The complex sequence composition of mammalian Y chromosomes, containing dense repeats and high-copy duplications, has led to their systematic omission from genomic analyses. While more than half of the Y chromosome is missing from the GRCh38 human reference (approx. 31 Mbp), the first complete human Y has recently been assembled in by the Telomere-to-Telomere (T2T) Consortium (Rhie et al. manuscript under review). To improve our understanding of human Y chromosome evolution and genetic diversity, we assembled an additional 43 Y chromosomes by combining high-coverage PacBio HiFi and Oxford Nanopore ultra-long sequence data from the Human Genome Structural Variation Consortium (HGSVC) and Human Pangenome Reference Consortium (HPRC). We selected samples to include major African and non-African Y haplotypes, with the root of the phylogenetic tree dated to approximately 185 thousand years ago (kya) (95% HPD interval: 162-212 kya), thus covering genetic variation across a substantial period of modern human Y chromosome evolution.

We report remarkable complexity and diversity in chromosome size and structure, in contrast with its low level of base substitution variation. Specifically, the size of the Y chromosome assemblies varies extensively from 45.2 to 84.9 Mbp, mostly due to differences in the Yq12 heterochromatic block. Other regions, including the centromere and the ampliconic regions, revealed bursts of DNA expansions and contractions over short periods of time. Half of the male-specific euchromatic region is subject to large inversions with a >2-fold higher recurrence rate compared to inversions in the rest of the human genome. Ampliconic sequences associated with these inversions further show differing mutation rates that are sequence context-dependent and some ampliconic genes show evidence for concerted evolution with the acquisition and purging of lineage-specific pseudogenes. The largest heterochromatic region in the human genome, the Yq12, is composed of alternating arrays of *DYZ1* and *DYZ2* repeat units that show extensive variation in the number, size and distribution of these arrays, but retain a 1:1 copy number ratio of the monomer repeats, consistent with the notion that functional or evolutionary forces are acting to balance this chromosomal region.

The availability of sequence-resolved Y chromosomes from multiple individuals provides a unique opportunity for identifying new associations of specific traits with Y-chromosomal variants and garnering novel insights into the evolution and function of complex regions of the human genome.

PB3095 Noncoding variant effect prediction with probabilistic machine learning models

Authors:

C. Shearer, A. Amin, D. Marks; Harvard Med. Sch., Boston, MA

Noncoding regions make up the majority of the genome and are causally related to human disease. Unfortunately we are often unable to distinguish noncoding variants that cause disease from "tag along" variants due to low statistical power. This presents a clear need for additional evidence to uncover pathogenic noncoding variants, both to extend clinical datasets and to identify specific variants that cause common disease. Given that substantial progress has been made in the development of computational methods for determining the effects of variants in proteins and design based on evolutionary selection, we hypothesize that similar techniques can be used for the noncoding genome. We present preliminary results for predicting pathogenic noncoding human variants unaligned genomic sequences from across evolutionary history.

Abu Dhabi, Abu Dhabi, United Arab Emirates, [2]Stanford Univ., Palo Alto, CA, [3]Stanford Sch. of Med., Palo Alto, CA, [4]Boston Univ. Sch. of Med., Boston, MA, [5]Stanford Inst. for Computational and Mathematical Engineering, Palo Alto, CA, [6]CINVESTAV, Irapuato, Mexico, [7]Univ. of Hawaii at Manoa, Honolulu, HI, [8]Univ. of Colorado, Boulder, CO, [9]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [10]UCSD, La Jolla, CA

We describe genetic founder effects in Pacific Islanders and Native Hawaiians, an under-studied population, who currently experience the shortest life expectancy across all populations in the United States. We characterize the genetic bottlenecks and founding population sizes of islands in the primary settlement path to Hawaii, together with the proximate geographic origin and timing of settlement of Hawaii, which has long been a subject of debate. This allows us to characterize signals of selection between the islands over this time period. In particular, we use ancestry-specific approaches to explore the genomic variation of over four thousand modern-day Hawaiians and other Pacific Islanders using more than 864,892 single nucleotide polymorphism markers. Based on Polynesian-derived allele frequencies and segments, we find these master navigators arrived to Hawaii from a proximate geographic origin in the Tuamotu Archipelago, which is in concordance with oral traditions. This contrasts previous hypotheses, which posited an origin in the Marquesas or Society Islands. We also characterize the admixture patterns between several major ancestries found across these remote Polynesian islands, and together with our selection analysis, are able to highlight a number of loci, providing targets for further study to extend personalized genetic health results to this important founder population within the United States.

PB3097 † Pattern of genetic variation and population structure in Native Hawaiians

Authors:

S. Jeon[1], B. Dinh[2], C. Fan[3], X. Sheng[4], F. Chen[3], L. Wilkens[5], L. L. Machand[5], C. Haiman[4], C. Chiang[3]; [1]Keck Sch. of Med., USC, Pasadena, CA, [2]Univ. of Southern California, West Hills, CA, [3]Univ. of Southern California, Los Angeles, CA, [4]Keck Sch. of Med., USC, Los Angeles, CA, [5]Univ. of Hawaii cancer center, Honolulu, HI

Populations with a special evolutionary history can lead to unique patterns of genetic variation and population structure, which, in turn, dictate the allelic architecture of complex traits and diseases. In particular, a population like the Native Hawaiians exemplifies all major features of human evolutionary history, including bottleneck, admixture, and natural selection. We investigated the impact of demographic history on the patterns of genetic variation and population structure using a total of 10,721 whole-genome sequenced individuals from five ethnic groups in the Multiethnic Cohort (MEC). In total, we identified 82 million SNPs and 5 million indels after quality control in this dataset, including 26 million SNPs and 2 million indels segregating in 1,065 self-reported Native Hawaiians. We found a large number of variants enriched in the Polynesian-ancestry population like Native Hawaiians, but rare elsewhere in the world. For instance, among 63 million variants found to be <0.5% in minor allele frequency in 9,656 MEC White, African American, Latino, and Japanese individuals, approximately 5 million of them have a frequency >5% in Native Hawaiians, suggesting that we would have increased power to detect associations at these variants only in the Polynesian-ancestry population. We leveraged the haplotypic information from the genome-wide sequence of genealogical trees to derive the expected genetic relationship matrix (eGRM). Based on the eGRM, we investigated the fine-scale structure in the Native Hawaiian population through principal components analysis (PCA) and uniform manifold approximation and projection (UMAP). We identified three major population subclusters within the data and found these subclusters to be differentiated among measures, such as runs of homozygosity, population size trajectories, and enrichment of functionally important alleles. Our results help provide insights into the fine-scale structure in the Native Hawaiian population and could aid in interpreting any differences in disease risk between Native Hawaiians and other continental populations.

PB3098 Patterns of population structure & genetic variation within the Saudi Arabian population.

Authors:

D. Malomane[1], S. Mangul[2], M. Abedalthagafi[3], C. W. K. Chiang[1]; [1]Ctr. for Genetic Epidemiology, Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [2]Sch. of Pharmacy, Univ. of Southern California, Los Angeles, CA, [3]Emory Univ., Atlanta, GA

The Arabian Peninsula is considered the initial site of historic human migration out of Africa. The modern-day indigenous Arabians are believed to be the descendants which remained from the ancient split of the migrants into Eurasia. Following the split, the Arabians have experienced limited admixture not only externally but also within their country borders. In Saudi Arabia, tribalism has been practiced for centuries, encouraging endogamy while limiting inter-tribal marriages. Here, we investigated how such population history and cultural practices have shaped the genetic variation of the Saudi population. We genotyped 3,352 individuals and whole genome sequenced 341 from the Saudi population. Principal component analysis (PCA) and Uniform Manifold Approximation and Projection (UMAP) revealed the presence of genetic structure within the Saudi population. We detected twelve genetic subclusters that corresponded to the geographical distribution of different tribal regions. The distinction between genetic clusters was further supported by the components of ancestry based on unsupervised admixture analysis. We observed clear differences in the proportion of ancestral lineages in the Saudi clusters, with some clusters showing more homogeneity with a single dominant ancestry component with an estimated proportion up to 94% of the genome, while others are admixed with multiple ancestry components with maximum proportion no more than 27%. Furthermore, we used the f_3-statistics to test for evidence of admixture in these clusters, finding five out of twelve clusters with admixture sources proxied by various HGDP reference populations. We found differences in the runs of homozygosity (ROH) across clusters with the median total sum of ROH ranging from 38.12Mb to 232.6Mb within a cluster, while the median number of ROH ranged from 42 to 150 ROHs. Consistent with the out-of-Africa event, all clusters experienced and subsequently recovered from a decline in the effective population size (N_e) about a 100,000 years ago. A second decline in N_e occurred around 6-7,000 years ago, and while N_e rebounded for most clusters, the N_e for one cluster remained persistently low until the present time. This particular cluster is from the western part of Saudi Arabia, contains the most numerous and the longest ROH, and has the highest proportion of a single ancestral lineage, consistent with long-term isolation of these people. Together, these results provide insights into the patterns of genetic variation present within the Saudi Arabian population and establish a foundation on which to interpret medical- and pharmaco- genomic findings from this population.

PB3099 Phasing of millions of samples achieves near perfect accuracy, enabling parent-of-origin classification of variants

Authors:

C. Williams[1], J. O'Connell[2], W. A. Freyman[2], 23andMe Research Team, C. R. Gignoux[3], S. Ramachandran[1], A. L. Williams[2]; [1]Brown Univ., Providence, RI, [2]23andMe, Inc., Sunnyvale, CA, [3]Univ. of Colorado Anschutz, Aurora, CO

Given the availability of large, ancestrally diverse genetic datasets and the potential for parent-of-origin association studies, we investigated state of the art intra-chromosomal phasing methods and developed a new inter-chromosomal phasing approach. Specifically, we applied SHAPEIT5 and Beagle 5 to chromosome 2 genotype data from both the UK Biobank (UKB) and >8 million diverse, research-consented 23andMe customers, finding that both perform exceptionally well. Beagle's median switch error rate (SER) (after excluding single SNP switches) in white British trios from UKB is 0.031% compared to zero for European ancestry 23andMe research participants (55.6% have zero phase errors). South Asian ancestry 23andMe research participants have the highest median SER amongst the 23andMe populations, but it is still remarkably low at 0.46%. SERs in non-European ancestry samples in UKB are up to ten times higher than their 23andMe counterparts, leading us to investigate best practices for phasing datasets with imbalanced ancestry compositions, e.g., the UKB where 94% of participants are described as having European ancestry. We find that SERs for African, South Asian, and East Asian ancestry samples from the UKB and 1000 Genomes Project are lowest when the white British are downsampled ~100-fold. In 23andMe we found mixed benefits of phasing with population-only samples vs. the 8 million research participants, motivating further inquiry. Building on these findings, we developed an inter-chromosomal phasing method that assigns paternal and maternal variants discretely genome-wide (whereas SHAPEIT and Beagle phase each chromosome separately). Our approach uses identity-by-descent (IBD) segments to phase variants on different chromosomes, representing the segments a focal individual shares with their relatives as nodes in a signed graph. We perform bipartite clustering on the signed graph using spectral clustering and tested our method on 1059 UKB trios, where it clustered IBD segments with a median precision of 99.7%, yielding a median phase accuracy of 99.8% in regions covered by IBD segments. We also ran the method in the 23andMe database and found a median global phase accuracy of 97.8% in Europeans and 98.2% in African Americans. The method's precision depends heavily on data from relatives, so will increase as datasets grow larger and more diverse. Our method enables analyses that require the parent-of-origin of variants, such as association studies and ancestry inference of untyped parents.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3100 † Population identification based on shared ancestry captures fine-scale population structure and population-specific medical insights across the US

Authors:

M. Isshiki[1,2], I. Raghuram[3], A. Griffen[1], P. Meissner[1], J. Greally[1], S. M. Raj[1]; [1]Albert Einstein Coll. of Med., Bronx, NY, [2]The Univ. of Tokyo, Tokyo, Japan, [3]Univ. of California Berkeley, Berkeley, CA

More than 90% of genomic studies have been conducted on European ancestry individuals. Due to the lack of knowledge, the performance of genomic prediction of health is still not good in underrepresented racial or ethnic groups. We aim to expand the benefits of medical genomics to underserved populations in the US, using population genetics approaches to understand ancestry, and investigate their associations with different phenotypic outcomes. We focused our initial research on the participants of the All of Us Research Program (AoU) living in New York City (NYC) (n= 13,817), one of the most diverse cities in the world. We conducted Identity-by-descent (IBD) network analysis to ascertain fine-scale population structure within NYC. By combining it with the BioMe biobank (n=11,549), another dataset including NYC residents, we detected 16 distinct IBD population groups based on the amount of recent shared ancestry. Of these groups, eight showed signatures of strong founder effect: Puerto Ricans (PR), Ashkenazi Jewish (AJ), Central/South Americans (CSA), South Asians, Southeast Asians, South Caribbean African ancestry, Roma-Southeast European and Other Jewish. Across the eight founder populations, we identified 53 Pathogenic/Likely Pathogenic variants (curated in the ClinVar database) that had frequencies ≥ 0.005, the typical threshold of inclusion to genetic screening. Of these variants, 27 were previously unknown to have a founder effect. We next asked whether the IBD segments used to determine the population groups were associated with phenotypes. We used an IBD mapping approach to identify associations between IBD segments and phenotypes registered in electronic health records in AoU, in founder IBD groups with $n > 1000$ in our sample, namely PR, AJ and CSA. We also conducted Phenome-wide association studies (PheWAS) for each population to identify phenotypes enriched in each population group. We expanded this NYC-specific analysis to the entire AoU dataset across the US (n~245K). As expected, we found regional differences in population structure and the strength of founder effect. In particular, variation of IBD groups of Hispanic and Latino individuals were different among regions. We also examined differences in interaction with environment (e.g. pollution, sunlight) between IBD groups. We will make the IBD population groups available for other researchers working on the AoU dataset.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3101 Population structure and genetic relatedness analysis of the UAE population.

Authors:

I. Morjane, On behalf of the UAE Healthy Future Study Team, Investigators and Collaborators; Publ. Hlth.Res. Ctr. , New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Assessing genetic risk in multi-ethnic and admixed populations has yielded significant insights and uncovered various genetic variants associated with complex phenotypes and diseases. However, conducting robust association mapping studies in admixed populations requires comprehensive genetic profiling and careful consideration of factors such as relatedness and population structure. In this regard, populations of the Middle East provide both challenges and opportunities. Here we report the results of the analysis of genotyping data of study participants of the UAE Healthy Future Study (UAEHFS), the first prospective cohort study in the UAE, aiming to examine the association between multiple exposures (including environmental, lifestyle and genetic risk factors) and multiple outcomes with a focus on obesity, diabetes and CVD. We developed a custom version of the Precision Medicine Diversity Array (>800,000 genetic variants), generated genotyping data for the UAEHFS cohort and developed a database with annotation and allelic frequency data. The data was used to perform population genetic and relatedness analyses using different methods. The results highlight the impact of past and recent demographic events on the genetic make-up of the UAE population. We also test the performance of various measures of relatedness and test the impact of accounting for relatedness on mapping of quantitative traits.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3102 Portability of tag SNPs used to determine ABO alleles across diverse populations: A systematic review.

Authors:

K. Martinez, A. Klein, J. R. Martin, C. Sampson, J. Giles, M. Beck, K. Bhakta, G. Quatraro, J. Farol, J. Karnes; Univ. of Arizona, Tucson, AZ

Introduction: The ABO gene codes for a major human alloantigen system. ABO blood types have widespread clinical use and are robustly associated with myriad phenotypes. Many studies genetically infer ABO blood type, but there is potential for misinference through use of inappropriate tag SNPs across diverse populations. This systematic review aimed to evaluate the portability and suitability of tag SNPs used to determine ABO alleles across diverse populations.

Methods: PubMed, Embase, Scopus, Medline/Ovid, CINAHL, and Dissertations and Theses were searched from 2005-2022 using keywords to identify tag SNPs to determine ABO alleles (O, A, and B). Primary data was extracted independently by two investigators and included: tag SNPs used for ABO alleles, presence of haplotype analysis, cohort size, population description, and primary phenotype. As almost all studies used race/ethnicity descriptors, we inferred continental ancestry for each study population based on 1000 Genomes superpopulations (AFR, AMR, EAS, EUR). We calculated linkage disequilibrium (r^2) between study-selected tag SNPs and ABO functional (O vs non-O and A vs B allele-determining) SNPs using inferred continental ancestry groups on a per study basis. Median r^2s for tag SNPs were compared between inferred continental ancestry groups using Kruskal Wallis followed by Dunn's test for multiple comparisons using rank sums.

Results: Inclusion criteria were met for 136 articles. Most studies were done in a EUR population (n=74) followed by EAS (n=31), AFR (n=19), AMR (n=5). Study tag SNPs had a wide range of linkage (r^2=0.387-0.975 for O vs non-O tag SNPs and r^2=0.187-1.00 for A vs B tag SNPs). 49.3% of the studies used the functional SNP to determine O vs non-O alleles and 66.2% of the studies a functional SNPs to determine A vs B alleles. The proportion of O allele tag SNPs with r^2<0.9 was 100% (AFR), 100% (AMR), 0% (EAS), and 89% (EUR). The proportion of O allele tag SNPs with r^2<0.5 was 100% (AFR), and 0% for AMR, EAS, and EUR. O vs non-O tag SNPs performed significantly worse in African populations (AFR median r^2=0.443) than in East Asian (EAS median r^2= 0.946; $p=1.1x10^{-5}$) and European populations (EUR median r^2=0.867; p=0.02).

Conclusion: Our results suggest a lack of portability of ABO tag SNPs across diverse populations. While continental ancestry is not equivalent to race and ethnicity, prior studies may have used inappropriate tag SNPs for their populations. This may have led to erroneous ABO allele determination and inaccurate associations, especially in individuals with African ancestry. This practice may exacerbate existing disparities in genomic research for underrepresented populations.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3103 Predicting stature and estimating allele effect size in ancient humans.

Authors:

K. Kaymak-Loveless, S. Cox, I. Mathieson, C. Shin; Univ. of Pennsylvania, Philadelphia, PA

Ancient DNA has made it possible to use genomics to understand the evolutionary history of complex traits. Here, we assemble the largest dataset to-date of 444 ancient West Eurasian individuals with paired stature and whole-genome genetic data to investigate the applicability of polygenic scores derived from present-day populations, the importance of environment, and the effect of individual variants on height.

We first confirm previous results that polygenic scores can predict height in ancient populations. Using summary statistics from UK Biobank, we observe that 6.9% of variation in femur length is predicted by PRS (SD=0.29%). Importantly, this remains consistent when PRS are calculated using GWAS from sibling pairs (R2=0.059, SD=0.28%), indicating these results are not inflated by population stratification. We also show that effects are highly transferable by replicating this analysis using GWAS conducted in present-day populations of European and East Asian ancestry (R2=0.045 and 0.057 respectively).

Previous work by Marciniak et al. (2022) suggested that early Neolithic farming populations had lower stature than would be expected based on genetics, potentially due to relatively poor nutrition. However, concerns remained about the small sample size and population stratification. In our dataset, approximately three times larger, we robustly replicate these results including using sibling GWAS. Specifically, we estimate that Neolithic individuals were significantly shorter than non-Neolithic individuals with the same genetic height (p=0.0092), emphasizing the importance of the environment for understanding complex trait evolution.

Finally, due to our large sample size we performed association tests for stature to measure the effects of individual variants. We find that effect sizes of SNPs identified in GWAS are highly correlated with those in ancient samples (β=1.525, SE=0.326). However, some SNPs shown to have been under selection but that do not have an effect on stature in present-day populations, do have an effect in ancient populations. These include the SNP responsible for adult lactase persistence (β=0.599 SD, SE=0.200 SD), emphasizing the difficulty of using present-day SNP effects to draw conclusions about effects in the past.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3104 Prehistoric ancestries are consistently associated with the complex trait landscape in European Biobanks.

Authors:

D. Marnetto[1], V. Pankratov[2], M. Mezzavilla[3], S. Aneli[4], D. Fusco[5], L. Pagani[3]; [1]Univ. of Turin, Torino, Italy, [2]Univ. of Tartu, Tartu, Estonia, [3]Univ. of Padua, Padova, Italy, [4]Univ. of Turin, Torino, Italy, [5]Università di Torino, Torino, Italy

The contemporary European genetic makeup formed in the last 8,000 years when local Western Hunter-Gatherers (WHGs) mixed with incoming Anatolian Neolithic farmers and Pontic Steppe pastoralists. Previous research efforts have indeed characterized evolutionary events specific to these populations which affected their phenotype, through the tracking of few highly characterized SNPs or polygenic scores. Nevertheless, while the first approach is limited in the number of variants analyzed and largely blind with regards to complex polygenic traits, the second builds on population-dependent effect sizes. Here we investigate how the unique tiling of genetic variants inherited from different ancestral components impacts the phenotypic landscape of 50,000 UK Biobank donors taken as representative of the Western European population. This work expands an analysis previously run on the Estonian Biobank which found significant trait-ancestry associations for 11 of the 27 complex traits investigated.
Using matching individual-level genotype and phenotype data from contemporary samples and genotype data from the ancient source populations, we quantify the correlation between each ancestry and present-day phenotypic variation in each complex trait. We rely on a metric (CovA) based on trait-associated genomic regions, without leveraging potentially population-specific effect sizes. The analysis is supported by a simulation framework to test the accuracy of our metric in a demographic scenario matching contemporary UK and probing several variables for their effect.
Among others, all anthropometric, hair pigmentation, heart rate trait-ancestry associations found in the Estonian Biobank were replicated in the UKBB population. Other complex traits reached significance possibly due to increased sample size: e.g we find a novel association between WHG ancestry and increased blood pressure. Furthermore we overcome the limitations of the previous analysis by a) increasing the number of traits analyzed and finding new associations e.g. between WHG ancestry and asthma; b) including a more rigorous simulation to help the signal interpretation; c) verifying that genome-wide ancestry associations are explained by either confounding factors or driven by highly polygenic local signals.
Our results show that these ancient components were differentiated enough, possibly through pre-admixture selection, to reveal ancestry-specific associations with the complex trait variability displayed by contemporary Europeans. Our findings are robust across biobanks and therefore representative of a continental trend rather than a population-specific result.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3105 Probing the role of structural variants in adaptation in Holocene Western Eurasia.

Authors:

J. Maravall López[1], A. Akbari[2], D. Reich[1,2,3,4], H. Li[2,5]; [1]Harvard Univ., Cambridge, MA, [2]Harvard Med. Sch., Boston, MA, [3]Broad Inst. of Harvard and MIT, Cambridge, MA, [4]Howard Hughes Med. Inst., Cambridge, MA, [5]Dana-Farber Cancer Inst., Boston, MA

Complex genetic variation beyond single nucleotide polymorphisms is notoriously difficult to resolve, which hinders understanding of their phenotypic effects and evolutionary dynamics. Here, we leveraged new bioinformatic methodology and the exponentially increasing number of available ancient genomes to study the frequency changes of structural variants over time in about 6000 Holocene West Eurasians. We leveraged k-mer based genotyping utilizing a pangenome graph built using data from the Human Pangenome Reference Consortium cohort to study structural variants in high association with SNPs that have been established as significant hits in genome-wide scans for selection in ancient DNA time-series data. We identified a set of structural variants, largely unreported, for which co-localization of these selection scans and orthogonal GWAS results align, consistent with the haplotypes carrying the structural variants having important phenotypic effects which were acted upon by selection.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3106 Reconstructing parent genotypes at direct testing-level accuracy using siblings and other relatives

Authors:

A. Williams[1], Y. Qiao[2], E. Jewett[3], K. McManus[4], W. A. Freyman[1], J. Blangero[5], The 23andMe Research Team; [1]23andMe, Inc., Sunnyvale, CA, [2]Cornell Univ., Ithaca, NY, [3]23andMe, Sunnyvale, CA, [4]23andMe, Inc., San Francisco, CA, [5]Univ. of Texas Rio Grande Valley Sch. of Med., Brownsville, TX

Reconstructing ancestors' DNA has tremendous potential to empower genome-wide association studies by increasing sample size, can improve direct genetic effect estimates, and can enhance forensic and genetic genealogical research. In expectation, n full siblings inherit a fraction of $1\text{-}1/2^n$ of each parents' genome or 93.8% when $n = 4$, thus providing rich information for reconstruction.

