promoter region of the NF2, MMP2 and TNFRSF11A gene. Also a whole genome analysis was accomplished with the Affymetrix 500K SNP array to identified additional factors witch maybe involved in that rare disease. Results: We detected no mutation in the NF2, MMP2 and TNFRSF11A gene. We further identified seven polymorphisms in MMP2 and TNFRSF11A gene that do not seem to cause GSS. Conclusion: The clinical, histological and molecularbiological findings lead to the 3 following differential diagnosis: Gorham Stout Syndrome, NF2 and enlarged chronic osteomyelitis . This case may represent a combination of these three diseases or a new entity because the findings do not match the typical profile of one of the three. Until now it is not conclusively settled if additional genes are involved in this rare disease.

## 1035/W/Poster Board #693

**Investigation of the NPAS3 gene as a candidate in gliomas.** *M.S. Rana[1], F. Morin[1], D. Kamnasaran[1,2].* 1) Pediatrics Research Unit, Laval Hospital Research Centre, Quebec, Canada; 2) Department of Pediatrics, Laval University, Quebec, Canada.

Gliomas are among the most common tumors occurring in ~50-60% of adults and ~30% of children with brain tumors. Overall, the prognosis is still poor especially with those patients diagnosed with a high grade glioma such as Glioblastoma multiforme (GBM). Moreover, there is a current paucity in our knowledge of relevant genetic pathways that contribute towards gliomagenesis. We previously cloned and discovered the NPAS3 gene, a transcription factor mapping to human chromosome 14q13, is mutated in patients with schizophrenia (J Med Genet. 2003 40(5):325-32). In our quest to understand the roles of NPAS3 in human diseases, we investigated this gene as a candidate for gliomas. With the use of RT-PCR, western blot analyses and immuno-histochemistry, we identified NPAS3 expression in human astrocytes. To investigate the link between NPAS3 and gliomagenesis, we identified loss/reduction of NPAS3 protein expression in a panel of human glioma cell lines (n=3/5), and in ~68% of human adult GBM surgical specimens (n=31/46), compared to levels of expression in normal astrocytes. With the use of FISH analyses, we identified both homozygous and heterozygous loss of function deletions of the NPAS3 gene in our panel of human glioma specimens with mutant NPAS3 expression. Furthermore, we discovered that an elevated expression of NPAS3 in a human malignant cell line could significantly suppress the in-vitro and in-vivo transformation potential. The function of the NPAS3 gene is relatively unknown to date. However, our data is the first to suggest a potential functional link between NPAS3 and gliomagenesis, with a potential tumor suppressive role.

## 1036/W/Poster Board #694

**Evidence for a shared CASP8 haplotype associated with multiple common cancers.** *R. Abo[1], Z. Cai[1], L. Wei-Yu[2], G. Elliott[2], SH. Rigas[2], DT. Bishop[3], LA. Cannon-Albright[1], DE. Neal[4], JL. Donovan[5], FC. Hamdy[6], A. Cox[2], NJ. Camp[1].* 1) Biomedical Informatics, Univ Utah, Salt Lake City, UT; 2) University of Sheffield, Sheffield, UK; 3) University of Leeds, Leeds, UK; 4) University of Cambridge, Cambridge, UK; 5) University of Bristol, Bristol, UK; 6) University of Oxford, Oxford, UK.

Recent studies identified a CASP8 variant to be associated with breast cancer in Caucasian women (Cox et al. 2007). Subsequently this was refined to a risk haplotype (Shephard et al. 2009). Given these findings and the key biological role of CASP8 in the apoptosis pathway, it is hypothesized that other common cancers may share CASP8 genetic risk factors. For this study, we analyzed previously generated case-control genotype data for 14 tagging SNPs across CASP8 for breast cancer (brca; n=2,277), prostate cancer (prca; n=2,618) and colon cancer (coca; n=2,178) using hapConstructor (Abo et al. 2008). The 3 cancers were analyzed separately to identify cancer-specific risk haplotypes, as well as together to determine the possibility for shared risk alleles across common cancers. HapConstructor is a haplotype-mining technique that can be used to identify risk haplotypes, which also allows for meta analyses. Very simply, it begins by testing single SNP associations and builds haplotypes SNP-by-SNP based on significance. The initial separate analyses indicated significant haplotypes in all three datasets. Although the haplotypes identified were not identical from each analysis, similarities were evident. The risk direction for brca and coca were in the same direction; however, for prca the direction of the effect appeared to be reversed. To investigate the possibility of shared CASP8 haplotypes across the three common cancers, we performed three hapConstructor meta-analyses: brca and coca: brca and prca (allowing the direction of risk to be reversed for prca); and for all three cancers (again, reversed for prca). Inspection of the most significant haplotypes from each of the three meta analyses indicated extreme consistency with each other and with the previous results from Shephard et al. (2009). From the brca and coca analyses, the most significant haplotype achieved a p-value of $9.0 \times 10^{-5}$. The most significant haplotype from the brca and prca analysis was $p=1.6 \times 10^{-4}$. From the combined three-cancer meta analyses the most significant haplotype was $p=3.0 \times 10^{-5}$. Similarities in these haplotypes results were quite striking and indicative of single underlying risk variant. Whilst these results require replication, the strong concordance observed suggests that a shared genetic factor in CASP8 may be associated with multiple common cancers.

## 1037/W/Poster Board #695

**Molecular characterization of P2X7 gene encoding polymorphisms in the Omani patients with gastric cancer.** *A. Alsaegh[1], A. Al-Shukaili[2], M. Al-Moundhri[3].* 1) University of Calgary/Sultan Qaboos University. 903, 80 Point McKay Cres.NW. Canada, Alberta, Calgary T3B 4W4; 2) Sultan Qaboos University, Department of Microbiology and Immunology. PO Box 35, Muscat 123, Oman; 3) Sultan Qaboos University, Department of Medicine. PO Box 35, Muscat 123, Oman.

Links between cancer and inflammation were first established in the nineteenth century, on the basis of observations that tumour arose at sites of chronic inflammation. The hallmarks of cancer-related inflammation include the presence of inflammatory cells and inflammatory mediators (for example, cytokines and prostaglandins) in tumour tissues, tissue remodelling and angiogenesis similar to that seen in chronic inflammatory responses, and tissue repair. One of the inflammatory mediators that have been proven to be a key mediator in inflammation is interleukin 1 beta (IL-1β). P2X7 receptor plays an important role in the production of IL-1 β. P2X7 is a member of P2X family of nucleotide-gated channels, which in the presence of ATP forms a non-selective channel that allows the passage of molecules. Arg-307 to glutamine (946 G →A ) that lies within the ATP binding pocket of the extracellular domain and if found abolishes the binding of ATP to the receptor. In our study, we are investigating the Arg-307 to glutamine (946 G →A ) polymorphism in exon 9 of the P2X7 gene, in patients with gastric cancer (n=25) and healthy control (n=25). PCR and direct sequencing methods were used to detect this polymorphism. Results: the SNP of P2X7 gene (946 G →A) in exon 9 was not detected in both groups. Conclusion: the loss of function of SNP (946 G→A) of P2X7 does not appear to be a common polymorphism in Omani population and does not seem to be a susceptibility gene locus for the development of gastric cancer in the Omani patients.

## 1038/W/Poster Board #696

**Variation in the adiponectin (ADIPOQ) and adiponectin receptor (ADIPOR1) genes and prostate cancer in African American men.** *J. Beebe-Dimmer[1], K. Zuhlke[2], A. Ray[2].* 1) Karmanos Cancer Institute, Detroit, MI; 2) University of Michigan Medical School, Ann Arbor MI.

Background and Purpose: Prostate cancer is the most common invasive cancer diagnosed among men in the United States and the second leading cause of cancer death. The incidence of prostate cancer is 60% higher among African American (AA) men and they are approximately two times more likely to die from their disease compared to Caucasian men. Adiponectin, a protein derived from adipose tissue is suspected to play an important role in prostate carcinogenesis. A genetic influence on circulating levels of adiponectin has been demonstrated in a number of studies. Variants in the adiponectin (ADIPOQ) and its type I receptor (ADIPOR1) genes have been recently linked to an increased risk of both breast and colorectal cancer. Therefore, we set out to examine the role of polymorphisms in these genes and risk of prostate cancer in AA men. Methods: Ten haplotype-tagging SNPs in ADIPOQ and ADIPOR1 were genotyped in DNA samples from 134 AA prostate cancer cases and 355 controls participating in the Flint Men's Health Study. A logistic regression modeling approach was used to test the association between these SNPs with risk of prostate cancer and obesity. Results: No significant associations were detected between any of the tested SNPs and prostate cancer. However, a single SNP in ADIPOQ (rs1501299) was associated with increased body mass. The +276G→T SNP was more commonly observed among obese men (BMI >30.0 kg/m2) compared to non-obese men (p=0.02). Conclusion: Based on these findings, genetic variation in ADIPOQ and ADIPOR1 does not predict prostate cancer in AA men. However, obese men were more likely homozygotes for the variant allele (TT) in rs1501299, a finding supported by studies linking this SNP to circulating adiponectin. Further investigation is warranted to determine if racial differences exist in the influence of the adiponectin pathway on prostate cancer risk.

## 1039/W/Poster Board #697

**Large-scale fine mapping of *HNF1B* reveals a more complex association with prostate cancer risk.** *S.I. Berndt[1], M. Yeager[1,2], K.B. Jacobs[1,2,3], R.B. Hayes[4], D.J. Hunter[5,6], R.N. Hoover[1], G. Thomas[1], S.J. Chanock[1] for the CGEMS Initiative.* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 2) Core Genotyping Facility, Advanced Technology Program, SAIC-Frederick, Inc., NCI-Frederick, Frederick,MD; 3) Bioinformed Consulting Services, Gaithersburg, MD; 4) Division of Epidemiology, New York University Medical Center, New York, NY; 5) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 6) Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Previous genome-wide association studies revealed an association between a locus in the *HNF1B* gene (rs4430796) and both prostate cancer and diabetes risk. Subsequently, a second locus (rs11649743) separated from the first by a recombination hot spot was reported to be associated prostate cancer risk. In order to fine-map genetic variation in this important prostate cancer region further, we genotyped 87 SNPs in the region harboring *HNF1B* in 10,272 prostate cancer cases and 9,123 controls of European ancestry from 10 case-control studies as part of the Cancer Genetic Markers of Susceptibility (CGEMS) initiative. SNPs were chosen from a region defined using the 0.2cM HapMap recombination data flanking the most significant SNP. Tag SNPs were selected using the HapMap CEU population with D'=0.6; notable SNPs ($P<10^{-3}$) from the initial genome-wide scan served as obligate-includes. TagSNPs were included if they were observed to be correlated with an $r^2 \geq 0.8$ in the HapMap CEU, YRI, and JPT+CHB populations with the obligate-includes. Of the SNPs evaluated, ten were significantly related to prostate cancer risk ($P < 1x10^{-7}$) with the most significant association being observed with rs4430796 ($P = 2.5x10^{-23}$). However, risk within this first locus was not entirely explained by rs4430796. Although modestly correlated ($r^2$=0.64), rs7405696 was also associated with risk ($P = 1.3x10^{-21}$) even after adjustment for rs4430769 (P = 0.009). As expected, rs11649743 was also related to prostate cancer risk ($P = 5.1 \times 10^{-8}$); however, the association within this second locus was stronger for rs4794758 ($P = 3.3 \times 10^{-14}$), which explained all of the risk observed with rs11649743 (P = 0.41 and P = 0.001 for rs11649743 and rs4794758, respectively, in the joint model). After mutual adjustment, all three SNPs (rs4430796, rs7405696, and rs4794758) remained associated the prostate cancer risk (P < 0.02). Compared to men without any risk alleles, men with six *HNF1B* risk alleles had a 1.8-fold increased risk of prostate cancer (95% CI: 1.47-2.19). Haplotype analysis also revealed a multifaceted pattern of association. In conclusion, this study demonstrates a complex association between genetic variation in the *HNF1B* gene and prostate cancer risk. Additional studies are needed to further characterize this important region and to assess the functional impact of genetic variation in this gene.

## 1040/W/Poster Board #698

**Association of chromosome 8q variants with prostate cancer risk in Caucasian, Hispanic, and African American Men.** *J. Beuten[1,2], J. Gelfond[3], M. Martinez-Fierro[5], K. Weldon[2], A. Crandall[2], A. Rojas-Martinez[5], I. Thompson[4], R. Leach[1,2,4].* 1) Department of Pediatrics; 2) Department of Cellular and Structural Biology; 3) Department of Epidemiology and Biostatistics; 4) Department of Urology, The University of Texas Health Science Center, San Antonio, TX; 5) Biochemistry and Molecular Medicine, School of Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico.

Multiple independent studies have demonstrated compelling evidence that genetic variations in at least 3 regions of 8q24 independently influence the risk of prostate cancer. We evaluated the association between prostate cancer (PCa) risk and variants within a 615kb region within 8q24 using a customized Illumina panel on a BeadXpress system. Genotyping of 49 haplotype tagged single nucleotide polymorphisms (SNPs) in 2380 samples (879 cases and 1501 controls) of three ethnic/racial groups found SNPs which are significantly associated with the risk for PCa. The highest significance in Caucasian men was found for rs6983267; the AA genotype reduced the risk for PCa (OR=0.48, 95%CI=0.35-0.65, p=2.74x10-6). This SNP also had a significant independent effect from other SNPs in the region in this group. In Hispanic men, rs7837328 and rs921146 showed independent effects (OR=2.55, 95%CI=1.51-4.31, p=4.33x10-4, OR=2.09, 95%CI=1.40-3.12, p=3.13x10-4, respectively). In African American men rs6985419 had an independent effect (OR=3.85, 95%CI=1.50-9.86, p=0.005). Significant synergist effects for increasing numbers of high-risk alleles were found in all three ethnicities. Haplotype analysis revealed major haplotypes, containing the non-risk alleles, that conferred protection against PCa. We found high linkage disequilibrium between significant SNPs within the region and SNPs within the Cub and Sushi Multiple Domains 1 gene (CSMD1), on the short arm of chromosome 8 in Caucasians and Hispanics. These data suggest that multiple interacting SNPs within 8q24, as well as different regions on chromosome 8 far beyond this 8q24 candidate region, may confer increased risk of PCa. This is the first report to investigate the involvement of 8q24 variants in the susceptibility for PCa in Hispanic men.

**Investigation of innate immunity genes CARD4, CARD8 and CARD15 as germline susceptibility factors for colorectal cancer.** *S. Buch[1, 2], N. Möckelmann[1], w. v. Schönfels[1], A. Franke[4], M. Brosch[1], H. Kalthoff[5], M. Krawczak[6], C.D. Bröring[3], C. Schafmayer[3], J. Hampe[1].* 1) Medical Dept, Inst Clinical Molec Biology, Kiel, Germany; 2) POPGEN Biobank project, Kiel, Germany; 3) Department of General and Thoracic Surgery, Kiel, Germany; 4) Institute of Clinical Molecular Biology, Kiel, Germany; 5) Institute for Experimental Cancer Research / Comprehensiv Cancer Center North, Kiel, Germany; 6) Institute of Medical Informatics and Statistics, Kiel, Germany.

Background: Variation in genes involved in the innate immune response may play a role in the predisposition to colorectal cancer (CRC). Several polymorphisms of the CARD15 gene have been reported to be associated with an increased susceptibility to Crohn disease. Since the CARD15 gene product and other CARD proteins function in innate immunity, we investigated the impact of germline variation at the CARD4, CARD8 and CARD15 loci on the risk for sporadic CRC, using a large patient sample from Northern Germany. Methods: A total of 1044 patients who had been operated with sporadic colorectal carcinoma (median age at diagnosis: 63 years) were recruited and compared to 724 sex-matched, population-based control individuals (median age: 68 years), Genetic investigation was carried out following both a coding SNP and haplotype tagging approach. Results: No significant differences were observed between the patient and control allelic or haplotypic spectra of the three genes under study. Conclusion: Variation in the innate immunity genes CARD4, CARD8 and CARD15 is unlikely to play an important role in the susceptibility to CRC in the German population.

## 1042/W/Poster Board #700

**Comprehensive resequence analysis of a 97kb region containing the MSMB gene associated with prostate cancer.** *L. Burdett[1,2], X. Deng[1,2], J. Boland[1,2], C. Matthews[1,2], J. Bacior[1,2], V. Lonsberry[1,2], A. Hutchinson[1,2], L. Qi[1,2], K. Jacobs[2,3], J. Gonzalez-Bosquet2[2], S. Berndt[2], R. Hayes[2], R. Hoover[2], G. Thomas[2], D. Hunter[4], M. Dean[5], S. Chanock[2], M. Yeager[1,2].* 1) Core Genotyping Facility, NCI Frederick, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, Center for Cancer Research, NCI, NIH, Bethesda, Maryland 20892, USA; 3) Bioinformed Consulting Services, Gaithersburg, Maryland 20877, USA; 4) Program in Molecular and Genetic Epidemiology, Department of Epidemiology, Harvard School of Public Health, Boston, Massachusetts 02115, USA; 5) Laboratory of Experimental Immunology, Cancer and Inflammation Program, NCI-Frederick, National Cancer Institute, Frederick, MD 21702.

Genome-wide association studies of prostate cancer have identified single nucleotide polymorphism markers in a region of chromosome 10q14, harboring the microseminoprotein-$\beta$ (MSMB) gene. Both the gene product of MSMB, the prostate secretory protein 94 (PSP94) and its binding protein, PSPBP have been previously investigated as serum biomarkers for high-grade prostate cancer risk. Recent functional work has shown that the different alleles of the promoter SNP, rs10993994, influence MSMB expression. Since it plausible that additional variants in this region contribute to the risk of prostate cancer, we have used next-generation sequencing technology to resequence a ~97kb region that includes the area surrounding MSMB (chr10:51168025-51265101) in 36 prostate cancer cases and 26 controls of European origin in order to nominate additional variants that may be investigated in functional studies. We identified 242 novel polymorphisms within this region, including 143 within the 51kb block of linkage disequilibrium (LD) that contains rs10993994 and the proximal promoter of MSMB. No sites were observed to be polymorphic within the exons of MSMB.

## 1043/W/Poster Board #701

**Fine-Mapping of the Prostate Cancer Locus on Chromosome 11q13 Reveals Three Independent Common Variants in CGEMS.** *C.C. Chung[1], J. Ciampa[1], N. Chatterjee[1], M. Yeager[1], K. Jacobs[1], J. Gonzalez-Bosquet[1], R.N. Hoover[1], D.J. Hunter[2], G.D. Thomas[1], S.J. Chanock[1].* 1) LTG/DCEG, NCI/NIH, Bethesda, MD; 2) Havard School of Public Health, Boston, MA.

Based on the second stage of the CGEMS genome-wide association study, we fine mapped a region of chromosome 11q13 marked by rs10896449 (p= 1.76E-09 in a combined analysis of stage 1 and 2). SNPs were chosen from a region defined using the 0.2cM HapMap recombination data flanking the most significant SNP. Tag SNPs were selected using HapMap CEU with D'=0.6; notable SNPs ($p < 1.00E-03$) served as obligate-includes. Tags were chosen with r2 of ≥ 0.8 in HapMap CEU, YRI, JPT+CHB with obligate-includes. In stage three, 94 SNPs passed quality control metrics and were analyzed in ten studies, totaling 10,272 cases and 9,123 controls, all of European background. Combined joint analysis adjusted for age, study, center, and population stratification indicated that 18 SNPs on chromosome 11q13.2 (Chr11q13.2:68660041-68765690) exceeded genome-wide significance (p values: 3.91E-09 to 7.94E-19). 14 of 18 SNPs segregates into three correlation bins; bin1: rs10896438, rs2924538, rs11228551, and rs11228553, bin2: rs4255548, rs4495900, and rs7950547, bin3: rs4620729, rs7931342, rs10896449, rs9787877, rs7939250, rs10896450, and rs11228583 ($r2 > 0.8$ threshold); 4 SNPs (rs10896437, rs2924540, rs12793759, and rs12281017) were singletons. To test for possible independent signals, we examined: 1) the linkage disequilibrium pattern by study, continental origin and all controls; 2) assessment of recombination hotspots using SequenceLDhot; and 3) multi-locus models conditioned on the initial signal, rs10896449. We detected two independent signals, marked by rs10896449 and rs12793759, that showed statistically significant effect after the conservative Bonferroni adjustment for multiple testing (p=4.76E-05). Other SNPs, notably rs10896438, also showed promising associations after accounting for both rs10896449 and rs12793759, but none reached global significance for the whole region. LD between rs10896449 and rs10896438, rs12793759, and between rs10896438 and rs12793759 in all controls (r2, 0.11, 0.17, and 0.14, respectively). Of three observed distinct recombination hotspots, two encompass all 18 SNPs and one separates bin1 from the other bins; notably, one of the new signals, rs12793759 is a singleton. Our study has identified a more complex architecture underlying the common variants contributing prostate cancer risk in this segment of 11q13. Further studies are required to investigate the biological basis of the observed multiple association signals.