We developed HAPI2, a method for jointly phasing $n \geq 2$ siblings that implicitly reconstructs their parents' DNA and also built HAPI-RECAP, a tool that combines HAPI2's output with identity-by-descent (IBD) segments from relatives to distinguish which haplotypes belong to each parent. More specifically, sibling data does not immediately provide inter-chromosomal parent assignments of the haplotypes, and intra-chromosomal parent assignments are sometimes ambiguous, but IBD segments to maternal/paternal relatives reveal cross- and within-chromosome linkage. Moreover, recombination breakpoints in the inferred transmitted haplotypes carry information about the sex of the transmitting parent since locus-specific recombination rates differ markedly between males and females.

We analyzed 72 nuclear families from the San Antonio Mexican American Family Studies (SAMAFS), each with data from both parents and ≥ 4 full siblings, and censored the parents' data before running HAPI2 to reconstruct parent genotypes. When analyzing 10 families with data for ≥ 8 full siblings, HAPI2 reconstructs an average of 98.9% of each parent's genotypes with a mean error rate of $< 10^{-3}$, or roughly equal to genotyping error rates. In turn, when applied to all 72 sibling sets, HAPI2 reconstructs an average of 92.5% of each parent's genotypes with a mean error rate $< 10^{-3}$.

To link the genotypes to each parent inter- and intra-chromosomally, we applied HAPI-RECAP and effectively linked the majority of the reconstructed DNA to one of the parents, again with a mean error rate of $< 10^{-3}$. We have previously found that use of sex-specific genetic maps can correctly infer the parent sexes using IBD break points from half-sibling data and will extend this methodology to infer the parent sexes using the recombinations inferred by HAPI2. Both IBD sharing with relatives and sex-specific maps together have the power to enable precise sex-specific assignments of reconstructed genotypes to parents.

Besides these results from the SAMAFS data, we will apply HAPI-RECAP to a collection of ancestrally diverse families from the 23andMe research participant database and present results quantifying the impact of including various numbers of close and distant relatives.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3107 Reconstructing the genetic history of Ancestral South Indians and Ancestral Austro-Asiatics

Authors:

A. Dey[1,2], A. Basu[1], D. Nandi[1]; [1]Natl. Inst. of BioMed. Genomics, Kalyani, India, [2]Univ. of Calcutta, Kolkata, India

South Asia has a complex population history. Using previously published genomic data of present-day and ancient individuals from South Asia and its neighboring regions, we identified an ancestral component that is ubiquitous in the genomes of many present-day South Asian tribal populations, henceforth Tribal South Asian (TSA) ancestry. TSA was also present in South Asian ancient individuals, but almost absent in the ancient individuals from the neighboring regions. Most importantly, it is the only ancestry that is found in all present-day individuals from mainland South Asia. Hence, it is likely to represent one of the oldest ancestries of this region. TSA is highly correlated with Ancestral South Indian (ASI) and Ancestral Austro-Asiatic (AAA) ancestries (r=0.98 and 0.88 respectively), which can only be inferred exclusively from present-day South Asian individuals, and hence they provide better resolution. Due to their centrality in the peopling of South Asia, we aim to understand the formation of AAA and ASI using the genomes of present-day Austro-Asiatic and Dravidian-speaking tribal populations, which have AAA and ASI as their major ancestries respectively. These tribal populations are mostly isolated and they have a scattered distribution in Central and South India. We have analyzed GenomeAsia 100K-generated whole genome sequencing data of 497 unrelated South Asian individuals, that included 141 unrelated individuals from 11 Dravidian tribal populations and 4 Austro-Asiatic tribal populations. Despite being mostly isolated, these tribal populations showed high genetic similarity relative to other South Asian populations in Principal Component Analysis and ADMIXTURE analysis. We constructed a phylogenetic tree and performed D-statistics and IBD-based analyses which suggested that the Dravidian tribes from Central India are genetically closer to the Austro-Asiatic tribes, than they are to the Dravidian tribes from South India. We have used site frequency spectrum-based analysis to distinguish among various plausible demographic models in order to understand the population history of Austro-Asiatic and Dravidian tribes and estimate the separation time between ASI and AAA. This study elucidates the interplay between ASI and AAA ancestries and their role in the peopling of South Asia.

PB3108 Reconstructing Western and Northern Mexico's Past through the PIPANOM Project.

Authors:

R. Curry[1], J. Sedig[2], J. Punzo Diaz[3], D. Reich[4]; [1]Harvard, Cambridge, MA, [2]Harvard Med. Sch., Cambridge, MA, [3]Inst. Natl. de Antropología e Historia, Mexico City, Mexico, [4]Harvard Univ., Cambridge, MA

Though ancient DNA has revolutionized our understanding of the past, America/Mexico remain understudied. The Proyecto de investigación de poblaciones antiguas en el norte y occidente de México (PIPANOM) addressed this imbalance through the examination of over 300 ancient individuals from central, western and northern Mexico. Data from these individuals have revealed population structure that is broadly associated with geographic distance across what is now modern Mexico, Belize, Guatemala, and the southwest United States. These data have also provided new insights into long-standing questions about migration and interaction of different archaeologically defined cultures in key eras of Mexico's past, such as the movement of people during the Postclassic period. Along providing new insights in an area that has been understudied with aDNA, PIPANOM has helped correct institutional imbalances in archaeological and paleogenetic research. PIPANOM is an archaeologist-led project that has brought together more than 20 collaborators. As part of the project, there have been numerous workshops, trainings, and visits bringing together Mexican and American archaeologists, geneticists, researchers, analysts, and students. As such, PIPANOM provides a roadmap for equitable large-scale projects that produce robust scientific results.

PB3109 Roles of Genetic Ancestry and Hypopigmenting Alleles on Skin Color in a Caribbean Native American Population

Authors:

K. Ang[1], V. A. Canfield[1], T. C. Foster[1], T. Harbaugh[2], K. Early[1], R. Harter[3], K. Reid[1], S. Leong[1], Y. Imamura[4], D. Liu[1], J. Hawley[5], K. Cheng[6]; [1]Penn State Univ., Hershey, PA, [2]Penn State Hlth., Milton S. Hershey Med. Ctr., Hershey, PA, [3]Penn State Univ., State College, PA, [4]Penn State Coll. of Med., Hershey, PA, [5]Salybia Mission Project, Kalinago Territory, Dominica, [6]Penn State Col Med, Hershey, PA

Shared genetic ancestry suggests the sharing of one or more hypopigmenting skin color alleles between Native Americans and East Asians. Quantitating the effect sizes of candidate alleles requires an admixed study population with African but minimal European admixture. We genotyped 458 individuals (~15%) from a Caribbean Native American population, the Kalinago from the Commonwealth of Dominica, using Illumina Infinium Omni2.5-8 BeadChip. Admixture-based genetic ancestry was confirmed to be shared with East Asians at K=3. Genetic ancestry at K=6 was 55% Native American 32% African, and 12% European. Skin pigmentation ranged from 20 to 80 melanin units, averaging 46. Three albino individuals were homozygous for a multi-nucleotide polymorphism $OCA2^{NW273KV}$ of African origin whose single allele effect size was -8 melanin units. European hypopigmenting allele frequencies for $SLC24A5^{A111T}$ and $SLC45A2^{L374F}$ were 0.14 and 0.06, with effect sizes per allele of -6 and -4, respectively. Native American genetic ancestry by itself reduced pigmentation by more than 20 melanin units (range 24 - 29). Taken together, these results suggest the presence of to-be-identified hypopigmenting alleles of high impact that may be uniquely Native American or shared with East Asians

PB3110 Selective dynamics of interruptions at short tandem repeats.

Authors:

M. Goldberg[1], H. Dashnow[1], K. Harris[2,3], A. Quinlan[4]; [1]Univ. of Utah, Salt Lake City, UT, [2]Univ. of Washington, Seattle, WA, [3]Fred Hutchinson Cancer Res. Ctr., Seattle, WA, [4]Univ of Utah, Salt Lake City, UT

Short tandem repeats (STRs) are hotspots of genomic instability that mutate at rates orders of magnitude greater than non-repetitive genomic loci. In the germline, STRs typically mutate through replication slippage, which manifests as expansions or contractions of a locus by one or more repeat units. A subset of STRs are likely functional: somatic and germline expansions at some loci are linked to certain Mendelian diseases, while variation at other loci has recently demonstrated association with complex traits. Accordingly, some STRs are inferred to be under purifying selection, regardless of their instability. A major determinant of an STR's mutation rate is the homology of its repeat units; one or more 'interruptions', or bases that disrupt the locus's canonical repeat, have been shown to significantly decrease mutation rate in both the germline and the soma. More broadly, interruptions may act as *cis*-acting anti-mutator alleles, in perfect linkage disequilibrium with the repeat allele whose mutation rate they decrease. We therefore hypothesized that interruptions would occur more frequently at loci under purifying selection, where the fitness effects of expansions would be more deleterious than at neutral loci. To test this hypothesis, we examined the distribution of high quality, segregating single nucleotide variants that occur within STRs. Intriguingly, we find the strength of purifying selection on loci significantly covary with the number of interrupting polymorphisms, regardless of SNV allele frequency and STR locus characteristics. Our findings may indicate that interruptions' abundance may be partially explained by resulting lower mutational burden at their linked loci.

PB3111 Sexual dimorphism in Early Neolithic Europe was driven by culture, not genetics or environment.

Authors:

S. Cox[1], N. Nicklisch[2], M. Francken[3], J. Wahl[4], H. Meller[5], W. Haak[6], K. W. Alt[2], E. Rosenstock[7], I. Mathieson[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Danube Private Univ., Krems-Stein, Germany, [3]State Office for Cultural Heritage Management Baden-Württemberg, Konstanz, Germany, [4]{Inst. fur Naturwissenschaftliche Archa}ologie, Tübingen, Germany, [5]State Office for Heritage Management and Archaeology Saxony-Anhalt, Halle, Germany, [6]Max Planck Inst. for the Sci. of Human History, Jena, Germany, [7]Univ. Bonn, Bonn, Germany

Human culture impacts health and disease as much as genetics or the natural environment, but their effects are often confounded. The combination of ancient DNA and polygenic scores derived from present-day populations provides an opportunity to estimate genetic effects directly and thus isolate the effects of culture and environment on health. Here, we take a multidisciplinary approach by combining published ancient DNA with osteological data on height, health, and diet to analyze cultural, environmental, and genetic contributions to variation in stature in four geographically defined populations of Early Neolithic Europe (8000-6000 years before present): North Central (n=203), South Central (n=1067), Southern (Mediterranean; n=127), and Southeastern (Balkan; n=139) Europeans. In individuals from North Central Europe, female stature is low ($p=9x10^{-7}$; β=-2.0cm), despite polygenic scores for height identical to males and to neighboring regions (p &gt 0.9). Dietary stable isotopes and paleopathological stress markers indicate increased environmental stress in this region that is equal in both sexes, even though it is only the females who appear stunted. This, combined with the high stature sexual dimorphism ratio (M:F=1.14) suggests strong effects from a cultural factor which preferentially supported the males to recover from environmental stress. In contrast, shorter average stature in Mediterranean Neolithic populations have been previously observed and reported to be associated with genetic differences; however, our analysis indicates this is likely an artifact of residual population structure in the genome-wide association studies (GWAS) as decreased polygenic scores do not replicate when calculated using summary statistics from between-sibling GWAS. Instead, we observe decreased height only in males ($p=5.5x10^{-7}$; β=-1.44cm), leading to reduced sexual dimorphism in the region (M:F=1.05), and which indicates a degree of male vulnerability in response to general environmental stress.
We conclude that while population-level stature trends in some cases reflect genetic factors, differences in sexual dimorphism in Early Neolithic Europe were largely driven by culture, or the interaction of culture and environment. Understanding these patterns is key to interpreting the evolution of genetic and socio-cultural determinants of health and the origins of social inequality.

PB3112 Shared and distinct natural selection signatures within the Japanese population.

Authors:

X. Liu[1], M. Matsunami[2], M. Horikoshi[3], S. Ito[4], Y. Ishikawa[5], K. Suzuki[1], Y. Momozawa[1], S. Niida[6], R. Kimura[7], K. Ozaki[8], S. Maeda[7], M. Imamura[9], C. Terao[10]; [1]RIKEN, Yokohama, Japan, [2]Univ. of the Ryukyus, Nishihara-cho, Japan, [3]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [4]Shimane Univ., Matsue, Japan, [5]Riken, Ctr. for Integrative Med. Sci., Yokohama, Japan, [6]NCGG, Obu, Japan, [7]Univ. of the Ryukyus, Nishihara, Japan, [8]The Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [9]Univ. of the Ryukyus, Nishihara, Okinawa, Japan, [10]RIKEN IMS, Yokohama, Japan

Differential natural selection signatures among the Japanese subpopulations are largely unexplored. Here we conducted genome-wide selection scans with 622,926 single nucleotide polymorphisms for 20,366 Japanese individuals, who were recruited from the main-islands of Japanese Archipelago (Hondo) and the Ryukyu Archipelago (Ryukyu), the two representative subpopulations. The integrated haplotype score analysis identified shared and distinct signals under positive selection. We found a novel locus at *IKZF2* especially in Ryukyu. Although the MHC showed significant signals in both subpopulations, the variants with the strongest signals exhibited the largest allele frequency differences between the subpopulations and tagged distinct haplotypes of HLA alleles, namely, *DQB1*06:02-DRB1*15:01* and *DQB1*06:04-DRB1*13:02* in Ryukyu and Hondo, respectively. The haplotype *DQB1*06:02-DRB1*15:01* is reported to be protective for human T lymphotropic virus type 1 (HTLV-1)-associated myelopathy/tropical spastic paraparesis (HAM/TSP), possibly mirroring the high prevalence of HTLV-1 infection in Ryukyu. In supporting to this link, *IKZF2* is frequently deleted in HTLV-1-associated adult T cell leukemia/lymphoma (ATL). The fastSMC analysis identified 14 loci under positive selection within the past 20-150 generations, and uncovered region-specific and time-dependent selection profiles, especially in *ALDH2*, a well-known East-Asian-specific signal. In summary, our study provided insights into the selection signatures within the Japanese and revealed potential sources of selection pressure.

PB3113 Single-locus imputation of ancient African DNA using novel regression-based approach

Authors:

R. Pornmongkolsuk, A. Ochoa; Duke Univ., Durham, NC

In the study of adaptations, ancient DNA has the unique potential of providing ancestral haplotypes that are not present among modern populations. Indeed, ancient samples are highly susceptible to degradation that often results in low-coverage sequenced data-a characteristic that calls for genotype imputation to improve the accuracy of downstream analyses. However, most of the common imputation approaches require high-quality reference haplotypes-generally from modern genomes, which excludes a majority of informative ancient genomes from the reference panel. Here, we present a new logistic regression-based model for imputing ancient DNA on a single locus. The model is trained on a set of reference genomes tailored for a target sample based on its missing loci pattern. As a result, the model allows the reference genomes to retain an arbitrarily high missing rate-as long as the target locus is not missing. To account for linkage disequilibrium (LD), we use a forward selection algorithm to identify independent SNP predictors. In this project, the method will be used to impute the Duffy null polymorphism on the *DARC* gene (chr1:rs2814778)-a well-known adaptive variant protective against one type of malaria-to study its evolutionary history in ancient African populations, which are notoriously challenging for existing imputation approaches. This model will be validated 1) on simulated data that resembles African demographic models and ancient DNA missing rate patterns and 2) by the leave-one-out cross-validation test with real data of ancient African genomes. Overall, this approach is promising for imputing individual variants of interest with high accuracy and improving our understanding of single-locus adaptation by leveraging ancient DNA.

PB3114 Sperm sequencing reveals extensive positive selection in the human germline.

Authors:

M. Neville, A. Cagan, A. Lawson, R. Sanghvi, T. Bayzetinova, F. Abascal, P. Nicola, I. Martincorena, M. Hurles, R. Rahbari; Wellcome Sanger Inst., Cambridge, United Kingdom

Mutations that occur in the germline are the source of all heritable genetic variation. Understanding the mechanisms creating germline mutations and the selection pressures shaping them are therefore crucial to the study of evolution and disease. Although the majority (~80%) of inherited mutations in humans originate from the paternal germline, direct observation of mutations in sperm has been limited by the need for an extremely low error rate sequencing technology. In this study, we utilized NanoSeq, a duplex sequencing method with an error rate below five per billion base pairs, to sequence 104 bulk sperm samples from individuals aged 24 to 75 years. Our findings revealed a steady accumulation of 1.4 mutations per year, consistent with classical trio studies. By conducting deep targeted sequencing on the bulk sperm samples, we identified over 10,000 coding mutations, equivalent to sequencing the coding regions in hundreds of parent-child trios for each sample. Leveraging these variants, we detected 7 known and 14 novel genes subject to significant positive selection in the male germline. Interestingly, our study shows that germline positive selection, which occurs via a proliferative advantage of mutant spermatogonia in the testis, extends beyond the RAS/MAPK pathway and can also involve loss-of-function mechanisms. Notably, nearly all positively selected genes identified in our study are associated with pathogenic disorders in children when inherited, likely leading to an increased birth prevalence of these disorders, especially to older fathers. Furthermore, we quantified the fraction of sperm carrying pathogenic variants and demonstrated that although no single pathogenic variant is typically found in a high fraction of an individual's sperm (all < 0.5%), estimates of the total pathogenic burden exhibited a strong correlation with age, reaching over 5% of sperm in certain older individuals. These findings shed light on the dynamics of germline mutations and have important implications for our understanding of human disease.

PB3115 Strategies for improving variant calling on the sex chromosomes

Authors:

M. Wilson[1], S. Plaisier[2], T. Phung[1], A. Oill[3]; [1]Arizona State Univ., Tempe, AZ, [2]Arizona State Univ., Chandler, AZ, [3]Translational Genomics Res. Inst., Phoenix, AZ

Mammalian sex chromosomes have a shared evolutionary history, as they were once a pair of homologous autosomes. Though X and Y are differentiated, they still share high levels of sequence similarity in some regions, like the pseudoautosomal regions (PARs) and the X-transposed region (XTR). Females typically have two X chromosomes and males typically have an X and a Y chromosome. Despite the importance of X and Y in human health and disease and their unique evolutionary history, there is limited understanding on how taking a standard approach for alignment and variant calling - one that is designed for the autosomes/diploid chromosomes - affects variant calling on the sex chromosomes. Here, we undertook a simulation study to assess the effects of standard autosomal versus sex chromosome complement-informed alignment, variant calling and variant filtering strategies on variants called on the human sex chromosomes. We find that aligning samples to a reference genome informed by the sex chromosome complement of the sample - either the entire Y hard masked when aligning genetic females (46, XX) or hard masking one copy of the PARs when aligning genetic males (46, XY) - increases the number of true positives called in the PARs, and additionally, in females only, the XTR. Unexpectedly, masking one copy of the XTR when aligning male samples results in a ten-fold higher rate of false positives in the XTR. We find that haploid calling on X and Y in male samples reduces the number of false positives compared to diploid calling but does not decrease the number of false negatives. We also find that using diploid-based filter thresholds on haploid chromosomes worsens variant calling for some filters. Finally, we find that - using a default alignment approach - joint genotyping the X chromosome between males and females slightly reduces the number of true positives called in females, while dramatically increasing true positives called in males, but this effect is mitigated when using a sex chromosome-complement informed alignment. By taking into account sequence similarities and ploidy differences on the sex chromosomes, we outline best practices for mapping, calling and filtering variants on the sex chromosomes. We recommend aligning samples to versions of the human reference genome informed on the sex chromosome complement of the sample and to use biologically accurate ploidy parameters when calling variants and setting filtering thresholds. This approach results in a more accurate way of identifying variants on the sex chromosome and will help improve to account for the unique biology of chromosomes X and Y.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3116 Strengths and limitations of using the CARTaGENE population-based cohort to assess carrier rates for recessive disorders in Québec

Authors:

A-M. Laberge[1], K. Mohler[1,2], R. Laflamme[3], G. Lettre[4]; [1]CHU Sainte-Justine, Service de génétique médicale, Montreal, QC, Canada, [2]CHUM, Montreal, QC, Canada, [3]Montreal Heart Inst., Montreal, QC, Canada, [4]Université de Montréal, Montreal, QC, Canada

Background: The French-Canadian (FC) population is known to have an increased frequency of specific monogenic conditions, due to a founder effect. Reported carrier frequencies of common Mendelian conditions in the Québec FC population are based on disease incidence using Hardy-Weinberg equilibrium. Accurate carrier rates for specific autosomal recessive conditions can inform population-based screening programs and individual risk assessment. CARTaGENE (CaG) is a large population-based cohort of 43 000 adults aged 40-69 recruited randomly to represent the Québec population, including individuals of FC, Haitian and Moroccan descent. **Methods:** We aim to estimate carrier frequencies of specific mutations associated with autosomal recessive conditions in the FC, Haitian and Moroccan populations of Québec. Based on a literature review, we identified recurrent variants specific to each population (102 FC, 5 Haitian, 33 Moroccan). Genotyping data on FC variants is available for 8 740 FC participants and genome sequencing data on 2 173 participants (1 756 FC, 163 Haitian and 131 Moroccan). Variant frequencies were calculated using the open-source genome analysis toolset PLINK and were compared to available reported carrier rates. **Results:** Observed variant frequencies confirmed reported carrier rates for some variants, however others were discordant with reported carrier rates. For example, carrier rates for four recessive conditions for which carrier screening is recommended in individuals from the Saguenay Lac-St-Jean (SLSJ) region were significantly lower than the carrier rates found in individuals eligible for carrier testing based on SLSJ origin. Potential explanations include a mismatch between representation of subregions of SLSJ in CaG and distribution of carriers within that region or that CaG may have recruited in SLSJ individuals who are not from SLSJ. Some variants were not found at all in the CaG cohort (26 FC, 3 Haitian, 13 Moroccan), suggesting that reported carrier rates may be overestimated, that some so-called founder mutations are not recurrent in the population or that the CaG cohort does not have the power to detect regional differences in variant frequencies. **Conclusion:** Our analyses show the strengths and limitations of using a population-based cohort to assess carrier rates when carriers are not uniformly geographically distributed in the population, for example if located in specific subregions. We plan for more detailed analyses to assess provincial and regional allele frequencies, including an assessment of regional carrier rates of current population instead of carrier rates based on region of origin of individuals.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3117 Structural variant adaptation between the Peruvian Andes and Amazon using long-read sequencing

Authors:

V. Borda Pua[1], S. M. Yan[2], M. Gouveia[3], S. Roy[1], K. Cifuentes Godinez[1], R. Juscamaita[4], C. Sanchez[5], O. Caceres[5], C. Padilla[5], H. Guio[6], E. Tarazona-Santos[7], C. Rotimi[3], R. McCoy[2], M. Santolalla[4], T. O'Connor[1]; [1]Univ. of Maryland Sch. of Med., Baltimore, MD, [2]Johns Hopkins Univ., Baltimore, MD, [3]NIH, Bethesda, MD, [4]Univ. Peruana Cayetano Heredia, Lima, Peru, [5]Inst. Natl. de Salud, Lima, Peru, [6]INBIOMEDIC, Lima 14, Peru, [7]Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil

The harsh environments, including the high-altitude Andean mountains and the Amazon rainforest, posed significant challenges to the early settlers of South America. Physiological adaptations to these environmental challenges have been well characterized. However, our understanding of the genetic basis of these adaptive processes, explored mainly through single nucleotide variants (SNVs), remains limited. It has been hypothesized that structural variants (SVs, ≥ 30 bp) could be pivotal in genome evolution and adaptation. We investigate the impact of SVs on the adaptation of Indigenous Americans to Andean and Amazon environments. For this purpose, we generated high-coverage long-read sequence data on two Peruvian individuals with predominant Indigenous American ancestry (>99%) using PacBio HiFi sequencing. By integrating our data with 34 publicly available PacBio HiFi from Human Genome Structural Variation Consortium, we created an SV panel with 200,341 SVs. Subsequently, we used a graph-genotyping method and our SV panel to genotype SVs in short-read data from the Peruvian Genome Project (n=150), HGDP, and 1KGP, including two Andean and three Amazonian populations.
Our population structure analyses revealed the clear continental separation with a contrasting structure between Andean and Amazonian groups, with higher differentiation observed among Amazonian groups. We used the population branch statistic (PBS) in the form ((Andes; Amazon); East Asia) to identify highly differentiated alleles as candidates for adaptation to Andes and Amazon rainforest. We identified two candidates with strong allele frequency (AF) differences between populations of these two geographical regions. First, a 30 bp deletion (derived allele) in intron 23 of the *JAK2*, a gene that plays a crucial role in tolerance to hypoxia. This locus is highly differentiated in Andean populations (PBS value above 99.5th percentile), with the ancestral AF exceeding 0.7 while the Amazonian ancestral AF was below 0.3. Second, a 3305bp insertion in an intron region of the *CASP8* gene was nearly fixed in Amazonian populations (PBS value above 98th percentile; Amazonian AF > 0.91; Andean AF <0.55). *CASP8* plays an essential role in innate inflammatory cytokine production during bacterial infection. Our approach to exploring structural variation provides new directions to discover genetic variants under natural selection to harsh environments during the peopling of the Americas.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3118 Structure and function of mammalian chitinases: Insights from chimeric analysis.

Authors:

K. Takahashi, E. Tabata, F. Oyama; Kogakuin Univ, Tokyo, Japan

Chitin, a predominant polysaccharide in nature, serves as a vital structural component in various organisms, including crustaceans, insects, nematodes, and fungi. Despite lacking chitin and its synthase, mammals produce two chitinases: chitotriosidase (Chit1) and acidic chitinase (Chia). Chit1, the first purified mammalian chitinase, shows elevated levels in the plasma of individuals with Gaucher disease, an autosomal recessive lysosomal storage disorder. Chia, highly expressed in mouse stomach tissues, exhibits optimal activity at pH 2.0. These mammalian chitinases are thought to act as defense mechanisms against chitin-containing pathogens and as digestive enzymes breaking down chitin in ingested material. However, the specific structural characteristics underlying their distinct properties remain elusive. In this study, we generated chimeric constructs of Chit1 and Chia to explore the structural elements contributing to the unique features of these mammalian chitinases. Our analysis of these chimeras identified multiple regions involved in the enhanced enzymatic activity of Chia under strong acidic conditions. To further refine our understanding, we are currently preparing a new chimera and conducting additional investigations.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3119 The Emirati Genome Program: 1 million genomes for a better healthcare in the United Arab Emirates.

Authors:

T. Magalhaes, F. Al Marzooqi, The Emirati Genome Program; G42 Hlth.care, Abu Dhabi, United Arab Emirates

The Emirati Genome Program (EGP) aims to whole-genome sequence at ~30X ~1 million Emiratis in the United Arab Emirates (UAE) by 2025. EGP will be amongst the largest national genome sequencing program worldwide and likely the largest in terms of proportion of the population sequenced. The primary objective of EGP is to translate unprecedented genomics datasets, integrated with phenotypic data, into clinical practice.
As of June 2023, we have collected DNA samples from 440,000 EGP voluntary participants covering a representative geographic, age and gender range. We have sequenced 422,000 participants at >90 gigabases (Gb) across three high-throughput sequencing (HTS) platforms. A unique feature of EGP is the combination of both short-read, Illumina and MGI, as well as long-read Oxford Nanopore Technologies (ONT) sequencing. Through the latter we are conducting an unprecedented characterization of structural variation (SV) and population in a human population.
We have matched these multi-platform HTS capacity with computing, storage and analytics infrastructure optimized for each sequencing technology. For the raw-to-VCF processing of Illumina data, we use the DRAGEN system fully on premise. For MGI, we combine both on-premise and cloud processing leveraging MGI-proprietary, open-source and commercial software. We find ONT analysis workflow the most complex due to the balancing of GPU (base-calling) and CPU (alignment and variant calling) resources, the high computational cost of base-calling (especially when including methylation) as well as the sequencing and computational changes in a fast-evolving technology such as ONT. In all three analysis workflows, we are trying to call not only small variants (SNP and INDEL) but also additional genomic features (SV, CNV, HLA, pharmacogenomics, regions of homozygosity) and epigenetics. To minimize the storage footprint, we have adopted CRAM and decided to only keep alignments, variant calls and summary statistics alternating archival and fast access storage. To efficiently mine millions of genetic variants across tens of thousands of genomes, we are implementing an infrastructure based on Glow coupled with commonly used bioinformatics software for downstream analyses, e.g. genome-wide association analyses.
We have started translating the resulting EGP datasets into pilot clinical applications - from the screening of the EGP cohort for actionable genes recommended by the ACMG and rare disease-causing variants to the characterization of large likely deleterious SV and the HLA - as well as the implementation of nation-wide programs (pre-marital, pre-implantation and newborn screening).

Session Title: Evolutionary and Population Genetics Poster Session III

PB3120 The evolutionary fate of Neanderthal introgression in recently admixed African-American genomes.

Authors:

A. Pfennig, J. Lachance; Georgia Inst. of Technology, Atlanta, GA

A recurring theme in studies of ancient introgression in Eurasian populations is that Neanderthal DNA was generally deleterious to modern humans, leaving 1-2% of Neanderthal introgressed DNA in present-day non-Africans. Although simulation-based studies suggest that negative selection alone can explain observed introgression patterns in Eurasians, the exact evolutionary mechanisms of this purging have not been definitively established. For instance, another initially hypothesized mechanism involves hybrid incompatibilities, i.e., synthetic lethality or sterility. Furthermore, the purging of introgressed DNA likely occurred quickly as Neanderthal ancestry remained constant in Europe during the last 45,000 years, suggesting Neanderthal DNA is evolutionary neutral nowadays. Genomes of recently admixed individuals with combinations of African-like and European-like ancestry allow the testing of evolutionary mechanisms behind the purging of Neanderthal DNA and its evolutionary fate in extant genomes. Because African genomes have very little Neanderthal ancestry, most Neanderthal-derived variants in admixed genomes were contributed by European populations. Thus, these Neanderthal alleles have recently been tested against African DNA as they were introduced into novel genetic backgrounds. Here, we leverage whole-genome sequences of ~50,000 recently admixed African-American individuals from the 1000 Genomes Project and *All of Us* databases to test for secondary selection of Neanderthal DNA. We identify putatively selected Neanderthal introgressed segments and novel introgression deserts in admixed African-American individuals relative to expectations from the source populations. Preliminary results suggest that there is a slight enrichment of Neanderthal ancestry in African Americans. Furthermore, selected introgressed segments coincide with GWAS signals for anthropometric traits like height and BMI.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3121 The evolutionary history of 17q21.31 structural haplotypes in ancient and modern humans

Authors:

S. Sridharan[1], J. Rocha[1], P. Sudmant[2]; [1]Univ. of California, Berkeley, Berkeley, CA, [2]Univ. of California Berkeley, Berkeley, CA

Structural variation accounts for a large proportion of genetic diversity within human populations, and between humans and other primates. One type of structural variation, inversions, are segments of the genome that are flipped end-to-end. Among the 150 large inversions segregating in human populations, one extraordinary example is at the 17q21.31 locus. The 17q21.31 locus spans greater than 900 kilobases and comprises ten genes, including *MAPT* and *KANSL1*. Variations in this locus have been implicated in human diseases such as Alzheimer's, Koolen de Vries microdeletion syndrome, and various autism spectrum disorders. There are at least seven major inversion haplotypes worldwide, each exhibiting distinct frequencies across geographic regions and subpopulations. Four haplotypes exist in the direct orientation (H1), and three exist in the inverted orientation (H2). Each of these haplotypes maintain a complex duplication architecture in addition to its inversion status. Some of these haplotypes have also been identified as being under selection, with studies evidencing women who carry these haplotypes presenting higher fecundity rates. Consequently, this locus provides a unique system to study the impact of copy number variation on recombination suppression and extended linkage disequilibrium in human populations.
Here, we report extensive and surprising patterns of temporal and geographic variation at the 17q21.31 locus in several primates and in different modern and ancient human populations. We find that while the inverted haplotype (H2) is the ancestral haplotype in humans, it is the less common haplotype in both archaic and modern-day human samples. We observe an exceptional amount of copy number diversity in direct orientation (H1) haplotypes globally, particularly in understudied modern populations including South Asians. Using Stone Age Eurasian genomes, we model how the distribution and frequencies of different haplotypes have changed over recent human history. As a result of these distribution patterns, we hypothesize that recombination suppression in large and structurally complex regions of the genome contributes to the differential accumulation of deleterious mutations. Finally, we observe several unique instances of ancient double recombination in African populations and date the timing of these events. Together, these results provide valuable insights into the role of chromosomal rearrangements in shaping evolution, diversity, disease susceptibility, and fitness.

PB3122 The genetic legacy of African Americans from Catoctin Furnace.

Authors:

É. Harney[1,2], S. Micheletti[1], K. Bruwelheide[3], W. Freyman[1], K. Bryc[4], A. Akbari[2], E. Jewett[1], E. Comer[5], H. Gates, Jr.[2], L. Heywood[6], J. Thornton[6], R. Curry[2], S. Ancona Esselmann[1], K. Barca[3], J. Sedig[2], K. Sirak[2], I. Olalde[7], 23andMe Research Team, N. Rohland[8], J. Mountain[4], D. Owsley[3], D. Reich[2]; [1]23andMe, Sunnyvale, CA, [2]Harvard Univ., Cambridge, MA, [3]Natl. Museum of Natural History, Smithsonian Inst., Washington DC, DC, [4]23andMe, Inc., Sunnyvale, CA, [5]Catoctin Furnace Historical Society, Thurmont, MD, [6]Boston Univ., Boston, MA, [7]Univ. of the Basque Country UPV/EHU, Vitoria-Gasteiz, Spain, [8]Harvard Med. Sch., Boston, MA

Few African Americans can trace their family histories to their earliest enslaved African ancestors in the United States. Genetic analysis of historical individuals and identification of present-day close relatives has the potential to restore this knowledge. We analyze 27 individuals buried in Maryland's Catoctin Furnace African American Cemetery during the 18th-19th centuries, and identify identical by descent DNA segments documenting 41,799 relatives among consenting research participants in 23andMe, Inc.'s genetic database of ~12.8 million people. One of the largest geographic concentrations of close relatives is in Maryland, revealing that some descendants of the enslaved and free African Americans at Catoctin Furnace stayed in the area after records indicate their removal from the ironworks, a finding not demonstrable through genealogical analysis alone. We show that many Catoctin individuals likely derived their ancestry from a small number of African groups, specifically the Wolof and Kongo, and that some carried risk factors for Sickle Cell anemia and G6PD deficiency, genetic diseases common in African Americans today. These analyses provide the first direct look at the genome-wide genetic ancestry of enslaved people in the United States, and demonstrate the power of joint analysis of DNA from historical individuals and the extremely large datasets generated through direct-to-consumer ancestry testing.

PB3123 The in-depth analysis of the Transylvanian Seklers' genetic profile using high-resolution autosomal markers

Authors:

B. Melegh[1,2], V. Ádám[1], K. Sümegi[1,2,3], A. Szabó[1,2], G. Büki[1,2], L. Magyari[1,2], K. Hadzsiev[1,2], M. Kásler[4], Z. Bánfai[1,2]; [1]Univ. of Pécs, Med. Sch., Dept. of Med. Genetics, Pécs, Hungary, [2]Univ. of Pécs, Szentágothai Res. Ctr., Pécs, Hungary, [3]Univ. of Pécs, Med. Sch., Dept. of Biochemistry and Med. Chemistry, Pécs, Hungary, [4]Natl. Inst. of Oncology, Budapest, Hungary

The Seklers, also known as Szekelys in Hungarian, are a Hungarian-speaking Catholic ethnic group residing primarily in Transylvania, Romania. The first written evidence of the Seklers dates back to the 12th century, but their exact origin remains unknown, and their internal population structure has yet to be investigated. In this study, our aim was to characterize their genetic composition by examining subpopulations from various regions of Transylvania. We analyzed a total of 319 Sekler samples collected from 10 different regions within Transylvania. Using Illumina 720K genotype data, we conducted a thorough investigation encompassing allele frequency and haplotype analyses. Our methods included principal component analysis, ancestry analysis based on maximum likelihood estimation, and various DNA segment analysis techniques such as identity-by-descent segment analysis. Our findings reveal that the Seklers of Transylvania exhibit similar ancestry components to a similar degree. This observation was strengthened by both allele frequency and haplotype-based analyses. However, our allele frequency-based investigations highlighted that individuals from the Szentegyhaza and Szovata regions show a significantly larger proportion of one specific ancestry component shared with East Europeans. Based on our investigations, the Seklers residing in Transylvania are generally genetically homogeneous, with the exception of two regions. These areas exhibit a noticeably higher proportion of the East European-West Asian ancestry component, which provides valuable insight into the presumed homeland and origin of the Sekler people. This discovery opens up further opportunities for studying the ancestral roots of the Seklers. Grant References: Supported by the NKFIH 138669.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3124 The longitudinal study of accumulation and inheritance of germline mutations is a way to understand microevolution.

Authors:

H-R. Park[1,2], H-M. Cho[1,2], S-H. Choe[1], M-K. Ko[1,2], Y-J. Lee[1,2], S-J. Park[1], Y-H. Kim[1], J-W. Huh[1,2]; [1]Korea Res. Inst. of BioSci. and Biotechnology, Cheongju, Korea, Republic of, [2]Dept. of Functional Genomics, KRIBB Sch. of BioSci., Korea Univ. of Sci. and Technology (UST), Cheongju, Korea, Republic of

Mutations are caused by errors in the DNA replication process or environmental factors such as radiation or chemicals and occur in germ cells can be transmitted to the next generation. Whether the process of transferring unrepaired mutations to the next generation is repeated, it can proceed to microevolution that changes population gene pool at the species level. In the case of sexual reproduction, compared to female, male germ cells have more opportunities to mutate due to spermatogenesis during whole lifetime. In the present study, we perform whole genome sequencing (WGS) to analysis of somatic/germline mutations accumulated within individuals and patterns of mutations transmitted to offspring by parents' age in crab-eating monkeys (*Macaca fascicularis*). We aim to analyze accumulation patterns of somatic/germline mutation throughout lifetime in crab-eating monkeys, which have yet not to be reported. And based on them, we identify tendency in which germline mutations are transmitted to the next generation and ultimately find out the effect of parental age on the next generation. We selected 4 families (total 16 monkeys; 10 males, 6 females) around various age to get data at all age point and considered that they can produce 3rd generation for detecting transmission to next generation. Also, we considered families with males as 2nd generation offspring in order to directly confirm the effect of transmitted mutations on the reproductive cells of the child, especially sperms. Both somatic cells (blood cells, buccal cells) and germ cells (sperms) were sampled annually to identify total mutations in an individual and sort out germline mutations, from comparative analysis with somatic mutations. As a result of 3 years process, WGS data of monkey families was built up, and based on that, diverse pipelines were devised to analyze mutations accumulated at each sampling time. The envisioned two pipelines are one that considers cell lineage developmental process of three samples and the other that classify *de novo* mutation according to family-related between monkeys. From these analysis, we demonstrate the effect of germline mutations accumulating with age in crab-eating monkeys throughout whole life on next generation. We plan to build a model for germline mutations during the course of aging in parents transferred to offspring, and this could be used as a way to observe microevolution by molecular perspective in crab-eating monkey species.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3125 The nature of selection on common diseases and complex traits

Authors:

N. Connally[1], E. Koch[2], N. Baya[3], B. Neale[4], E. Lander[3], A. Bloemendal[3], S. Sunyaev[2]; [1]Harvard Med. Sch., Brigham & Women s Hosp., Cambridge, MA, [2]Harvard Med. Sch., Brigham & Womens Hosp., Boston, MA, [3]Broad Inst., Cambridge, MA, [4]Broad Inst., Massachusetts Gen. Hosp., Cambridge, MA

The question of how various evolutionary forces maintain variation in complex traits is a mainstay of evolutionary quantitative genetics. Modern human genetics has contributed by demonstrating that effect sizes estimated using GWAS are negatively correlated with allele frequencies. This evidences negative selection on trait-affecting alleles which scales with the magnitude of those effects. For quantitative traits there is good theoretical justification for supposing this reflects the action of stabilizing selection. However, for disease traits one might intuitively expect that selection acts primarily against risk-increasing alleles in order to reduce the prevalence of a deleterious condition. We developed a framework to explicitly compare different models of selection using top GWAS loci from a set of disease, anthropometric, and metabolic traits. All traits under investigation showed a characteristic U-shape when plotting the effect-sizes and frequencies of risk/trait-increasing alleles. When distinguishable from neutrality, we found support (log10 BF>1) for models of stabilizing selection for both disease and quantitative traits. Schizophrenia and Type-2 Diabetes had strongest evidence for stabilizing selection among disease traits. The evidence against directional selection is due to the symmetry of frequencies when conditioning on the risk allele. Long-term directional selection should yield a bias towards risk alleles, yet high-frequency protective alleles are common. Within the realm of stabilizing selection, we also compared a model where the focal trait represents the only relevant fitness dimension (1D) to one where fitness is highly pleiotropic (HD). While we found consistent support for the HD model, we note that it is weaker for disease traits, sensitive to the inclusion of top loci, and not necessarily expected from simulations. Further investigation into the pleiotropic nature of selection on human complex traits is needed.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3126 The Origin and Global Distribution of the 17q21 Inversion.

Authors:

D. Shriner[1], C. Pedicone[2], S. Weitzman[2], A. Renton[2], B. Fulton-Howard[2], A. Adeyemo[3], A. Goate[2], C. Rotimi[4]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]NIH, Bethesda, MD, [4]NIH, Woodstock, MD

A common inversion polymorphism exists at chromosome 17q21.31, with the highest frequencies of the inversion occurring in Italy and Turkey (~30%). The inverted region covers 19 genes, including microtubule-associated protein tau (*MAPT*), which is associated with Alzheimer disease and other tauopathies. The primary assembly of the human reference sequence represents the noninverted orientation and contains a haplotype called H1. The human reference sequence also contains an alternate sequence, chr17_GL000258v2_alt, that represents the inverted orientation and contains a haplotype called H2. Previous studies have identified 20 SNPs that tag H1 and H2 haplotypes. We investigated the genetic diversity of the inversion in 3,569 present-day individuals and 9,990 ancient individuals. Using tag SNP genotypes, we inferred that the present-day data included 6,489 H1 haplotypes, 647 H2 haplotypes, and two H1-H2 recombinants. Using read depth from short-read sequence data, we inferred the presence of zero inverted H1 haplotypes and three noninverted H2 haplotypes, suggesting that the H2 haplotype predated the inversion. Phylogenetic analysis revealed a monophyletic origin of all extant H2 haplotypes. All 37 H2 haplotypes from African individuals occupied derived positions in the phylogeny, consistent with an origin after Out-of-Africa followed by gene flow back to Africa and subsequent introgression. From the ancient DNA collection, the earliest H2 haplotype was in an individual from Taforalt (Morocco) from 12,900-12,100 BCE. No H2 haplotype was detected in 51 individuals from Ice Age Eurasia. The earliest H2 haplotype in Europe was observed in Serbia in an individual from 6,223-6,064 BCE, with genetic similarity to an Anatolian individual from 6,435-6,257 BCE, suggesting a Neolithic introduction of the H2 haplotype from a Middle Eastern source. Among 23,629 African Americans, we detected 2,180 H2 haplotypes, with 99.4% mapping to European ancestry at the locus, likely reflecting recent admixture and introgression from European sources. These results support origins of both the H2 haplotype and the inversion after Out-of-Africa, possibly in the Middle East, and highlight the importance of gene flow in introducing the inversion to new populations over the last 8,000 years.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3127 Threading new data into reconstructed genealogies

Authors:

A. Ignatieva[1,2], S. R. Myers[1]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Univ. of Glasgow, Glasgow, United Kingdom

The evolutionary history of a sample of genomes can be fully captured by their genealogy in the form of an ancestral recombination graph (ARG): a graph connecting the genomes through shared ancestors in the past, annotated with the mutation events that have shaped the present-day genetic diversity. Inference methods that directly use ARGs as inputs thus offer a powerful way of estimating evolutionary parameters of interest from sequencing data, such as past population sizes or selection coefficients. However, the true genealogy is generally unobserved, and must be inferred from the data at hand: this is a notoriously difficult problem that has seen impressive recent progress, with several powerful and scalable ARG reconstruction tools now available.

The related problem of adding new data to a fixed reference ARG (and avoiding the computational cost of redoing the reconstruction from scratch) has also drawn significant interest. We present a new approximate but principled method for accurately and quickly threading a sequence into an existing ARG. We use the timing of the mutations that are shared by the reference ARG and the new sequence to construct a reduced state space of possible edges with which the new sequence can coalesce at each genomic location, from which the threading position is chosen. Simulation studies with human-like parameters demonstrate that the method maintains excellent accuracy while scaling sub-linearly in the sample size, for both simulated and reconstructed reference ARGs, and running in a fraction of the time compared to *de novo* genealogy reconstruction; the method is also exact in certain cases. Crucially, our method naturally handles issues such as the presence of recurrent mutation, missing data and sequencing errors, and allows for types of data which most ARG reconstruction methods do not accommodate, such as unphased genotypes and non-contemporary samples. This has myriad applications, for instance in adding low-coverage ancient DNA data into previously inferred large-scale human genealogies, allowing for integrated analysis of modern and ancient samples, and improved understanding of selection, trait evolution and demographic history.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3128 Time series data reveal selection on blood group phenotypes over the past 10,000 years in West Eurasia

Authors:

A. Barton[1,2], A. Akbari[3,1,2], D. Reich[4,3,5,2]; [1]Dept. of Human Evolutionary Biology, Harvard Univ., Cambridge, MA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA, [3]Dept. of Genetics, Harvard Med. Sch., Boston, MA, [4]Dept. of Evolutionary Biology, Harvard Univ., Cambridge, MA, [5]Howard Hughes Med. Inst., Harvard Med. Sch., Boston, MA

The discovery that selection on the *HBB* gene conferred resistance to malaria first indicated that blood traits may be important targets of selection in humans; however, identifying adaptation at other blood-related loci has proven difficult. Using a generalized linear mixed model approach and leveraging time series data from ancient DNA (method detailed in separate abstract), we detected evidence of selection on several blood-group related genes over the past 10,000 years in West Eurasia, including *ABO*, *FUT2*, and *GYPA*.

At *ABO*, variant rs8176746 (G>T) defines the B blood-type allele and is under selection (s=3.3%, $P=6x10^{-26}$). ABO blood types have previously been associated with differential resistance to infectious diseases. Our results showed selection on the B allele led to a decrease in the A allele frequency, but a stable frequency of O allele over the past 4,000 years in West Eurasia. Prior studies have supported the hypothesis that the O blood type provides some resistance to infection by malaria. The A and B phenotypes have been suggested to provide protection against cholera, plague and tuberculosis, and blood type B specifically has been proposed to protect against smallpox and norovirus. Similarly, rs601338 (G>A) in *FUT2*, a variant responsible for secretor status of blood type antigens, is also associated with resistance to norovirus and shows evidence for selection (s=1.0%, $P=2x10^{-14}$) during the same period.

Furthermore, genome-wide association analysis demonstrates that variants that define the A and B alleles have opposite effects on some polygenic phenotypes. One such trait is alkaline phosphatase level, which has been associated with differences in chylomicron absorption in the intestine for the A and B type alleles. *ABO* and *FUT2* have been linked to microbiome composition that affects both infection and autoimmune disorders of the bowels. These results along with the observation of selection on linked missense variants rs7658293 and rs7687256 in the *GYPA* gene (s=1.0%, $P=6x10^{-36}$), which contribute to the MNS blood group, support the hypothesis that blood types have been important candidates of selection, and further study of their frequencies in the past might lend insight into their role in human health today.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3129 Tracing the genetic link of Mizo people of India: Genetic & archaeological evidence

Authors:

B. Bankura[1], P. Singh[2], G. Chaubey[2], M. Das[3]; [1]Med. Coll. Kolkata, Kolkata, India, [2]Banaras Hindu Univ., Varanasi, India, [3]Univ. of Calcutta, Kolkata, India

The Himalayan region played a crucial role in the human dispersal and colonization of South Asia. It forms a unique and narrow passage that connects the Indian sub-continent to East and South East Asia. Archaeological and anthropological studies suggest migration and cultural diffusion in this region with the Tibetan plateau in the north. Mizoram is the southernmost state in the northeast region, sharing its borders with Tripura, Assam, and Manipur, along with Myanmar and Bangladesh. The Mizo people are believed to be a part of the Mongoloid feature and Mizoram has the highest number of tribal people among all states of India. Therefore, our study is an attempt to clarify the origins of the Mizo people and their migration roads to their present settlements. Thus, issues of ethnicity and migration are complex but highly relevant to the modern state. A more concentrated effort is required to track these population movements and dispersals linking archaeology and genetics. Plausible migration histories of these groups have been addressed based on linguistic, ethnographical, historical, and folkloristic data, however; less attention has been given to genetics or modern genome mapping. Given the vastness of the region and considerable diversity in the topography, a specific region has been selected for the study: the region adjoining the Indo-Myanmar border in the Champhai district of Mizoram. Therefore, our study is an attempt to clarify the origins of the Mizo people and their migration roads to their present settlements. In the present study, we have investigated 110 individuals belonging to different clans of Mizo people for a genome-wide autosomal marker study. Our results suggest that they are a unique and isolated tribal group and have a very distinct population history. Haplotype and allelic frequency-based analyses indicate that they substantially shared ancestry primarily with East Asian populations and Tibeto-Burman speakers of India but also differentiated from them and became a distinct population with time.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3130 Uncovering the genetic roots of androgenic alopecia in African men: a novel dataset reveals ancestry-specific loci and pathways.