## 1044/W/Poster Board #702

**Genetic interaction contributing to prostate cancer risk identified in 8q24.** *R. Culverhouse[1,2], P. Pal[3], R. Deka[3], C.H. Jin[4], W.J. Catalona[5], B.K. Suarez[4,6].* 1) Department of Internal Medicine, Washington University School of Medicine, St Louis, MO; 2) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO; 3) Department of Environmental Health, Center for Genome Information, University of Cincinnati Medical Center, Cincinnati, OH; 4) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO; 5) Department of Urology, Robert H Lurie Comprehensive Cancer Center, Feinberg School of Medicine, Northwestern University, Chicago, IL; 6) Department of Genetics, Washington University School of Medicine, St. Louis, MO.

Few genetic findings in the field of prostate cancer (PC) have been as significant and persuasively replicated as the association signals observed in the region of chromosome 8q24. We recently reported the results of a case/control study of 49 SNPs spanning the 3 regions of 8q24 in 596 men of European descent with histologically verified PC and 567 unrelated men of European descent. These cases were ascertained from patients seen at Washington University School of Medicine between 1989 and 2001. The control subjects were recruited from the same catchment area as the cases and were followed for many years as part of a long-term prostate cancer screening study in which PSA blood tests and digital rectal examinations (DRE) were performed at 6 to 12 month intervals and who met the following criteria: (a) at least 65 years old, (b) never had a DRE suspicious for PC, (c) never had registered a PSA level >2.5 ng/ml, and (d) had no known family history of prostate cancer. In these data, 4 SNPs (rs1016342, rs1378897, rs871135 and rs6470517) were found to be significantly associated with PC after adjusting for multiple comparisons using an allele frequency test. We report here an interaction analysis of SNP genotypes (or tightly linked genetic elements) explaining trait variation in PC. These interactions were identified with the Restricted Partition Method (Culverhouse et al. Genet Epidemiol 2004) and validated using logistic regression. The most significant 2-way interaction involves rs6983267 and rs871135, which individually account for 0.5% and 2.0% of the trait variation for PC, respectively, but which jointly account for 9.7% of the variance. The most significant 3-way interaction involves the same 2 SNPs plus rs1016342 which, by itself, accounts for 1.0% of the trait variation. However, the full three-way interaction model accounts for 12.7% of the variation in susceptibility to PC. In both the 2-way and 3-way models, the addition of the interaction terms decreases the p-value of the respective models by over 5 orders of magnitude.

## 1045/W/Poster Board #703

**Association of polymorphisms in the TGF Beta pathway with breast cancer risk and breast density.** *E. Dean[1], L. Fejerman[1], I. Romieu[2], E. Lazcano-Ponce[2], S. Huntsman[1], K. Beckman[3], E. Burchard[1], G. Torres-Mejia[2], E. Ziv[1,4].* 1) Dept of Medicine, Inst for Human Genetics, Medical Effectiveness Res Cntr and Helen Diller Family Comp Cancer Cntr, University of California, San Francisco, CA; 2) Inst Nacional de Salud Publica, Cuernavaca, Morelos, Mexico; 3) University of Minnesota, Minn, MN; 4) Dept of Epi and Biostats, University of California, San Francisco, CA.

Background: Transforming growth factor beta 1 (TGFB1) is a regulator of cellular proliferation that suppresses early tumor formation, but, paradoxically, also promotes tumor invasion. A polymorphism in TGFB1 has been associated with breast cancer in a meta-analysis. We evaluated the association between polymorphisms in the TGFB ligands (TGFB1, TGFB2, TGFB3) and the types 1 2 and 3 TGFB receptors (TGFBR1, TGFBR2 and TGFBR3) and breast cancer in a case-control study of breast cancer among Mexican women. We also evaluated the association between these polymorphisms and mammographic breast density, a strong predictor of breast cancer which is highly heritable. Methods: Our study included 579 breast cancer cases and 1057 controls ascertained from clinics and hospitals in 3 districts of Mexico (Mexico City, Veracruz and Monterey). Cases and controls were matched by ascertainment site and by age. We selected tag SNPs using hap map data (CEU and Asian populations) and successfully genotyped 133 SNPs. We also included 106 ancestry informative markers which were used to estimate genetic ancestry. Associations with breast cancer and breast density were tested using logistic regression models and linear regression models, respectively and adjusted all models for genetic ancestry. Results: We found a nominally significant association between 10 of the 133 polymorphisms and breast cancer. The strongest association with breast cancer was with a SNP in the 3' end of TGFBR3 (p=0.002). Only 2 polymorphisms were nominally significant for association with breast density. The strongest association with breast density was with a SNP in TGFBR2 (p= 0.001). We found no polymorphisms that were associated with both breast density and breast cancer. Conclusions: Polymorphisms in the TGFBeta pathway do not clearly explain the association between breast density and breast cancer risk. The nominal associations we identified should be retested in larger studies.

## 1046/W/Poster Board #704

**Association of UGT2B17, UGT2B7 and UGT2B28 gene copy number with prostate cancer risk.** *F. Demichelis[1,2], S.R. Setlur[3], R.R. Hossain[1], C.X. Chen[1], V.E. Van Doren[1], B. Stenzel[4], D.A. Oldridge[1], N. Katabayashi[1], J.S. Ha[3], J.Y. Chen[3], G. Schäfer[4], C. Lee[3,5], M.A. Rubin[1,5], H. Klocker[4].* 1) Pathology and Laboratory Medicine, Weill Cornell Medical College, New York, NY; 2) Institute for Computational Biomedicine, Weill Cornell Medical College, New York, NY; 3) Pathology Department, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Urology, University Hospital Innsbruck, Innsbruck, Austria; 5) Broad Institute of MIT and Harvard, Boston, MA, USA.

Statement Of Purpose: Prostate cancer has been known to have a strong germline component. Recently, several publications have examined the role of germline deletions of the gene, UDP glucuronosyltransferase 2 family, polypeptide B17 (UGT2B17) for association with prostate cancer risk. This gene belongs to a family of UDP glucuronosyltransferases that are involved in the catabolism of steroids. UGT2B17 in particular catalyzes the conjugation of DHT, testosterone and 3a-Diol, thereby regulating androgen homeostasis. Two recent studies reported an association between copy number loss of UGT2B17 with an increased risk of developing prostate cancer while two other studies failed to find association. Methods: The current study takes advantage of a carefully screened population of men at risk of having prostate cancer to explore for associations with copy number variation of UGT2B17, UDP glucuronosyltransferase 2 family, polypeptide B7 (UGT2B7) (both sharing the same substrate specificity) or its neighboring gene UDP glucuronosyltransferase 2 family, polypeptide B28 (UGT2B28). We examined 427 individual (214 cases and 213 controls) drawn from the Tyrol Early PCA Detection Program (Austria), which includes PSA testing on men between 45 and 75 years of age. The PSA threshold is age dependent and is a low as 1.25 ng/ml. The cases are men with prostate cancer and the controls are defined as men with PSA levels below 0.5 ng/ml for 3 years following a negative biopsy. We characterized all samples for copy number changes of the genes UGT2B17, UGT2B7 and UGT2B28. Copy number status was validated for a subset of samples by QPCR. Summary of Results: We did not detect copy number changes in UGT2B7. The overall incidences of homozygous and hemizygous deletion for UGT2B17 were 10.1% and 41.9%, respectively and UGT2B28 were 2.6% and 23.2%, respectively. We found no association of either gene with conferring risk of prostate cancer when examined both individually and in combination. We therefore conclude that these two genes do not play a major role in prostate carcinogenesis. We hypothesize that the discordance between independent studies may be driven by either different criteria in case selection (PSA levels) or by non-specificity of primers for the evaluation of copy number status of the gene of interest (UGT2B17 and UGT2B15 show 95% homology).

## 1047/W/Poster Board #705

**Association of CRYBB2 Gene Polymorphism with Prostate Cancer in African Americans.** *M. Faruque[1, 4], C. Ahaghotu[2], L. Ricks-Santi[3], E. Jingwi[1], T. Mason[1], C. Mouton[4], M. Fidelia-Lambert[5], G. Dunston[1].* 1) National Human Genome Center, Howard University College of Medicine, Washington, DC; 2) Department of Surgery, Howard University College of Medicine, Washington, DC; 3) Howard University Cancer Center, Washington, DC; 4) Department of Community and Family Medicine, Howard University College of Medicine, Washington, DC; 5) Department of Pathology, Howard University College of Medicine, Washington, DC.

Prostate cancer shows disproportionately higher incidence and disease associated mortality rate in African American men, compared to their counterpart in other population groups. Human crystallin beta B2 (CRYBB2) gene has been reported as one tumor signature gene that differentiated between African-Americans and European-American by gene expression profiling and comparison of prostate tumors tissue, thereby suggesting differences in tumor biology between the two groups. Mutations in CRYBB2 gene have been found to also be associated with cataracts. We investigated the role of CRYBB2 variants in prostate cancer in a case-control study of African Americans, consisting of 145 prostate cancer cases and 155 controls (n= 300). Six haplotype-tagged SNPs spanning a region of 6.7 kb upstream of the transcription start site and thus containing the putative promoter were selected for genotyping and association studies. Genotyping was performed by pyrosequencing. One SNP (rs16979774) was found monomorphic in the study population and thus excluded from further analyses. Association was examined by logistic regression analyses with adjustment for age. We found a significant association of prostate cancer with rs9620497 (-1873G>T) in a dominant model. The odds ratio (OR) of T allele for prostate cancer was estimated to be 0.375 (95% CI = 0.157-0.894; P = 0.027). None of the other four SNPs (rs12167370, rs2213882, rs8136087 and rs2267078) was statistically significantly associated with the disease risk. Additional studies are warranted to further confirm the association as well as to examine the role of this variant in the biology of prostate cancer.

## 1048/W/Poster Board #706

***PDE11A*, a dual-specificity phosphodiesterase that is frequently polymorphic in the general population and conveys risk to adrenal and testicular tumors, may also be a susceptibility gene for prostatic cancer.**

*F.R. Faucz[1,2], A. Horvath[1], A. Rothenbuhler[1,3], D.M. Carraro[4], R.B. Alexandre[2], M. Nesterova[1], C.A. Stratakis[1].* 1) Section on Endocrinology & Gen, PDEGEN, NICHD, NIH, Bethesda, MD, USA; 2) Laboratory of Molecular Genetics, NIMA, PPGCS, Pontificia Universidade Catolica do Parana, Curitiba, Brazil; 3) Pediatric Endocrinology Unit, Groupe Hospitalier Cochin-Saint Vicent de Paul, Paris Descartes University, Paris, France; 4) Laboratory of Genomics and Molecular Biology - A.C. Camargo Hospital, São Paulo, Brazil.

Despite significant advances in molecular genotyping, Prostate cancer (PC) does not appear to have a major single gene responsible for the disease. Among the genomic loci that have been suggested to harbor potential candidate genes is the 2q31-35 chromosomal area. The gene encoding phosphodiesterase 11A (*PDE11A*) is located on 2q31-32; it belongs to the family of phosphodiesterases (PDE)-enzymes that catalyze the hydrolysis of the second messengers cAMP and cGMP. Four different isoforms are known for *PDE11A*: *PDE11A4* is the isoform with the highest expression in prostate, compared to all other studied endocrine tissues. We recently reported *PDE11A*-inactivating mutations to be associated with a predisposition to endocrine neoplasm, including adrenocortical (ADT) and testicular germ-cell tumors (TGCT), which also express the *PDE11A4*. In the present study we screened 50 unrelated PC patients of Brazilian descent for PDE11A sequence defects. We identified 8 different coding alterations in a total of 16 patients (32%): 7 missense and one stop-codon mutation. Three of the missense were novel (R202C, Y658C and E840K); constructs containing the mutations were tested *in vitro* in HEK293 human cells. All mutant transfectants impaired the ability of the protein to degrade cAMP *in vitro*; an additional four mutants (Y727C, R804H, R867G and M878V) and the R307X stop-codon mutation that had also been found in association with ADT and TGCT, have been tested and published elsewhere as impairing the ability of the enzyme to mediate PDE activity. We compared the type of the mutations and their frequencies with those in 287 healthy control individuals: the newly identified substitutions were not found in the control group and a significantly higher number of *PDE11A* missense and nonsense variations were seen in the PC patients (allelic frequency 0.16 vs 0.043 in the controls, $\chi^2$=18.23, p<0.0001, OR=4.18, 95%CI 2.14 - 8.16). Immunostaining and additional genetic studies aim at further clarifying the role of these sequence changes in PC. We conclude that these preliminary data point to *PDE11A* genetic changes as a potential susceptibility factor for PC; this is consistent with PDE11A's essential role in the regulation of cAMP signaling responses in other endocrine tissues and its involvement as a risk factor for ADT and TGCT. Interestingly, *PDE11A* is inhibited by some of the PDE-inhibitors used for erectile dysfunction by patients of the same age as those that are at risk for PC.

## 1049/W/Poster Board #707

**Analysis of the breast cancer-associated gene PALB2 in familial and sporadic pancreatic cancer.**

*N. Hamel[1,2], M. Tischkowitz[2,3], N. Sabbaghian[2,3], A. Borgida[4], S. Holter[4], H. Rothenmund[4], C. Rosner[2,3], N. Taherian[1,2,3], A. Srivastava[2,3], P. Ghadirian[5], W.D. Foulkes[1,2,3], S. Gallinger[4,6].* 1) The Research Institute, McGill University Health Center, Montreal, Canada; 2) Program in Cancer Genetics, Depts of Oncology and Human Genetics, McGill University, Montreal, Canada; 3) Segal Cancer Center, Sir M.B. Davis Jewish General Hospital, Montreal, Canada; 4) Dr. Zane Cohen Digestive Diseases Clinical Research Center, Mount Sinai Hospital, Toronto, Canada; 5) Epidemiological Research Unit, Centre Hospitalier de l'Université de Montréal (CRCHUM), Montréal, Canada; 6) Dept of Surgery, University Health Network, University of Toronto, Canada.

PALB2 (Partner and Localizer of BRAC2) plays a major role in localizing the breast cancer susceptibility gene BRCA2 in the nucleus, thus facilitating DNA repair. PALB2 is itself a modest contributor to breast cancer susceptibility and truncating germline mutations have been observed to segregate with breast cancer in several families. Recently, Jones et al screened 96 familial pancreatic cancer patients and truncating PALB2 mutations were identified in three patients (3.1%) (Science 2009;324:217). We sought to examine a larger cohort of pancreatic cancer cases, including both familial and sporadic types, to determine the wider contribution of PALB2 mutations in pancreatic cancer. We are currently screening the exons and intron-exon boundaries of PALB2 using a combination of HRM (High Resolution Melt), direct sequencing and MLPA (Multiplex Ligation-dependent Probe Amplification) in 276 individuals with pancreatic cancer of which 84 have a family history of pancreatic cancer, 45 have a family history of breast/ovarian cancer and 24 have a history for both. The remaining 123 cases have no family history for either cancer type. Using MLPA we detected a heterozygous, germline deletion including exons 12 and 13 of PALB2 in a patient who was affected by both breast and pancreas cancer (ages 47 and 61, respectively) and whose mother died of pancreas cancer at age 83. There are no other reported cases of cancer in this family. We confirmed the presence of the deletion in the patient by long-range PCR and were able to estimate its size to approximately 6.7kb. Our findings to date support previous observations that germline PALB2 mutations predispose to pancreas cancer in a small fraction of all familial cases.

## 1050/W/Poster Board #708

**The impact of maternal genetic effects in the initiation of childhood acute lymphoblastic leukemia.**

*J. Healy[1], M. Bourgey[1], C. Richer[1], J. Dionne[1], M. Larivière[1], M.H. Roy-Gagnon[1,2], D. Sinnett[1,3].* 1) CHU Sainte-Justine Research Center, Montreal, Qc, Canada; 2) Department of Social and Preventive Medicine, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada; 3) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada.

Acute lymphoblastic leukemia (ALL) is the most common cancer in children but the underlying determinants of this disease remain poorly understood. ALL is a complex disease that involves the combination of multiple genetic and environmental factors during fetal life and early childhood. In terms of genetics, both the affected individual's inherited genotype and parental-mediated mechanisms (i.e. parental genotypes) can affect the initiation of this type of cancer. In particular, a mother can influence the offspring's risk of disease not only as a genetic donor but also because she provides the fetal environment. To investigate the role of maternal genotypes in ALL onset, we genotyped 28 promoter SNPs from 12 cell-cycle genes in a sample of 203 child-parent triads, 118 unrelated cases and 329 unrelated controls. A log-linear, likelihood-based approach was used in a stepwise procedure to assess child and maternal genetic effects and combined feto-maternal effects. Our results reveal novel maternal-mediated effects at CDKN2A rs36228834 (P= 0.017) and CDKN2B rs36229158 (P= 0.022) that were shown to act in combination with the child's genotype to increase susceptibility to disease. Further experimental analysis showed that the promoter variant rs36228834 influences transcriptional activity and alters DNA-protein complex formation in an allele-specific manner. A protective feto-maternal combination effect was also identified at CDKN2B rs2069416 with maternal/child carriage of at least one T allele leading to reduced susceptibility to childhood pre-B ALL in offspring (P= 0.027). Our study suggests that regulatory SNPs in cyclin-dependent kinase inhibitor genes CDKN2A and CDKN2B could influence maternal and fetal gene expression. Disregulated cell division and disruption of tissue homeostasis during gestation could disrupt the maternal-fetal interface and interfere with important physiological processes such as the growth of the fetus and/or normal haematopoiesis and potentially lead to increased susceptibility to ALL. Unraveling offspring from maternal genetic effects will provide invaluable insights into the genetic mechanisms underlying childhood ALL and help refine our understanding of the etiology of this and perhaps other pediatric cancers.

## 1051/W/Poster Board #709

**Expression and activity of carbonyl reductase 1 and hydroxysteroid dehydrogenase11B1; two enzymes responsible for the conversion of NNK to NNAL.** *A.K. Hull[1], A.L. Knipe[2], C.J. Gallagher[2], G. Chen[2], D. Marshall[1], P. Lazarus[2], J.E. Muscat[2].* 1) Biology, Lincoln University, Lincoln University, PA; 2) Penn State Cancer Institute, Cancer Control & Population Science, Public Health Sciences and Pharmacology,The Milton S. Hershey Medical Center, Penn State College of Medicine, Hershey, PA.

Lung cancer is the most common cause of cancer related deaths in the US. Smoking is estimated to account for 87% of all lung cancer cases. However, only some smokers develop cancer, indicating that they may be more susceptible to the effects of tobacco smoke carcinogens. One of the major carcinogens in tobacco smoke is the nicotine derived nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). NNK is reduced to another potent lung carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), which can be glucuronidated by the uridine glucuronosyltransferase (UGT) enzyme family and excreted. Metabolism of NNK to NNAL is predominantly carried out by carbonyl reductase 1 (CBR1) and hydroxysteroid dehydrogenase 11B1 (HSD11B1). The current study focuses on discovering individual differences in DNA sequence, mRNA expression, and enzyme activity of CBR1 and HSD11B1. These differences may result in an increased risk of cancer in smokers. The coding region of the HSD11B1 gene was analyzed for nonsynonymous single nucleotide polymorphisms (SNPs). SNP data has previously been published for CBR1; only low prevalence alleles (<2%) were found. Human liver cDNA from 24 individuals were sequenced to identify coding changes in HSD11B1. No coding SNPs were observed in these samples. mRNA expression levels of CBR1 and HSD11B1 from 110 adjacent normal tissue liver samples were found to vary significantly between individuals. Carbonyl reductase activity assays performed with either cytosol (to measure CBR1 activity) or microsomal extracts (to measure HSD11B1 activity) demonstrated no correlation between expression levels of CBR1 mRNA levels and enzymatic activity in cytosol or between HSD11B1 and enzymatic activity in microsomes. The current data shows that variation in activity levels cannot be explained by either DNA sequence variation or mRNA expression. The lack of correlation between mRNA expression and enzymatic activity suggests a complex picture in which either post-transcriptional regulation of protein expression or post-translational regulation of enzyme activity are involved. Alternatively, other enzymes capable of NNK reduction may play a greater role than previously suggested. Currently, variation in CBR1 and HSD11B1 protein levels among the same individuals is being measured.

**Developing an Innovative High-Throughput MALDI-TOF MS Based 40-Plex Assay for Simultaneous Mutational Analysis of Breast Cancer-Linked Genes in Breast Cancer Cell Lines.** *C. Kohler[1], R. Radpour[1], Z. Barekati[1], R. Asadollahi[1], XC. Fan[1], W. Holzgreve[2], XY. Zhong[1].* 1) Department of Biomedicine, Woman`s Hospital Basel, Basel, Switzerland; 2) University Medical Centre of Freiburg,University Freiburg, Freiburg, Germany.

Developing innovative high-throughput techniques for mutational analysis of cancer-related genes may provide the basis for a new dimension of high-throughput diagnostics. Recently we developed a novel high-throughput MALDI-TOF MS based assay, which enables simultaneous detection of up to 40 single-nucleotide variants on various genes in one single reaction. We explored the feasibility of our approach using the newly developed MALDI-TOF MS based 40-plex assay for the investigation of the mutational status of candidate cancer genes in 6 human breast cancer cell lines. These candidate cancer genes have been shown to be mutated at a significant frequency in breast cancer, what could make them an ideal candidate for a breast cancer screening approach. By analyzing assay quality parameters like call rate and call probability and by visually analyzing the spectrograms we could confirm a good performance of the 40-plex assay; with mean call rates ranging between 85 and 100, what is suggested as optimal and with a mean call probability score ranging from 0,78 to 0,91 (1=high quality). Using the MALDI-TOF MS based 40-plex assay we were able to show the possibility of reliable and robust analysis of up to 40 allelic variants simultaneously in a single reaction.

## 1053/W/Poster Board #711

**Rapid detection of sequence variation in the NAT1 3' UTR by Pyrosequencing® technology.** *D. Koontz, J. Huckins, S. Nikolova, M. Gallagher.* Dept DLS, CDC, Atlanta, GA.

N-acetyltransferase 1 (NAT1) mediates activation and detoxification pathways for several known carcinogens. Polymorphisms in this gene have been postulated to modify human risk to a variety of cancers by altering the rate at which potentially carcinogenic compounds are either neutralized or activated. Several allelic variants occur in the 3' untranslated region (UTR) of the gene. These variants are widely studied for their potential to affect mRNA stability, which in turn affects NAT1 enzyme levels. Considerable effort has been invested in the development of genotyping methodologies to detect NAT1 gene variants for pharmacogenomic and epidemiological applications. Most NAT1 genotyping approaches are gel based and consist of PCR-restriction fragment length polymorphism (RFLP) analysis or allele-specific PCR. However, these approaches are slow, labor intensive, and not amenable to the automation needs of large population studies. We developed a novel Pyrosequencing assay, which allows for simultaneous interrogation of the most common variants in the 3' UTR region. The initial assay validation was performed on 90 DNA samples from the Coriell Polymorphism Discovery Resource (PDR) and results confirmed by cycle sequencing. In addition to the wild-type allele, NAT1*4, four variant alleles (NAT1*3, *10, *11, and *26) were detected. These variant alleles consisted of two SNPs, a 9bp deletion, and the rare 3bp insertion. We were able to detect the most frequent combinations of these alleles (*4/*4, *4/*10, *10/*10, *3/*4, *3/*11, and *4/*11), which capture >90% of the variation in this region that affects NAT1 activity. Genotype calls were derived from quantitative peak height ratios within signature regions of the Pyrogram traces that give predictive values for each allelic combination. We genotyped 4 ethnic groups: Hispanic (N=32), Pacific Rim (N=54), African American (N=47), and European Caucasian (N=48) from the Coriell Human Variation Collection. Despite small sample sizes, NAT1*10, designated as the at-risk allele for various cancers by numerous investigators, was considerably less prevalent in European Caucasians than in the other ethnic groups. This method could be of great value to epidemiological studies for screening NAT1 gene variation in large populations to detect informative biomarkers of susceptibility to cancers.

## 1054/W/Poster Board #712

**Identification of a candidate tumor suppressor gene for breast and colorectal cancer from the chromosomal region 11q23.** *A.S.G. Lee[1,2], D.C.T. Ong[1], Y.M. Ho[1].* 1) Div Med Sci, National Cancer Ctr, Singapore, Singapore; 2) Yong Loo Lin School of Medicine, National University of Singapore, Singapore.

The chromosomal region 11q23-q24 is frequently deleted in breast and colorectal cancer, as well as in a diverse range of malignancies. By utilizing loss of heterozygosity (LOH) analysis and microarray comparative genomic hybridization (Array-CGH), a 6-Mb region on 11q23 was examined. A candidate gene *LARG* (also known as *ARHGEF12*), identified from the region, was found to be frequently underexpressed in primary breast (32%; 12/38) and colorectal (54%; 20/37) cancers, and also breast (100%; 11/11) and colorectal (50%; 5/10) cell lines. Underexpression of the *LARG* transcript was significantly correlated with genomic loss (p = 0.00334). A lack of *LARG* promoter methylation was observed in primary breast (n=24) and colorectal cancers (n=26) by qualitative high-throughput analysis of DNA methylation by bass-specific cleavage and mass spectrometry. *In vitro* treatment of four breast and four colorectal cell lines with 5-aza-2'-deoxycytidine and/or trichostatin A did not result in reactivation of LARG. Growth suppressive activity of the breast and colorectal cancer cell lines, MCF-7 and SW620, stably transfected with constructs containing *LARG* or empty vector were assessed using colony formation, cell proliferation and wound healing assays. Reduced cell proliferation and colony formation in both breast and colorectal cancer cells, and a markedly slower cell migration rate in colorectal cancer cells were observed, suggesting that *LARG* has functional characteristics of a tumor suppressor gene.

## 1055/W/Poster Board #713

**Genome-wide Linkage Analysis of Nasopharyngeal Carcinoma in 223 Multiplex Families.** *X. Liang[1], F. Kuo[2], XR. yang[1], KF. Kerstann[3], C. Huang[2], AM. Goldstein[1], A. Hildesheim[4], C. Chen[5], SR. Diehl[2].* 1) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 2) Center for Pharmacogenomics and Complex Disease Research, UMDNJ, Newark, NJ; 3) Winship Cancer Institute, Emory University, Atlanta, GA; 4) Infections and Immunoepidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 5) Genomics Research Center, Academia Sinica, Taipei, Taiwan.

Nasopharyngeal carcinoma (NPC) is one of the most common malignant tumors in southern China and Southeast Asia. Genetic susceptibility has been suggested to play an important role in the pathogenesis of NPC, but no major susceptibility genes have been identified so far. Power of previous studies has been limited by small numbers of cases and inclusion of few multiplex families. Therefore we conducted a genome-wide linkage scan in 223 multiplex NPC families by genotyping 400 microsatellite markers (10cM spacing) on 2800 individuals (including 515 cases). We analyzed NPC status and anti-Epstein-Barr virus (EBV) seropositivity (absent/present) separately using both parametric and non-parametric linkage analysis. Since shared environmental/viral factors are likely to contribute to the observed familial clustering, we used an ordered subset analysis (OSA) to define a more genetically homogeneous subset of families based on covariates including age at onset (AAO), number of affecteds in a family, anti-EBV seropositivity among unaffected individuals, and cigarette smoking. A region on chromosome 2 (chr2) showed suggestive evidence for linkage at marker D2S364 (non-parametric two point (NPL_2pt) LOD score=2.88, p=0.0001). This marker also had NPL_2pt LOD>1.0 in 4 subset analyses (families with more than 3 affecteds: LOD=1.27, p=0.0078; AAO≤40 yrs: LOD=2.35, p=0.0005; cigarette smoking duration ≥20 yrs: LOD=1.86, p=0.0017; more than 3 anti-EBV seropositive unaffecteds in a family: LOD=2.00, p=0.0012). Multipoint analyses confirmed findings on chr2 in both the overall and subset analyses. The same region on chr2 was also linked to EBV seropositivity. The region defined by both traits was 18.5 cM. In addition to the region on chr2, our study identified a potential linkage region on chr4. D4S2964 (88.4cM) had 2pt LOD=2.72 in families with more than 3 affecteds; 1.72 in early-onset subset; 1.40 in families with more than 3 anti-EBV seropositive unaffecteds, under a recessive model assuming heterogeneity. D4S392 (79.0cM) showed evidence for linkage to EBV status with OSA 2pt LOD=2.25 in younger group using average AAO as a covariate. LOD scores were more modest with NPC as the outcome (LOD=1.06 in the overall set and 1.26 in the EBV positive subset). This marker was close to the peak region identified by a previous study. Additional fine mapping is being conducted to further refine the linkage findings and to narrow down these regions for candidate gene sequencing.

## 1056/W/Poster Board #714

**RUNX3 polymorphisms associated with intestinal-type gastric cancer susceptibility.** *B. Lim, C. Kang.* Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon, Korea.

Genetic association of human RUNX3 gene polymorphisms with gastric cancer susceptibility was examined in this case-control association study using 925 unrelated Korean subjects, who were individually genotyped for nine single-nucleotide polymorphisms (SNPs), covering the entire HapMap-enlisted SNPs in the RUNX3 gene. A SNP around the distal promoter of RUNX3 was significantly associated with intestinal-type gastric cancer susceptibility (P = 0.0028) but not with diffuse-type cancer and found to affect CREB1 binding and regulate the promoter activity. Because the intestinal-type is characteristically more differentiated than the diffuse-type, expression and cell growth function of p44-RUNX3 were tested in differentiated and undifferentiated gastric cell lines. RUNX3 expression level was negatively correlated with differentiation status of gastric cancer, and restoration of p44-RUNX3 inhibited proliferation of differentiated gastric cancer cells more prominently than that of undifferentiated cells. Because the intestinal-type gastric cancer is known to develop through chronic inflammation, several inflammation-related phenotypes such as NF-kB activity and cytokine levels were measured in the cells established to stably produce p44- or p33-RUNX3. While p44-RUNX3 reduced NF-kB activity and mRNA levels of IL-1$\beta$ and IL-6, p33-RUNX3 enhanced them. In conclusion, a SNP in the RUNX3 distal promoter is associated with intestinal-type gastric cancer susceptibility, and the risk allele enhances the promoter activity allowing for CREB1 binding and increases production of p33-RUNX3. Increased p33-RUNX3 enhances NF-kB activity and IL-1 abundance, possibly operating a dominant negative role against p44-RUNX3, and finally confers intestinal-type gastric cancer susceptibility.

## 1057/W/Poster Board #715

**Structural variant discovery in a liver cancer-related 39Mb region using capture-sequencing approach.** *C.H. Lin[1], J.S. Su[1], K.M. Wu[1], Y.H. Chang[1], J.C. Li[1], Y.F. Lin[1], Y.M. Liu[1,2], T.T. Liu[2], S.F. Tsai[1,2].* 1) National Health Research Institutes, Zhunan, Taiwan; 2) Genome Research Center, National Yang-Ming University, Taipei, Taiwan.

There are lots of DNA sequence variants, including single-nucleotide polymorphisms, indels and structural variants (SVs) in the human genome. SVs can affect expression of nearby and distant genes, and some of them might cause certain phenotypic differences. SVs vary slightly in location and frequency among different populations. Currently, sequencing personal genome is feasible using high-throughput sequencing systems, and it provides complete genomic information at the base-pair resolution. As an alternative, capture sequencing is an inexpensive strategy to enrich target DNA for sequencing specific regions of interest with acceptable sequence coverage. Chromosome 4q13.3-25 is a well-characterized region for DNA loss-of-heterozygosity in hepatocellular carcinoma (HCC). Genomic sequences (from 76Mb to 115Mb) were used to design a high-density hybridization array (Roche/NimbleGen) to enrich target DNA for sequencing. The 39Mb target sequencing was carried out in 10 HCC tumors and 2 paired non-tumor samples using the Illumina/Solexa system. DNA sample was sheared, ligated to adaptors and purified to obtain 150bp for pair-end sequencing (2x36) in two lanes. In average, the number of mappable reads for each sample was ~9.3 millions, which cover ~84% of the target region. Besides 12 larger-scale chromosomal abnormalities (>1Mb), 42 small SVs (241bp~178kb, average size: 8kb) were identified based on the numbers and pair-end positions of reads. Twenty-one SVs (50%) were found in at least two cases, and some were somatically acquired SVs. Twenty-nine SVs (69%) had been reported in the database of genomic variants. Nineteen protein-coding genes, e.g., UBE2D3 and PDLIM5, are affected by SVs. This study provided the candidate genomic variants for studying the HCC tumorgenesis, and also demonstrated the application of capture sequencing to SV discovery. Although a large proportion of the identified SVs might not be related to HCC tumorgenesis, they can be used as informative and powerful markers for future genetic studies, e.g. copy number variation association studies.

## 1058/W/Poster Board #716

**A Large Scale Genetic Association Study of Esophageal Adenocarcinoma Risk.** *C. Liu[1], G. Liu[2], D. Christiani[1].* 1) Dept Environmental Hlth, HSPH, Boston, MA; 2) Department of Medical Biophysics, Princess Margaret Hospital, University of Toronto, Canada.

The incidence of esophageal adenocarcinoma (EA) is increasing rapidly, particular among white males, over the past few decades in the United States. However, the etiology of EA and the striking male predominance is not fully explained by known risk factors. To identify susceptible genes for EA risk, we conducted a pathway-based genetic association study on 335 Caucasian EA cases and 319 Caucasian controls. A total of 1330 SNPs selected from 354 genes were analyzed using an Illumina GoldenGate assay. The selected candidate genes were in the pathways of cell growth, inflammation, angiogenesis, apoptosis, cell cycle control, sex hormone signal, DNA repair, and carcinogens /procarcinogens metabolism. The genotyped common SNPs include missense and exonic SNPs, SNPs in the promoter and UTR regions, and tagSNPs for genes with little functional information available. Logistic regression adjusted for age, sex, body mass index (BMI) at age 18, and smoking status was used to assess the genetic effect of each SNP on EA risk. We also tested gene-gender interactions using the likelihood ratio tests. SNPs in three genes that play a critical role in apoptosis (*CASP9*, *CASP7*, and *CHEK1*) were found to be associated with an increased risk of EA after correcting for multiple comparisons. Strong gene-gender interaction effect was observed on SNP rs572483 in *progesterone receptor* (*PGR*) gene (nominal p=0.0001; FDR p=0.07). Protective effect was observed among women carrying the variant *G* allele (adjusted OR= 0.27; 95%CI=0.12-0.57) but was not observed among men (adjusted OR= 1.27; 95% CI=0.95-1.69). In conclusion, we found the genetic variants of *CASP9*, *CASP7*, and *CHEK1* in the apoptosis pathway may be associated with EA risk and *PGR* in the sex hormone signaling pathway may be associated with the gender differences of EA risk.

**Predisposition for TMPRSS2:ERG fusion in prostate cancer by variants in DNA repair genes.** *C. Maier[1], M. Luedeke[1], C.M. Linnert[1], R. Kuefer[2], H.M. Surowy[1], A.E. Rinckleb[1], J. Hoegel[1], M.A. Rubin[3], W. Vogel[1].* 1) Inst of Human Genetics, Univ Ulm, Ulm, Germany; 2) Dept of Urology, Univ Ulm, Ulm, Germany; 3) Dept of Pathology and Laboratory Medicine, Weill Cornell Medical Center, New York, NY.

The oncogenic TMPRSS2:ERG fusion is a common event in prostate cancer. We hypothesized that defects in repair genes lead to an increase of chromosomal rearrangements and thus to the occurrence of the TMPRSS2:ERG fusion. We have previously conducted a genome wide linkage analysis in fusion positive prostate cancer families, revealing potential susceptibility loci on chromosome 5q14, 9p13, 9q21, 10q26, 11q24, 12q15, 13q12, and 18q. In the present study we investigated candidate genes related to DNA damage response and repair from these regions. A total of eleven candidate genes were screened for mutations in TMPRSS2:ERG positive families. We found 17 non synonymous variants (6 had a MAF < 0,05). Fourteen variants were investigated in a case control analysis, including 507 controls versus 327 sporadic and 203 familial cases. A polymorphism in RMI1 (RECQ-mediated genome instability) was associated with prostate cancer in general (OR = 1.33; 1.04 - 1.70; p = 0.02) and an uncommon variant of BRCA2 was associated to familial prostate cancer (OR = 6.16; CI95% 1.19 - 32; p = 0.03;), both however were independent of the TMPRSS2:ERG fusion status. Two variants in ESCO1 (Establishment of Cohesion 1, OR = 4.27; 1.62 - 11.3; p = 0.0034) and POLI (Polymerase iota, OR = 4.62; 1.84 - 11.6; p = 0.0011;) were highly significant associated with TMPRSS2:ERG fusion positive prostate cancer cases, and withstood the correction for multiple testing (Bonferroni threshold p = 0.0038). These results need validation and the variants with high OR may become useful in risk estimates for prostate cancer.

## 1060/W/Poster Board #718

**MATRIPTASE-2 (TMPRSS6) AS A BREAST CANCER RISK FACTOR.** *A. Mannermaa[1,2,3], J. Kauppinen[1,2,3], R. Sironen[1,2,3], Y. Soini[1,2,3], M. Eskelinen[4], V. Kataja[5,6], V.-M. Kosma[1,2,3].* 1) Institute of Clinical Medicine, Pathology and Forensic Medicine, University of Kuopio, Kuopio, Finland; 2) Department of Pathology, Kuopio University Hospital, Kuopio, Finland; 3) Biocenter Kuopio, Kuopio, Finland; 4) Department of Surgery, Kuopio University Hospital, Kuopio, Finland; 5) Department of Oncology, Kuopio University Hospital, Kuopio, Finland; 6) Department of Oncology, Vaasa Central Hospital, Vaasa, Finland.

*TMPRSS6* encodes for matriptase-2, a member of the type II transmembrane serine protease family that has been implicated in tumor progression. Low expression of matriptase-2 has been reported to predict poor patient survival.

We have previously reported chromosomal region 22q12-q13 and further a SNP rs733655 in matriptase-2 gene (*TMPRSS6*) to be associated with breast cancer. Here we report extensive case-control association analysis of the *TMPRSS6* gene by using 13 SNPs across the gene region in an Eastern Finnish population sample of 497 breast cancer cases and 458 controls. Genotyping was done using Taqman chemistry. In a total sample set markers rs733655 and rs2543519 were significantly associated with breast cancer (p=0.041, OR 1.36 and p=0,027, OR 1.38) and a 6-marker haplotype analysis of a 15kb region with high linkage disequilibrium showed a permutated p value of 0.001. In a more homogeneous subpopulation altogether 6 individual markers showed significant association with breast cancer with p-values ranging between p=0.05 and p=0.0002 and in a haplotype analysis with 8 markers a p-value of 0.01 was reached.

Our results provide further evidence for *TMPRSS6* as a risk factor in breast cancer and urges for additional studies on the role of matriptase gene family in breast cancer.

## 1061/W/Poster Board #719

**GSTM1, GSTT1 genes polymorphisms in esophageal squamous cell carcinoma: a case-control study in North-East IRAN.** *H. Marjani[1], F. Biramijamal[1], A. Hossein-Nezhad[1], R. Malekzadeh[2].* 1) National Institute of Genetic Engineering & Biotechnology (NIGEB); Tehran-Iran; 2) Digestive diseases research center-tehran university of medical siences .Tehran -IRAN.

From the early years of 1970's Golestan province in North-east Iran have been recognized as one of the most prevalent areas for esophageal squamous cell carcinoma (ESCC) in the world. Smoking, opium consumption, poor oral hygiene, low nutritional quality and hot tea drinking are thought to be the most important environmental factors in esophageal cancer risk. Exposure to polycyclic aromatic hydrocarbons (PAH) is an evident risk factor for many human cancers specially gastrointestinal tract malignancies.PAHs are generated from incomplete combustion of organic materials such as cigarette and broiled foods. PAHs' electrophilic nucleuses can invade DNA and impose many random mutations in its sequence so make the cells prone to undergo malignant changes. We have studied the genetic polymorphisms of two PAH (xenobiotics) metabolizing enzymes; GSTT1, GSTM1, because of their biologic contributions in detoxification and elimination of many kinds of PAHs.The mentioned two proteins belong to phase II xenobiotic metabolizing enzymes which can reduce electrophilic chemical radicals and make them conjugated with some natural compounds such as glucoronids and finally help them to be excreted in water soluble forms in liver. This study was performed on ESCC patients and healthy controls in Golestan province. For GSTM1 no significant difference was found between cases and controls group but we have noticed that GSTT1 null genotype was significantly high among the case group so there was a statistically meaningful relation between ESCC and GSTT1 null polymorphism (pvalue=0.04).