Authors:

R. Janivara[1], Men of African Descent and Carcinoma of the Prostate (MADCaP) Network, T. Rebbeck[2,3], A. O. Adebiyi[4], I. Agalliu[5], J. Lachance[1]; [1]Georgia Inst. of Technology, Atlanta, GA, [2]Harvard TH Chan Sch. of Publ. Hlth., Boston, MA, [3]Dana Farber Cancer Inst., Boston, MA, [4]Univ. of Ibadan, Ibadan, Nigeria, [5]Albert Einstein Coll. of Med., New York, NY

Androgenic alopecia is a highly heritable trait, with a varying prevalence across the globe. Unfortunately, much of our understanding regarding the genetics of male pattern baldness comes from individuals of European descent, and it is unknown whether the genetic architecture of this trait varies by ancestry. Therefore, we examined a novel dataset comprising 2,136 men of African descent recruited from Ghana, Nigeria, Senegal, and South Africa that were genotyped on a custom array that was optimized for sub-Saharan African populations. To remedy existing knowledge gaps, we tested how well recent polygenic risk scores for male pattern baldness generalize to African men, conducted the first African GWAS of androgenic alopecia, and examined functional and evolutionary genetic causes of continental differences in the genetics of this complex trait. Applying polygenic risk scores for male-pattern baldness that were ascertained in men of European descent to African individuals yielded AUC statistics that ranged from 0.514 to 0.546, i.e., genetic predictions only slightly surpassed random chance. Subsequently, we conducted an African GWAS of androgenic alopecia on 19 million genotyped and imputed variants, focusing on baldness at age 45. After correcting for present age, population structure, and study site, we identified 266 moderately significant associations (p-value < 10^{-5}), 54 of which were independent. Marginally significant associations were found at 47 loci. These GWAS loci included previously identified baldness-associated genes such as HIPK1 and IRF4, as well as novel Africa-specific hits. Loci associated with baldness in African men were enriched for cellular processes such as keratinization, olfactory signaling, cell death in skin, and GPCR signaling. Although most of the loci associated with baldness were autosomal, X-linked variants contributed significantly to the SNP-based heritability of this trait in African populations, including intronic variants in the androgen receptor (AR) gene. To understand the source of continental variation in the risk, we inferred the evolutionary ages of baldness-associated alleles and tested whether this trait has been a target of recent natural selection. Further, we analyzed the impact of ancient human introgression on continental differences in the genetic architecture of male pattern baldness. Collectively, our findings underscore the limited transferability of predictions across different ancestries and emphasize the importance of conducting genetic studies encompassing a wide range of populations.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3131 Unearthing the overlooked founder effect of Beauce (Quebec, Canada)

Authors:

M. Gagnon[1], C. Moreau[1], J. Ricard[2], A. Bureau[2], H. Vézina[1], M. Maziade[3], S. Girard[1]; [1]Université du Québec à Chicoutimi, Chicoutimi, QC, Canada, [2]Université Laval, Québec, QC, Canada, [3]Ctr. de recherche IUSMQ, Quebec, QC, Canada

Quebec is known for its founder effects and unique regional characteristics shaped by historical events such as settlement patterns and high natality rate. Sub-regions of Quebec such as Saguenay have been studied for decades for the obvious impact of the past on the genetics of the current population and its consequences on human health. However, our recent research on schizophrenia (SZ) and bipolar disorders (BD) has shed a light on an understudied founder effect that is particularly prominent in the Beauce region despite its proximity to major cities and lack of physical barriers limiting immigration. It is essential to understand the genetic structure of populations for unbiased research on genetic disorders. Therefore, we intend to investigate the founder effect in Beauce and its impact on the population before proceeding with our genomic sequence research on SZ and BD.

Our study focuses on Beauce, its founder effect, and how it impacts the population's genetic structure. We analyzed Illumina OmniExpress or Global Screening Array SNP chip imputed genotypes of 648 Beaucerons from 28 extended families, including both SZ and BD patients, as well as their healthy relatives. They were matched with regional population controls. Additionally, we reconstructed their genealogies spanning back 15 generations using the BALSAC population database. To ensure the independence of our findings from the phenotypes, we also obtained genealogical data for 32,169 supplementary Beaucerons from BALSAC, and performed a comparative analysis. The kinship and inbreeding coefficients showed no significant difference between our patients' families and the BALSAC dataset. With our genetic dataset, we compared Beauce to other well-studied regions using principal component analysis, runs of homozygosity, and identical-by-descent segments. With the genealogies, we characterized them with various measurements such as kinship and inbreeding coefficients.

Our analyses revealed that Beauce displayed higher values than the surrounding populations for the kinship and inbreeding coefficients, and that the genetics of this population substantially differ from the regions of Quebec which encountered no strong regional founder effect.

By investigating the understudied founder effect in Beauce, our results raise the need of considering population structure in genetic research. Our findings advocate for a shift towards investigating geographically and historically distinct subpopulations with unique genetic profiles.

Session Title: Evolutionary and Population Genetics Poster Session III

PB3132 Unraveling Genetic Associations and Ancestral Influences on Fibroproliferative Diseases

Authors:

G. Hampton[1], J. Hellwege[2], M. Puckelwartz[3], Y. Luo[4], D. Velez Edwards[5], T. Edwards[6]; [1]Dept. of Human Genetics, Vanderbilt Univ., Nashville, TN, [2]Div. of Genetic Med., Dept. of Med., and VGI, Nashville, TN, [3]Ctr. of Genetic Med., Northwestern Univ., Chicago, IL, [4]Inst. for Augmented Intelligence in Med., Inst. for Innovations in Dev.al Sci., (IPHAM): Ctr. for Hlth.Information Partnership, Northwestern Univ., Chicago, IL, [5]DRVE affiliation: Div. of Quantitative Sci., Dept. of Obstetrics and Gynecology, Dept. of BioMed. Informatics TLE: Div. of Epidemiology, Dept. of Med., Vanderbilt Genetics Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN, [6]Vanderbilt Genetics Inst., Div. of Epidemiology; Dept. of Med., Vanderbilt Univ. Med., Nashville, TN

Fibroproliferative diseases (FPD), such as asthma and lupus, share a common etiology and often co-occur, suggesting the presence of shared genetic risk factors. Racial disparities reveal higher prevalence among individuals of African ancestry, possibly due to a Th2-favored genome resulting from generational exposure to helminth parasites in Africa. To investigate this hypothesis further, we analyzed global and local ancestry for associations with FPDs. Data on FPDs and genotypes were obtained from electronic health record (EHR) biobanks BioVU from Vanderbilt University Medical Center and the Electronic Medical Record and Genomics (eMERGE) Network. Global and local ancestry analysis employed logistic regressions in BioVU and eMERGE with ancestry proportions based on 1000 Genomes Phase 3 populations, specifically West African (WAFR), East African (EAFR), Southern European (SEUR), and Northern European (NEUR) populations. Regression analyses were conducted separately for self-identified non-Hispanic blacks (NHB) and non-Hispanic whites (NHW), adjusted for sex, age, and body mass index (BMI). Effect estimates are reported per 10% increase in genetically inferred ancestry proportions. Significant positive associations were observed between sarcoidosis with EAFR (odds ratio [OR]=1.17 [95% confidence interval [CI]: 1.12, 1.22]) and WAFR (OR=1.21 [95% CI: 1.16, 1.27]). Conversely, European ancestry demonstrated significant negative associations, with the most pronounced effects seen in sarcoidosis (SEUR: OR=0.87 [95% CI: 0.85, 0.90], NEUR: OR=0.88 [95% CI: 0.84, 0.91]). Local ancestry analysis in BioVU NHB revealed significant peaks at chr2p23.3 for sarcoidosis, chr19p12, chr4p15.33-32 for lupus, and chr10p13-15.1 for asthma. Targeted associations using BioVU NHB GWAS summary statistics identified potential causal SNPs in these regions. Notably, *CELF2* (rs543494131: OR=5.33[95% CI: 2.67, 10.64) was implicated in asthma, *TWIST2* (rs73104883: OR=6.38[95% CI: 2.97, 13.69]) in sarcoidosis, and *ZNF724* (rs188752820: OR=7.35 [95% CI: 3.23, 16.70]) in lupus. These genes have been previously associated with these phenotypes and implicated in T-cell activation and the inflammatory immune response. Our findings illustrate a shared immune-mediated susceptibility to FPDs in NHB, potentially contributing to the increased prevalence of FPDs in individuals of African ancestry. Furthermore, our results indicate a possible protective relationship between European ancestry and the development of FPDs, potentially attributed to variations in T-cell regulation and inflammatory responses.

Session Title: Evolutionary and Population Genetics Poster Session I

PB3133 Unraveling the Haplotype Diversity of the Immunoglobulin Heavy Chain Constant Locus Using Targeted Long-Read Sequencing

Authors:

U. Jana[1], O. Rodriguez[1], A. Dorgham[1], W. Gibson[1], K. Shields[1], C. Silver[1], M. Emery[2], G. Deikus[2], R. Sebra[2], E. Eichler[3], M. Smith[1], C. Watson[1]; [1]Univ. of Louisville, Louisville, KY, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Univ of Washington, Seattle, WA

The heavy chain constant region of antibodies (Ab) plays a crucial role in immune function by facilitating antigen neutralization and elimination through various effector functions. These functions are mediated by different Ab isotypes, namely IgM, IgG, IgA, IgE, and IgD, encoded by genes within the immunoglobulin heavy chain constant (IGHC) locus. Despite previous studies highlighting extensive allelic and structural variation (SV) within IGHC, our understanding of haplotype diversity in this region remains limited. Technical barriers have impeded the use of standard next-generation sequencing to resolve these complex loci, underscoring the need for improved genomic resources and tools to effectively characterize IGHC diversity.To address these limitations, we employed targeted long-read sequencing (Pacific Biosciences) of genomic DNA and fosmid clones, combined with the bioinformatics pipeline IGenotyper. This approach enabled us to generate high-quality haplotype-resolved assemblies spanning the IGHC region for six individuals of African, East Asian, and European ancestry, providing comprehensive coverage of IGHC diversity. In our analysis, we identified an elevated number of single nucleotide variants (SNVs; ranging from 2.01 to 5.24 per kilobase) compared to the genome-wide average. Additionally, we observed the presence of large SV including segmental duplications involving the IGHG4 gene, deletions, and inversions. Notably, our study resolved these SVs at the nucleotide level, leading to the discovery of novel IG genes and alleles.Furthermore, we employed these assemblies and two sets of trios to benchmark our novel high-throughput targeted long-read sequencing protocol and bioinformatics pipeline. Our results demonstrated that our approach generates highly accurate assemblies and genotype callsets, outperforming alternative methods. This enables large-scale studies of IGHC genetic variation and their functional effects.By unraveling the haplotype diversity of the IGHC locus, our findings provide an initial understanding of IGHC haplotype diversity. These assemblies serve as valuable resources to accurately interrogate IGHC polymorphisms. This advancement enhances the characterization of IGHC gene diversity at the genome and population levels, crucial for elucidating the roles of germline variation in antibody effector functions in disease and clinical phenotypes.In conclusion, our study offers new insights into the complex IGHC locus and its diversity, enabling further advancements in understanding the impact of genetic variation on antibody-mediated immune responses.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3134 Unravelling the impact of admixture and adaptation on patterns of genetic diversity at the *TAS2R* bitter taste receptor genes in distinct African populations from Cameroon

Authors:

A. Lisi[1,2], X. Liu[2], C. Battaggia[1], R. Johnson[2], P. Anagnostou[1,3], G. Destro Bisol[1,3], M. C. Campbell[2]; [1]La Sapienza Università di Roma, Rome, Italy, [2]Univ. of Southern California, Los Angeles, CA, [3]Istituto Italiano di Antropologia, Rome, Italy

Bitter taste perception is a highly variable trait in humans, and the ability to detect bitter compounds has been largely attributed to genetic variants in 25 bitter taste receptor (*TAS2R*) genes located on chromosomes 5, 7, and 12. Moreover, bitter taste perception has been hypothesized to be a dietary adaptation in humans. While prior analyses have examined patterns of genetic diversity at many of the *TAS2R* genes mainly in non-Africans, relatively few studies have characterized patterns of diversity and signatures of selection at these bitter taste genes in ethnically and culturally distinct African populations. Given the extensive genetic substructure and evidence for local adaptation in response to diet in Africa, we hypothesized that African populations practicing diverse subsistence strategies (such as hunting/gathering and agriculture) could have distinct patterns of selection resulting from divergent diets. To test this hypothesis, we examined sequence variation at 22 bitter taste receptor genes in 120 African hunter-gatherers (Baka, Bakola, and Mbenzele) and Bantu-speaking agriculturalists (Bassa, Ewondo, and Ngoumba) from Cameroon. Here, we identified 353 single nucleotide polymorphisms (SNPs) across the *TAS2R* genes, and among these SNPs 35 of them have never been previously described. We also observed striking departures from neutral evolution at several *TAS2R* genes based on summary statistics—indicative of positive selection—in both hunter-gatherer and agriculturalist populations. To further investigate this evidence for selection, we characterized long-range linkage disequilibrium across chromosomes 5, 7, and 12 in our populations using *i*HS and EHH statistics. These analyses uncovered unusually long haplotype structure around alleles at the *TAS2R* genes (e.g., *TASR2R14*, *TAS2R19*, and *TAS2R20*). In addition, some of these signals of positive selection were shared between hunter-gatherer and Bantu-speaking populations. To better understand these results, we performed genomic genotyping in our hunter-gatherer and Bantu-speaking populations. Interestingly, we observed varying proportions of ancestry originating from Bantu-speakers in hunter-gatherers with the highest levels of admixture occurring in the Bakola population over the last 1,300 years. Indeed, these findings demonstrate that gene flow from neighboring Bantu-speaking agriculturalists has contributed to patterns of diversity in hunter-gatherers, including genetic variation at the *TAS2R* genes. Overall, this study provides new insights into the evolution of biologically relevant bitter taste genes in diverse African populations.

PB3135 Unveiling Global Disparities in Idiopathic Infantile Hypercalcemia: A Genetic and Population-Based Study

Authors:

A. Tomaszewski[1,2,3], K. Lovrenert[2,3], D. Bodner[3,1], F. Schumacher[4], C-H. Wu[2,3]; [1]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [2]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. and Univ. Hosp., Cleveland, OH, [3]Dept. of Urology, Case Western Reserve Univ. and Univ. Hosp., Cleveland, OH, [4]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Introduction/Objective: Idiopathic infantile hypercalcemia (IIH) is a rare autosomal recessive disorder caused by an impairment in the 24-hydroxylase enzyme encoded by the *CYP24A1* gene. The most common clinical presentation is related to symptoms of hypercalcemia due to increased osteoclast activity and decreased calcium excretion, eventually resulting in nephrolithiasis and nephrocalcinosis. Children receiving vitamin D supplementation are especially at an increased risk of developing these complications due to their inability to appropriately regulate calcium levels. The clinical prevalence of IIH is not well characterized. This study seeks to identify global superpopulations in which IIH may be more common to implement improved screening protocols and prevent complications from delayed treatment or inappropriate vitamin D supplementation.
Methods: Known pathogenic variants of *CYP24A1* causing IIH were procured from the Human GeneMutation Database (HGMD). The 1000 Genomes (1KG) database was used to identify healthyindividuals with *CYP24A1* variants. HGMD and 1KG databases were intersected to find sharedvariants, and prevalence was calculated using the Hardy-Weinberg equation. Individual allele frequencies were calculated using the same method divided into the following superpopulations: Africans (AFR), Admixed Americans (AMR), East Asians (EAS), Europeans (EUR), and South Asians (SAS).
Results: After intersecting the HGMD and 1KG databases, three disease-causing variants were identified in 8 heterozygote individuals. This yields a carrier rate of 1 in 314 and an affected rate of 1 in 391,876. Importantly, these variants were identified only among the AMR and EUR superpopulations at carrier rates of 1 in 174 and 1 in 168 and affected rates of 1 in 120,409 and 1 in 28,112, respectively. None of the pathogenic variants were found in the AFR, EAS, or SAS populations.
Conclusion: There exist marked disparities in the affected rate: 1 in 120,409 and 1 in 28,112 in the AMR and EUR populations respectively, and zero in AFR, EAS, or SAS populations. The probable causes for these variations could stem from the genetics of IIH and CYP24A1 being less researched in non-white populations. Additionally, there could be a founder effect present in the EUR/AMR populations, and it is plausible that pathogenic variants possess higher frequencies within EUR and AMR. Further research is imperative for the identification of other pathogenic variants within diverse populations in addition to more comprehensive evaluation of potential differences in carrier and affected rates for IIH across different populations.

PB3136 Using 858,635 individuals' haplotype-sharing between British and Danish populations to infer the North Sea migration history

Authors:

X. Zhang[1], T. Fitzgerald[1], K. Banasik[2], S. Brunak[2], E. Birney[1]; [1]European Bioinformatics Inst., Hinxton, Cambridge, United Kingdom, [2]Univ. of Copenhagen, Copenhagen, Denmark

The North Sea has been a strategically important area with an extensive history of people and goods flowing through and around. However, it remains unclear how the historical migration events across the North Sea have affected the genetic structure of the modern human population in its coastal nations. Here we use the pairwise haplotype sharing from 858,635 British and Danes, to assemble population genetic evidence and infer the migration history between British and Danish populations within the past 1,000 years.

Using nation-wide healthcare registries in Denmark, we analyze the haplotype sharing from 370,259 Danes. Compared with previous studies that reveal the Danish population as highly genetically homogeneous, we identify discernible population structure based on haplotype sharing, which reconstructs the geography of Denmark. We use the haplotype sharing between 370,259 Danes and 488,376 British from UK Biobank to detect regions with excess haplotype sharing across the two populations. We find individuals from South Jutland share the most of their genome with British while English from Eastern coast spanning from Yorkshire to the South East share the most of their genome with Danes. Finally, we characterize the change of the haplotype-sharing patterns over time and estimate the time periods when the patterns emerge.

Our work provides a novel fine-scale view on haplotype sharing patterns within and across Denmark and Britain, identifying regions of interests to population history, and demonstrating the use of multiple nationwide biobanks as a powerful tool to study history across populations.

Session Title: Evolutionary and Population Genetics Poster Session II

PB3137 Using networks of short IBD to identify ethnolinguistic-related groups in African population

Authors:

J. Zhang[1], A. Sedghifar[1], N. Swinford[2], R. Curtis[2], A. Kim[1], J. Lang[1]; [1]Ancestry.com DNA, LLC, San Francisco, CA, [2]Ancestry.com DNA, LLC, Lehi, UT

Long chromosome segments of identity by descent (IBD) which are suggestive of recent common ancestry can be used to estimate how people are related to one another while distant matches mostly reflect population or demographic history instead of family history and can be difficult to distinguish from shared haplotypes. Here we look at networks of short IBD tracts in samples from Africa to learn about population structure. We used public and non-public samples and the samples cover 19 countries, 129 tribes and 44 language families from Africa. We detected ancestral groups by subdividing the IBD network into unsupervised clusters using the Louvain Method and taking country, tribe, and language information into consideration. We found that most of the samples in the same group came from a single country or adjacent countries and people from the same population or language family are mostly likely to be assigned to the same group. In addition, we observed some of the groups have samples from many different countries and samples from the same country could be assigned to different groups. There were also cases where samples from the same population or language family had been assigned to different groups. In conclusion, groups that we have detected were showing geography and population/language family aggregation while capturing extra relatedness that is different from what country or which population people are coming from.

PB3138 Variation and novelty: Evolutionarily new genes enable protein structural innovation and function in the brain

Authors:

V. Luria[1,2,3], A. Karger[2], J. Cain[4], K. Nam[2], D. Marten[5,6], M. Kirschner[2], A. O'Donnell-Luria[5,6], N. Sestan[1]; [1]Yale Univ., New Haven, CT, [2]Harvard Med. Sch., Boston, MA, [3]Boston Children's Hosp., Boston, MA, [4]Harvard Univ., Cambridge, MA, [5]Broad Inst. of MIT and Harvard, Cambridge, MA, [6]Boston Children's Hosp., Boston, MA

How genuinely new protein-coding genes originate is a central question in biology. Many novel genes arising de novo from intergenic genomic DNA long considered to be "junk", or from long non-coding RNAs, were recently found in Eukaryotes. Novel genes are taxon-restricted, may encode structurally novel proteins with new protein domains, and thus illuminate the emergence of protein structure. To understand how novel genes arise, we built a mathematical model based on gene and genome parameters, and dynamic factors such as mutation rates. Combining phylostratigraphy and proteogenomics, we identified novel genes in over 100 eukaryotic genomes ranging from human to paramecium and evaluated their predicted biophysical properties. Compared to ancient proteins, novel proteins are shorter, more fragile, disordered and promiscuous, yet less prone to forming toxic aggregates. We experimentally measured structure content and protease resistance of novel human proteins and showed novel genes function in vivo in zebrafish brains. We showed novel human genes have fewer regulatory elements than ancient genes but more than control intergenic open reading frames. Several novel genes show depletion for loss of function variation in reference population data such as gnomAD. In a GTEx RNA expression analysis, we found that novel human genes are expressed in many tissues. Using single-cell RNA-Seq and proteomics, we found novel genes are expressed in human brains at multiple ages. Thus, genomic sequence turnover generates many novel genes encoding short proteins with distinct structural features and function in the brain. Variation in large eukaryotic genomes having large intergenic "dark matter" regions continuously generates new protein structures and new functions.

PB3139 Visualization of geographic variation in linkage disequilibrium across human populations

Authors:

A. Zagal Norman[1], L. Anderson-Trocmé[1], A. Biddanda[2], J. Novembre[1]; [1]Univ. of Chicago, Chicago, IL, [2]Johns Hopkins Univ., Baltimore, MD

Regions of the human genome are co-inherited in large blocks due to meiotic recombination and as a result, mutations exhibit non-random association along the genome -- or linkage disequilibrium (LD). Large cohorts of human genomic data have revealed a rich diversity of genetic variation and patterns of LD that reflect the impact of evolutionary and demographic processes over time. LD patterns can substantially impact the interpretation of analyses of human genetic variation, playing a critical role in determining the statistical power of genome-wide association studies, fine mapping causal variants for complex traits, and highlighting the differential impact of natural selection across populations. Current methods for visualizing LD are designed to be used for single populations, often by representing the covariance between markers around a single locus in the form of a LD matrix. However, there are currently no tools that can visualize LD patterns at a single locus across multiple populations. To address this, we developed geoLD, a user-friendly, web-based tool capable of displaying LD matrices across multiple populations at the same time. geoLD enables rapid queries of LD matrices centered on a specific genomic coordinate across multiple populations within seconds. The visualizations rendered are initially interactive but can be exported to publication-ready graphics for loci of interest. We additionally provide an implementation of geoLD to run as a local offline instance, for smaller-scale exploration in education or field settings or when public sharing of genomic data may be restricted.

Using data from the 1000 Genomes Project, we provide visualizations of LD at loci related to complex trait associations and signatures of natural selection. Specifically, our visualizations show patterns of LD patterns at random regions of the genome, and the outlier patterns generated by strong instances of positive and negative selection respectively.

Beyond human genetics, we envision that our tool may be of use for visualizing LD patterns across any organism with genetic polymorphism data and geographically sampled populations (e.g. Arabidopsis, Drosophila, etc.). geoLD is also well-suited to support educational curricula on human genetic diversity, particularly for geographic differences in haplotypic patterns relative to single allelic variants. We anticipate that geoLD will provide intuitive visualizations for researchers and educators in human genetics.