## 1062/W/Poster Board #720

**Non-sense mediated mRNA decay and microRNA array analysis of Finnish HPCX-linked families.** *H. Mattila[1], T. Ikonen[1], M. Vihinen[2], J. Isotalo[1], H. Oja[3], T. Tammela[4], T. Wahlfors[1], J. Schleutker[1].* 1) Laboratory of Cancer Genetics, Institute of Medical Technology, University of Tampere and Tampere University Hospital, Tampere, Finland; 2) Bioinformatics, Institute of Medical Technology, University of Tampere, Tampere, Finland; 3) Tampere School of Public Health, University of Tampere, Tampere, Finland; 4) Division of Urology, Tampere University Hospital and Medical School, Tampere, Finland.

Several predisposition loci for hereditary prostate cancer (HPC) have been suggested, including HPCX at Xq27-q28. In Finnish population HPCX seems to be very significant, but the susceptibility gene for the locus is still not identified, as the region itself is extremely complicated by structure. Gene identification by non-sense mediated mRNA decay inhibition has proven to be a useful technique for genome-wide discovery of genes containing truncating mutations. Six brother pairs (prostate cancer patient and healthy brother) were selected from families showing linkage to HPCX locus and total mRNA was isolated from cells after pharmacological treatment. Altered levels of gene-specific mRNA expression were measured using Agilent 44K oligoarrays and selected genes were screened for mutations by direct sequencing. For microRNA expression analysis the number of families was increased by five and miRNA expression levels were measured by Agilent Human miRNA V2 Oligo microarrays. MiRanda algorithm was used to identify genomic targets for miRNAs. Seventeen genes were selected for resequencing based on NMD array results but no truncating mutations were found. The most interesting identified variant for follow-up was MAGEC1 Met1Thr and a borderline association was seen between the variant and unselected PRCA (odds ratio (OR), 1.99; 95 % confidence interval (CI), 0.98-3.88) and HPC (OR, 2.86; 95 % CI 0.83-7.55). miRNA profiles were also analysed in HPCX-linked families and 16 miRNAs were found to have altered expression between patients and controls. In further analysis, hsa-miR-770-5p, was found to have highest expression in the group of healthy individuals and lowest expression in the group of aggressive cancer cases. The miRNA target analysis by MiRanda algorithm revealed that 12 of the 16 miRNAs having significantly altered expression also had possible targets site in the found variant sites. Interestingly, hsa-miR-770-5p has a possible target site in the MAGEC1 gene. The role of MAGEC1 Met1Thr variation and hsa-miR-770-5p and their possible involvement in the HPC risk in Finnish population need to be studied further. Also joint profiling and analysis of genes and miRNAs in the HPCX region may be required to fully understand their genetic contribution to prostate cancer risk.

## 1063/W/Poster Board #721

**Genetic variants encoding carcinogen-metabolizing enzymes may modify the association between breast cancer risk and active cigarette smoking.** *L. Mirea[1,2], M. Cotterchio[1,2], N. Kreiger[1,2], H. Ozcelik[2,3].* 1) Population Studies and Surveillance, Cancer Care Ontario, Toronto, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 3) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada.

The evidence regarding breast cancer risk and cigarette smoking is inconclusive. To evaluate the possible interaction between genetic susceptibility and active smoking, we conducted a case-control study and examined a number of candidate gene variants encoding carcinogen-metabolizing enzymes. DNA and smoke exposure (active and passive) data were obtained from a subset of breast cancer cases (N=1399) and controls (N=1492) that participated in the "Ontario Women's Diet and Health Study" during 2002-2003. Associations between breast cancer risk and genetic main effects (36 SNP's in carcinogen-metabolizing candidate genes CYP1A1, CYP1A2, CYP1B1, CYP2E1, EPHX1, NAT1, NAT2, UGT1A7, SOD2, SULT1A1, GSTM1, GSTT1), active smoking (former/current status and pack-years versus "never active and never passive" referent group), and all gene*smoking interactions were evaluated using multivariate logistic regression models adjusted for confounders. Analyses were also performed separately in pre- (PRM) (cases/controls = 541/626) and post-menopausal (PSM) (cases/controls = 1173/1148) subgroups. Several gene variants were significantly associated with increased breast cancer risk: GSTT1 locus (Deletion vs Present: OR (95%CI)=1.24 (1.05-1.54)), CYP2E1 rs6413432 (AA/AT vs TT: 1.23 (1.03-1.46)), and UGT1A7 rs17868323 (TT vs GG: 1.24 (1.01-1.53)) in the pooled data, CYP1A1 rs4646903 (CC vs TT: 2.64 (1.24-5.58)) in PSM and CYP2E1 rs 2480259 (TT vs CC: 1.70 (1.01-2.85)) in PRM women. Preliminary results suggest no statistically significant association between active smoking and breast cancer risk; however, several gene*smoking interactions were significant. Strongest evidence for effect modification was observed for active smoking status with NAT1 rs4921880 (p=0.01) in PRM and SOD2 rs4880 (p=0.01) in PSM women. A significant interaction was also seen between CYP1B1 rs1056836 and pack-years in the pooled data (p=0.03) and retained in both PSM (p=0.04) and PRM (p=0.05) women. Additional significant interactions were detected in PSM women for GSTT1 (p=0.03), CYP1A2 rs2470890 (p=0.04) and CYP1A1 rs2646903 (p=0.04) with smoke status. Specific to PRM, borderline interactions were seen for UGT1A7 rs11692021 (p=0.05) with smoke status, and for CYP1B1 rs2855658 (p=0.05) with pack-years. Our findings suggest that genetic variants may play a role in modifying the association between breast cancer risk in both pre- and post-menopausal women with active cigarette smoking.

## 1064/W/Poster Board #722

**Sequencing, phylogenetic analysis, and multipopulation studies suggest ABCB5 SNPs may be associated with diverse cancer subtypes.** *K. Moitra, M. Scally, K. McGee, M. Nickerson, G. Lancaster, J. Gould, B. Gold, M. Dean.* Cancer & Inflammation Program, NCI-FCRDC, Frederick, MD.

ABCB5 is a member of the ATP binding cassette (ABC) superfamily of transporters which function in the ATP dependent transport of structurally diverse molecules. Previously, ABCB5 was demonstrated to be a melanoma progression marker predominantly expressed in melanoma stem cells. Cancer stem cells are characterized by their capacity for self renewal and enhanced drug efflux capability thus protecting them from chemotherapeutic regimes. In this context it is crucial to determine the role of genetic variations in *ABCB5*. A phylogenetic analysis indicated that ABCB5, along with ABCB1, ABCB4, and ABCB11, shared a common ancestor which began duplicating early on in the evolutionary history of chordates. ABCB1, ABCB4 and ABCB11 are all full transporters with two nucleotide binding domains (NBDs) and two transmembrane domains. A comparative sequence analysis of the full length ABCB5 transporter indicates that the N-terminal transmembrane and NBD domains have been conserved during mammalian evolution indicating that the gene encodes a full transporter. *ABCB5* contains several relatively common non-synonymous polymorphisms which lie in functionally significant regions of the ABCB5 protein. The functional effect of these variations were predicted using Panther and SIFT programs combined with our knowledge base of ABC transporter function. Results from the in silico studies were applied to predict cSNPs which may crucially impair protein function. From genotyping studies of these SNPs in 52 human populations (HGDP) we found that the SNPs rs34603556, rs2301641, rs6461515 and rs58795451, would be important targets for cancer stem cell association studies. The SNPs rs2301641 and rs6461515 were also present in a number of the melanoma cell lines included within the NCI 60 panel. These cell lines have abundant data available on the effect of over 100,000 compounds on growth, and the genotype information can be used for functional studies.

## 1065/W/Poster Board #723

**Nonsense-mediated decay escaping mutations in microsatellite-unstable colorectal cancer.** *I. Niittymäki[1], A. Gylfe[1], L. Ahonen[2], H.J. Lehtonen[1], M. Laakso[3], J. Sirkiä[1], K. Nousiainen[3], J. Pouwels[2], H. Järvinen[6], K. Nuorva[7], J-P. Mecklin[8], A. Ristimäki[4], T.F. Ørntoft[5], S. Hautaniemi[3], A. Karhu[1], M.J. Kallio[2], L.A. Aaltonen[1].* 1) Department of Medical Genetics, Genome-Scale Biology Research Program, University of Helsinki, Finland; 2) VTT Technical Research Centre of Finland, Medical Biotechnology, Turku, Finland; 3) Computational Systems Biology Laboratory, Institute of Biomedicine and Genome-Scale Biology Research Program, Biomedicum Helsinki, University of Helsinki, Finland; 4) Department of Pathology, HUSLAB and Haartman Institute, and Genome-Scale Biology Research Program, University of Helsinki, Finland; Department of Pathology, Institute of Diagnostics, University of Oulu and Oulu University Hospital, Oulu, Finland; 5) Molecular Diagnostic Laboratory, Department of Clinical Biochemistry, Aarhus University Hospital, Aarhus, Denmark; 6) The Second Department of Surgery, Helsinki University Hospital, Finland; 7) Department of Pathology, Jyväskylä Central Hospital, Jyväskylä, Finland; 8) Department of Surgery, Jyväskylä Central Hospital, Jyväskylä, Finland.

Genomic instability drives tumorigenesis by allowing the accumulation of genetic alterations that provide cells with growth advantage. Microsatellite-instability (MSI) and the underlying mutator phenotype caused by a defect in mismatch repair (MMR) functions is the hallmark of Lynch syndrome, and is also observed in a subset of all colorectal cancers (CRC). In cells with a defective MMR system, spontaneous length changes of repetitive microsatellite sequences accumulate all over the genome at highly increased rates. At coding regions instability may lead to frameshift mutations and altered protein products. Genes that mutate this way under MMR deficiency giving selective advantage to cells in tumorigenesis are called MSI target genes. It is generally anticipated that the frameshift mutation-containing transcripts that lead to prematurely terminated proteins undergo nonsense-mediated decay (NMD), followed by a reduction in gene expression levels. However, when a premature stop occurs in the carboxyl-terminal end of the gene it might escape decay mechanisms, which may lead to either dominant-negative or oncogenic effects. Aim of this study was a genome-wide unbiased identification of new MSI CRC target genes that escape NMD. By combining bioinformatic search to expression profiling, we created a list of 330 genes that contained mononucleotide repeats from 6 to 10 base pairs and were likely to be translated despite potential mutations. A novel frameshift predictor software was developed to search all repeat-containing transcripts in the human genome that would escape NMD after one nucleotide deletion. To enhance the odds of identifying oncogenic mutants, the analysis was restricted to genes that were overexpressed in MSI CRC versus normal colonic mucosa. All of these genes were screened initially by sequencing the given repeat in a panel of 30 MSI CRCs. Whenever the mutation frequency exceeded 20% in the tumor set, which was considered evidence for possible selection in MSI tumorigenesis, an additional set of 70 MSI CRCs was sequenced. The great majority of the successfully sequenced genes had no mutations. Altogether four genes were mutated in over 20% of the samples in the extended 100 MSI tumor panel. These candidate driver target genes are being evaluated further by various methods, including sequencing of MSI CRC cell lines and microsatellite-stable (MSS) CRCs, statistical analyses, and functional *in vitro* experiments.

## 1066/W/Poster Board #724

**Differential biallelic expression of PTEN and mRNA degradation in Cowden syndrome patients with heterozygous germline PTEN mutations.** *M. Orloff[1, 2], H. Zhu[1], C. Eng[1, 2, 3, 4].* 1) Genomic Med Inst, Cleveland Clinic, Cleveland, OH; 2) Taussig Cancer Institute, Cleveland Clinic, Cleveland, OH; 3) Department pf Genetics, Case Western Reserve University, Cleveland, OH; 4) CASE Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH.

Heterozygous (het) germline mutations in PTEN are associated with Cowden Syndrome (CS), a dominant disorder characterized by a high risk of breast and thyroid cancers. Previous studies on het PTEN mutation-positive patients showed unexplainable discordance between PTEN genotype and their protein and transcript expression. This led us to hypothesize that some het PTEN mutations may have differential bi-allelic expression that cannot be explained by nonsense-mediated decay (NMD). We also postulated that this differential bi-allelic expression may play a pathogenic role in PTEN mutation-positive CS patients. To test our hypothesis, we used allele-specific quantitative (q) RT-PCR to compare the expression of allele-specific transcript levels in 51 unrelated patients carrying 3 different classes of PTEN mutations. In parallel, we measured PTEN protein expression by q-Western blot in all patients. Relative to the mean total transcript levels of controls (set at 1.0, 99%CI 0.86-1.14), all 3 nonsense mutations (NS) studied, R130X, R233X and R335X, from 39 individuals, showed decreased total transcript levels ranging from 0.22 (0.16-0.29) to 0.56 (0.52-0.60). Relative to mean control PTEN protein levels (set at 1.0, 99%CI 0.91-1.1), normalized PTEN protein levels from these 3 NS groups ranged from 0.22 (0.19-0.25) to 0.3 (0.26-0.34). Of note, het germline R335X was associated with almost no wildtype (WT) transcript (0.1 that of control levels) but relatively higher expression of the mutant allele (2-fold higher than their paired WT allele). All 8 individuals bearing 3 different missense mutations at codon 130 had equal bi-allelic transcription and either normal or slightly decreased protein levels. Unexpectedly, a synonymous variant, G44G found in CS but not controls, showed low (0.23+/-0.04) PTEN mRNA levels with a relatively high expression of the variant-bearing allele. Measurement of mRNA half-lives revealed that all the NS had mutant transcripts with a shorter half-life compared to normal transcripts. Moreover, both the mutant and WT transcripts from G44G had a significantly lower half-life compared to normal transcripts. While we have no direct evidence, our observations may suggest that specific mutations and variants, illustrated by R335X and G44G, can promote degradation of their counterpart WT-allele transcript. This may therefore represent a novel “double whammy” type of mechanism of PTEN dysfunction with decreased dosage of WT PTEN.

## 1067/W/Poster Board #725

**Family-based Association Analysis of 42 Hereditary Prostate Cancer Families Identifies a 15 Kb Gene Locus on Chromosome 22q12.3.** *E.A. Ostrander[1], B. Johanneson[1], S.K. McDonnell[2], D.M. Karyadi[1], P. Quignon[1], L. McIntosh[3], S.M. Riska[2], G. Johnson[1], K. Deutsch[4], G. Williams[1], J.L. Stanford[3,6], D.J. Schaid[2], S.N. Thibodeau[5].* 1) Cancer Genetics Branch, Bldg 50, National Human Genome Research Institute/NIH, Bethesda, MD; 2) Dept. of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle WA; 4) Institute for Systems Biology, Seattle, WA; 5) Depts. of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 6) Dept. of Epidemiology, School of Public Health, Univ. of WA., Seattle, WA.

Dozens of genome-wide scans for hereditary prostate cancer (HPC) susceptibility loci have been published to date, with putative loci identified on nearly every chromosome. However, few studies have been replicated with statistically significant results. One exception is chromosome 22q, for which five independent studies, including our own, identified strong linkage evidence for a susceptibility locus. Previously, we refined this region to a 2.53 Mb interval using recombination mapping in a set of 42 linked HPC pedigrees from the Mayo Clinic and the PROGRESS family collections. In the present study, we refine this locus to a 15 kb region spanning one major gene by performing family-based association analyses. Prostate cancer cases from 42 families linked to the 22q12.3 region were compared to a set of 533 unrelated population controls. This allowed exclusion of potential phenocopies and unaffected risk-variant carriers, thus increasing the power and accuracy of the overall analysis. The two family collections independently identified SNPs within a 15 kb locus at the 5’ end of the same gene as having the strongest associations, with the most robust results coming from a combined analysis of cases from all 42 families. Analysis of 15 tagSNPs across the 5’ end of the locus identified six SNPs with P-values ≤ 1.5x10-4 (200,000 simulations). Additional analyses using the LAMP program provided consistent results. Two independent family collections, highlighting the same two linkage disequilibrium (LD) blocks within the same gene strongly suggest that a variant within the minimal 15 kb interval, or one in strong LD with it, contributes to prostate cancer risk. This work highlights the values of combined approaches for follow-up of initial findings of linkage for complex traits.

## 1068/W/Poster Board #726

**Are Endothelial Nitric Oxide (NOS3) Gene Polymorphisms Important in Chronic Myeloid Leukemia (Ph+)?** *S. Pehlivan[1], M. Pehlivan[2], L. Kaynar[3], T. Sever[1], M. Yilmaz[2], B. Eser[3], V. Okan[2], M. Cetin[3].* 1) Medical Biology and Genetics, Gaziantep University, Medical Faculty, Gaziantep, Turkey, PhD; 2) Hematology, Gaziantep University, Medical Faculty, Gaziantep, Turkey, MD; 3) Hematology, Erciyes University, Medical Faculty, Kayseri, Turkey, MD.

Purpose: It was aimed to investigate whether there was an association between Nitric Oxide (NOS3) gene polymorphisms and Philadelphia positive (Ph+)-Chronic Myeloid Leukemia (CML). Method: DNA was isolated from the bloods of 59 patients diagnosed with CML and 100 healthy controls. NOS3 (+894) gene polymorphism was analyzed by PCR-RFLP whereas NOS3 (intron 4 VNTR) gene polymorphism was analyzed by means of PCR. The association between these polymorphisms and CML was analyzed using chi-square test and de-Finetti program. Conclusion: When the control and CML groups were compared in terms of Hardy-Weinberg Equilibrium (HWE), no deviations were observed in NOS3 (+894) polymorphism in CML whereas a deviation was detected in the control group (p:0.033). When the control and CML groups were compared in terms of HWE, no deviations were observed in NOS3 (intron 4 VNTR) polymorphism in the control group whereas a deviation was detected in CML patient group (p:0.015). A significant association was detected between the control and CML groups in terms of both allele and genotype frequencies in the 2 polymorphisms analyzed. In terms of haplotype frequency, it was found out that haplotype 13 (AATT) increased significantly while haplotypes 23, 31, 32 and 33 (ABTT, BBGG, BBGT, BB, TT) were present only in CML. Discussion: It is considered that the significant increase in TT allele of NOS3 (+894) polymorphism in CML patients has 7.8 times (OR:4.382/0.499) more risk for the etiopathogenesis of CML in comparison to the healthy group. It is considered that the significant increase in BB allele of NOS3 (intron 4 VNTR) polymorphism in CML patients has 3.2 times more risk for the etiopathogenesis of CML in comparison to the healthy group (OR:1.839/0.580). 2 polymorphisms of NOS3 gene in CML patients were simultaneously analyzed for the first time in this study and it was demonstrated that these polymorphisms could play a role in the etiopathogenesis of CML.

## 1069/W/Poster Board #727

**Updated genome-wide analysis identifies colon neoplasia susceptibility locus at chromosome 7q36.** *L.S. Phillips[1,2], R.C. Elston[1,2], S. Lewis[3], S.D. Markowitz[4,5], G.L. Wiesner[3,6].* 1) Epidemiology/Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Case Comprehensive Cancer Center, Case Western Reserve Univ, Cleveland, OH; 3) Genetics, School of Medicine, Case Western Reserve University, Cleveland, OH; 4) Molecular Biology and Microbiology, School of Medicine, Case Western Reserve University, Cleveland, OH; 5) Howard Hughes Medical Institute, Cleveland, OH; 6) Clinical Genetics, University Hospitals of Cleveland, Cleveland, OH.

Heritable factors account for ~20% of all colorectal cancers, but only a few genes associated with highly penetrant colon cancer syndromes have been identified to date. The Colon Neoplasia Sibling study (CNSS) identified 9q21-23 as a susceptibility locus in a genome-wide linkage analysis of non-HNPCC, non-FAP kindreds with two or more siblings affected with colon adenomatous polyps, advanced adenomas or colon cancer (Wiesner, 2003; Daley, 2008). Since then, several genome-wide association and linkage studies have suggested many other loci of interest, including 8q21 and 8q24, 10p14, 11q23, 14q22, 15q13, 16q22, 18q21, 19q13, 20p12, and most recently 7q31. Our initial results did not find significant linkage signals at any of these loci except for a minimally significant linkage signal at 7q36 (P=0.0011), which was telomeric to the 7q31 region identified in a family based study of colon cancer sibpairs (Neklason, 2008). We then sought to test whether an updated analysis of the CNSS dataset would confirm a putative susceptibility locus on chromosome 7. Phenotypic information for the entire CNSS dataset was updated by additional review of medical records for colon neoplasia in the index cases and siblings. Colon screening results changed affection status for some participants from unknown to either affected or unaffected. Three kindreds were excluded because subsequent tumor microsatellite instability testing identified them as possibly having HNPCC. Haseman-Elston linkage analyses on the updated set of 191 pedigrees (884 sib pairs, including 369 concordantly affected, 427 discordant, 88 concordantly unaffected, and 360 uninformative) showed a strengthened linkage signal at marker D7S3070 at 163 cM on 7q36 (P=0.0004). Removing families containing affected sib pairs with the most severe diagnoses (advanced adenomas and/or colon cancer) lessened but did not eliminate the peak. The region spans 15 cM and is 37 cM from the 7q31 signal found by Neklason et al. This updated analysis strengthens our initial linkage signal as a possible susceptibility locus in familial colon neoplasia and lessens the likelihood of phenotypic misclassification. Further, this putative locus is separate and distinct from the region previously identified at chromosome 7q31. Our results can be used to further identify the genetic factors that cause a predisposition to familial colon cancer and adenomatous polyps.

## 1070/W/Poster Board #728

**Association of FPGS and MLL variants with childhood acute lymphoblastic leukemia in different ethnicities.** *D. Piwkham[1,4], J. Gelfond[3], B. Rerkamnuaychoke[4], S. Pakakasama[5], G. Tomlinson[1,2], J. Beuten[1,2].* 1) Greehey Children's Cancer Research Institute; 2) Department of Pediatrics; 3) Department of Epidemiology and Biostatistics, The University of Texas Health Science Center, San Antonio, TX; 4) Department of Pathology; 5) Department of Pediatrics, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Acute lymphoblastic leukemia (ALL) is the most common malignancy in children. Genetic variation may explain the risk of developing childhood ALL. We present data on 2 genes that were analyzed as part of an ongoing study investigating the association of 8 candidate genes with ALL risk. The gene encoding folylpolyglutamate synthetase (FPGS), an important enzyme in the folate metabolic pathway, plays a central role in intracellular accumulation of folate and antifolate in the cell. Loss of FPGS activity results in decreased cellular levels of antifolates and consequent drug resistance in leukemia. The second gene, the mixed lineage leukemia (MLL) gene, is involved in many chromosomal translocations at 11q23 leading to a diverse subset of hematologic disorders, including childhood ALL. We investigated possible associations between single nucleotide polymorphisms (SNPs) and haplotypes of the FPGS and MLL genes with ALL susceptibility in different ethnic groups. Sixteen tagged SNPs, including SNPs with potential functional effects, were genotyped in ethnicity and age matched case-controls of Caucasian, Hispanic, African-American and Thai children using a customized Illumina panel on the BeadXpress platform. Significant differences in allele frequencies between cases and controls were observed for rs525549 ($p<0.001$) and rs6589664 ($p=0.02$) (MLL) in Hispanics and rs629470 ($p<0.01$) (MLL) in African-Americans. Three SNPs within FPGS (rs7039798, rs1544105 and rs10106) showed a significant association with ALL risk in the Thai sample ($p=0.014$, $p=0.010$, $p=0.026$, respectively). SNP rs1544105 (FPGS) was also significantly associated with ALL risk in the Caucasians ($p=0.041$). Four MLL variants significantly conferred ALL risk; rs573971 and rs6589664 in Caucasians, rs525549 and rs6589664 in Hispanics and rs629470 and rs6589664 in African-Americans (p=0.004-0.042). In addition, a significant gene-dosage effect for increasing numbers of potential high-risk genotypes was found in the three ethnic groups (OR=4.91-7.41; p= 0.001-0.002). Haplotype analysis further showed major haplotypes of the MLL gene that were significantly associated with ALL in our sample (p= 0.001-0.015). This study suggests that common genetic variants in the FPGS and MLL genes are associated with the ALL risk and that susceptibility shows population specific differences.

## 1071/W/Poster Board #729

**Fine-mapping of JAZF1 region associated with prostate cancer susceptibility.** *P. Porter-Gill[1], M. Tarway[1], A. Burrell[1], W. Tang[1], G. Thomas[2], M. Yeager[2], D. Albanes[3], L. Prokunina-Olsson[1], CGEMS Initiative.* 1) LTG/DCEG, NCI/NIH, Bethesda, MD; 2) CGF/DCEG, NCI/NIH, Bethesda, MD; 3) NEB/DCEG, NCI/NIH, Bethesda, MD.

The single nucleotide polymorphism (SNP), rs10486567, located in intron 2 of JAZF1 has been identified as a novel risk factor for prostate cancer (PC) susceptibility (Thomas et al., Nat Gen, 2008). We performed additional genotyping and show that this SNP is associated with prostate cancer susceptibility based on an adjusted model using the genotype test with 2 degrees of freedom; the observed p-value is 1.83x10-11 in 9,331 cases and 10,558 controls of European origin in the Cancer Genetic Markers of Susceptibility (CGEMS) Initiative. The rs10486567 is located 203 Kb from and has low correlation (D'=0.34, r2=0.038) with another JazF1 SNP, rs864745, associated with susceptibility to type 2 diabetes (Zeggini et al., Nat Gen, 2008). To explore the genetic landscape surrounding the PC-associated SNP, we first sequenced a region of 56 Kb in genomic DNA from 5 individuals (3 prostate cancer cases and 2 HapMap controls) and genotyped 11 SNPs (novel and variants from dbSNP with unknown frequencies) in three HapMap populations (European, Asian and African). Based on LD pattern observed in the HapMap samples of European descent (CEU), we selected 15 SNPs in r2>0.5 with the original SNP rs10486567 and genotyped this set of markers in 500 controls and 500 prostate cancer cases from Finland (ATBC study). We observed that the pattern of LD in this region differed from the HapMap samples substantially. To further explore the LD structure and genetic variation in this region, we are conducting deep resequencing with the next-gen technology (454 Roche) over a 127 Kb region (chr7:27,899,757-28,027,351) in 96 samples representing several ethnic groups. The fine mapping will help to refine the genetic landscape of the region in relevant sample sets and to select variants for follow up with larger scale association studies.

## 1072/W/Poster Board #730

**The breast cancer-associated SNP, rs11249433, is associated with expression of NOTCH2 splicing forms in human tissues.** *L. Prokunina-Olsson[1], J.P. Arhancet[1], A. Shah[1], J.L. Hall[2].* 1) LTG/DCEG, NCI/NIH, Bethesda, MD; 2) Lillehei Heart Institute, University of Minnesota, Minneapolis, MN.

A recent Genome-Wide Association Studies (GWAS) in breast cancer identified a novel locus at a pericentromeric region of chromosome 1p11.2, associated with susceptibility to breast cancer (BC) (p-value of 6.74x10-10) for SNP rs11249433 (Thomas et al., Nature Genetics, 2009). Since the NOTCH2 gene is located within this region, it represents an attractive candidate for investigation of the underlying mechanism related to the association signal. The NOTCH2 family of receptors plays a significant role in regulation of cell-cell communication, cell proliferation and differentiation. We identified and cloned two splicing forms of NOTCH2, one form encodes a full-length protein and the second form encodes a truncated protein that is predicted to have a dominant-negative function compared to the full-length protein. We examined the mRNA expression of both splicing forms in a set of human tissues and NCI 60 cell lines. In monocytes (n=64), liver (n=62) and pancreas (n=41), mRNA expression of the full-length form was significantly increased, while expression of the truncated form was decreased proportionally to the number of alleles of rs11249433. At the same time, expression of NOTCH2 splicing forms was not significantly affected by another NOTCH2 SNP, rs10923931, recently associated with susceptibility to type 2 diabetes (Zeggini, et al., Nature Genetics, 2008); these SNPs are located 662 Kb from each other and the correlation between them is D'=0.05, r2=0.0 in HapMap CEU samples. It is possible that the BC-associated variant rs11249433 might affect the ratio in expression of two splicing forms of NOTCH2. Overexpression of the full-length form together with decreased expression of the truncated form might favor cell proliferation and development of cancer in expense of cell cycle arrest and differentiation. The ongoing studies are focused on the expression of NOTCH2 splicing forms in normal and cancer breast samples. These studies form the basis of the biological exploration of the signal on chromosome 1 associated with breast cancer risk. Further studies are warranted to pursue these initial observations.

## 1073/W/Poster Board #731

**High-throughput hacking of the methylation profiles of 22 candidate genes in breast cancer using in vitro transcription and thymidine-specific cleavage mass array on MALDI-TOF silico-chip.** *R. Radpour, C. Kohler, Z. Barekati, R. Asadollahi, X.Y. Zhong.* Department of Biomedicine, University of Basel, Basel, Switzerland.

Alterations of DNA methylation patterns have been suggested as biomarkers for diagnostics and therapy of cancers. Every novel discovery in the epigenetic landscape and every development of an improved approach for accurate analysis of the events may offer new opportunity for the management of patients. Existing methods for quantitative analysis of methylation are limited, and are often too laborious for high throughput or inadequate. Recently, a MassCLEAVETM assay has been developed using a matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) to analyze base-specific methylation patterns after bisulfite conversion. To find an efficient and more cost effective high-throughput method for analyzing the methylation profile in breast cancer, we developed a method that allows for the simultaneous detection of multiple targets CpG residue by employing thymidine-specific cleavage mass array on MALDI-TOF slico chips. Using this novel high-throughput mass spectrometry method, we determined semi-quantitative methylation changes of 22 candidate genes (APC, BIN1, BMP6, BRCA1, BRCA2, CADHERIN 1, CST6, DAPK1, EGFR, ESR2, GSTP1, NES1, Nm23-H1, P16, P21, Progesterone receptor, Prostasin, RAR-b, RASSF1, SRBC, TIMP3, TP53) in breast cancer tissues. For the first time we analysed the methylation status of a total of 42,528 CpG dinucleotides on 22 genes in 96 different paraffin-embedded tissues (48 breast cancerous tissues and 48 paired normal tissues). A two-way hierarchical cluster analysis was used to classify methylation profiles. In this study, 10 hypermethylated genes (APC, BIN1, BMP6, BRCA1, CST6, ESRb, GSTP1, P16, P21 and TIMP3) were identified to distinguish between cancerous and normal tissues according to the extent of methylation. Individual assessment of the methylation status for each CpG dinucleotide indicated that cytosine hypermethylation in the cancerous tissue samples was mostly located near the consensus sequences of the transcription factor binding sites. These hypermethylated genes may serve as biomarkers for clinical molecular diagnosis and targeted treatments of patients with breast cancer.

## 1074/W/Poster Board #732

**Genetic Variation in Adiponectin and Adiponectin Receptor 1 and Prostate Cancer.** *A. Ray[1], K. Zuhlke[1], S. Chen[2], J. Douglas[2], J. Beebe-Dimmer[3], K. Cooney[1,4].* 1) Dept of Internal Medicine, Univ of Michigan Medical School, Ann Arbor, MI; 2) Dept of Human Genetics, Univ of Michigan Medical School, Ann Arbor, MI; 3) Barbara Ann Karmanos Cancer Center, Wayne State Univ, Detroit, MI; 4) Dept of Urology, Univ of Michigan Medical School, Ann Arbor, MI.

Prostate cancer (PCa) is the most commonly diagnosed cancer and the second leading cause of cancer death among American men. In addition to age and African American ancestry, family history is a leading risk factor for developing PCa suggesting that germline genetic variation plays a role in PCa initiation and/or progression. Recently, common variants in the adiponectin (*ADIPOQ*) and adiponectin receptor 1 (*ADIPOR1*) genes have been identified as being associated with breast and colorectal cancer risk. Circulating adiponectin, an adipokine that plays a role in cell proliferation and insulin resistance, is associated with PCa risk and grade, and adiponectin receptor 1 expression is decreased in PCa tissue compared to normal prostate tissue. Here we examine the role of *ADIPOQ* and *ADIPOR1* genetic variants in PCa risk. Ten haplotype-tagging SNPs in *ADIPOQ* and *ADIPOR1* were genotyped in a set of discordant sibling pairs (676 PCa affected and 583 unaffected men) from the University of Michigan Prostate Cancer Genetics Project. Using family-based association tests, 3 of these SNPs were found to be associated with early onset (EO) PCa. SNPs rs753942 and rs10920531 in *ADIPOR*, which were in strong linkage disequilibrium ($r^2$=0.71), were both associated with EO PCa (138 affected men) ($p<0.05$) under an additive model. Notably, the G allele of rs7539542, which is associated with decreased expression of the ADIPOR1 mRNA, was under-transmitted to affected men with EO PCa. SNP rs266729 in *ADIPOQ* was associated with EO PCa ($p<0.05$) under a dominant model. Interestingly, rs7539542 and rs266729 have been previously associated with breast and colon cancers respectively, but both in the opposite directions seen here. These results suggest that germline genetic variation in *ADIPOQ* and *ADPOR1* may be involved in PCa susceptibility, and further investigation into the exact role of these genes is warranted.

## 1075/W/Poster Board #733

**NUP98-PHF23 fusion gene impairs TPA-induced cellular differentiation and alters normal PHF23 protein distribution.** *J. Reader[1], Q. Leng[2], Y. Ning[1,2].* 1) Program in Human Genetics, University of Maryland, Baltimore, Baltimore, MD; 2) Department of Pathology, University of Maryland, Baltimore, Baltimore, MD.

*NUP98* is a promiscuous fusion partner gene linked to hematological malignancies. We identified a cryptic 11;17 translocation in an acute myeloid leukemia (AML) patient creating a novel in-frame fusion between *NUP98* exon 13 with *PHF23* exon 4. *NUP98* encodes a nucleoporin and has been involved in more than 20 different fusions. *PHF23* encodes a protein containing a plant homeodomain (PHD) involved in chromatin remodeling. The fusion partners of NUP98 can be categorized into two distinct groups: homeobox (HOX) genes and non-homeobox (non-HOX) genes. The non-HOX fusion partner genes, which include *NUP98-PHF23*, are diverse in function and are only related by possessing and retaining coiled-coil domain(s). The majority of research has focused on the mechanism of NUP98-HOX genes in leukemogenesis; therefore, our interests lie in further characterizing this novel non-HOX fusion gene. In order to test if *NUP98-PHF23* and normal *PHF23* are able to confer an oncogenic phenotype and to further characterize the gene, we cloned the full length fusion gene and normal *PHF23* and generated deletion constructs using an expression vector, and expressed it in fibroblast cell line NIH-3T3 and myeloid cell line K562 for localization and differentiation analyses, respectively. The PHF23 protein consists of only a coiled-coil and PHD domain. Taking advantage of this simple structure, we generated a series of deletion constructs, by removing the coiled-coil domain (ΔCoil), the PHD domain (ΔPHD) or both of the domains creating a double deletion mutant (ΔCoil-PHD), to delineate the function of these domains. We have shown that the NUP98-PHF23 fusion protein has a unique nuclear localization pattern, which is different from normal PHF23. The mutant proteins also demonstrated altered distribution within the cell. In addition, we demonstrated that NUP98-PHF23 fusion protein and the ΔCoil mutant protein partially blocked TPA-induced differentiation in K562 cells indicating that the PHD domain in the fusion gene is required to inhibit differentiation. Preliminary chromatin immunoprecipitation and real time quantitative PCR analysis of the fusion gene exhibited increased binding of the fusion protein to the promoter of *HOXA9*. These results indicate that NUP98-non-HOX fusions may function through HOX dependent pathways. Elucidation of the leukemogenic mechanism of NUP98 fusion proteins could lead to greater understanding of leukemogenesis and development of targeted therapy.

## 1076/W/Poster Board #734

**Interrogating genomic signatures of health disparities in prostate cancer.** *L. Ricks-Santi[1], V. Apprey[2], T. Mason[2], R. Kittles[4], M. Faruque[2], G.M. Dunston[2,3].* 1) College Med, Howard Univ Cancer Ctr, Washington, DC; 2) National Human Genome Center at Howard University, Washington, DC; 3) Department of Microbiology, Howard University, Washington, DC;; 4) Department of Medicine, The University of Chicago, Division of Biological Sciences, Chicago, IL.

Background: Prostate cancer (PCa) is a common malignancy and a leading cause of cancer death among men in the US. With regards to populations, the incidence and mortality rate of PCa among African American (AA) men is higher compared to Caucasians. The molecular mechanisms underlying this disparity, in addition to PCa's development remain poorly understood. Methods: For this study, SNPs (n= 79) within 15-35Mb of genes previously associated with PCa in AAs(1q, 7q, and 12p) and with significant allele frequency differences between Africans and Europeans were genotyped in a cohort of AA men enrolled in PCa genetic association studies by the Howard University Cancer Genomics Core. Pairwise linkage disequilibrium (LD) techniques were applied and strong LD was found among SNPs, within each chromosomal region, resulting in analysis of SNPs selected to represent each region. Results: Of the 34 SNPs analyzed, 9 SNPs (on 7q and 12p) were significantly associated with PCa risk. The level of significance varied according to the genetic effect model used. Using the additive genetic model, rs1993973 (IVS) had the strongest association with PCa (p=0.006). With the dominant genetic model, rs1993973 remained significant (p=0.03). However, rs1963562 and rs585224 had the strongest association when applying the dominant genetic model (p=0.008 for both SNPs). With the general model, only one SNP, rs615382 (RacGAP1), emerged as being associated with PCa risk (p=0.03). We also tested the independent effect of each significantly associated SNP and rs1561131 (p=0.04), rs1963562 (p=0.04), rs219821 (TRRAP) (p=0.0025), and rs883403 (CPSF4) (p=0.05) remained significantly associated with PCa. Intergenic SNPs were evaluated for pairwise association with other SNPs within 50kb using HapMap and rs1993973 was found to be in high LD (r2>0.80) with SSPN, an oncogene. Sequence analysis also revealed that transcription factor binding could be affected in 6 of the 9 SNPs. Methylation could also be potentially affected due to creation or ablation of CpG methylation sites in 2 of the SNPs. Conclusions: For this study, genetic markers with significant allele frequency differences between African and Caucasian populations where used to identify genetic variants associated with PCa in African Americans. We believe that this novel approach could help us determine if allele frequency differences in populations could be linked to the biology of disease in health disparities.

## 1077/W/Poster Board #735

**Assessment of genetic diversity of EpHB2 and its role as a genetic risk factor for prostate cancer among African American men.** *C.M. Robbins[1], W. Hernandez[2], S. Beckstrom-Sternberg[1], W. Tembe[1], S. Hooker[2], T.Y. Moses[1], J. Beckstrom-Sternberg[1], J. Pearson[1], R.A. Kittles[2], J.D. Carpten[1]*. 1) TGen, Phoenix, AZ; 2) Section of Genetic Medicine, Department of Medicine, The University of Chicago Pritzker School of Medicine, Chicago, IL.

Our group was the first to implicate the EpHB2 tyrosine kinase receptor as a tumor suppressor in prostate cancer (PC), where we reported somatic inactivating mutations occurring in 5% - 10% of sporadic tumors. With its role in maintaining normal epithelial architecture and functional data suggestive of a tumor suppressor in prostate cancer, EphB2 is an attractive candidate genetic risk factor for PC. Following previous findings, we hypothesized that there might be other common variants in EpHB2 that confer risk of sporadic prostate cancer among AA men. To test this hypothesis, 490 AA sporadic prostate cancer cases and 567 matched controls were genotyped with 335 genetic variants mapping within the EpHB2 locus. SNPs genotyped included 1) haplotype tagging SNPs with minor allele frequencies >5% based on the Yoruban population, International HapMap II data, 2) known coding variants, and 3) novel coding variants discovered by our group through sequencing of 24 AA cases and controls using Sanger sequencing. Logistic regression has revealed ten EpHB2 variants showing statistically significant association with prostate cancer risk after correction for multiple testing. Eight of these SNPs are located within the intron 1 region of which four are in strong linkage disequilibrium along with near identical odds ratios (1.5 or 1.6). Furthermore, to supplement these data, we used Next Generation Sequencing to interrogate the entire EpHB2 genomic locus in a pool of 400 African American cases and controls for discovery of all EpHB2 common variants in our cohort. This represents ~200,000 basepairs of total genomic sequence in 800 haploid genomes or 160,000,000 bases of DNA sequence. Using the Applied Biosystems SOLID system, we generated >500,000,000 bases of sequence. We are currently analyzing these data using bioinformatics tools to discover novel common and rare variants in the EpHB2 gene, with a focus on regions encompassing the ten SNPs that show association to prostate cancer. We will present data on validation of variants detected by SNP prediction algorithms from pooled data. We hope to further validate SNPs showing association to prostate cancer and any nearby novel SNPs identified by our sequencing efforts in an independent cohort of men of West African ancestry. These data form the basis of an extremely thorough analysis of EpHB2 as a genetic risk factor for prostate cancer among men of recent African descent.