Sch., New Haven, CT, [2]Boston Children's Hosp., Boston, MA, [3]Penn State, Hershey, PA, [4]Lancaster Univ., Lancaster, United Kingdom, [5]Dana Farber Cancer Inst., Boston, MA, [6]Cure Intl., Mbale, Uganda, [7]Mbale Regional Referral Hosp., Mbale, Uganda, [8]Mbarara Univ. of Sci. & Technology (MUST), Mbarara, Uganda, [9]N-Power Med., Redwood, CA, [10]Boston Children`s Hosp. / Harvard Med. Sch., Boston, MA

Hydrocephalus is a complex neurological disorder marked by an abnormal accumulation of cerebrospinal fluid. Infant hydrocephalus (IH) is the most frequent indication for early neurosurgery in sub-Saharan Africa. Genetic risk contributes to 10% of congenital hydrocephalus in prior cohorts composed of mainly European ancestry. To determine the genetic contribution to IH in Uganda, we performed whole genome sequencing (WGS) of blood samples from 400 infants with IH and 600 infants without IH (non-IH). Using Ward or Classification and Regression Tree clustering, four populations were identified in the IH cohort and three in the non-IH cohort. In the overall cohort, Admixture analysis identified four populations. Moreover, we observed a discernible genetic distance between these populations, as evidenced by a calculated Fst index of 0.004. After filtering for variants with a minor allele frequency >0.1, 988 samples were included in an genome-wide association study (GWAS) to identify variants associated with IH. After accounting for batch effects detected through principal component analysis, we conducted a GWAS using Plink2.0. Our analysis revealed 11 specific genomic regions, some of which were either overlapping or in close proximity to CDC42, CRB2, YBX2, and CDR2L, that were associated with IH. To facilitate our analysis and shed light on their intricate relationship with the presence of pathogens, we developed a computational method called mbQTL, which allowed us to report on the association between the identified genetic variants and the presence of pathogens through various novel statistical approaches. Through the integration of metagenomic and WGS approaches, our study provides a comprehensive understanding of the genetic landscape underlying hydrocephalus susceptibility in the Ugandan population. These findings also offer potential avenues for the development of targeted interventions and personalized treatments.

PB3141 6q25.2q25.3 duplication and 2q14.1q14.2 deletion due to a three-generation familial chromosomal insertion is identified in a proband with the unbalanced form presenting with multiple congenital anomalies

Authors:

N. DeMetrick[1], J. Biscoe[1], S. Morsey[1], V. Stinnett[1], J. Murry[2]; [1]Johns Hopkins Hosp., Baltimore, MD, [2]Johns Hopkins Sch. of Med., Baltimore, MD

Background: Chromosomal insertions are uncommon structural rearrangements involving two or more chromosomes. Most balanced insertions lack any phenotypic consequence; however, unbalanced rearrangements can confer a phenotype associated with multiple congenital anomalies.
Methods: Conventional cytogenetic analysis was performed on peripheral blood in a child presenting with multiple congenital anomalies (developmental delay, cognitive delay, and growth abnormalities). Fluorescent in situ hybridization (FISH) studies using standard DiGeorge and subtelomeric-specific probes proved unremarkable. Given the high clinical suspicion for a chromosomal abnormality, Single Nucleotide Polymorphism (SNP) array using the Illumina® 850k BeadChip was performed.
Results: SNP array showed an interstitial deletion on chromosome 2 from cytobands q14.1 to q14.2 that was 7.6 Megabases (Mb) in size, along with an interstitial duplication on chromosome 6 between cytobands q25.2 and q25.3 (9.4 Mb in size). To clarify the orientation for these loci, FISH was performed using custom probes mapping within both copy number changes. FISH confirmed an unbalanced insertion involving chromosomes 2 and 6, whereby the gain of chromosome 6 material was inserted into the deleted loci on chromosome 2. A high-resolution karyotype was repeated on this patient, revealing a subtle change within chromosome 2 at the same bands identified by array. As the region involved did not differ in its banding pattern relative to the normal chromosome 2 homolog, visualization of the insertion was difficult to discern by karyotype alone. However, parental testing using the same informative FISH probes revealed that the unbalanced insertion was maternally derived and that the proband's maternal grandmother also carried the balanced form.
Conclusion: We confirmed the suspected chromosome abnormality in the proband using complementary cytogenomic methods. In this case, the genomic imbalance was identified upon array testing and would have been missed if using conventional cytogenetics alone. Other family members should be tested to see if they are carriers of this insertion for genetic counseling and estimation of recurrence risk. Emerging cytogenomic technologies may be considered to clarify the rearrangement further.

PB3142 A case of 17p13.3 microdeletion with breakpoint in the gene for *CRK*

Authors:

I. Ohashi[1,2], J. Matsuda[3], M. Nagata[4], Y. Ishihara[4], Y. Miyashita[4], Y. Asano[4], Y. Yamanouchi[5,2], K. Takao[2], K. Tawa[2], T. Otomo[2,6], K. Kurosawa[7], M. Masuno[8]; [1]Mitoyo Gen. Hosp., Kanonji, Japan, [2]Dept. of Med. Genetics, Kawasaki Med. Sch. Hosp., Kurashiki, Japan, [3]Dept. of Pathophysiology and Metabolism, Kawasaki Med. Sch., Kurashiki, Japan, [4]Dept. of Cardiovascular Med. (IRUD Analysis Ctr.), Osaka Univ. Graduate Sch. of Med., Suita, Japan, [5]Kawasaki Univ. of Med. w, Kurashiki, Japan, [6]Dept. of Molecular and Genetic Med., Kawasaki Med. Sch., Kurashiki, Japan, [7]Kanagawa Children s Med Ctr, Yokohama, Japan, [8]Genetic Counseling Program, Graduate Sch. of Hlth.and Welfare, Kawasaki Univ. of Med. Welfare, Kurashiki, Japan

The Miller-Dieker syndrome caused by deletion of the 17p13.3 region, including PAFAH1B1, is well known, and case reports of 17p13.3 microdeletion syndrome, characterized by facial dysmorphic manifestations, developmental delay, growth disturbance, and abnormal brain structure, caused by deletion of two genes, YWHAE and CRK, have become more common. We have now seen scattered case reports of 17p13.3 microdeletion syndrome. In this presentation, we report a case of 17p13.3 microdeletion with a breakpoint in the CRK gene and the deleted region is not contained with PAFAH1B1 or YWHAE. The patient, a 1 year and 2 months old boy, consulted with our clinic with the chief complaint of small for gestation age, significant failure to thrive, and relative macrocephaly. There was no family history of growth disturbance. Physical examination revealed height (-2.8 SD), weight (-4.0 SD), head circumference (+0.4 SD), prominent forehead, hypertelorism, and inverted triangular face. Enjohji developmental test revealed his DQ was 97.5 at 1 years old. Echocardiography and head MRI showed no significant abnormal findings. Endocrinological examination revealed thyroid function within normal range, but IGF-I was markedly low. Chromosome analysis (GTG) showed normal male karyotype, and methylation analysis performed to differentiate Silver-Russell syndrome also showed no abnormalities. In whole exome sequencing, it was not detected disease-specific variant. Array CGH showed an interstitial deletion of approximately 830 kb in the 17p13.3 region, and the region contained 19 protein-coding genes and breakpoint at p-terminal was within the CRK gene. CRK gene is conjugated a proto-oncogene. It is not only involved in carcinogenesis, but is also thought to be related to growth regulation. Overgrowth in duplicated cases and growth restriction in deleted cases have already been reported. It was found that growth retardation can occur partial deletion of the CRK gene in the present case. Growth hormone administration has been shown to improve growth retardation in complete deletions of CRK, and is expected to be effective in this case as well. Array CGH analysis is useful for the diagnosis of unexplained short stature and growth disturbance and can predict the effect of treatment.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3143 A case with critical risk for X chromosome aneuploidy in non-invasive prenatal testing (NIPT); confirmed to deletion of Xq27.3-q28 and duplication of Xq28

Authors:

J. Kim[1], H. Kim[1], J. Park[1], K. Kang[1], H. Jang[2], M. Go[3], S. Yang[1], D. Cha[4], S. Shim[5]; [1]CHA Biotech Inc., Seoul, Korea, Republic of, [2]CHA Univ., Seoul, Korea, Republic of, [3]CHA Univ., Seoul, Korea, Republic of, [4]Gangnam CHA Hosp, Seoul, Korea, Republic of, [5]Cha Univ., Seongnam, Korea, Republic of

Background: Non-invasive prenatal testing (NIPT) has been widely used for prenatal screening of common fetal aneuploidy such as trisomy 13, 18, 21. According to several large-scale cohort studies, the positive predictive value (PPV) of NIPT varies depending on the chromosomes, with ranges of 50%~73% for trisomy 21, 20%~58% for trisomy 18, and 4%~47% for trisomy 13. NIPT has been expanded to include sex chromosome aneuploidies (SCAs), rare chromosomal aneuploidies (RCAs), and copy number variants (CNVs), although the PPV for SCAs is low. **Case:** A 38-year-old pregnant woman was referred for NIPT at 12+1 weeks of gestation because of advanced maternal age. No ultrasound abnormalities were identified. There was no specificity in her anthropometric characteristics such as weight, height, and body mass index (BMI). NIPT result showed a critical risk of sex chromosome [fetal fraction (FF) = 6.89%]. For accurate diagnosis, amniocentesis was recommended, and conventional karyotyping and chromosome microarray (CMA) were performed. Fetal karyotype was 46, XX but, CMA results showed a 3.6 Mb deletion of the Xq27.3q28 region [arr Xq27.3q28(146,806,191_150,386,543)x1] including *FMR1* and immediately followed by a 4.8 Mb duplication of the Xq28 region [arr Xq28(150,408,165_155,233,731)x3] including *MECP2.* Parents showed normal karyotypes. At first, it was assumed that the abnormal X was inherited from the mother, but maternal CMA result showed no deletion or duplication at these sites. Deletion of *FMR1* gene and duplication of MECP2 in the fetus were confirmed by PCR/Southern blot and multiple ligation-dependent probe amplification (MLPA) methods, respectively. And X chromosome inactivation (XCI) assay showed highly skewed X-inactivation pattern of the paternal X chromosome. From the above results, it can be assumed that the fetus inherited a normal X chromosome from the mother and an abnormal X chromosome from the father. The paternal abnormal X chromosome might be occurred *de novo* in spermatogenesis. Paternal CMA and SNP-array to identify the origin of the abnormal X chromosome was not performed and the follow-up observation related to fetal development could not be performed due to abortion. **Conclusion:** In this study, we report a case of critical risk of X chromosome in NIPT results, and a case in which genetic counseling based on the result of an invasive diagnostic test and additional molecular genetic test was provided as an important reference for prenatal decision-making.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3144 A combination of cytogenetic and molecular genetic tools, including long-read sequencing, resolves multiple breakpoints in a patient with complex structural variation.

Authors:

J. Knijnenburg, S. Kloet, Y. M. C. Hendriks, T. T. Koopmann, W. van den Ende, M. E. Y. Laurense-Bik, K. Heijboer, F. de Vries, G. W. E. Santen; Leiden Univ. Med. Ctr., Leiden, Netherlands

A combination of different cytogenetic and molecular genetic tools is often needed to unravel complex translocations and structural variation to a base pair level. The current first-tier tests in patients with developmental delay and/or multiple congenital anomalies are CNV and SNV analysis using SNP-array and/or whole exome sequencing. These approaches are in general not capable of detecting structural variation such as (complex) balanced translocations or rearrangements.
In a patient with dysmorphisms, hypotonia and developmental delay, genome wide CNV analysis on whole exome captured short-read NGS data revealed two relatively large interstitial deletions in the long arms of chromosome 13 and chromosome 14, both around 5 Mb in size. SNV analysis did not reveal additional variants that could explain the phenotype. Overlapping deletions, especially of the 14q region, were previously published in patients with similar phenotypic features, making pathogenicity likely.
Both interstitial deletions appeared to be de novo and (balanced) carriership of the deleted regions in both parents was ruled out with CNV analysis and FISH. Subsequent karyotyping and FISH on metaphases of the proband confirmed the 13q and 14q deletions, as expected. Surprisingly, these classic cytogenetic tests additionally showed involvement of the terminal part of the long arm of chromosome 3, which was exchanged with the part of chromosome 13, distal to the deletion.
To resolve the complete nature of the complex structural variation found in the presented patient, we eventually performed genome-wide long-read sequencing using the Oxford Nanopore PromethION sequencing technology. This technology allowed us to determine the composition of the derivative chromosomes, clearly showing the diagnostic potential of long-read sequencing.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3145 A distinct genotype and phenotypes in pediatric patients with biventricular noncompaction

Authors:

K. Hirono[1], Y. Hata[1], K. Tsuboi[1], S. Takarada[1], M. Okabe[1], H. Nakaoka[1], S. Ozawa[1], N. Nishida[1], F. Ichida[2]; [1]Univ. of Toyama, Toyama city, Japan, [2]Intl. Univ. of Hlth.and Welfare, Tokyo, Japan

Background: Ventricular noncompaction (VNC) is a hereditary type of cardiomyopathy characterised by prominent trabeculaitons. VNC mainly involve the left ventricle, however, isolated right ventricles (RV) and biventricular noncompaction (BiVNC) also occur. This study aimed to clarify the clinical characteristics and genetic landscape of BiVNC. **Methods:** We enrolled 234 children (127 male and 107 female; mean age 4 months [range, 0-6.6 years]) with VNC from 2013 to 2021 in Japan. VNC was classified as follows: BiVNC, congenital heart defects (CHD), arrhythmia, dilated phenotype (DCM), or normal function. In the enrolled patients, 203 genes associated with cardiomyopathy were screened using next-generation sequencing (NGS). Cardiac death, left ventricular (LV) assist device implantation, heart transplant (HT), and appropriate implantable cardioverter-defibrillator (ICD) shock were classified as major adverse cardiac events (MACE). **Results:** Twenty-five patients were enrolled in BiVNC group, 38 in CHD, 32 in arrhythmia, 84 in DCM, and 55 in normal function group. Patients with BiVNC was significantly younger at diagnosis than those with other VNC phenotype ($P < 0.0001$). Eight patients (32.0%) and nine patients (36.0%) in BiVNC group had perinatal abnormality. Poor LVEF was more common in the DCM and BiVNC group than in other groups ($P < 0.0001$). Dyskinesis of LV region was most frequently observed in BiVNC group. Noncompacted layer was most prominent in BiVNC. There were 140 pathogenic variants in 120 patients with VNC including all phenotypes (51.3%): 108 missense, 9 deletion, 6 insertion, 10 nonsense, and 7 splice-site variants. Overall, the *MYH7* gene was most commonly identified (22.1%), followed by the *TAZ* (7.4%) and *TPM1* (6.6%) genes. As for BiVNC patients, there were 11 pathogenic variants were in 11 patients (44.0%): 10 missense, 1 insertion, 10 nonsense. Variants in genes associated with sarcomere group, ion channel group, mitochondrial group, heart development group, and desomosomal group accounted for 45.5%, 9.1%, 18.2%, 18.2%, and 9.1%, respectively. Of note, novel variants in *NKX2-5* gene and *TBX5* gene were identified in BiVNC patients. In the BiVNC group, MACE was noted in 5 patients (20.0%). The BiVNC group had the worst survival rate among all groups in contrast to the CHD group ($P = 0.0009$). **Conclusions:** This is the first study that focused on genotype-phenotype correlations in a pediatric patients with BiVNC. Our study suggests that comprehensive screening of multiple disease-causing genes may help identify VNC patients with specific cardiac phenotypes who are at a high for MACE.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3146 A novel DNA collection method for genomic sequencing in infants

Authors:

A. Nagy[1], L. M. Mahanta[1], L. Hutchinson[1], S. Adelson[2], L. M. Sack[1,2,3], S. T. Ryall[1,3,2], B. Zettler[2], I. A. Holm[4,3,5], R. C. Green[3,2,6,5], M. S. Lebo[1,3,2,5], H. Zouk[1,3,7]; [1]Mass Gen. Brigham Lab for Molecular Med., Cambridge, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Harvard Med. Sch., Boston, MA, [4]Boston Children's Hosp., Boston, MA, [5]The Broad Inst. of MIT and Harvard, Cambridge, MA, [6]Ariadne Labs, Boston, MA, [7]Massachusetts Gen. Hosp., Boston, MA

Introduction: Genomic sequencing (GS) is becoming more common in both diagnostic and screening settings and is being explored for use in newborn screening across many clinical studies. However, obtaining samples from infants can be challenging. Specifically, venipuncture is invasive and other non-invasive techniques such as saliva sampling yield inconsistent results. Additionally, while dried blood spot cards could be used for sequencing, they are not always readily available. Moreover, the workflow for extracting DNA from these two other sample types can be labor-intensive. We aimed to explore alternative DNA collection methods that are less invasive, yet yield consistent results. To this end, we investigated whether the use of volumetric absorptive microsamplers (VAMS) for blood collection in infants would reliably yield sufficient high-quality DNA for GS. Methods: Blood samples from 17 infants at Boston Children's Hospital's Primary Care Center (CHPCC) were collected through a heel stick into Neoteryx Mitra® VAMS devices (4x 30ul tips) for DNA yield optimization for GS. Extraction using membrane spin columns (QIAamp DNA Investigator Kit, QIAGEN) was determined to be the most reliable method and as such, blood microsampling from an additional five infants was used for its validation. Nine families of infants with a previous microsampling collection were surveyed about their preferences and comfort with this method as compared to venipuncture. Results: All 5 microsamples extracted on membrane columns yielded enough high-quality DNA for GS despite an incomplete tip collection for 3 of the samples. The mean yield was 1.7 ug (range 0.8-3.3 ug) for infants and was directly correlated with a qualitative estimate of the proportion of tips filled. The majority of families surveyed (8/9, 88.9%) indicated their preference for heel stick microsampling for potential future blood collection from their infant. This method has since been adopted by the BabySeq Project, which is exploring the clinical utility of GS for screening in presumably healthy infants. Since recruitment began, an additional 7 samples have been extracted in our laboratory, with an average yield of 2.6 ug (range 1.3-3.5 ug). Conclusions: High quality DNA for GS can be isolated from infant blood samples collected on VAMS devices. Additionally, this collection method was found to be acceptable and preferable by the infants' families. This noninvasive method has been used successfully in various clinical applications including immunological and pharmacokinetic studies, but now has the potential to be leveraged for GS in newborns and in other patient cohorts, expanding access to genomic medicine.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3147 A Novel Method for the Detection of 40 Amino Acids Relevant to Inborn Errors of Metabolism, in Under 60 Minutes Using Reverse Phase High Performance Liquid Chromatography

Authors:

K. Wilson[1,2]; [1]Children's Natl. Hosp., Washington, DC, [2]Natl. Human Genome Res. Inst., Bethesda, MD

Assessment of amino acid concentrations is important for the diagnosis and management of a number of inborn errors of metabolism (IEMs). There have been many methods developed that attempt to measure these biologically important metabolites, however, they are often cost-prohibitive and/or excessively time consuming. Currently, most amino acid assessments are conducted using either ion-exchange chromatography, which is a multiple hours long process that uses expensive dedicated technologies for amino acid analysis, or more recently mass spectrometry detectors which greatly increase the cost. We have previously developed a methodology for the rapid, repeatable, and cost-efficient separation of approximately 20 amino acids and now, based on this initial methodology, we have expanded it to additional amino acids relevant to IEMs. We thus describe here our protocol of amino acid separation using reverse phase high performance liquid chromatography (RP-HPLC) combined with ultraviolet-visible spectrum absorbance (UV-VIS) paired with derivatization just prior to injection with the agent o-phthaladehyde (OPA). We show reproducibility via concentration assessments for all amino acids separated in the method, in triplicate. We assess amino acids not only in prepared standard solutions but also in biologic samples with pathologic amino acids added to confirm separation. Quantitation was established using a single internal standard. We achieved a less than 60min separation runtime with our lower cost systems that obtain good separation of 40 primary amino acids as well as quantitation of ammonia in a single run. As the need for analysis of amino acids grows, and thus the number of assessments conducted both in the US and globally, so does the need for improved methodologies that decrease both the cost and time associated with accurate measurement. This rapid and accurate methodology that only requires a small volume of sample could greatly increase efficiency in many settings and has broad applications for both clinical utility and research investigations.

PB3148 A sequencing first approach improves access to a precise genetic diagnosis in kids newly diagnosed with atypical development

Authors:

K. Dipple[1,2,3], D. Doherty[1,2], K. Anderson[1], O. Sommers[1], T. Wenger[1,2], K. MacDuffie[1], A. Keefe[1,2], M. Sikes[2], A. Scott[2], L. Kruidenier[2], H. Gildersleeve[1], C. Davis[1], K. Buckingham[1], J. Chong[1], D. Veenstra[1], D. Miller[1,2,3], D. Copenheaver[4], J. Juusola[4], K. Retterer[4], K. McWalter[4], A. Snook[4], P. Kruszka[4], J-H. Yu[1], M. Bamshad[1,2,3]; [1]Univ. of Washington, Seattle, WA, [2]Seattle Children's Hosp., Seattle, WA, [3]Brotman Baty Inst., Seattle, WA, [4]GeneDx, Gaithersburg, MD

Background and Hypothesis: The Seq First Developmental Differences (DDi) project aims to improve early and equitable access to a precise genetic diagnosis (PrGD) for children with atypical development by providing whole genome sequencing (WGS) upon identification of abnormal development, rather than after a conventional staged approach to evaluation and testing. We hypothesized that a simplified clinical workflow and early access to WGS would lead to a PrGD for more participants than for those receiving conventional care. **Methods:** Participants were referred for the study from one of two Early Intervention Centers (EICs) or an academic Neurodevelopmental clinic from 4/2021 to 6/2023. Eligibility criteria included less than 3 years of age with moderate or severe delay alone, or mild developmental delay plus an abnormal growth parameter or organ system. Exclusion criteria included prior evaluation or genetic testing for atypical developmental or a non-genetic explanation. To date, 198 participants have been referred, 28 were ineligible, 76 declined, and 94 were enrolled. Each eligible participant was randomized to either an immediate WGS (test; n=49) or control (conventional care for two years followed by WGS; n=45) group. Results from WGS were returned to families in the test group by a clinical geneticist. **Interim Results:** Of the 49 participants who received WGS, 21 (49%) had a PrGD that explained or partially explained their atypical development. In the control group, who were enrolled for at least 6 months (n=31), 22 (71%) had access to genetic testing. Yet in only 5 (16%) was a PrGD made that explained or partially explained their atypical development. **Discussion/Conclusions/Future directions:** Compared to the control group, a simplified clinical workflow in the test group including broad inclusion criteria led to increased access to a PrGD. Moreover, despite a more inclusive approach to offering testing, the overall diagnostic rate remained high. These observations suggest that children who might not otherwise be offered testing, or offered testing later in childhood, could benefit substantially (earlier access to precise interventions, reduced morbidity, etc.) and that this strategy could reduce healthcare costs (fewer non-specific evaluations, tests, etc.). Whether these benefits are realized is under evaluation. Surprisingly, recruitment from EICs proved challenging and nearly 40% of eligible families declined to participate. Identifying the hurdles to referral and enrollment and developing alternative strategies (e.g., community or primary-care based) will be critical to ensuring we build equitable capacity for a PrGD.