## 1078/W/Poster Board #736

**Zoom-in CGH-array on 10 genes implied in breast cancer susceptibilities in a cohort of 413 *BRCA1*/*BRCA2*-negative patients : 4 new large rearrangements validated.** *E. ROULEAU[1], A. BRIAUX[1], V. CHABAUD[2], S. TOZLU-KARA[1], B. JESSON[2], C. ANDRIEU[1], V. SYLVAIN-VIDAL[2], V. VIDAL[2], L. DEMANGE[1], C. NOGUES[1], I. BIECHE[1], R. LIDEREAU[1]*. 1) Oncogenetic Lab, Centre René Huguenin, St Cloud, France; 2) IMAXIO Division Diagnogene, Saint-Beauzire, France.

Hereditary breast cancer accounts for up to 5-10% of all breast carcinomas. *BRCA1* and *BRCA2* remains the main pathway to explain high penetrance of breast cancer (BC). However, in the diagnostic process, biologists are often faced the major challenge in typical families without any deleterious mutations. Several hypothesis may explain these hereditary breast cancers; 1) *BRCA1*/*BRCA2* are affected but the mutations have not been characterized by conventional screening techniques, 2) a series of other susceptibility genes are implied in the DNA repair system and can confer a moderate risk to breast cancer. Many studies had already explored the presence of deleterious mutations in those genes (heterozygous *ATM*, *RAD50*, *RAD51*, *CHEK2*, *PALPB2*, *RAP80*, *BRIP1*, *BARD1*). Very few point mutations were found and no large rearrangement were reported in breast cancer susceptibility, except for *CHEK2*. We then explored the large rearrangements in 413 patients with typical families phenotype but negative *BRCA1*/*BRCA2* by routine techniques (sequencing, MLPA, QMPSF). We used a dedicated zoom-in CGH-array covering the whole gene (introns and exons) and the 5' and 3' flanking regions (100kb on average). A dedicated zoom-array (8x15k Agilent Technologies) was home designed : *BRCA1* (2427 oligonucleotides), *BRCA2* (2810), *ATM* (821), *BARD1* (493), *CHEK2* (358), *BRIP1* (674), *RAD50* (520), *RAD51* (301), *RAP80* (536), *PALPB2*(370) and covering the whole genome (4722). A dedicated software was programmed. The arrays were shared and hybridized in two differents platform with 5 common positive and 4 common negative control DNA. The rearrangement identified were confirmed with qPCR (LightCycler480, Roche Diagnostic) and specific classic PCR. No large rearrangements were found for the following genes : *ATM*, *RAD50*, *RAD51* and *PALB2*. 13 large rearrangements (4 duplications - 9 deletions) were identified in which 6 were fully confirmed at that time. Two large rearrangements already described in the litterature involved exons 9 to 10 in the CHEK2 gene. Most of the other rearrangements were identified in non-coding region and the deleterious impact should be further assessed. Several interesting conclusions were drawn from the quality data of arrays. This study confirmed that MLPA and QMPSF covered all possible coding large rearrangements in the *BRCA1* and *BRCA2* genes. The deleterious impact of events found could have some important consequences in the routine testing in breast cancer susceptibility.

## 1079/W/Poster Board #737

**Genetic Variation in Apoptosis Genes and Susceptibility to non-Hodgkin Lymphoma.** *J. Schuetz[1], J.J. Spinelli[2], D. Zamar[3], J.M. Connors[4], R. Gascoyne[5], D. Daley[3], A. Brooks-Wilson[1,6]*. 1) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, BC, Canada; 2) Cancer Control Research, British Columbia Cancer Research Centre, Vancouver, BC, Canada; 3) James Hogg iCAPTURE Centre, University of British Columbia, Vancouver, BC, Canada; 4) Medical Oncology, British Columbia Cancer Agency, Vancouver, BC, Canada; 5) Pathology and Laboratory Medicine, British Columbia Cancer Agency, Vancouver, BC, Canada; 6) Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, BC, Canada.

**Background**. Non-Hodgkin Lymphoma (NHL) is the 5th most common cancer in the United States and Canada. NHL is a complex disease, with both environmental and genetic contributions. Most cases are sporadic. This study aims to identify genetic factors contributing to NHL susceptibility in the general population by means of a population-based case/control study in Vancouver, Canada. Lymphocytes have properties that would be advantageous to a cancer, such as a long lifespan and the ability to divide rapidly when stimulated. If such a cell escapes apoptosis, it creates an ideal environment for further mutations. Low apoptosis levels could contribute to increased survival of pre-cancerous lymphoid cells, enlarging the pool of available cells in which mutations leading to cancer can occur. We are examining whether inherited genetic variation in 16 candidate genes with key roles in apoptosis influences susceptibility to NHL.

**Methods**. We are using constitutional DNA samples from 800 NHL patients and 800 controls previously collected.Targeted re-sequencing was used to supplement the choice of tagSNPs from public databases, for a subset of genes for which genetic variation information was limited. Re-sequencing was done in DNA samples from 47 NHL. TagSNPs and novel variants were genotyped using an Illumina custom GoldenGate multiplex assay. The contribution of the genotyped variants to NHL overall and major NHL subtypes is being assessed by logistic regression. Analysis is presently ongoing and results will be presented.

**Significance**. The identification of markers of genetic susceptibility to lymphoma will lead to a better understanding of this cancer. It will also contribute to the prediction of NHL risk and the development of surveillance programs for at-risk individuals, and potentially insight into treatment options.

**Capture Sequencing of Chromosome 4q21.3-25 Region Frequently Lost in the Hepatocellular Carcinorma.** *J. Su[1,12], K. Wu[1,2,12], Y. Chang[1,12], J. Li[1], Y. Lin[3], Y. Liu[1], C. Lin[1], H. Weng[4], T. Liu[4], A. Lin[1], H. Chen[1], C. Yuh[1,5,6], S. Huang[1,7], M. Tsou[8], S. Yeh[9,10], P. Chen[10,11], S. Wang[1], S. Tsai[1,2,3,4].* 1) Division of Molecular and Genomic Medicine, National Health Research Institutes, Zhunan, Taiwan; 2) Institute of Biomedical Informatics, National Yang-Ming University, Taipei, Taiwan; 3) Department of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, Taiwan; 4) Genome Research Center, National Yang-Ming University, Taipei, Taiwan; 5) College of Life Science and Institute of Bioinformatics and Structural Biology, National Tsing-Hua University, Hsin-Chu, Taiwan; 6) Department of Biological Science & Technology, National Chiao Tung University, Hsin-Chu, Taiwan; 7) Department of Pathology, Chang Gung Memorial Hospital, Taipei, Taiwan; 8) Department of Pathology, Koo Foundation Sun Yat-Sen Cancer Center, Taipei, Taiwan; 9) Department of Microbiology, National Taiwan University College of Medicine, Taipei,Taiwan; 10) Hepatitis Research Center and Division of Gastroenterology, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 11) Graduate Institute of Clinical Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan; 12) These authors contribute equally to this work.

Multiple genomic lesions occur in tumor tissues of hepatocellular carcinoma (HCC)have been studied by loss of heterozygosity mapping and comparative genomic hybridization (CGH). However, the exact position and nature of the genetic changes often cannot be determined because of individual variation and resolution limit. We developed a procedure for enriching genomic sequences from chromosome 4q13.3-q25, a region well characterized for DNA copy loss in HCC. After hybridization with a high-density oligonucleotide array designed for the 4q region (76-115 Mb), the captured DNA was eluted and processed for parallel sequencing, using both Roche/454 and Illumina/Solexa systems. We found that the returned sequences were significantly enriched for the target region, allowing us to perform nucleotide-level sequence comparison between the tumor and control tissues for the region. Taking paired samples from one HCC case, we identified 15,486 variations by comparing the captured sequences with the reference genome, and validated allelic changes involving the coding sequences, including DAPP1 (Arg143Gln) and MANBA (Leu749His). Additionally, 13 somatic mutations in the non-coding sequences were confirmed by Sanger sequencing. Our protocol connects capture sequencing with array CGH and enables high-resolution analysis of a selected target in the HCC genome. The experimental procedures reported here can facilitate future discovery of HCC-related genes and are generally applicable to mutation detection for cancers or genetic disorders.

## 1081/W/Poster Board #739

**Abnormal expression of candidate genes and miRNAs and their association with lung carcinoma.** *J. Wang[1], X. Wang[1], J. Xu[2], Y. Bao[2], H. Dong[1], Y. Wang[1], Z. Zhao[1], Y. Ma[1], Z. Xu[2], M. Xiong[1,3], L. Jin[1].* 1) State Key Laboratory of Genetic Engineering, MOE Key Laboratory of Comtemporary Anthropology, Fudan University, Shanghai, China; 2) Department of Cardiac and Thoracic Surgery, Changhai Hospital, Shanghai, China; 3) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030, USA.

TGF-β is a multifunctional cytokine and plays a central role in the signaling networks. According to our and other's research, the disruption of TGF-βpathway, such as the defective expression of the components downstream of TGF-β, contributed a lot in carcinogenesis of lung cancer. In this study, microarray analysis of gene expression and miRNA expression of 7 pairs of pulmonary squamous cell carcinoma tissues was conducted, and a robust statistical method was developed to determined the differentiated expressed genes and miRNAs between tumor and normal samples. Differentially expressed genes downstream of TGF-β were selected as candidate genes and examined in a larger sample size consisting of 92 pairs of lung tumor tissues and 10 strains of lung cancer cells. Differentially expressed miRNAs which might contribute to the changes of the candidate genes and other genes associated with carcinogenesis were also examined in these tissues and cells. Statistical analyses were performed to find the association among gene expression, miRNA expression and lung carcinogenesis. As results, nine genes (8 were down-regulated and 1 was up-regulated in cancer) in TGF-β pathway and 51 miRNAs (30 down-regulated and 21 up-regulated) were found significantly differentially expressed between the tumor and normal samples. Pathway-based LCT analysis suggested that eight sets of gene expression including 2 to 9 genes were associated with lung tumorigenesis. Chi square analysis indicated DACH1 expression was associated both with patient gender and subtype. The expression of 8 genes was associated with metastasis. According to miRNA database and our expression data, the irregular expression of COL1A2 mRNA in tumors might be caused by the changes in miR-29c, 196a, or 224, which had opposite expression with COL1A2. The aberration of LPHN2, COL11A1, and NRP1 expression might associated with the expession changes in miR-9, 224, 521, and/or 767-5a. Other differentially expressed miRNAs, such as miR-133a, 133b, and 375, might contribute to API5 and JAK2 expression, which were not included in the above 9 genes but associated with carcinogenesis. Other 5 genes in TGF-β pathway have not shown correlation with miRNA expression accoding to gene-miRNA-regression analysis. Their differentiated expression might come from differentiated methylation status or gene mutation or other factors. The association between genes and miRNAs will be further validated by functional analysis.

## 1082/W/Poster Board #740

**Identification of a Novel Lung Tumor Suppressor Candidate at the Lung Cancer Susceptibility Locus 6q23-25.** *I.M. Wilson, R.C. Chari, T.P.H. Buys, S.L. Lam, W.L. Lam.* British Columbia Cancer Research Centre, Vancouver, British Columbia, Canada.

Background: Familial heritance of lung cancer risk has long been suspected. Indeed, recent work examining familial lung cancers has identified a region associated with lung cancer susceptibility located at 6q23-25. Although gene candidates from this region have been pursued, none have yet been confirmed as the focal point of the region. The identification of novel tumor suppressor genes (TSGs) within this region would provide targets for therapeutics and screening, as well as insights into the germ line and somatic alterations responsible for lung cancer susceptibility.

Objective: Our primary goal is to identify novel TSGs in the lung cancer susceptibility locus using a two-hit integrated screen that highlights genes somatically silenced by both DNA hypermethylation and deletion.

Methods: 30 lung adenocarcinomas and histologically normal parenchyma were obtained during surgery. After pathology review, tumor cells were isolated by microdissection and DNA/RNA were extracted from the tumor and parenchyma. Copy number status was determined by aCGH using the BCCRC whole-genome tiling path array. DNA deletions were defined using a aCGH Smooth. DNA methylation status was determined for tumor and parenchyma DNA using the Illumina Infinium assay. Hypermethylated genes were identified where the difference between tumor and normal β-values was ≥0.25. Gene expression data were generated using the Agilent 44k expression microarray. Combined analysis of DNA copy number and methylation data in each tumor detected two-hit regions of alteration. The frequency of two-hit alteration was calculated, and those probes altered in ≥15% of samples were investigated further. This included analysis of mRNA expression, validation of DNA hypermethylation (MSPCR), and evaluation of DNA methylation control by 5'-aza treatment of cancer cells.

Results: Importantly, our analysis identified frequent somatic hypermethylation and deletion of two genes located within the susceptibility locus (6q23-25). One of these genes was also significantly under-expressed in tumors relative to normal lung ($p \leq 0.05$). DNA hypermethylation of this gene was validated by MSPCR in lung cancer samples as well as in lung cancer cell lines. Cell lines with methylated alleles were treated with 5'-aza, which restored expression of the gene.

## 1083/W/Poster Board #741

**Replication study of genetic variants associated with prostate cancer in African American men: The Flint Men's Health Study.** *K. Zuhlke[1], A. Ray[1], Y. Wang[2], T. Rebbick[3], K.A. Cooney[1], E.M. Lange[2].* 1) Dept Internal Med, Univ Michigan, Ann Arbor, MI; 2) Depts. Genetics and Biostatistics, Univ North Carolina, Chapel Hill, NC; 3) Dept. Epidemiology and Biostatistics, Univ. Pennsylvania, Philadelphia, PA.

Prostate cancer is the most common cancer among men in the United States with 186,320 new cases diagnosed and 28,660 deaths estimated in 2008. In addition to increasing age, race is one of the most important recognized risk factors for the disease. African-American men have an approximately 1.6 fold greater chance of being diagnosed with prostate cancer compared to European-American men and a 2.4 fold greater chance of dying from the disease. Genome-wide association studies (GWASs) have been successful in identifying a number of single nucleotide genetic polymorphisms (SNPs) that are associated with prostate cancer in men of European descent. Many of these association findings have been replicated successfully across multiple studies. Unfortunately, despite their increased risk for developing and dying from the disease, African-Americans are typically under-represented in genetic association studies of prostate cancer. We genotyped 24 SNPs previously reported to be associated with prostate cancer in men of European descent in a population-based case-control sample (n = 127 cases and 345 screened controls) of African-American men from the Flint Men's Health Study (FMHS). We found significant evidence for association ($p < 0.05$) between 5 SNPs and prostate cancer in unadjusted logistic regression models with SNP analyzed assuming a multiplicative risk model: rs6983561 (p=0.004; OR=1.55), rs7000448 (p=0.03; OR=0.71), and rs16901979 (p=0.003; OR=1.60) at 8q24; rs7904463 (p=0.03; OR=0.70) and rs10740051 (p=0.01; OR=0.51) at 10q11 in MSMB. One additional SNP, rs6983267 (p=0.06; OR=0.61) at 8q24 had suggested evidence for an association. ORs > 1.0 reflect increased frequency of minor allele in cases. Results were similar when covariate adjustment was made for age and estimated proportion of African ancestry. These results, combined with two other recent reports, show that a subset of SNPs that have been identified to be associated with prostate cancer in men of European descent are important risk factors for prostate cancer in African-Americans.

## 1084/W/Poster Board #742

**Chromosomal and genetic alterations in human hepatocellular adenomas associated with type Ia glycogen storage disease.** *L. Li[1], P. Kishnani[2], T. Chuang[3], D. Bali[2], D. Koeberl[2], S. Austin[2], D. Weinstein[4], E. Murphy[5], Y. Chen[3], K. Boyette[2], C. Liu[3], Y. Chen[1,2].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Division of Medical Genetics, Duke University Medical Center, Durham, North Carolina, USA; 3) National Genotyping Center, Academia Sinica, Taipei, Taiwan; 4) Glycogen Storage Disease Program, University of Florida College of Medicine, Gainesville, FL, USA; 5) Charles Dent Metabolic Unit, National Hospital for Neurology and Neurosurgery, London, UK.

Hepatocellular adenoma (HCA) is a frequent long-term complication of type I glycogen storage disease (GSD I) and malignant transformation to hepatocellular carcinoma (HCC) is known to occur in some cases. There has been no systematic study of chromosomal and genetic alterations in HCA associated with GSD I. We performed genome-wide SNP analysis and mutation detection of target genes in ten GSD Ia associated HCA and compared the results to seven general population HCA cases. Chromosomal aberrations were detected in 60% of the GSD Ia HCA and 57% of general population HCA. Intriguingly, simultaneous gain of chromosome 6p and loss of 6q were only seen in GSD Ia HCA (3 cases) with one additional GSD I patient showing submicroscopic 6q14.1 deletion. The sizes of GSD Ia adenomas with chromosome 6 aberrations were larger than the sizes of adenomas without the changes (10.9 +/- 1.8 cm versus 5.7 +/- 2.2 cm, p= 0.012). Expression of two selected candidate tumor suppressor genes at 6q was reduced in more than 50% of GSD Ia HCA that were examined (n= 7). None of the GSD Ia HCA had biallelic mutations in the HNF1A gene. Conclusions: These findings strongly suggest that chromosome 6 alterations could be an early event in the liver tumorigenesis in GSD I. Genetic alterations in GSD I HCA were different from that in the general population HCA, suggesting that molecular pathways responsible for the pathogenesis of GSD Ia HCA could be distinct. These results also suggest an interesting relationship between GSD Ia HCA and steps to HCC transformation.

## 1085/W/Poster Board #743

**The Application Of SNP-based Array CGH For The Detection Of Novel Cancer Susceptibility Genes In Multi-cancer Families.** *G. Chenevix-Trench[1], N. Wayte[1, 2], P. Simpson[2], L. DaSilva[2], S. Lakhani[2], N. Hayward[1], D. Duffy[1], kConFab.* 1) Queensland Inst Medical Res, Brisbane, Australia; 2) University of Queensland, Brisbane, Australia.

Most heritable cancer syndromes have a restricted range of tumour types associated with them, even though most of the responsible tumour suppressor genes are ubiquitously expressed. We hypothesise that there are general cancer susceptibility syndromes, caused by rare germline mutations in other tumour suppressor genes, and that loss of heterozygosity (LOH) will constitute the 'second hit' in these tumours. There are seldom enough living affected individuals in these 'general cancer families' for linkage analysis because of the high mortality rates of many cancers, but we propose that the genes responsible can still be located by SNP-based array CGH analysis, because all the tumours in the family will share retention of the risk haplotype but lose the other allele. Based on population age-, sex- birth cohort- and cancer rates, we have identified 6 non-BRCA1/2 families ascertained by kConFab with a significant excess of multiple cancer types (at least 3), as well as 2 non-CDKN2A families with multiple cases of melanoma and other cancer types. Because the tumours in these families are often small and the DNA rate-limiting, we have assessed the performance of formalin-fixed, paraffin embedded (FFPE) tumour samples on the GoldenGate Assay (Illumina) which is suited to the use of fragmented DNA, using small amounts of template DNA. We found that lower amounts of DNA input (down to 75ng) perform adequately in the GoldenGate assay, and that loss of information and miscalling was minimal when SNP calls for the FFPE samples were compared to matched fresh frozen pairs. We also assessed the performance of a panel of 30 FFPE tumours from the multiple cancer families we had identified, that ranged in tumour site, age of pathology block (2-20 years) and processing pathology lab. Included in this panel were tumours of the breast, ovary, colon, testis, pancreas, brain, stomach, thyroid and melanoma. We successfully obtained SNP genotyping data from 28/30 tumours and used the R package beadarraySNP to perform concurrent analysis of DNA copy number and LOH on these tumours, comparing tumours within each family to identify common regions of loss or gain. This approach will be combined with genetic linkage analysis in families where germline DNA samples are available to identify candidate cancer predisposition genes in families with apparent inherited cancer susceptibility but for which no known cancer syndrome is apparently responsible.

## 1086/W/Poster Board #744

**Contribution of MTAP variation to disease phenotype in melanoma-prone families with CDKN2A mutations.** *A.M. Goldstein, X.R. Yang, M.A. Tucker, Core Genotyping Facility/DCEG/NCI.* Genetic Epidemiology Branch, DCEG, National Cancer Inst, NIH, Bethesda, MD.