PB3149 A universal blood genotyping array tailored for research by transfusion services achieves high accuracy in a large, ethnically diverse cohort

Authors:

J. Schmidt[1], J. Gollub[1], **R. Varma**[1], E. van der Schoot[2], A. Harmer[3], C. Westhoff[4], W. H. Ouwehand[5,6], B. Veldhuisen[2,7], N. Gleadall[6], W. J. Lane[8,9]; [1]Thermo Fisher Scientific, Santa Clara, CA, [2]Dept. of Experimental Immunohematology, Academic Med. Ctr., Univ. of Amsterdam, Amsterdam, Netherlands, [3]Histocompatibility and Immunogenetics Lab., NHS Blood and Transplant, London, United Kingdom, [4]Immunohematology and Genomics Lab., New York Blood Ctr., New York, NY, [5]Dept. of Haematology, Univ. Coll. London Hosp., London, United Kingdom, [6]Dept. of Haematology, Univ. of Cambridge, and NHS Blood and Transplant, Cambridge, United Kingdom, [7]Sanquin Diagnostic Services, Amsterdam, Netherlands, [8]Dept. of Pathology, Brigham and Women's Hosp., Boston, MA, [9]Harvard Med. Sch., Boston, MA

Background: Extended blood group matching substantially reduces sensitization to non-self antigens as a side effect of transfusion. For broad application, affordable high-throughput typing of relevant antigens is required. Following an earlier proof-of-concept study, our consortium presents here the development of a tailored universal blood donor genotyping array, including the results of an international study comprising an ethnically highly diverse panel of samples. **Methods:** The custom-designed, research use only Applied Biosystems™ Axiom™ UBDT_PC1 array contains 39,000 probes tagging 20,000 variants relevant for investigation of blood typing and other blood-related phenotypes. It has a 384-sample format and runs on the GeneTitan-MC™ instrument, which can generate data for 3,000 samples/week. The array allows simultaneous typing of human erythroid (HEA), platelet (HPA), and leukocyte (HLA) antigens. For the study, DNA samples and antigen typing data from 13,908 donors provided by seven blood services were analyzed. Samples representing diverse ethnic groups (74% European, 11% African, 15% others) were genotyped at three blood services in the Netherlands, USA, and UK. Array-inferred antigen types were analyzed for concordance with provided antigen types for the first 6,953 samples. **Results:** Reproducibility between sample results from the testing laboratories was outstanding for the vast majority of the 20,000 variants. The overall concordance for HEA, HPA, and HLA antigens with previous testing was high. For ~100,000 comparisons between blood service determined HEA antigen types and array determined types, the concordance exceeded 99.8%. Over 80% of the discordances can be resolved by simple algorithmic modifications and over half of the remaining ones were caused by incorrect serology. The results of the study were highly accurate for non-European genotype configurations. The 778 samples of African ancestry showed a HEA concordance rate >99.7%. The HLA class I and II concordance level, which could be assessed for 1319 DNA samples, was excellent. **Conclusions:** An affordable and comprehensive DNA-based test for automated high-throughput typing of donors is reported here. The universal blood typing array is tailored for the research needs of transfusion services and evaluated in an international, diverse cohort. The array represents a promising new tool to facilitate broader research in extended blood matching and identification of rare blood types.

PB3150 Advancing Precision Diagnosis through Simultaneous Detection of Diverse Variant Types: Insights from Clinical Whole Genome Sequencing

Authors:

H. Dai[1], R. Rigobello[2], C. Settler[3], M. Chau[4], W. Bi[5], C. Eng[5], P. Liu[5], L. Meng[6], N. Owen[1], L. Vossaert[6], C. Wu[5], F. Xia[6], X. Zhao[5]; [1]Baylor Coll. of Med. / Baylor Genetics, Houston, TX, [2]Baylor Genetics, Houston, TX, [3]Baylor Genetics, Hoston, TX, [4]Baylor Coll. of Med., Houston, TX, [5]Baylor Coll. of Med./Baylor Genetics, Houston, TX, [6]Baylor Coll. Med./Baylor Genetics, Houston, TX

Introduction: Genetic disorders arise from diverse types of molecular variants. Historically, clinical genetic testing assays could only assess for specific types of variants. This resulted in many patients with complex phenotypes remaining undiagnosed or required to submit to multiple rounds of testing with alternate assays to reach a diagnosis. Whole genome sequencing (WGS) now offers healthcare providers the ability to test for many types of variants with one assay, providing a powerful tool to pinpoint an etiology accurately and more rapidly for these patients, thus avoiding the diagnostic odyssey. Here, we summarize our experience performing clinical WGS at Baylor Genetics to highlight its utility as a first-tier diagnostic test capable of detecting a spectrum of variant types. **Methods:** This is a retrospective evaluation of WGS results at Baylor Genetics. For each patient, the type of variant(s) reported as well as demographic data, clinical history, diagnostic findings were investigated. **Results:** We reviewed 233 cases that had diagnostic findings by WGS related to reported phenotype. Single nucleotide variations (SNVs) and small indels were the most common variant types, observed in 180 cases (77.3%). Copy number variations (CNVs) were reported in over one-fifth of the total cases (n = 46, 19.7%). Other variant types, such as short tandem repeats (STRs) (n = 4), chromosomal abnormalities (n = 16), and variants within the mitochondrial genome (n = 3), comprised 9.9% of the total solved cases. 70.4% (n = 164) of total solved cases were explained by SNV and indel findings alone. An SNV/indel and a non-SNV/indel finding leading to at least one diagnosis were identified in 16 cases. Variant type did not correlate significantly with clinical history. **Conclusion:** This review demonstrates that up to 30% of patients with a diagnostic WGS finding related to phenotype would not have been captured by assays only focusing on SNV/indels. These data affirm the utility of WGS as a comprehensive test for detecting an assortment of molecular variants to make a diagnosis. As many patients with hard-to-diagnose phenotypes are critically ill, this data supports WGS as an expedient tool which can improve patient outcomes and avoid diagnostic odysseys.

PB3151 Aligning timely diagnosis of Duchenne Muscular Dystrophy with return of results from molecular diagnostic testing

Authors:

M. Hegde[1], A. Martin[2]; [1]PerkinElmer, Waltham, MA, [2]Parent Project Muscular Dystrophy, Washington, DC

Molecular diagnosis for Duchenne and Becker muscular dystrophies (DMD/BMD) has evolved significantly in last[EO1] two decades with advances in molecular technologies. It is now possible to sequence the entire 2.2MB *DMD* gene sequence using next generation sequencing in a single assay to detect all copy number and sequence variants in both index males and carrier females. Full-sequence analysis of the entire gene allows for detection of deep intronic pathogenic variants and accurate breakpoint detection of CNVs involving similar exons, which could have an impact on the outcome of clinical trials. This comprehensive assay is highly sensitive for diagnostic testing for DMD and is also suitable for confirmatory testing for newborn screening for DMD. Despite these advances, the time to diagnosis for DMD is still stagnated at ~5yrs. We performed a review of the data generated from a clinical laboratory offering *DMD* testing using single gene testing, neuromuscular and autism panels, exome and genome sequencing. *DMD* testing performed for molecular confirmation of clinical diagnosis has a diagnostic yield of 90% (diagnostic yield from a sponsored testing program for DMD/BMD). Upon retrospective analysis of >1000 panels, exome and genome samples, a *DMD* pathogenic variant was identified in 1.5% of the cases not specifically referred for DMD. This detection rate signifies the importance inclusion of *DMD* in neuromuscular and autism panels, given that many individuals have reported to be on the autism spectrum in the early years without specific muscular signs[EO2] . A subsequent analysis of consent forms for reporting of secondary pathogenic gene findings revealed a wide variation in opt in and opt out selections for panels, exomes and genomes. There is heterogeneity in how labs approach inclusion of secondary/incidental genetic findings within their reports to clinicians. Of the 8 labs researched, 25% of labs default to not providing secondary findings unless the form completer opts in to receiving them within the report; 25% of labs will include secondary findings in reports by default unless the completer opts out; 25% of labs will not provide any results (assumed) unless the completer chooses between opting in or out of receiving secondary findings within the report; and 25% of labs make no mention of secondary findings within their requisition/consent forms, which makes it unclear whether or not these findings are included by default. Given the detection rate of 1.5% pathogenic variants in *DMD* when a targeted *DMD* test is not ordered prompts the importance of return of results of secondary findings, which may facilitate early diagnosis and intervention.

PB3152 Allelic drop-out (ADO) caused by variability in primer-binding sites and beyond influences an accuracy of PCR-based sequencing methods

Authors:

E. Zaklyazminskaya, A. G. Shestak; Petrovsky Natl. Res. Ctr. of Surgery, Moscow, Russian Federation

Background: PCR-based sequencing methods have a risk of allelic dropout (ADO) phenomenon which leads to selective allele amplification in the PCR process. This phenomenon reduces the accuracy, zygosity counts, and diagnostic yield of the genetic testing.
Methods: We compared BAM, VCF files (NGS) from 232 patients with selective ABI (Sanger) chromatograms to identify the cases of ADO. The primer binding sites were analyzed using the gnomAD database to reveal variations causing ADO. All amplicons with suspected ADO cases were re-sequenced using the alternative oligoprimers pairs.**Results:** We have identified 8 cases of ADO in both targeted genes panels (NGS) and Sanger sequencing results. The fact of selective allele amplification was confirmed in all cases by re-sequencing using an alternative pair of primers. Most cases of ADO (6 cases, 75%) were caused by common or rare single nucleotide genetic variants (SNVs) within primer-binding sites. In two cases ADO was presumably mediated by the presence of six- or more nucleotides indels located beyond primer-binding sites. Size of amplicons may also play a role in some cases of the selective allele amplification. Additionally, we found the under-representation of several SNVs on the NGS reads or the presence of the SNV only on reads of one amplicon out of two. We hypothesize that selective allele amplification may affect up to 1% of amplicons what is not negligible considering the growing amount of the massively parallel sequencing.**Conclusion:** ADO may decrease a DNA-diagnostic yield in both NGS and targeted Sanger sequencing approaches. We have demonstrated the impact of "point" substitutions in primer- binding sites and indels in amplicons on the amplification efficiency.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3153 An efficient design for whole genome trio sequencing identifies key variants in rare neurological disease cases.

Authors:

S. Kruglyak[1], K. Ramsey[2], M. Naymik[2], B. R. Lajoie[1], K. N. Blease[1], M. Sanchez-Castillo[2], S. Billings[1], W. Jepsen[2], M. Huentelman[2], V. Narayanan[2]; [1]Element BioSci.s, San Diego, CA, [2]TGen, Phoenix, AZ

We sequenced nine trios in which the probands in an underserved population from Sonora, Mexico were affected by a rare and undiagnosed disease with neurological features. Families were enrolled in the study, with proband phenotypes including developmental delay, intellectual disability, language and motor difficulties, cardiac anomalies, a blood disorder, and/or short stature. We sequenced one trio per sequencing run, leveraging the design of sequencing the proband at twice the coverage of the parents. The reduced coverage in the parents led to sequencing efficiencies while retaining the benefits of trio sequencing: the ability to discover de novo variants and the ability to trace inheritance patterns of rare variants. Once the sequencing data was generated, our two teams used independent informatics pipelines for variant calling and interpretation. This enabled us to determine whether the two labs would arrive at the same conclusions when starting with the same data sets. In five of the nine cases, both teams found a single SNV or small indel that was deemed causal pending clinical validation. The findings matched exactly despite independent informatics pipelines used for variant prioritization. In three of the nine cases, both teams failed to identify the causal variant. In the final case, an additional scan for large CNVs performed by one of the teams identified a de novo duplication in the proband which is the likely cause of the underlying disease. The sequencing of the parents with the proband was critical. In addition to establishing de novo calls and verifying the inheritance of homozygotes, we were able to disqualify potentially pathogenic heterozygous calls that were observed in one of the (healthy) parents. Pending confirmation via clinical sequencing, we anticipate a 6/9 or 67% diagnostic yield for the study. The results across cases with significant findings showed a variety of affected genes (CFAP52, DYNC1H1, FANCE, TCF4, and TOP3A), variant types, and inheritance patterns. In three cases, the presumed causal variant was de novo, including a frameshift insertion, a splice altering SNV, and a CNV. Intriguingly, the other three cases showed a homozygous SNV or indel that was extremely rare according to gnomAD yet carried by both (unrelated) parents. Following confirmation via clinical sequencing, families will be counseled about potential therapies, disease management, current research studies (i.e. gene therapy), and family planning. This study not only demonstrated a successful sequencing approach for rare disease but also has the potential to provide families with a means of moving forward toward finding treatment options.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3154 An efficient variant phasing utilizing a replication cycle reaction system

Authors:

A. Mitsutake[1,2], H. Ishiura[1,3], T. Matsukawa[1], J. Mitsui[4], S. Tsuji[5], T. Toda[1]; [1]Dept. of Neurology, Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [2]Dept. of Neurology, Intl. Univ. of Hlth.and Welfare Mita Hosp., Tokyo, Japan, [3]Dept. of Neurology, Okayama Univ. Graduate Sch. of Med., Dentistry, and Pharmaceutical Sci., Okayama, Japan, [4]Dept. of Precision Med. Neurology, Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [5]Inst. of Med. Genomics, Intl. Univ. of Hlth.and Welfare, Chiba, Japan

[Introduction] When two heterozygous variants are detected in genes with autosomal recessive inheritance, it is required to determine whether the two variants are located in *cis* or in *trans*. Although the analysis of gDNAs of the parents is usually employed, we face difficulties when parental DNAs are unavailable. Subcloning of long-rage PCR products obtained from gDNA is useful, but long-range PCR fails to amplify segments usually exceeding 10kb. Subcloning of cDNA is another possibility, but its success depends on the availability of cells expressing mRNA. Droplet digital PCR is useful even when distance between variants is up to 100 kb, but designing specific probes remains challenging. To accomplish amplification of a large genomic DNA segment carrying two heterozygous variants, we employed a replication cycle reaction (RCR) (Su'etsugu M, et al. Nucleic Acids Res. 2017;45:l525-34). [Methods] gDNAs were cleaved by CRISPR/Cas9 in such a way that two variants were in cleaved fragments, which were then ligated to *oriC*-cassette containing *rop*, *ori*, and *AmpR* from pBR322. Various molar ratios of gDNA to *oriC*-cassette (1:10, 1:100, 1:1000, 1:10000) were evaluated to determine the optimal conditions for the ligation step. RCR amplification of each sample was conducted in 5-8 tubes. RCR products in each tube were then subjected to direct nucleotide sequence analysis. When both alleles were amplified in RCR products, RCR products were transformed into *E. coli* (HST08). The resultant colonies were picked, followed by direct nucleotide sequence analysis. We analyzed gDNAs from seven patients carrying two heterozygous pathogenic variants in *SYNE1*, *CYP27A1*, *ATP7B*, *COQ4*, or *CLCN2* with distances ranging from 4.3 to 152 kb. [Results] The molar ratio considerably influenced RCR success. At a high ratio (1:10), success rate was low (4/24), and only one allele was amplified (4/4). In contrast, at a low ratio (1:10000), success rate was high (20/24), and both alleles were amplified (18/20). Intriguingly, we observed clonal amplification in six of the seven cases, resulting in RCR products containing only one allele. In one case, both alleles were simultaneously amplified. Transformation of *E. coli* with the RCR products enabled us to separate the alleles and to determine the zygosity. The limit of amplification range was 84 kb. In the case where the distance was 152 kb, we were able to reconstruct the haplotype by utilizing a heterozygous SNP located 78 kb away from the variant. [Discussion] The study showed that RCR enables phase-resolved analysis for the region up to 84 kb, which is useful for determination of zygosity for two heterozygous variants.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3155 An interstitial deletion of chromosome 6q16 in an infant with multiple congenital anomalies: A case report.

Authors:

N. Hara, K. K. Gulen, X. Tang, C. Kumar; Westchester Med. center, Valhalla, NY

Interstitial deletions of chromosome 6q16 have been associated with Prader-Willi Syndrome-like (PWS-like) phenotype in most patients, featuring obesity, hypotonia, short extremities, and developmental delay. Recent studies have shown that certain rare single-minded 1 (SIM1) loss-of-function variants were associated with a high intra-familial risk for obesity with or without features of PWS-like phenotype. Although SIM1 seems to have a key role in the phenotype of patients carrying 6q16 deletions, some data support a contribution of other genes, such as GRIK2, to explain associated behavioral problems. To date a study has confirmed that the PWS-like phenotype is strongly linked to 6q16.2q16.3 deletions and varies considerably in its clinical expression. Recently, an unusual finding of two de novo microdeletions in cis position on chromosome 6q16.1q16.2 and 6q16.3 have been reported in a 19-year-old patient with intellectual disability and autism.

Here we present a new case of a pre-term male baby born with intra-uterine growth restrictions at 31 weeks 2 days by C-section due to mother's severe preeclampsia. He was born small for gestational age with a birth weight of 1.59 kg (~45 percentile). He had respiratory failure requiring ventilating support, cardiomegaly, thrombus in atrium, germinal matrix hemorrhage and hyperbilirubinemia. The mother had an amniocentesis due to prenatal findings of bilateral clubfeet and hypoplastic corpus callosum that revealed an interstitial deletion of chromosome 6q16. The cytogenetic and chromosomal microarray investigations were indicated. He underwent chromosome analysis on GTG banded metaphases prepared from peripheral blood cultures revealed the karyotype as 46,XY,del(6)(q16.3q16.3). The chromosomal microarray performed on whole blood for further characterization of the deletion and detected 8.2 megabase interstitial deletion from 6q16.1 to 6q16.3. The deleted interval involves 25 known genes (18 protein coding), including SIM1. Overlapping deletions of this region that include SIM1 and the other genes. Clinical correlation and genetic counseling were recommended. Parental chromosome and microarray studies were recommended to determine whether this abnormality is inherited or de novo in origin.

In conclusion, this case demonstrates the effective use of cytogenetics and microarray studies to characterize the interstitial deletion of 6q16 for patient's diagnosis and clinical management. Further research will improve our understanding of how loss of other genes in the 6q16.1q16.3 region may contribute to the genesis of neurodevelopmental diseases and other phenotypic disorders.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3156 Analysis *GNAS* inactivation disorders in a large Korean cohort with pseudohypoparathyroidism using whole exome sequencing (WES) and methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA).

Authors:

H. LEE; seoul Natl. Univ. Hosp., seoul, Korea, Republic of

Background: Pseudohypoparathyroidism (PHP) is caused by pathogenic variants (PHP-Ia or PHP-Ic) or epigenetic changes (PHP-Ib) at the complex *GNAS* locus on chromosome 20q13.3. Here, we investigated 53 patients suspected with pseudohypoparathyroidism using whole exome sequencing (WES) and methylation-specific multiplex ligation-dependent probe amplification (MS-MLPA).
Methods: A total of 53 patients was enrolled. To identify pathogenic variants in the coding exons of *GNAS*, sequence analysis of exon 1 through 13 was performed using WES. MS-MLPA was performed to identify deletions in *STX16*, and epigenetic changes at the four differentially methylated regions within *GNAS*.
Results: Among 53 patients, forty-nine ones proceeded with both WES and MS-MLPA, three only with MS-MLPA, and the last one with only WES. A pathogenic *GNAS* variant was identified in 9.4% (5/53) and abnormal epigenetic changes were identified in 45.3% (24/53). Four patients with abnormal epigenetic changes were *STX16* deletion-related familial PHP-Ib and the remaining 20 patients could be classified as sporadic PHP-Ib. The most frequent pathogenic variant, c.565_568delGACT resulting in frameshift mutation was discovered in 3 of 5 patients. The other two mutations were c.348_349insC and c.197_198insA respectively.
Conclusion: This study demonstrates molecular mechanisms of *GNAS* inactivation disorders in a large Korean cohort with pseudohypoparathyroidism. In this cohort, sporadic PHP-Ib was the most common, and followed by inactivating *GNAS* variant and *STX16* deletion-related familial PHP-Ib. Overall, the distribution of PHP patients shown in this study is expected to serve as meaningful data for promptly and accurately diagnosing PHP patients in the future.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3158 Array-CGH analysis in a cohort of Czech patients with intellectual disabilities and autism spectrum disorders

Authors:

M. Fiser, H. Kucerova, M. Schwarz, R. Michalovska; PRENET - Prenatal Diagnostics and Genetics, Pardubice, Czech Republic

Background In this study, we used array comparative genomic hybridization (aCGH) for identification of copy number variants (CNV) in a cohort of Czech patients with intellectual disabilities (ID) and/or developmental delay (DD) and/or autism spectrum disorders (ASD). **Methods** Array CGH is a high-resolution technique that can detect submicroscopic deletions/duplications. The genomic DNA extracted from blood samples of 223 patients was analyzed. All patients had normal karyotype and tested negative for fragile X syndrome. We performed aCGH using 8x60 ISCA format (Agilent, Santa Clara) with an average resolution of 240 kb (48 kb in ISCA regions). **Results** Aberrations of significance/potential significance were found in 43 (19,3%) of the 223 patients. *SHOX* gene duplications were found in 4 of the 43 patients. Recurrent microdeletion/microduplication syndromes were found in 15 of the 43 patients. Aberrations of candidate genes were found in 12 of the 43 patients. 6 of the 43 aberrations are linked to well-described genes. Large aberrations encompassing more genes were found in 6 of the 43 patients. **Conclusions** All data are consistent with literature. There seems to be a significance in frequency of *SHOX* gene duplications. Aberations of *SHOX* gene are well described as the cause of Léri-Weill Dyschondrosteosis, Langer Mesomelic Dysplasia and Idiopathic Short Stature. Only few papers describe association of *SHOX* gene duplications with developmental delay and/or autism spectrum disorders. Our study suggests potential significance of *SHOX* gene duplications in ID, DD and/or ASD, but more evidence is needed and further studies are necessary.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3159 Artificial Intelligence Based Chromosome Analysis

Authors:

S. Pallavoor; CARAIO Technologies, Bangalore, India

Human chromosome analysis through **Karyotyping** involves identification of 23 pairs of Chromosomes in human cell, out of which the first 22 pairs are autosomes and the 23rd pair is sex chromosome. This process is typically performed by experts in conventional cytogenetics. However, expertise across karyotyping and cytogenetics in general are very less and are mostly limited to cities across world.
With ever increasing number of cases for chromosomal disorders being seen worldwide, consisting predominantly cases such as down syndrome, infertility and repeated pregnancy loss, there is pressing need to make karyotyping available much beyond the current levels to make early diagnosis possible. This calls for widespread medical diagnostic tests for chromosome analysis of prenatal babies, newborn babies and adults screened for karyotyping. The main problems being faced in making karyotyping available for widespread adoption are **accessibility** and **affordability**, with heavy dependency on limited availability of **skilled cytogeneticists**. Adoption of **Artificial Intelligence** and **Digital Transformation** can solve this problem to a great extent, by way of application of image processing and computer vision techniques through the implementation of deep learning and other machine learning algorithms. We can achieve automation of processes involving heavy cognitive skills towards identifying chromosomes from digital images of metaphase precisely within few seconds which would otherwise take an expert in cytogenetics to spend anywhere between ten to twenty minutes to do the job per image. Medical diagnosis report generation typically would need about twenty digital images of different metaphase for a sample to be analyzed normally, and in cases of any abnormalities it could be even higher. AI can provide steep reduction in time and effort towards this. Suitable combination of human decision making in conjunction with machine produced results can ensure reliable level of accuracy needed for such decision-making processes. Karyotyping is the Gold Standard for detecting structural anomalies and numerical anomalies in chromosome defects in humans. Even newer techniques like Microarray can handle only at DNA level, not at structural and numerical levels of chromosomes. Karyotyping is the most suitable form of chromosome test for testing Amniotic Fluids. Through digital transformation, we can achieve **tele-medicine** for Karyotyping by provision of the AI platform-based software through cloud computing. This would solve the two predominant issues namely **accessibility** and **affordability** to a great extent for making Karyotyping available for the wider population.

Pitteloud[9]; [1]centre Hosp.ier universitaire vaudois, lausanne, Switzerland, [2]Univ. of Lausanne, Lausanne, Switzerland, [3]Univ. of Toronto, Toronto, ON, Canada, [4]Hôpitaux Neuchâtelois, Neuchâtel, Switzerland, [5]Poznan Univ. of Med. Sci., Poznań, Poland, [6]Univ. of Lausanne, lausanne, Switzerland, [7]Pediatric Inst. of Southern Switzerland, Bellinzona, Switzerland, [8]Univ. of Southern Switzerland, Lugano, Switzerland, [9]centre Hosp.ier universitaire vaudois, Lausanne, Switzerland

Background/Objectives: Delayed puberty (DP) in boys is defined by the absence of puberty by age 14. Most individuals with DP exhibit a transient form of GnRH deficiency and will eventually complete puberty (constitutional delay of growth and puberty [CDGP]). A minority of individuals have a permanent form of GnRH deficiency with absent or partial puberty known as congenital hypogonadotropic hypogonadism (CHH). The aim of this study is to use machine learning approaches to facilitate the early clinical distinction between these two conditions thus helping the clinicians to design the appropriate therapeutic strategy. **Methods:** 41 male patients aged 14 to 16.5 years with delayed puberty (DP) and hypogonadotropic hypogonadism were followed up until final diagnosis (18-19 years). We employed an anomaly detection algorithm, Isolation Forest to distinguish these two groups. We used 21 clinical and biochemical markers such as testicular volume, testosterone and gonadotropin levels from the first visit and a polygenic score from rare variants in known CHH causative genes to predict final diagnosis. **Results:** Out of 41 DP patients, 27 had CDGP, 6 complete CHH (cCHH) and 8 patients exhibited partial CHH (pCHH). Isolation Forest, trained with clinical parameters, enabled identification of pCHH from CDGP with a diagnostic accuracy of 79%, and reached 86% when including all CHH patients. The addition of a polygenic score based on exome variants further improved this performance by an additional 4%. **Conclusion:** Machine learning with polygenic scores improves diagnostic accuracy up to 89% to differentiate CHH from CDGP and can decrease greatly the difficulty for early diagnosis.

PB3161 Automated decision support for the clinical interpretation of copy number variants

Authors:

J. Budiš[1,2,3], T. Sládeček[1,2], M. Gaziova[1], M. Kucharik[1,2], Z. Pos[1,4,5], O. Pos[1,2,4], W. Krampl[1,2,4], R. Hekel[1,4,3], T. Sedlackova[1,2], J. Radvanszky[1,2,5], T. Szemes[1,2,4]; [1]Geneton Ltd., Bratislava, Slovakia, [2]Sci. Park, Comenius Univ. in Bratislava, Bratislava, Slovakia, [3]Slovak Ctr. of Scientific and Technical Information, Bratislava, Slovakia, [4]Dept. of Molecular Biology, Faculty of Natural Sci., Comenius Univ., Bratislava, Slovakia, [5]Inst. of Clinical and Translational Res., BioMed. Res. Ctr., Slovak Academy of Sci., Bratislava, Slovakia

Introduction: Clinical interpretation of copy number variants (CNVs) is a complex process that often leads to different decisions between diagnostic centers. In order to alleviate this obstacle, technical standards for the interpretation and reporting of variants have been developed, called ACMG guidelines. Several semiautomatic computational methods have been proposed to recommend appropriate choices. Alternately, the emerging machine learning based tools showed promising ways of even fully automated predictions.
Materials and Methods: We evaluated state-of-the-art computational prediction tools on CNV records collected from the ClinVar database. We compared their accuracy and showed the superior accuracy of their combination. We also tweaked the key parameters and underlying data sources to demonstrate their impact on the overall prediction.
Results: We demonstrate that the choice of underlying data sources significantly affects the prediction of CNV pathogenicity. We also show how automated prediction tools, especially their combination, further improve the evaluation of ACMG guidelines and thus lead to more reliable clinical decision support for clinicians.
Conclusions: Modern clinical decision support tools for the clinical interpretation of CNVs are able to provide valuable guidance to clinicians, relieving them of a great share of tedious annotation and interpretation processes.

PB3162 Automated ultra-high molecular weight DNA isolation from various sources enables high-throughput optical genome mapping.

Authors:

A. Hoischen[1], T. Hofste[1], L. Vullings[1], K. Huijbers[1], R. van Beek[1], E. Kamping[1], B. van der Sanden[1], J. Donner[2], S. Nothjunge[2], D. Laubscher[2], B. Ottenwälder[2], A. Files[3], Y. Zhang[3], M. Yadav[3], K. Neveling[1]; [1]Dept. of Human Genetics, Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [2]Hamilton Bonaduz AG, 7402 Bonaduz, Switzerland, [3]Bionano Genomics Inc., San Diego, CA

The power of long-read genomic technologies is becoming increasingly apparent in both human genetics research and in clinical applications. One emerging technology that utilizes Ultra-High Molecular Weight (UHMW) DNA is Optical Genome Mapping (OGM) via Bionano Genomics, Inc. (San Diego, USA). We also refer to OGM as 'next generation cytogenetics', as this may replace most cytogenetics tests including karyotyping, fluorescence in situ hybridization (FISH) and CNV-microarrays. While the analytical part of OGM is largely automated, the pre-analytical part and mainly the isolation of UHMW DNA would allow faster uptake of routine use. To date, automated UHMW DNA isolation has been very challenging, mainly due to the fact that one aims to prevent fragmentation and to preserve its megabase-long molecular size. Here, we demonstrate for the very first time the automated isolation of 12 UHMW DNAs each from three different cell types: cell pellets, EDTA blood and bone marrow aspirates using the Long String VANTAGE robotic solution from Hamilton (Bonaduz, Switzerland). This resulted in UHMW DNA that matched or exceeded DNA quality of manual procedures for all samples; resulting in molecule-N50 of at least 230kb and fulfilling standard labeling quality metrics. The subsequent processing of this UHMW DNA on Bionano's Saphyr enabled genome-wide structural variant (SV) detection. Here, we demonstrate its utility to detect >10,000 structural variants (SVs) >300bp in germline analysis; and show its sensitivity for acquired i.e. somatic SVs of all types with variant allele fractions (VAF) down to 5%. The final SV data of manual vs. automated procedure are indistinguishable. This approach has recently led to the discovery of hidden pathogenic SVs in previously undiagnosed rare disease patients. The demonstrated use of fully automated UHMW DNA isolation will allow higher throughput and robustness - and will therefore further improve clinical research and routine use of OGM. Ongoing developments focus on automation of the downstream labeling procedure to additionally facilitate the scaled adaptation of OGM workflows.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3163 Automation and miniaturization of high-throughput qPCR for gene expression profiling

Authors:

S. Tomei, S. Raveendran, A. Saeed, R. Mathew, H. Manjunath, M. Kalikiri; Sidra Med., Doha, Qatar

Background. Quantitative PCR (qPCR) is a technique commonly employed in laboratories and core facilities. QPCR results are strictly dependent on pipetting accuracy. Automation solutions overcome the variability generated by manual pipetting. The Mosquito HV liquid handler is a new generation automation system that offers multichannel pipetting with additional capability of assay miniaturization. In our previous study, we had shown the possibility to automate steps in the Standard BioTools gene expression workflow by pairing Mosquito HV with BioMark HD (Manjunath HS *et al*., 2022). Here we aimed at automating the full workflow and at exploring miniaturization capabilities.**Methods.** Each step of the Standard BioTools gene expression workflow was programmed on Mosquito HV genomics software. Mosquito HV liquid handling system was utilized for all pipetting steps followed by qPCR on Biomark HD. We performed three different runs: 1. Reference RNA samples (pooled healthy individuals; n=10) were run on an immunology gene expression panel. We tested the full reaction (FR) and three miniaturization conditions: 1.5x, 2.5x and 5x. 2. Test RNA samples (isolated from n=45 individuals) were run as FR and 1.5x on the immunology gene expression panel. 3. Test RNA samples (isolated from n=45 individuals) were run as FR and 1.5x on a pregnancy gene expression panel. The expression of each gene was calculated by $2^{-\text{deltaCt}}$ method. **Results**. In the reference RNA samples, successful amplification was observed when using FR and 1.5x conditions with a success rate of 96.81% and 93.42% respectively. The 2.5x reaction exhibited suboptimal amplification with a success rate of 37.55% while 5x reaction showed no amplification. Therefore, 2.5x and 5x conditions were excluded from further runs. A significant positive correlation was observed between the manual and automated workflows (manual vs automated FR, $r=0.9542$, $p<0.0001$; and manual vs automated 1.5x reaction, $r=0.9477$, $p<0.0001$). The validation of the automation workflow using patient samples with the immunology panel resulted in a success rate of 97.7 % and 96.8 % for FR and 1.5x reactions respectively. A positive correlation was observed with FR and 1.5x ($r=0.9$; $p<0.0001$). Consistent with the immunology panel, a positive correlation was also observed when using the pregnancy gene expression panel between FR and 1.5x reactions ($r=0.9952$; $p<0.0001$). Our results show that adoption and miniaturization capabilities of Mosquito HV system for automating the gene expression workflow did not interfere with data quality and reproducibility.

PB3164 Baby Detect, the first European genomic newborn screening initiative: project spreading and analytical validation.

Authors:

K. Hovhannesyan[1], L. Helou[1], F. Piazzon[1], T. Dangouloff[1], D. Mashhadizadeh[1], L. Palmeira[2], F. Boemer[2], L. Servais[3]; [1]Univ. of Liege, Liege, Belgium, [2]CHU Liege, Liege, Belgium, [3]Univ. of Oxford, Oxford, United Kingdom

The rapid development of new therapies for severe rare genetic conditions underlines the need to incorporate first-tier genetic testing into newborn screening (NBS) programs for treatable disorders that cannot be screened by biochemical assays. Next-generation sequencing (NGS) has an advantage over first-tier biochemical screening for diseases without accurate biomarkers.
For two years we have developed a workflow to screen 126 severe pediatric treatable disorders among newborns in Baby Detect pilot project in Liege area (www.babydetect.com). As of June 07th, 2022 - 1879 parents were proposed to participate in Baby Detect and 1694 agreed (90,1% acceptance rate).
The validated workflow includes extraction of DNA from the dried-blood spots (DBS), a targeted NGS (tNGS) by Twist Bioscience technology, Illumina sequencing, in-house developed pipeline for secondary analysis, variant interpretation using artificial intelligence-based Alissa Interpreter of Agilent. The methodology of the workflow was validated for manual operation and for the pilot screening considering the criteria acceptable for diagnostic settings.
The isolation of DNA from DBS was done by QIAamp DNA Investigator Kit (Qiagen) with sufficient yield and quality to perform tNGS. We have developed a custom-designed targeted-panel of 361 genes to perform deep sequencing of regions of interest. Twist Bioscience library preparation was optimized to be well suited for DBS-extracted DNA samples. Sequencing was performed using Illumina technologies on NovaSeq 6000 and NextSeq 550 systems. Raw sequencing data was analyzed by an in-house developed bioinformatic pipeline. Different performance parameters were calculated, and the quality criteria were established.
In the first year of the project, we are reporting disease-causative pathogenic and likely pathogenic SNV variants. For variant interpretation we developed a decision tree for smart filtering of variants using Alissa Interpret, which was validated on large number of positive and negative samples (600 samples). Validation of Baby Detect workflow allows demonstrating unbiased information on the technical feasibility and potential clinical utility of NGS-based NBS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3165 Beyond genomics: Using RNA-seq in filter cards to unlock the clinical relevance of non-coding variation in splicing.

Authors:

P. Bauer[1,2], R. Al-ali[2], M. Radefeldt[2], L. M. Pardo[3], J. Pinto Basto[3], A. Bertoli-Avella[2]; [1]CENTOGENE, Börgerende-Rethwisch, Germany, [2]Centogene GmbH, Rostock, Germany, [3]CENTOGENE, Rostock, Germany

Clinical exome and genome sequencing are first line diagnostic methods in rare diseases with diagnostic yields going up to 60%. Still variants of unknown significance (VUS) account for up to 5% of reported variations in ClinVar database. Here we assessed the impact of splicing variants reported in our laboratory using RNA Sequencing experiments (RNA-seq) to gain insight into their clinical relevance.**Methods** A total of 108 consecutive patients with 113 splicing variants reported after exome/genome sequencing were selected for RNA sequencing (RNAseq). A protocol was developed to perform RNAseq using filter card (dried blood spots - DBS), library preparation and bioinformatic pipeline analysis. Relative gene expression was calculated using house-keeping genes and compared against controls. Splicing patterns in cases were inspected using IGV interactive program and adding three independent controls. **Results and Discussion** Forty-nine variants were located at canonical intronic positions 1-2 (43%), 64 (57%) were affecting other intronic regions (up to 824 bps). Eighty-one variants were heterozygous (72%), 26 were homozygous (23%) and six were hemizygous variants (5%). Of the 113 variants, 65 (58%) were confirmed as leading to abnormal splicing (with a minimum of 5 supporting reads), 15 (13%) did not have any evident splicing effect and 33 (29%) were inconclusive. The main reason for the inconclusiveness was insufficient coverage of the area. **Conclusions** We propose a method for a systematic experimental evaluation of the splicing impact of intronic variants, integrated in diagnostic exome/genome sequencing, which impact the assessment of their clinical relevance. The approach can be implemented in the routine workflow by diagnostic laboratories, adding an additional -omics layer to the diagnosis of rare disorders.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3166 † Beyond the exome: Finding answers for clinical exome-negative patients

Authors:

S. Meyn[1], A. Hall[2], H. Motiff[1], J. Heilmann[1], L. Frater-Rubsam[3], H. Nguyen[4], X. Shao[4], V. Horner[4], D. Pavelec[5], B. Webb[2]; [1]Ctr. for Human Genomics and Precision Med., Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI, [2]Dept. of Pediatrics, Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI, [3]State Lab. of Hygiene, Univ. of Wisconsin Sch. of Med., Madison, WI, [4]State Lab. of Hygiene, Univ. of Wisconsin - Madison, Madison, WI, [5]Biotechnology Ctr., Univ. of Wisconsin - Madison, Madison, WI

Background: Just over half of 9,000+ rare genetic disorders have a known cause and most patients who undergo clinical WES fail to obtain a diagnosis. To address these issues we created the University of Wisconsin Undiagnosed Disease Program (UW UDP), which takes a "beyond the exome" approach to evaluating genetics patients.
Objectives: 1) discover new disease genes; 2) improve our understanding of genetic disorders; 3) provide patients with actionable diagnoses; and 4) evaluate novel technologies. We select patients, in part, based on the complexity/rarity of phenotype and the number of affected family members. Our workflow begins with clinical WES reanalysis, followed by trio short read genome sequencing. Long read sequencing, RNA-Seq, optical mapping, and epigenomic profiling are utilized *ad hoc*.
Results: To date, the UW UDP has enrolled 59 families, including 67 affected individuals and 110 unaffected relatives. ~90% of probands had prior clinical WES. We identified candidate causal variants for 8 of the first 14 patients. Short and long read WGS, WES reanalysis, and RNA-Seq each played a role in finding i) a 15q11.2 deletion and an instance of chromoplexy involving chromosomes 2, 3, 8, and 21 missed by clinical testing; ii) two new candidate disease genes; and iii) a patient whose novel phenotype is the likely result of synergy between pathogenic variants in genes causing a glycosylation disorder and grey platelet syndrome. A clinical diagnosis of Aicardi Goutieres syndrome was ruled out by RNA-Seq. Additional analyses are on-going.
Conclusion: Our initial results suggest that a significant fraction of clinical WES-negative patients can be diagnosed using combinations of WGS, long-read WGS, optical mapping, and RNA-Seq, indicating that diagnostic rates of >65% are attainable. An undiagnosed genetic disease program can serve as an important component of a comprehensive center for rare diseases, as it offers patients access to emerging technologies, increases diagnostic rates, and facilitates the discovery of new disease genes while advancing our understanding of rare genetic disorders.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3167 Beyond the exomeUtility of long-read whole genome sequencing in exome-negative autosomal recessive diseases

Authors:

F. Alkuraya; King Faisal Specialist Hosp. & Res. Ctr., Riyadh, Saudi Arabia

At least 50% of patients with suspected Mendelian diseases remain negative after exome sequencing. Several factors have been identified at the technical and interpretation levels to explain this diagnostic gap. Long-read whole genome sequencing (lrWGS) has the potential to address the technical limitations of exome sequencing e.g. structural variants (SV). However, its utility in autosomal recessive Mendelian diseases is largely unknown. In a selected cohort of 34 families in which the suspected autosomal recessive diseases remained undiagnosed despite careful consideration of interpretation challenges of their exomes, lrWGS was performed at an average depth of 10x on the Pacific Bioscience Sequel IIe platform. Likely causal variants were identified in 14 (41%) of the cohort. These include: 1) a homozygous splicing SV in *TYMS* as a novel candidate gene for lethal neonatal lactic acidosis, 2) a homozygous SV that we propose impacts *ANO7* and *STK25* and causes a unique combination of albinism and microcephaly, 3) a compound heterozygous SV in *RP1L1* with complex inheritance pattern in a family with inherited retinal disease, 4) a homozygous UTR SNV in *MZT1* and deep intronic variants in *LEMD2* and *SNAP91* as novel candidate genes for neurodevelopmental disorders in three families, and 5) a promoter SNV in *SLC4A4* causing non-syndromic band keratopathy. Surprisingly, we also encountered causal variants that could have been identified by short read exome sequencing in 7 families. The latter highlight scenarios that are especially challenging at the interpretation level including complex compound heterozygosity, high allele frequency, intrafamilial genetic heterogeneity, isoform confusion, and phenotyping challenges. Our data highlight the continued need to address the interpretation challenge in parallel with our effort to improve the sequencing technology itself. We propose a path forward for the implementation of lrWGS sequencing in the setting of autosomal recessive diseases in a way that maximizes its utility.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3168 Bringing constitutional genome sequencing to a children's hospital.

Authors:

J. Hunter, A. Otero Bravo, B. Kelly, B. P. Chaudhari, D. Corsmeier, J. Garee, V. Jayaraman, H. Jenkins, H. Kuck, G. Lammi, M. Leung, A. McKinney, S. Ravagnani, J. Scholl, E. Stonerock, P. White, C. Cottrell; Nationwide Children's Hosp., Columbus, OH

Genome sequencing (GS) is making its way into mainstream clinical genetic testing paradigms and provides a lifelong resource for medical care. Many aspects of our health are rooted in our genetic sequence, especially in infants and children who have had less environmental exposures that modify their health. We describe the reasoning for, and process of, validating and implementing clinical GS and rapid genome sequencing (RGS) at a U.S. children’s hospital.GS provides important advantages over other testing modalities. GS dramatically reduces hands on time in the lab, requires fewer steps at which errors can occur, and uses fewer PCR cycles resulting in reduced artifacts. GS yields cleaner, more even sequencing coverage, and comprehensive variant calling. GS has the highest diagnostic yield of any clinical genetic test available, providing the best chances of successful diagnosis for critically ill infants and children. While GS requires more sequencing and thus more computing and storage, these obstacles are mitigated in many ways by reduced lab time, decreasing sequencing time and costs, and decreased computing and storage time and cost.To validate GS and RGS as clinical genetic tests, we used 185 GS data sets primarily from a translational research protocol. We validated saliva, peripheral blood, and cord blood as acceptable sample types. Variant concordance was determined for over 200 variants from more than 100 cases reported through clinical ES or GS sequencing by internal or external clinical sequencing labs. We determined the limit of detection for GS at multiple sequencing depths and performed downsampling experiments to establish accurate variant calling saturation levels.We validated RGS as a true STAT test with a verbal report turn-around-time (TAT) of 3-5 days with a final report in 5-8 days. To meet this aggressive TAT, we optimized many processes including wetlab procedures, bioinformatics pipelines, and use phenotype-driven variant prioritization. Furthermore, we worked to optimize and expedite hospital logistics prior to sample receipt.Future work includes evaluation of additional bioinformatics pipelines including DRAGEN and additional data analysis of mitochondrial DNA, structural variants, as well as infectious disease identification.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3169 CardioSeq: A prospective study investigating the impact of clinical genome sequencing in a diverse patient population with cardiovascular disease

Authors:

D. Lanfear[1], L. Amendola[2], K. Robinson[2], T. Ebai[2], T. Kalista[2], W. Cabral[1], K. Collins[1], D. Hostin[2], A. Huertas-Vazquez[2], M. Longoni[2], R. Taft[2]; [1]Henry Ford Hosp., Detroit, MI, [2]Illumina Inc., San Diego, CA

Introduction: Cardiovascular disease (CVD) is responsible for 1:5 deaths in the United States and is one of the leading causes of mortality globally. Targeted genetic testing is recommended for multiple CVD indications; however, society guidelines are inconsistently followed. The role of comprehensive genomic testing in cardiology has not been fully investigated.
Methods: The CardioSeq study is a prospective, open label, single-center investigation conducted at Henry Ford Health cardiology clinics, testing the diagnostic efficacy and clinical utility of clinical genome sequencing (cGS) that includes a 200-gene CVD panel, 4 CVD risk alleles, 10 PGx genes, 35 non-CVD ACMG secondary finding genes, and a polygenic risk score for coronary artery disease (CAD). The planned enrollment is 1500 adult participants. Enrollment criteria include a diagnosis of aortopathy, arrhythmia, cardiomyopathy or heart failure, coronary or peripheral artery disease, or dyslipidemia, without a prior molecular genetic diagnosis. The primary outcome is the proportion of patients who receive a new molecular diagnosis. Secondary outcomes include the proportion of participants with a finding leading to a change in management (CoM) compared to an EHR-derived contemporaneous matched (2:1) usual care group.
Results: To date, 158 participants have been enrolled in CardioSeq, among whom self-reported race is 49% Black or African American, 48% White, 1% Middle Eastern, 1% Asian. Self-reported ethnicity is 1% Hispanic or Latino. The majority of participants (105/158, 66%) have at least two concurrent CVD diagnoses, with the most common being dyslipidemia (88%) and arrhythmia (81%). Enrollment is anticipated to complete by early 2024.
Conclusion: The integration of a comprehensive cGS test into the care of diverse cardiology patients increases access to genetic information and will generate evidence on the clinical utility of the genome as a platform for enhancing CVD care.

PB3170 Case report: A 3 year old female with skin hamartoma, facial masses, trismus and mosaic chromosome 22 trisomy.

Authors:

J. Fu[1], P. D'Souza[1], E. Macnamara[1], M. Sabii[1], N. Hanchard[2], T. Toluwani[3], E. Banfield[2], L. Castelo-Soccio[4], H. Kim[5], B. Pusey[1], NIH Undiagnosed Diseases Network, D. Adams[1]; [1]Undiagnosed Diseases Program, Intramural Res. Program, NIH, Bethesda, MD, [2]Childhood Complex Disease Genomics Section, Ctr. for Precision Hlth.Res., Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [3]UCSF Sch. of Med., San Francisco, CA, [4]Natl. Inst. of Arthritis and Musculoskeletal and Skin Diseases, NIH, Bethesda, MD, [5]Natl. Inst. on Deafness and Communication Disorders, NIH, Bethesda, MD

Introduction: The NIH Undiagnosed Diseases Program (UDP) evaluates participants with significant illnesses that remain undiagnosed after standard of care clinical evaluation. We present a case of mosaic trisomy 22 with progressive skin lesions, deforming facial masses and trismus.
Methods: Study participants are enrolled in the UDP using an IRB approved protocol.
Results: A 33 m/o female presented with a history of congenital, evolving skin lesions involving the scalp, face and upper thigh. Lesions were non-painful nodules on an erythematous base, some with sebaceous-appearing components. The largest was a right-sided 30 mm x 20 mm periauricular lesion. Congenital right-sided facial hemi-hypertrophy primarily involved the right supra-zygomatic and pre-auricular areas. Growth and development were normal. A face ultrasound at 3 m/o revealed a 17 mm x 14 mm ill-defined hypoechoic complex mass adjacent to the right parotid gland. At NIH evaluation, a new diagnosis of moderate trismus was made. Facial MRI revealed T2-bright fat-non-enhancing infiltration-like signal involving the of masseter, pterygoid, parotid gland, and facial adipose tissue. The TMJ appeared intact, suggesting trismus secondary to infiltrated muscles. Biopsy of superficial neck lesions revealed an abnormal mixture of tissue types (vessels, nerves, skeletal and smooth muscle, eccrine glands and ducts) normally found in the skin. Some vessels showed a perivascular lymphocytic infiltrate, prominent in the deeper reticular dermis. The findings were consistent with a cutaneous hamartoma. Clinical genome analysis did not reveal diagnostic variants; research analysis did not yield research-candidates. A high-density Illumina SNP array performed on blood DNA showed a B-allele signal consistent with mosaic trisomy 22.
Conclusions: Previous reports have described trisomy 22 mosaicism in association with dysmorphic features not found in our case. However, hemihyperplasia has been described, leading us to hypothesize that our participant is affected by more restricted distribution of mosaicism than described in prior reports. We present imaging and further laboratory evaluation in a case report detailing this rare presentation and potential diagnosis.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3171 Challenge to elucidate complex structural variants using long-read sequencing

Authors:

Y. Enomoto, Y. Kuroda, Y. Saito, K. Kurosawa; Kanagawa Children's Med. Ctr., Yokohama, Japan

Complex structural variants involving multiple chromosomes are sometimes detected in patients with congenital anomalies. G-banding is one of the methods for analyzing complex structural variants, however the resolution is low and it is difficult to elucidate the details of variants. Long-read sequencing is a useful method for analysis of complex structural variants. In this study, we try to elucidate complex structural variants in a Japanese girl patient with developmental delay. She was the second child of healthy parents. She was born at 38 weeks gestation with a birth weight of 2296 g (-1.53 SD) and length of 44.3 cm (-1.79 SD), and head circumference 32 cm (-0.74 SD). Apgar scores were 9 at 1 min and 10 at 5 min. She was referred to the hospital for suspected multiple congenital anomalies syndrome at the age of two months. She had developmental delay and facial features including arched eyebrows, ptosis and a triangular nose. At the age of 3 years, her weight of 10.85 kg (-1.4 SD) and length of 84.2 cm (-2.4 SD). She could speak a single word. G-banding detected complex structural variants: der(5)(5pter→5q13.1::?), der(6)(5qter→5q15::6p23→6qter), der(9)(?::9p24→9q22.1::?), der(10)(9qter→9q22.3::?::10p11.2→10qter), der(18)(18pter→18q22.1::?). Long-read sequencing revealed four translocation breakpoints out of the seven breakpoints detected by standard karyotyping. Furthermore, long-read sequencing identified 1.28Mb inversion at the breakpoint of t(5;6) and uncovered the additional fragments of der(9) and der(18). These results indicated that the long-read sequencing can identify complex rearrangements of cytogenetic translocations at high resolution and reveal the underlying mechanisms of the structural variations. A detailed study of phenotypic associations with genes adjacent to breakpoints created by translocations remains a future challenge.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3172 Challenges and breakthroughs in unified digital laboratory systems in diagnostics and research core laboratories.