CDKN2A, the major susceptibility gene for cutaneous melanoma (CM), is located on chromosome 9p21. A subset of CM-prone families with CDKN2A mutations has an increased risk for pancreatic cancer (PC) but the reasons for this association are not fully understood. One gene in the 9p21 region, MTAP (that encodes methylthioadenosine phosphorylase), is often co-deleted with CDKN2A in CM and PC tumors. The goals of this study were to determine whether variation in MTAP might influence disease risk in families with CDKN2A mutations. 23 American CM-prone families with CDKN2A mutations (96 CM patients, 143 related controls, 75 spouse controls) were genotyped for variation in MTAP. MTAP tagging based on minor allele frequency >5% and $r^2<0.8$ yielded 17 SNPs. Conditional logistic regression, matched on families to account for family ascertainment and differences in disease prevalence, was used to estimate the odds ratio and 95% confidence interval between CM risk and each SNP, using co-dominant coding for genotypes (0, 1, 2) with the homozygote of the common allele as the referent group. Examination of all families revealed 7 MTAP SNPs that showed significant associations with CM risk. After adjustment for CDKN2A mutation status, no SNPs were significant. Evaluation of families stratified by type of CDKN2A mutation (PC-related vs not PC-related) also showed several different SNPs significantly associated with CM risk. Again, however, after adjustment for CDKN2A mutation status and total nevi, no SNPs remained significant. To further evaluate variation in MTAP, we examined the association between MTAP and several well-known melanoma risk factors including dysplastic nevi (DN), total number of nevi, freckles, complexion, and solar injury. No significant associations were seen between DN, total nevi, complexion or freckles and any MTAP SNPs after adjustment for confounding factors. In contrast, increased solar injury was significantly associated with multiple MTAP SNPs in controls and all subjects together even after adjustment for confounding factors. Given the small sample size, additional CM-prone families with CDKN2A mutations are needed to further evaluate whether MTAP variation might lead to increased solar injury in susceptible individuals. Larger studies are also needed to further examine whether variation in MTAP may contribute to some of the increased risk for CM or pigmentary or nevus-related factors in CM-prone families with CDKN2A mutations.

## 1087/W/Poster Board #745

**A novel family with tylosis with oesophageal cancer: haplotype and expression analysis of the TOC minimal region.** *S. Saarinen[1], P. Vahteristo[1], R. Lehtonen[1], T. Kiviluoto[2], V. Launonen[1], L. Aaltonen[1].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Department of Surgery, Helsinki University Central Hospital.

Tylosis is an autosomal, dominantly inherited disorder with palmar and plantar skin keratosis. So far, three families have been reported in which tylosis segregates together with oesophageal cancer. The tylosis with oesophageal cancer (*TOC*) locus has been mapped to chromosome 17q25 in a 42.5 kb region. The *TOC* minimal region has been fully sequenced, but the causative gene defect has not been identified. Only two known genes are located within the *TOC* minimal region, Cytoglobin (*CYGB*) and Rhomboid 5 homolog 2 (*RHBDF2*).Here we introduce a novel Finnish family with tylosis and oesophageal cancer. Three family members have been diagnosed with tylotic keratoderma and three other members with oesophageal cancer. In addition, one family member has breast cancer, one has died of colon cancer and one of cardia cancer. To evaluate whether the Finnish family is linked to the *TOC* minimal region, we performed a haplotype analysis of chromosome 17q25 using microsatellite markers and SNPs. We also sequenced all the known and predicted genes and their promoter regions located in the *TOC* minimal region. In addition, the expression profiles of *CYGB* and *RHBDF2* were obtained from blood derived RNA of three affected family members. The haplotype analysis revealed a common haplotype in both tylosis and the breast cancer patients. This common region was larger than the previously reported *TOC* minimal region of 42.5 kb. Mutation screening of the known and predicted genes did not reveal a disease specific alteration. Expression analysis of *CYGB* and *RHBDF2* revealed that the relative expression of *CYGB* was highly reduced in the tylosis patients compared to the controls. Although it has been possible to refine the *TOC* minimal region to 42.5 kb, disease causing mutations have not been found. Here we have characterized a novel family with *TOC* and shown that it is compatible with linkage to *TOC* minimal region. The expression of *CYGB* was highly reduced in blood of three members of the Finnish tylosis family. It was recently reported that in eosophageal biopsies from tylotic patients the expression of *CYGB* is reduced by 70% and *CYGB* was supposed to be a strong candidate for contributing the *TOC* phenotype. Our study also suggests a possible role for *CYGB* in the pathogenesis of *TOC*. However, more studies are needed to understand the underlying alteration in the *TOC* minimal region causing both tylosis an oesophageal cancer.

## 1088/W/Poster Board #746

**Variation at 8q24 and 9p24 and Risk of Epithelial Ovarian Cancer.** *K.L. White[1], R.A. Vierkant[1], C.M. Phelan[2], B.L. Fridley[1], J.M. Schildkraut[3], Y. Tsai[2], H. Song[4], D.J. Duggan[5], P.P.D. Pharoah[4], F.J. Couch[1], J.M. Cunningham[1], T.A. Sellers[2], E.L. Goode[1].* 1) Mayo Clinic College of Medicine, Rochester, MN; 2) H. Lee Moffitt Cancer Research Institute, Tampa, FL; 3) Duke University, Durham, NC; 4) University of Cambridge, Cambridge, UK; 5) The Translational Genomics Research Institute, Phoenix, AZ.

The chromosome 8q24 region is known to harbor variants associated with risk of breast, colorectal, and prostate cancer, and functional studies have started to emerge shedding light on underlying mechanisms. One recent association study of 1,975 invasive ovarian cancer cases and 3,411 controls found evidence of the 8q24 ovarian cancer susceptibility loci rs10505477 (per-allele OR 1.14, 95% CI 1.04-1.23, p-trend 0.002) and rs6983267 (per-allele OR 1.11, 95% CI 1.03-1.20, p-trend 0.01) [Ghoussaini et al., 2008]. Here we used a multi-site case-control study of 749 women with invasive ovarian cancer and 1,041 controls to evaluate associations between SNPs in 8q24, as well as in the 9p24 colorectal cancer associated-region [Poynter et al., 2007], and risk of ovarian cancer. A total of 35 tagging SNPs and SNPs associated with risk of other cancers were assessed using an Illumina GoldenGate array; logistic regression was used to estimate odds ratios (ORs) and adjust for population structure and other potential confounders. No association between genotypes and risk of ovarian cancer was observed considering all invasive cases or invasive serous cases only. Although 8q24's rs10505477 and rs6983267 were associated with ovarian cancer risk in a previous report, analyses here yielded per-allele ORs of 0.95 (95% CI 0.82-1.09, p-trend 0.46) and 0.97 (95% CI 0.84-1.12, p-trend 0.69), respectively. Risk estimates for the breast cancer risk SNP 8q24 rs13281615 were also close to 1.0 (OR 0.97, 95% CI 0.85-1.12, p-trend 0.72), consistent with data from the Ovarian Cancer Association Consortium [Song et al., 2009]. These null results indicate that despite intriguing initial ovarian cancer associations, confirmed associations with risk of other cancers in 8q24, and our hypothesis that 9p24 variants may associate with ovarian cancer risk, the 35 informative SNPs studied here are not related to etiology of this gynecologic malignancy. Thus, much remains to be learned about the site-specific role that variants in these regions play in carcinogenic processes.

## 1089/W/Poster Board #747

**Causative mutations in Lynch syndrome: what are we missing?** *M. Clendenning[1], D.D. Buchanan[1], M.D. Walsh[1], M.A. Jenkins[2], J.L. Hopper[2], J.P. Young[1].* 1) Queensland Institute of Medical Research, Herston, QLD, Australia; 2) Centre for MEGA, School of Population Health, University of Melbourne, Carlton, VIC, Australia.

The current practice for identifying individuals with Lynch syndrome (defined as carriers of a deleterious mutation within one of the four primary DNA mismatch repair (MMR) genes, *MLH1*, *MSH2*, *PMS2* or *MSH6*) involves obtaining an extensive family history and assessing Lynch syndrome associated tumours for microsatellite instability and/or immunohistochemical (IHC) loss of MMR proteins, followed by a targeted approach, guided by the IHC findings, of large deletion screening via MLPA and exonic sequencing. Serrated neoplasia families are separated from Lynch syndrome via somatic *BRAF* mutation testing in MLH1 deficient tumours. This approach has proven both logical and efficient for the identification of mutations in the MMR genes, however there are still many families who fail to have a mutation identified, despite multiple affected individuals displaying loss of staining for one or more of the MMR proteins. The inability to identify a mutation in these families is of significant clinical importance as individuals, who have an increased risk of developing CRC, cannot be identified. In an attempt to address these issues we performed basic linkage analysis, across three regions that contain the four main MMR genes (2p21, 3p22.2 and 7p22.1), in families where a mutation had not been identified despite immunohistochemical indications of gene inactivation in these regions. Three families containing a known mutation were used as a proof of principle, and in each case a common, mutation associated, haplotype was identified that was not present in any non-mutation carriers. Within each family where no mutations had been detected, we were able to identify a common haplotype which correlated with the IHC findings of affected individuals. These haplotypes suggest that any causative mutation in these families lies in *cis* with the IHC associated gene and as such, current screening procedures must be failing to detect them. Regulatory regions such as promoters and intronic enhancer elements may prove to be a source of mutations that affect transcription and/or translation, and the recent identification of germline methylation of *MSH2* and mutations in the *TACSTD1* gene also supports a role for mutation screening beyond current practices. Such common haplotypes may also prove to be very useful from a clinical point of view, as they could be used as an alternative way to identify family members who are at an increased risk of developing Lynch syndrome.

## 1090/W/Poster Board #748

**Genetic associations with mean telomere length and risk of breast cancer.** *K.A. Pooley[1], J. Tyrer[2], M. Shah[2], K.E. Driver[2], B.A.J. Ponder[3], P.D.P. Pharoah[2], D.F. Easton[1], A.M. Dunning[2].* 1) Cancer Research UK Genetic Epidemiology Unit, Dept. of Public Health, Strangeways Research Lab, Worts Causeway, Cambridge, United Kingdom; 2) Dept. of Oncology, Strangeways Research Lab, Worts Causeway, Cambridge, United Kingdom; 3) Cancer Research UK Cambridge Research Institute, Li Ka Shing Centre, Robinson Way, Cambridge, United Kingdom.

Previous studies have indicated that telomere length is heritable and that shorter mean telomere length in lymphocytes is associated with an increased risk of common cancers, including breast cancer. A recent report has suggested that a SNP (rs401681) in the TERT gene region is associated with reduced mean telomere length and increased risk of certain cancers (Rafnar et al. Nat Genet 41.2 (2009): 221-27). We measured mean telomere length, in blood-extracted DNA, using a high throughput quantitative real time PCR assay (McGrath et al. CEBP 16.4 (2007): 815-19). Estimates of mean telomere length obtained with this assay are reproducible, they display the established reduction of length with increasing age and they demonstrate the heritability of mean telomere length - with a broad-sense heritability estimate of 0.48 among 2000 siblings. In 7000 subjects, assayed for mean telomere length and genotyped for the TERT rs401681 SNP, we see no association between genotype at this locus and age-adjusted telomere length (p-trend=0.77). In a sample of 6600 cases and 6800 controls from the East Anglian SEARCH study, there was no association between the TERT rs401681 SNP and breast cancer risk. However, in this study, mean telomere length was approximately 3 percent shorter in cases than controls. Subjects with a mean, age-adjusted telomere length in the lowest quartile group had an Odds Ratio of being a breast cancer case of 15.51 (11.57 - 20.80), p-het=$5.7 \times 10^{-75}$, relative to those in the highest quartile. Since SEARCH is a retrospective case-control study i.e. the blood samples from SEARCH cases are obtained after diagnosis, it is not clear if this association is indicative of a genuine aetiological relationship, or it occurs after tumour development or treatment. Ongoing studies to further understand the relationship between cancer status and mean telomere length are underway. In conclusion, we see no association of rs401681 with either mean telomere length or increased risk of breast cancer. However, we are currently conducting genome-wide studies to identify loci associated with both mean telomere length and cancer susceptibility.

## 1091/W/Poster Board #749

**The relationship between single nucleotide polymorphisms in inflammation genes and serum androgen levels.** *T. Meyer[1], L. Chu[1], Q. Li[1], K. Yu[1], P. Rosenberg[1], I. Menashe[1], W. Huang[1], J. Weiss[1], R. Kaaks[2], R. Hayes[1], S. Chanock[1], A. Hsing[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland, USA; 2) German National Cancer Center, Division of Cancer Epidemiology, Heidelberg, Germany.

It has been shown that serum androgens correlate with inflammation and expression of inflammation-related genes. Much less is known about the relationship between variants in inflammation genes and circulating androgen levels. Therefore, we evaluated the correlation between 10,867 single nucleotide polymorphisms (SNPs) in 778 inflammation-related genes and four serum androgen measures (total testosterone [T], 3$\alpha$-androstanediol glucuronide [3$\alpha$diol G], androstenedione, and the calculated ratio of T to its binding protein, sex hormone binding globulin [T:SHBG]), in 570 healthy male subjects (median age 64) from the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial. SNP-hormone correlations were evaluated using linear regression of log-transformed hormone variables adjusted for age. SNPs were coded in additive genetic form. Preliminary results show that several SNPs from inflammation-related genes were associated with circulating androgen levels. One SNP in *CD14*, which encodes a surface protein involved in pathogen recognition, was associated with total T (rs3822356 $P$=2.4x10$^{-5}$). Two SNPs in the *MMP2* gene, which is involved in remodeling of injured tissue, were associated with total T (rs893226 $P$= 1.4x10$^{-5}$ and rs1816595 $P$=6.1x10$^{-5}$). Two SNPs in *SMAD7* and *LTBP1*, genes thought to interact with transforming growth factor $\beta$ to help regulate pro-inflammatory and fibrotic signaling cascades, were associated with T:SHBG (rs884013 $P$=3.4x10$^{-5}$ and rs11885904 $P$=7.7x10$^{-5}$, respectively). Finally, variants in genes involved in the T-cell immune response, including rs348373 in *TNFSF9* and rs4240205 in *CD8B* were associated with androstenedione ($P$=5.3x10$^{-6}$) and 3$\alpha$diol G ($P$=8.4x10$^{-5}$), respectively. Further adjustment for body mass index attenuated effects only slightly. Our results show that SNPs in genes involved in different stages/mechanisms of inflammation are associated with serum androgens, suggesting a complex interplay between androgens and inflammatory processes, which together may play a role in certain hormone-related cancers. Future studies are needed to confirm our findings and to clarify the interrelationship between inflammation and androgens and their effects on cancer.

## 1092/W/Poster Board #750

**Familial Haematological Malignancies: The search for a causative gene continues.** *E.M. Tegg[1,2], R. Thomson[1], J. Stankovich[1], D. Perera[1], K.A. Marsden[2], J. Charlesworth[1,5], Y. Hu[3], P. Danoy[4], M. Brown[4], M. Bahlo[3], G.K. Smyth[3], R.M. Lowenthal[2], S. Foote[1], J.L. Dickinson[1].* 1) Menzies Research Institute, Hobart, Tasmania, Australia; 2) Royal Hobart hospital, Hobart, Tasmania, Australia; 3) The Walter and Eliza Hall Institute, Melbourne, Victoria, Australia; 4) UQ, Diamantina Institute, University of Queensland, Queensland; 5) Southwest Foundation for Biomedical Research, Texas, USA.

**Aim:** To identify genes that result in an increased susceptibility to develop a haematological malignancy (HM) **Background:**The Tasmanian Familial Haematological Malignancy Study was commenced in 2006, to the investigate the genetics of HMs in a dataset comprising families ascertained from a population based study conducted between 1972-1980 in Tasmania, Australia, which recruited all cases of HMs diagnosed during that period. **Methods:** Extensive genealogical research and use of the Tasmanian Cancer Registry (TCR), has permitted the identification of 13 priority families demonstrating a marked dense aggregation of multiple HM disease types. Of 133 reported HM cases in these families, 105 have been confirmed by a pathologist and reclassified according to the current WHO classification of HM. Pathology specimens (bone marrow smears, formalin fixed paraffin embedded tissues) for confirmed cases have been collected, and used as a source of DNA for deceased cases. Consenting living affected people in the 13 priority families and children of deceased affected individuals have been genotyped using the Illumina 610 array (124 people). **Results and Discussion:** Familial genetic linkage analysis of the SNP genome wide scan data is underway. One rare family, LK16 family contains an unusual cluster of 5 siblings, 4 with CLL and one with diffuse large B cell lymphoma, whose parents were first cousins. Initial analysis of the SNP data arising from this family using sub-pedigree analysis of IBD sharing by Merlin, and subsequent microsatellite genotyping of pathology specimens from deceased individuals identified a 8MB region on chromosome 15. In addition, RNA has been obtained from EBV transformed cell lines generated from selected individuals from this family to provide differential gene expression data. Analysis of these samples utilizing the Affymetrix Human Exon 1.0 ST expression array identified three significant differentially expressed genes. Closer examination of one of these genes has identified a known SNP of interest. This SNP results in a non conservative amino acid change, and the frequency of this SNP is rare in populations were CLL is rare (Asian populations). Gene expression array data has been examined in the context of the 8MB region of interest and genetic analyses are continuing.

## 1093/W/Poster Board #751

**CFTR, SPINK1, PRSS1 and CTRC mutations are not associated with pancreatic cancer in German patients.** *M. Stuhrmann[1], K. Brakensiek[1], F. Traub[2], E. Schreiber[3], J. Gaedcke[2], M. Maelzer[1], A. Hein[1], B. Marohn[1], K. von Kopylow[1], H. Kreipe[2], S. Schubert[1].* 1) Inst Human Gen, Med Hochschule, Hannover, Hannover, Germany; 2) Dep Pathology, Med Hochschule, Hannover, Hannover, Germany; 3) Celera Diagnostics, Foster City, USA.

Mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene, the serine protease inhibitor Kazal type 1 (SPINK1) gene, the cationic trypsinogen (PRSS1) gene and the chymotrypsinogen C (CTRC) gene are associated with an elevated risk for chronic pancreatitis. Chronic pancreatitis is a known risk factor for pancreatic cancer. Therefore, we hypothesised that mutations in the above mentioned genes may be associated with pancreatic cancer (PC). DNA was extracted from paraffin embedded tissue samples from 124 PC patients, 54 of which were classified as having had chronic pancreatitis. 33 of the most frequent CFTR mutations were analysed by an oligonucleotide ligation assay (OLA), polycrylamide gel electrophoresis (PAGE) and direct sequencing, covering 90% of cystic fibrosis (CF) alleles in the German population. Additionally, we sequenced the relevant exons and flanking intronic regions of the SPINK1, PRSS1 and CTRC genes for the detection of the most common mutations. Of 124 PC samples tested, one was compound heterozygous for F508del and I148T, one patient was heterozygous for the 5T (12TG) allele in CFTR intron 8, and seven patients were heterozygous for 5T (11TG). The distribution of CFTR mutations was not significantly different between PC patients with or without pancreatitis. The CFTR mutation/variation frequency in PC patients was even lower, albeit statistically not significant, in comparison to 136 healthy controls, mostly partners of CF patients or carriers. In the SPINK1 gene, heterozygosity for IVS3+2T>C was observed in one PC patient with pancreatitis, only. Compared to the expected SPINK1 mutation prevalence in the German population, no elevated frequency was observed. No mutation was detected in the PRSS1 and CTRC genes. We conclude that CFTR, SPINK1, PRSS1 and CTRC mutations do not play a major role in the aetiology of pancreatic cancer.

## 1094/W/Poster Board #752

**An unusual case of Fanconi Anemia with adult onset, mosaicism in an asymptomatic sibling, and a possible molecular explanation.** *M.A. Johnson[1], S. Olson[1], B.P. Alter[2], N. Giri[2], W.J. Hogan[3], C.S. Richards[1].* 1) Dept Molec & Med Gen, MP350, Oregon Health & Sci Univ, Portland, OR; 2) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, MD; 3) Division of Hematology, Mayo Medical Center, Rochester, MN.

The proband is a 42 year old female with aplastic anemia (AA) who died following a bone marrow transplant. Fanconi Anemia (FA), the most common genetic cause of AA, should be considered in patients with no apparent cause for AA. Lymphocyte chromosome breakage analysis confirmed the diagnosis of FA in the proband, complementation analysis indicated complementation group A (FA-A), and molecular analysis identified two mutations in the FANCA gene. One mutation, p.S1208S (c.3624C>T) was a splice site mutation occurring in exon 36 and was previously described. The second mutation was a novel nonsense mutation in exon 23, p.S674X (c.2021C>A). This individual's six adult siblings were tested by breakage analysis of lymphocytes and fibroblasts prior to selection of a donor for the transplant. Five siblings had normal breakage results; four were heterozygous for the nonsense mutation and one was negative for both mutations. The sixth sibling, an asymptomatic 55 year old female, had increased chromosome breakage in fibroblasts, diagnostic of FA, while breakage within the blood was within normal limits. This individual with mosaicism for FA had the familial splice mutation in both blood and fibroblasts, and the familial nonsense mutation in fibroblasts, but was skewed heavily toward wild-type in blood. cDNA studies confirmed that the predicted splice mutation created an alternate splice site resulting in multiple transcripts, including exon skipping, which varied in different tissues. Mosaicism is common in FA patients, estimated at 20-30%, and multiple molecular explanations have been demonstrated, including mitotic recombination, a second mutation in cis, and a reversion to wild type. While the molecular mechanism is not completely clear, it is most likely the result of a back mutation due to a hot spot. In this case, reversion of one FANCA mutation probably occurred in a hematopoietic stem cell which was selected for and repopulated the blood. In addition, a plausible explanation for the lack of FA clinical features in this individual is the leaky splice mutation which may provide sufficient levels of protein for normal function in DNA repair. In families with diagnosed FA, family members should be tested by breakage analysis of fibroblasts in order to identify those who may be mosaics, at risk for solid tumors which occur in FA, as well as AA, myelodysplastic syndrome, and leukemia, if a non-gene corrected hematopoietic stem cell were to emerge.

**Identification of men with a genetic predisposition to prostate cancer: targeted screening of *BRCA1/2* mutation carriers and controls: The IMPACT study.** *E.K. Bancroft[1, 2], E.C. Page[1], A.V. Mitra[1], E. Castro[1], R.A. Eeles[1, 2], IMPACT Steering Committee and Collaborators.* 1) Institute of Cancer Research, London, United Kingdom; 2) Royal Marsden NHS Foundation Trust, London, United Kingdom.

**Introduction:** IMPACT, an international collaborative study, is a targeted prostate cancer screening study of men with a known germline mutation which is thought to predispose to the disease. The study is recruiting male *BRCA1/2* mutation carriers and a control group who have tested negative for a mutation known to be present in their family.

**Method:** Eligible men aged between 40 and 69 years are being recruited through 33 collaborating genetics centres in 10 countries, and offered annual serum PSA testing for five years. The PSA threshold used to determine prostate biopsy is >3ng/ml. To date (May 2009) 655/1700 men have been recruited. The pilot data of 300 men have been analysed to determine the feasibility and acceptability of the study approach.

**Results:** The latest recruitment data will be presented together with the results from this pilot analysis. Analysis of the pilot cohort demonstrated that 28/300 men had a raised PSA, which is a threshold rate for biopsy of 9.3%, of which 11 had a prostate cancer diagnosed, 9 in mutation carriers and 2 in controls. A larger proportion of gene carriers developed clinically significant prostate cancers (those that would need radical treatment on UK treatment guidelines) compared with the control group.

**Summary:** Targeted screening based on *BRCA1/2* germline mutation is an acceptable and feasible approach. Biopsy rates are lower and a larger proportion of men developed clinically significant prostate cancer than previously reported in population screening studies. The positive predictive value of PSA is higher than has been reported in population screening studies but the confidence intervals are wide. The study is on target to complete recruitment by the end of 2011 and further work looking at the psychosocial impact of targeted screening is being undertaken.

## 1096/W/Poster Board #754

**Using Action Research to Evaluate and Innovate Personalized Cancer Genetics Training for Personalized Medicine.** *K. Blazer[1], S. Sand[1], D. MacDonald[1], J. Culver[1], C. Huizenga[1], L. Rose[2], J. Weitzel[1].* 1) City of Hope Medical Center, Department of Population Sciences, Division of Clinical Cancer Genetics, 1500 E. Duarte Road, Duarte, California 91010; 2) University of California Los Angeles, Graduate School of Education and Information Studies, Educational Leadership Program, 1029 Moore Hall,Los Angeles, California 90095.

Action research is a disciplined process of reflection, progressive inquiry and informed action, frequently employed within educational communities of practice to generate program improvements and enhance practitioner professionalism. The City of Hope conducts an annual R25E-funded intensive course to address the national need for clinicians trained to provide genetic cancer risk assessment services. As designed, the course cannot meet the demand for interdisciplinary cancer genetics training. An action research project was conducted from January to June of 2008 to evaluate course effectiveness and generate ideas to make the course accessible to more practitioners with diverse training needs. METHOD: A mixed-methods approach was employed, combining quantitative outcomes assessment and evaluation data with interviews, surveys and roundtable sessions with key course stakeholders (participants, alumni and faculty). Qualitative data were triangulated with quantitative outcomes data, summarized and reviewed by course leadership to generate action items for course improvements and innovations. RESULTS: Findings demonstrate that the course is effective in training clinicians from diverse professional disciplines and practice settings. Interdisciplinary case-based training and collegial interactions were identified as the most efficacious learning experiences. The action research process stimulated immediate improvements in the current course and generated a project to incorporate case conferencing into distance-mediated training, as well as the development of specialized training and leadership tracks, as part of a new course design that is more flexible, personalized and accessible to clinicians across the globe. These developments demonstrate the practical utility of using action research to evaluate and improve education and training initiatives for medical professionals.

**Clinical validation of a buccal mouthwash collection and extraction protocol increases accessibility to *BRCA1* and *BRCA2* genetic testing.** *K. Bowles, S. Rajamani, S. Chen, R. Henderson, J. Trost, R. Wenstrup, B. Leclair, B. Roa.* Myriad Genetic Laboratories, Myriad Genetics, Inc, Salt Lake City, UT.

**Background:** Early identification of individuals carrying *BRCA1* and *BRCA2* genetic mutations by full sequencing DNA analysis strongly impacts clinical management, significantly reducing morbidity and mortality from hereditary breast and ovarian cancer. As healthcare providers continue to recognize the importance of genetic testing, testing must be more accessible. Analysis of DNA extracted from blood is the gold standard of molecular diagnostic testing. However, a blood venipuncture can pose a challenge due to lack of on-site phlebotomy services, patient non-compliance with outsourced testing, and the inability of some patients to provide a blood sample due to poor venous access or needle anxiety. We have developed and validated a buccal mouthwash collection and DNA extraction method for full sequencing DNA analysis which provides results identical to blood-based clinical testing. **Methods:** Patient samples were obtained with informed consent through healthcare providers, who collected blood and buccal samples from approximately 450 patients ordering clinical full sequencing DNA analysis. Our laboratory extracted DNA and performed full gene sequencing and large rearrangement analysis of the *BRCA1* and *BRCA2* genes on both sample types. **Results:** Full sequencing DNA analysis results obtained from blood and buccal samples were compared. Sequencing results based on analysis of 2090 sequence variants found among 450 patients were 100% concordant for blood and buccal samples. While equivalent in test performance for detecting presence/absence of mutations, statistical analysis indicated that sequencing data quality of buccal samples was enhanced over that of blood. Results of large rearrangement analyses showed 100% concordance between buccal and blood samples, based on 468 paired samples for the large rearrangement panel test of 5 *BRCA1* large rearrangements, and 437 paired samples for the large genomic rearrangements covering the entire *BRCA1* and *BRCA2* coding regions. **Conclusions:** Clinical validation studies demonstrated that buccal wash samples provide DNA of sufficient quality and quantity to perform accurate full sequencing DNA analysis. Genetic analyses of DNA extracted from paired blood and buccal wash samples were 100% concordant. Development of a buccal wash protocol should make genetic analysis for hereditary breast and ovarian cancer more accessible to healthcare providers and their patients, especially when a blood venipuncture is a challenge.

## 1098/W/Poster Board #756

**Tumour Pathology Predicts Microsatellite Instability in a Population-Based Cohort of Colorectal Cancer Cases.** *A. Hyde[1], D. Fontaine[2], S. Stuckless[3], R. Green[1], A. Pollett[4], M. Simms[1], P. Parfrey[3], H.B. Younghusband[1].* 1) Discipline of Genetics, Memorial University of Newfoundland, St John's, NL, Canada; 2) Discipline of Pathology, Memorial University of Newfoundland, St John's, NL, Canada; 3) Discipline of Medicine, Memorial University of Newfoundland, St John's, NL, Canada; 4) Department of Pathology, Mount Sinai Hospital, Toronto, ON, Canada.

Background: Lynch Syndrome is an autosomal dominant trait that accounts for 2% to 5% of all cases of colorectal cancer (CRC). It is caused by mutations in DNA mismatch repair (MMR) genes, causing high levels of microsatellite instability (MSI-H) in the tumours. Approximately 15% of CRCs are MSI-H, and of these about one quarter are due to Lynch Syndrome. MSI testing of all CRCs to identify potential Lynch Syndrome cases is not practical. Purpose: to create and validate a model for predicting MSI-H tumours, using clinical and pathological features to compare the accuracy of our model with existing models of predicting MSI-H tumours, Methods: We collected a population-based cohort of 716 CRC cases diagnosed before age 75 years in Newfoundland. For each of these cases we collected family history, performed MSI analysis, and scored a number of pathological features. Univariate and multiple linear logistic regression analyses were performed to determine the value of the clinical and pathological features at predicting MSI-H tumours. The most powerful predictors were used to create a new model. We compared our model with the Revised Bethesda Guidelines (Umar et. al. 2004), which is based on clinical features and family history, and the MsPath model (Jenkins et. al. 2007) for predicting MSI-H tumours. The MsPath model is based on the histological features described in the rarely used 3rd Bethesda criterion. Results: Our model has a sensitivity of 96% and a specificity of 55% for identifying MSI-H tumours. This is an improvement over the existing models. In our population the MsPath model has a sensitivity of 95% and a specificity of 39%, while the Bethesda Guidelines have a sensitivity of just 67% and a specificity of 51%. Our model has been validated in a different cohort, by an independent pathologist. Conclusions: Predictive models of MSI-H are more accurate, cheaper, and faster when dependent upon histology than when dependent upon family history. Our model demonstrates that histological features other than those used in the Bethesda Guidelines can also be predictive of MSI-H tumours. Although both the MsPath and Bethesda Guidelines limit the use of their histology-related criteria to patients diagnosed less than age 60 years, we have found that this limitation can be removed, and the criteria applied to at least those diagnosed up to age 75 years.

## 1099/W/Poster Board #757

**Gastrointestinal Polyposis and *PTEN* Mutations: An Under-Acknowledged Diagnostic Criterion.** *B. Leach, J. Mester, C. Eng.* Genomic Med Inst, Cleveland Clinic, Cleveland, OH.

The International Cowden Consortium (ICC) created operational diagnostic criteria that specify gastrointestinal (GI) hamartomas as a minor criterion. Previous review of reported case studies found that 35-85% of Cowden syndrome (CS) patients had GI hamartomas. Our goal is to describe the GI phenotype of our PTEN mutation positive(+) series. Blood was collected for PTEN mutation analysis and medical records were requested to document diagnoses. Patients who are PTEN+ with ≥5 GI polyps, ≥1 of which is hyperplastic (hyp) or hamartomatous (ham, n=4) or who met relaxed ICC criteria (n=118) were analyzed. Upper and lower GI endoscopy and pathology reports were reviewed and findings are reported descriptively. Fisher's 2-tailed exact test and unpaired T-tests were utilized for comparison of PTEN+ patients with and without polyps. Out of 122 PTEN+ patients, 64 underwent ≥1 endoscopy, and 60(50%) had polyps or colorectal cancer (CRC). Average age at first colonoscopy and upper endoscopy was 37yrs(range: 2-73) and 40(2-73) respectively. Number of polyps ranged from 1-innumerable. Polyps were found in the colorectum, ileum, duodenum, stomach, and esophagus. Pathology includes serrated adenomas; ham, hyp, adenomatous (ade), and inflammatory polyps; lymphoid aggregates; neuromas; lipomas; and ganglioneuromas. 16 patients had a hyp or ham polyposis mixed with other types of polyps, 13 had purely hyp or ham polyposis, and 6 had ganglioneuromatosis. 8 patients (6.6%) had CRC, 1 of whom did not have colorectal polyposis. One patient had gastric signet ring cell carcinoma in the setting of diffuse mixed hyp and ade polyposis. Polyposis patients were older at the time of study enrollment (mean=41.6yrs) compared to non-polyposis patients (26.7yrs, p=0.0001). The most common CS feature in polyposis patients was macrocephaly (70%). When compared to patients without polyps, those with polyps were more likely to have goiter/thyroid nodules (p=0.0001), trichilemmomas (p=0.0018), and papillomatous papules (p=0.0001) but less likely to have breast cancer (p=0.0412) and mental retardation/developmental delay (p=0.0062). GI polyposis is the second most common CS feature in our series. Inclusion of this manifestation as a major criterion would result in an additional 19 patients (16%) meeting ICC criteria. We propose that the ICC revise their guidelines to include GI polyposis (defined as ganglioneuromatosis, mixed hyp or ham polyposis, ham or hyp polyposis) as a major criterion.

## 1100/W/Poster Board #758

**Clinical and histopathological characteristics of Finnish familial prostate cancer cases.** *S. Pakkanen[1], M.P Matikainen[2], N. Ha[1], P. Kujala[3], P. Koivisto[4], J. Schleutker[1], T.L.J Tammela[2].* 1) Lab Cancer Genetics, Inst Medical Technology, Tampere, Finland; 2) Department of Urology,Tampere University Hospital and Medical School, University of Tampere, Finland; 3) Department of Pathology, Tampere University Hospital and Medical School, University of Tampere, Finland; 4) Laboratorio of Molecular Genetics, Tampere University Hospital, Finland.

Background: Prostate cancer (PrCa) is the most common malignancy in men in many industrialized countries and positive family history of the disease is one of the known risk factors. However, clinical features of familial PrCa are still poorly known. Families with prostate cancer have been collected in Finland since 1995. Here the aim was to describe clinical characteristics of the Finnish PrCa families through detailed analysis of the cases in the families. Materials and methods: 202 Finnish families with 617 PrCa cases with confirmed genealogy was collected. Complete clinical data including age and PSA at diagnosis, stage, grade and primary treatment. All the diagnostic biopsy samples (n=323) were gathered and re-graded by the same experienced uropathologist. The mean number of affected men per family was 3.1. Results: The mean year of diagnosis was 1993 (range 1962-2006) and the mean age at diagnosis was 68 (range 43 -98). The mean value of primary PSA was 133 (median 16.0, range 0.8-11000). 17% of the affected had metastases at the time of diagnosis. The most common primary treatments were surgical castration (27%), followed by radical prostatectomy (24%), chemical castration (11%) and radiation therapy (10%.) 11% of the males had WHO III, 56% had WHO II and 33% WHO I, which changed after re-gradering to 22% WHO III, 65% WHO II and 13% WHO I, respectively. In Gleason grading the changes were even larger from 42% of Gleason score 2-5, 48% of Gleason score 6-7 and 10 % of Gleason score 8-10 to 3.7 % of Gleason score 2-5 71% of Gleason score 6-7 and 25% of Gleason score 8-10, respectively. The changes were statistically significant (p=0.0015 in WHO grading and p= $6.9 \times 10^{-8}$ in Gleason grading). Conclusions: Familial PrCa has an earlier age of onset than sporadic PrCa. The criteria for Gleason grading has changed remarkably during the 14 years of collection. Therefore, when comparing pathological grading from a long time period the tumours should be carefully regarded by the same experienced uropathologist.

## 1101/W/Poster Board #759

**Uptake of genetic testing and long-term tumor surveillance in von Hippel-Lindau disease.** *A. Rasmussen[1,2], E. Alonso[2], A. Ochoa[2], I. De Biase[1], I. Familiar[3], M. Lopez-Lopez[4], S.I. Bidichandani[1].* 1) Dept Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Dept Neurogenetics and Molecular Biology, Instituto Nacional de Neurologia y Neurocirugia, Mexico City, Mexico; 3) Dept of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Dept Biological Systems, Division of biological and Health Sciences, Universidad Autonoma Metropolitana-Xochimilco, Mexico City, Mexico.

von Hippel-Lindau (VHL) disease is a hereditary cancer syndrome caused by germline mutations in the *VHL* gene. Patients have significant morbidity and mortality secondary to vascular tumors. Disease management is centered on tumor surveillance that allows early detection and treatment. Presymptomatic genetic testing is therefore recommended, including in at-risk children. We tested 17 families (n = 109 individuals) for *VHL* mutations including 43 children under the age of 18. Personalized genetic counseling was provided pre- and post-test and the individuals undergoing predictive testing filled out questionnaires gathering socio-demographic, psychologic and psychiatric data. Mutations were identified in 36 patients, 17 of whom were asymptomatic. In the initial screening, we identified at least one tumor in five of 17 previously asymptomatic individuals. All mutation-carriers were offered follow-up annual examinations. At the end of five years, only 38.9% of the mutation-carriers continued participating in our tumor surveillance program. During this time, 14 mutation carriers developed a total of 32 new tumors, three of whom died of complications. Gender, education, income, marital status and religiosity were not found to be associated with adherence to the surveillance protocol. Follow-up adherence was also independent of pre-test depression, severity of disease, or number of affected family members. The only statistically significant predictor of adherence was being symptomatic at the time of testing (OR=5; 95% CI 1.2 - 20.3; p = 0.02). Pre-test anxiety was more commonly observed in patients that discontinued follow-up (64.7% vs. 35.3%; p = 0.01). The high initial uptake rate of genetic testing for VHL disease, including in minors, allowed the discontinuation of unnecessary screening procedures in non mutation-carriers. However, mutation-carriers showed poor adherence to long-term tumor surveillance. Therefore, many of them did not obtain the full benefit of early detection and treatment, which is central to the reduction of morbidity and mortality in VHL disease. Studies designed to identify the determinants of adherence to vigilance protocols will be necessary to improve treatment and quality in life of patients with hereditary cancer syndromes.

## 1102/W/Poster Board #760

**Clinical Description of Hereditary Paraganglioma Syndrome identified through a High-Risk Cancer Genetics Clinic.** *V. Raymond[1], M. Marvin[1,3], J. Everett[1], C. Bradford[2], S. Gruber[1, 3, 4].* 1) Internal Medicine, University of Michigan, Ann Arbor, MI; 2) Otorhinolaryngology, University of Michigan, Ann Arbor, MI; 3) Human Genetics, University of Michigan, Ann Arbor, MI; 4) Epidemiology, University of Michigan, Ann Arbor, MI.

Hereditary Paraganglioma Syndrome (HPGL) due to *SDHB*, *SDHC*, *SDHD* (collectively termed *SDH*x) mutations has been described as having defined genotype-phenotype correlations, with *SDHD* mutations more frequently presenting with head and neck(H&N) paraganglioma(PGL) and a parent of origin inheritance pattern, and *SDHB* mutations more frequently presenting with abdominal PGL/pheochromocytoma and a higher probability of malignant tumors. *SDHC* mutations have less well described genotype-phenotype correlations due to the small number of identified families. In 17 mutation positive families identified through the University of Michigan Cancer Genetics Clinic we demonstrate that these genotype-phenotype correlations are imperfect and can be used to guide, but not restrict a sequential genetic workup. *SDHC* should be included in the diagnostic workup of HPGL regardless of clinical presentation. Among 34 unrelated probands presenting with features suggestive of HPGL, 17 (50%) were positive for an SDHx mutation (8-*SDHB*, 2-*SDHC*, 7-*SDHD*). Eleven mutation-positive probands (65%) had a family history of PGL. Six of 23 (26%) cases of isolated PGL were positive for an *SDH*x mutation (2-*SDHB*, 2-*SDHC*, 2-*SDHD*). Eleven mutation-positive probands presented with H&N PGL (2-*SDHB*, 2- *SDHC*, 7-*SDHD*). Six mutation-positive probands presented with abdominal PGL/pheochromocytoma (6-*SDHB*). Four mutation-positive probands presented with malignant tumors (3-*SDHB*, 1-*SDHD*), illustrating that the malignant phenotype is not restricted to *SDHB*. Five of 7 *SDHD* families carried the recurrent P81L mutation. All 5 families with *SDHD* P81L presented with H&N PGL between ages 16-48, 4 of 5 probands had a positive family history, and 1 proband had metastatic PGL. Two families that presented with H&N PGL were found to have *SDHB* mutations rather than the more commonly reported *SDHD* mutations associated with H&N PGL. Among all families, an average of 2.94 relatives had testing for the family mutation. Family history is reasonably sensitive (65%) and specific (100%) for *SDH*x mutations, with acceptable positive predictive value (100%) and negative predictive value (73.9%) in a high risk population. Genotype-phenotype correlations can be used to prioritize genetic testing sequentially, but phenotype information should not be used to exclude a mutation given the varying clinical presentation of HPGL families. Screening recommendations should consider the full phenotypic spectrum of *SDH*x mutations.