Authors:

B. Dunn; L7 Informatics, Austin, TX

Recent advances in scientific procedures and best practices have been matched with a proliferation of specialized software solutions. This leads to most diagnostics and research labs using multiple software systems that each only track, manage, or process a subset of the lab's overall operations - thus effectively siloing each team member, group, or process from the rest of the lab. These silos then result in decreased data flow through the lab, decreased visibility into sample and data status, and decreased sample processing throughput. Here we demonstrate breakthroughs in digitizing laboratory processes in fully compliant systems from the point of sample collection through to data reporting. This leads to an increase in laboratory efficiency, increased data integrity, better decision making due to better data visibility, and reduced costs for diagnostics laboratories and research cores. As a proof of principle we highlight how two different academic research cores have implemented this new technology, L7|ESP, to reduce their laboratory silos. Laboratory 1 is a sequencing core at an academic institution and processes hundreds of samples per day. Utilization of L7|ESP provided them with the ability to send information and samples across various groups within their core and seamlessly output final reports to their customers. Laboratory 2 is a cutting-edge protein sciences group at a large nonprofit biomedical research institution. Their work utilizes multiple different instruments, sample types, and desired outputs and thus requires flexibility and adaptability without sacrificing throughput, data integrity, or user experience. Through modeling these processes in L7|ESP they are able to run specialized processes at scale while still running generalized processes to meet the changing needs of their clients. These case studies show that modern diagnostics and research core laboratories can leverage today’s latest breakthroughs in computer science and software to enable them to successfully scale and grow to tomorrow’s scientific needs.

PB3173 Chronic mucocutaneous candidiasis due to*Candida auris*in patients with a mild*TP63*-associated ectodermal dysplasia

Authors:

H. Vahidnezhad[1], F. Palizban[2], A. Saeidian[3], L. Youssefian[4], H. Hakonarson[5], S. Khodavaisy[6]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]IBB, Tehran, Iran, Islamic Republic of, [3]Children s Hosp. of Philadelphia, Philadelphia, PA, [4]UCLA, Los Angeles, CA, [5]Children's Hosp. of Philadelphia, Philadelphia, PA, [6]Tehran Unuiversity of Med. Sci., Tehran, Iran, Islamic Republic of

Persistent fungal infections are associated with host immune status and the type of fungal species. Genetic variants that lead to immunological susceptibility to fungi have long been sought and recognized. Understanding these genetic underpinnings will be a powerful tool in the age of personalized medicine. In this study, unbiased, whole-transcriptome sequencing by RNA sequencing (RNA-Seq) was utilized as a first-tier strategy for the concomitant detection of the genetic determinant of abnormal host immunity and the causative fungal agent in a father and daughter of Iranian descent who presented with chronic mucocutaneous candidiasis (CMC), mild ectodermal dysplasia, and recurrent bacterial infections. Additionally, the patients' humoral and cellular immunity were evaluated, and the patients' peripheral blood DNA were analyzed with whole-exome sequencing (WES). Skin, hair, and nail biopsies were independently evaluated by conventional mycological tests and fungal DNA sequencing. WES and RNA-Seq disclosed a monoallelic mutation in *TP63* that matched with the clinical phenotypes of our patients. In addition, RNA-Seq confirmed the pathogenicity of detected sequence variants and expression profiling. Additionally, non-albicans *Candida* species, *Candida auris,* were detected in CMC lesions of both patients and *Candida parapsilosis* was isolated in the father's samples. Both patients had normal humoral and cellular immunity. Although a strong association between ED and *TP63* mutations exists, the mechanism of immune dysregulation remains unclear. This study represents the first case of CMC caused by the multidrug-resistant emerging pathogen *C. auris* in the context of *TP63*-associated ED and demonstrates the RNA-Seq utility for concomitant host mutation detection and accurate identification of rare and often misidentified pathogens.

PB3174 Chronic recurrent pancreatitis: importance of genetic testing.

Authors:

S. Carlo[1,2], N. Arciniegas[2,1], L. Rodriguez[1], F. Benitez[1], A. Cornier[3], E. Albino[4]; [1]Ponce Hlth.Sci. Univ., Ponce, PR, [2]Mayaguez Med. Ctr., Mayaguez, PR, [3]San Jorge Children s & Women s Hosp., San Juan, PR, [4]Univ. of Puerto Rico - MSC, San Juan, PR

Pancreatitis occurs when there is inflammation in the pancreas because of autodigestion by enzymes secreted from the exocrine portion of this organ. Clinical diagnosis of the disease can be differentiated into the following types based on duration: acute (few days to six months), acute recurrent (more than one episode of acute pancreatitis), and chronic (more than six months). An earlier onset of pancreatitis tends to correlate with phenotypic presentations of mutations on pancreatic associated genes. Those that have been previously associated with pancreatitis include the *SPINK1*, *CTRC*, *PRSS1* and *CFTR* genes, which will be further discussed in this case report. We introduce the case of a 6-year-old Puerto Rican female who has suffered from seven episodes of acute pancreatitis in the past year. A diagnosis of acute recurrent pancreatitis with unknown etiology was initially made. As part of the diagnostic criteria for patients who present with unexplained episodes of pancreatitis, tests were performed in order to verify possible genetic etiology. Testing revealed that the patient was heterozygous for two variants that predispose to pancreatitis found on genes *CTRC* and on *SPINK1* . Both of these genes are essential in the control of trypsin, a proteolytic enzyme that regulates the exocrine enzymatic cascade in the pancreas.

PB3175 Clinical and Genetic Features of 22 Neonatal Dubin-Johnson Syndrome in Japan

Authors:

T. Togawa[1], S. Ito[1], K. Imagawa[2], H. Hayashi[3], K. Ito[1], T. Endo[1], T. Sugiura[1], S. Saitoh[4]; [1]Nagoya City Univ., Nagoya, Japan, [2]Univ. of Tsukuba, Tsukuba, Japan, [3]The Univ. of Tokyo, Tokyo, Japan, [4]Nagoya City Univ, Nagoya, Japan

Dubin-Johnson syndrome (DJS, [MIM 237500]) phenotype results from biallelic pathogenic variants in *ABCC2* which encodes a member of the large ABC transporter family. DJS was rarely diagnosed in the neonatal period and thus few case reports with molecular genetically confirmed neonatal DJS have been reported. Our previous study reported 10 patients with neonatal DJS determined by molecular genetic diagnosis using targeted next-generation sequencing (Togawa T, et al. *J Pediatr 2018*). After the study, we further identified 12 more patients with neonatal DJS. Here, we aimed at clarifying clinical and genetic features in 22 East-Asian patients with neonatal DJS. We recruited 22 patients with neonatal DJS from pediatric centers in Japan between September 2013 and February 2021. We defined neonatal DJS as follows: onsets of clinical manifestations of cholestasis, such as prolonged jaundice and acholic stools, during the neonatal period; increased serum direct bilirubin (D Bil) value; homozygous or compound heterozygous pathogenic variants in *ABCC2*. Clinical course, laboratory findings, and variants concerning *ABCC2* were retrospectively and prospectively examined. Regarding genetic analysis, we previously developed targeted next-generation sequencing and bioinformatics methods. The median duration of gestation and birth weight was 39 weeks and 2956 g, respectively. All 22 patients presented persistent jaundice starting from the neonatal period. The median values of the highest serum total bilirubin (T Bil) and D Bil were 10.5 mg/dL and 5.9 mg/dL, respectively. Ten of the 22 patients who received hepatobiliary scintigraphy examinations showed abnormal results. For all patients, cholestasis which was determined by serum D Bil value improved rapidly and serum D Bil value decreased to <1.5mg/dL within 12 months. Regarding causative pathogenic variants, all patients harbored compound heterozygous or homozygous pathogenic variants in *ABCC2*: Six variants (R768W, c.1967+2T>C, R100Ter, c.2125T>C, c.2439+2T>C, and c.2882A>G) occurred in multiple alleles accounting for 9, 7, 4, 4, 4 and 3 of 44 affected alleles, respectively. We identified 5 novel pathogenic variants, A364NfsTer37, I719T, L984R, c.3614+1G>A, and D1361N. The clinical courses of the 22 patients with neonatal DJS were similar. Severe cholestasis developed from the neonatal period and disappeared rapidly during the infantile period. This clinical course is unique to neonatal DJS. Several hot spots of pathogenic variants in *ABCC2* might exist in patients with neonatal DJS among the East Asian population. Molecular genetic testing can uncover patients with neonatal DJS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3176 Clinical and genetic overlap between CHH and CLP

Authors:

I. Habibi[1,2], F. De-Azevedo-Correa[1,2], J. Zhai[1,2], A. Boizot[1], M. Adamo[1,2], K. Chachlaki[1], P. Luca[3], M. Rauch[4], V. Popovic[5], R. Quinton[6], M. Clemente Leon[7], A. Nemeth[8], B. Hosp., Service of Endocrinology, Diabetology and Metabolism, Lausanne, Switzerland, [2]Univ. of Lausanne, Lausanne, Switzerland, [3]Dept. Endocrinologia e Malattie del Metabolismo, IRCCS Istituto Auxologico Italiano, Milano, Italy, [4]Inst. of Med. Genetics, Univ. of Zurich, Zurich, Switzerland, [5]Inst. of Endocrinology Dept. of Neuroendocrinology, Belgrade, Serbia, [6]Dept of Endocrinology, Newcastle-upon-Tyne, United Kingdom, [7]Unidad de Endocrinología Pediátrica, Barcelona, Spain, [8]St. John's Hosp., Budapest, Hungary, [9]Dept. of Orthodontics, Univ. of Cologne, cologne, Germany

Purpose. Congenital hypogonadotropic hypogonadism (CHH) and Cleft lip palate (CL/P) are two complex genetic conditions. Here we report an overlapping syndrome. **Methods**. First, we identified patients with CHH and CL/P through international collaboration. Genetic and clinical analysis of 41 patients with CL/P and reproductive defects were completed. Second, we focused on 442 probands with CHH without CL/P and studied the implication of CL/P genes in this population. **Results**. We found pathogenic (P) and likely pathogenic (LP) variants in 11 patients (27%) with CL/P & CHH in CL/P genes and/or CHH genes (*FGFR1, SOX9, CHD7, KLB+PROKR2, CTNND1*, and *SOX10*). Given the broad roles of SOX9 during development, it is a putative candidate gene for CL/P. Interestingly, *SOX9* has been associated in one patient with CHH. As expected, the most frequent CL/P gene involved in the CHH cohort without CL/P was *FGFR1* (31 P and LP variants, 60%), a gene known to be involved in CHH. The second most prevalent gene was *CHD7*, with 9 CHH patients exhibiting mutations in this gene. Other CL/P genes appear in our CHH cohort including two variants in *DVL3* and one P or LP variant in *PLCB4, PIEZO2, TP63, TGFBR2, TCOF1, NIPBL, CHD1, KMT2D, INTS1* and *COL2A1*. We were surprised to identify several P and LP variants in CL/P genes among our CHH cohort. **Conclusion.** Taken together, this extensive clinical and genetic study revealed heterogeneity in the genetic landscape of patients exhibiting both CL/P and central reproductive defects.

PB3177 Clinical whole genome sequencing after non-diagnostic genetic testing identifies distinct types of genetic variants

Authors:

S. Berger[1], E. Delot[2], G. Pitsava[1], A. Cohen[3], J. Lotempio[4], S. Marmolejos[3], A. Kahn-Kirby[4], S. Knoblach[1], A. Ko[5], R. Nussbaum[6], V. Fusaro[4], E. Vilain[4]; [1]Childrens Natl. Res. Inst., Washington, DC, [2]Children s Natl. Res. and Innovation Campus, Washington, DC, [3]Children's Natl. Res. Inst., Washington, DC, [4]Univ. of California - Irvine, Irvine, CA, [5]Children's Natl. Res. Inst., Washingtion,DC, DC, [6]Invitae, San Francisco, CA

Background: Exome sequencing has become the genetic test of choice for a wide range of clinical presentations but has limitations. Genome sequencing is a possible alternative as a first-tier test in the clinical environment as it promises to overcome many of these limitations. We analyze here the improvement of the diagnostic yield and the types of variants whose detection is facilitated by genome sequencing.Methods: Participants without diagnosis from clinical testing including CLIA exome sequencing were enrolled in the Pediatric Mendelian Genomics Research Center (PMGRC), a Genomics Research to Elucidate the Genetics of Rare disease (GREGoR) Site. Genome sequencing and analysis were performed utilizing clinical pipelines. Diagnostic results were categorized as "coding region", "near coding intronic", "deep intronic", and "structural variant". For variants affecting exons or within 20 bases of an exon, original clinical testing was reassessed to understand the reasons why variants were not initially reported.Results: For 122 probands enrolled in the PMGRC, 31 (25%) had variants considered likely diagnostic by whole genome sequencing. Diagnostic variants not detectable by exome included deep intronic or exon-copy neutral structural variants (e.g. deletion of promoter into 5'UTR or rearrangement and inversion of exons). RNA sequence analysis provided supporting evidence for pathogenicity for several deep intronic variants. Diagnostic variants affecting exonic regions were most often for genes that lacked published clinical validity at the time of the original exome but had since been published as associated with a novel syndrome. Additionally, several known pathogenic exonic variants were identified that had not been reported on the original exome due to clinical pipeline exclusion of regions with frequent artifactual calls.Conclusions: While some increased diagnostic yield from genome resulted from being an interval reanalysis after exome, diagnostic yield was also improved through detection of non-exonic variants, structural variants, and technically challenging exonic regions.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3178 Clinically Significant Copy Number Variants (CNVs) are associated with Common Fragile Sites at their breakpoints - A novel approach in the study of CNV biogenesis

Authors:

F. Islam, S. Chandrashekar, K. Awayda, M. Iqbal; Univ Rochester Med Ctr, West Henrietta, NY

Intro: Copy number variants (CNVs) occur when parts of the genome are duplicated or deleted. CNVs are commonly caused by non-allelic homologous recombination (NAHR) but other mechanisms may exist. Common fragile sites (CFSs) are regions of the genome susceptible to breakage through chromosome condensation, leading to oncogene-induced DNA damage. CNV induction by CFSs remains unknown. In this study, we retrospectively reviewed clinically significant CNVs reported as per the ACMG guidelines in our microarray CGH laboratory database. We investigated the association of CNVs breakpoints overlap within 200+ CFSs. This is a novel approach being undertaken to understand CNV biogenesis.
Methods: We recruited and anonymized 523 CNVs from our DNA microarray CGH laboratory database, including pathogenic (P) (n=89), clinically uncertain-likely pathogenic (CULP) (n=51), and clinically uncertain (CU) (n=383) CNVs. ACMG guidelines and lab criteria were used to select CNVs; P, CULP, CU: >250 kb with >1 morbid gene. A list of over 200 CFSs was compiled from published studies into a BED file and uploaded into cytogenomic analysis software (4x180 CGH+SNP Microarray Kit, Agilent). A Python pipeline was developed to map CNV breakpoints to CFS coordinates, and subsequent analyses were undertaken to further examine the nature of this association.
Results: 37.7% (n=197) of analyzed CNVs overlapped CFSs. By category, these were CU (33.4%, n=128), P (44.9%, n=40), and CULP (56.9%, n=29). Most CNVs (P, CULP, U) analyzed ranged from 100Kb to 1Mb. No significant size distribution difference was observed between CNV groups positive and negative for CFS overlap, as CNVs of all sizes overlapped with CFSs. A high number of overlaps were found to occur on 15q, with the CFSs FRA15Bi and FRA15C having the most overrepresentation in the data set (17 and 10 events, respectively). Ongoing studies are being conducted to determine the 5' and 3' breakpoint regions of CNV/CSF junctions and will be presented.
Conclusion: In breakpoints of a substantial population of clinically relevant CNVs, nearly 40%, overlap with CFSs. Over 100 different CFSs located amongst almost every chromosome were found to overlap CNVs, but clusters of implicated CFSs exist. We hypothesize that the notable overlap between CNVs and CFSs could be the result of DNA instability which exists in CFSs during replication, which proffers a novel mechanism for CNV biogenesis. Furthermore, we speculate there may be more CFSs in the genome which have yet to be discovered and may be associated with the CNVs which are found not to associate in the current study. Future studies will seek to better define the association of these two genetic elements.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3179 CNVviewer: A web-based interactive visualization and annotation tool for accurate clinical diagnosis and reporting of copy number variations.

Authors:

J. Zhou, K. Jiang, C. Li, C. Peng, J. Zhang, F. Chang, Q. Zhang, X. Cai, Y. Wang, P. Fang, S. Tang, W. Mu; KingMed Diagnostics, ShangHai, China

DNA copy number variations (CNVs) play a pivotal role in the development of inherited and acquired diseases. While optimized bioinformatics algorithms for CNV detection from next-generation sequencing (NGS) data are essential for accurate clinical diagnosis, it is equally important to have an interactive visualization tool with user-friendly interface that enables efficient assessment of technical validity and clinical significance of CNV calls.
To address this need, we present CNVviewer, a web-based interactive analysis tool designed for accurate clinical analysis and reporting of CNVs for both germline and somatic applications. CNVviewer accepts CNV results from widely used read depth-based calling tools such as CNVkit and CNVnator, with a particular optimization for whole-genome sequencing (WGS) data to enhance loading and response time through down-sampling. Moreover, CNVviewer allows for the importation of results from split read/read pair-based methods for the same sample, enabling additional supporting evidence for more precise breakpoints delineation. The tool provides both a global view and a local view, displaying copy ratio signals, B-allele frequency (BAF), cytobands, and gene annotations across the whole genome and for individual CNVs. In trio analysis and paired tumor-normal analysis, CNVs from multiple samples can be displayed together, aiding in the determination of CNV origin. In addition, CNVviewer performs key clinical gene annotations such as OMIM inheritance (MOI) and haploinsufficiency/triplosensitivity scores, presenting valuable clinical insights in a tabular view. The tool includes sorting capability for CNVs based on specific annotations (e.g. size, MOI) and dynamic link-outs to important public CNVs databases, further simplifying the prioritization and interpretation of potentially significant findings.
Our molecular geneticists have successfully utilized CNVviewer in our routine clinical practice for over 15 months. Our results demonstrate that CNVviewer is a versatile and comprehensive tool that can facilitate the identification of various CNVs at different resolutions, including intragenic exon-level duplications/deletions, focal gene-level alterations, and chromosome arm-level changes. Furthermore, we were able to use CNVviewer to review and in silico confirmed CNVs as small as 1.8kb in a WGS trio case and a 2-exon deletion in a targeted sequencing panel. We prove CNVviewer's strong capabilities in improving clinical yield and enhancing operational efficiency through diverse case studies in a clinical diagnostic setting.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3180 Comparative medical genetics to facilitate the interpretation of rare missense variation

Authors:

B. Haque[1,2], G. Guirguis[2], M. Curtis[1], H. Mohsin[2,3], S. Walker[4,5], M. Morrow[6], G. Costain[1,2,7,8]; [1]Genetics and Genome Biology, SickKids Res. Inst., Toronto, ON, Canada, [2]Dept. of Molecular Genetics, Univ. of Toronto, Toronto, ON, Canada, [3]NeuroSci. and Mental Hlth., SickKids Res. Inst., Toronto, ON, Canada, [4]Genomics England, London, United Kingdom, [5]The Ctr. for Applied Genomics, The Hosp. for Sick Children, Toronto, ON, Canada, [6]GeneDx, Gaithersburg, MD, [7]Div. of Clinical and Metabolic Genetics, The Hosp. for Sick Children, Toronto, ON, Canada, [8]Dept. of Paediatrics, Univ. of Toronto, Toronto, ON, Canada

Background: Interpreting rare missense variants is a major challenge in human genetics. Existing in silico prediction tools often consider evolutionary conservation of a residue. However, the correlation between disease associations of specific variants across species is not well characterized. We hypothesized that for variants causing Mendelian disease in non-human livestock and domestic species, the orthologous variant would be similarly functionally significant in humans.Methods: We extracted missense variants from the Online Mendelian Inheritance in Animals (OMIA) database that were classified as likely causal for Mendelian phenotypes in one of nine species (cat, cattle, chicken, dog, goat, horse, pig, rabbit, sheep). We mapped the genomic coordinates to the human reference genome (GRCh38) using UCSC's LiftOver tool, and manually inspected each genomic region in the UCSC human genome browser to confirm that the reference and alternate amino acid residues were conserved. To assess clinical classifications in humans, we cross-referenced these variants with publicly available genetic databases, and from a large private commercial genetic laboratory database of genomic testing results from >400,000 individuals with suspected rare Mendelian disorders and their family members. Results: Of the 339 variants from the OMIA database were mappable to the human genome and impacted conserved residues, 57 had been previously seen in humans and classified with respect to pathogenicity: 32 (56.1%) as pathogenic/likely pathogenic, 24 (42.1%) as variants of uncertain significance, and 1 (1.8%) as benign/likely benign. The odds ratio for these variants having a pathogenic or likely pathogenic classification in ClinVar was 6.45 (95% CI, 3.81-10.94, $p<0.0001$), compared to all other germline missense variants in these same genes. Overall, 338 of the 339 variants were very rare in humans (minor allele frequency <0.001 in gnomAD). Most variants (n=228; 67.3%) had REVEL scores ≥0.644 (supporting evidence for pathogenicity) and only 13.6% variants had REVEL scores ≤0.290 (supporting evidence for benignness). Conclusion: Cross-species comparisons could facilitate the interpretation of rare missense variation. These results provide further support for comparative medical genomics approaches that connect big genomic data initiatives in human medicine and veterinary contexts.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3181 Comparison of Cytoscan Xon array with other existing molecular methods for detecting exonic copy number variants.

Authors:

Y. Kim[1], J-S. Lee[2], M. Kim[1], M-W. Seong[3]; [1]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of, [2]Jee-Soo Lee, Seoul, Korea, Republic of, [3]Seoul Natl. Univ Hosp, Seoul, Korea, Republic of

Background: Recently, exonic copy number variants (CNVs) could be detected through next-generation sequencing-based (NGS-based) methods and multiple ligation-dependent probe amplification (MLPA). However, there are no fully established NGS-based methods, and MLPA has a limited number of probes. Cytoscan Xon was developed to enable detection of exonic CNVs with improved resolution by adding probes for each exon. In this study, based on the exonic CNVs verified by previous molecular methods, we analyzed the results of Cytoscan Xon. Using the summarized log2ratio values from Cytoscan Xon, we investigated optimal cut-off values to determine copy number state.Methods: In total, 59 patients' blood samples were used for testing. A total of 45 clinically-relevant exonic CNVs identified in MLPA or NGS-based methods were compared by Cytoscan Xon results. The copy ratio for each exon was determined by following two methods: 1) Xon region copy number-state (Xon Region CNS) data provided by Chromosome Analysis Suite (ChAS) software, 2) Summarized Log2ratio data, assigned to each region. In case of the latter, receiver operating characteristic (ROC) curve analysis was performed to assess the optimal cut-off value of Summarized Log2ratio for CNVs detection using MedCalc software v.22.3. Results: Compared to the MLPA and NGS-based methods, Xon Region CNS in ChAS yielded concordant results in 41 out of 45 (91.1%) samples. The Summarized Log2ratio, based on cut-offs of >0.427 for gain and <-0.351 for loss, yielded concordance results in 42 (93.3%) samples. There were a total of 4 discrepancies, 2 of which were single-exon level CNVs. For single-exon level CNVs, two out of 21 cases showed discrepant results. The remaining two other discrepant results were multiple exonic CNVs, including two independent exonic CNVs. In the Xon Region CNS data, these were considered single exonic CNVs. Conclusion: The Cytoscan Xon results showed relatively good concordance with MLPA and NGS-based methods. In addition, we demonstrated that higher concordance rate can be achieved by adjusting the cut-off value of the Summarized Log2ratio. However, it should be noted that there are some challenges for Cytoscan Xon to be utilized in clinical diagnosis like accurate identification of single-exon level CNVs or multiple adjacent exonic CNVs.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3182 Comparison of two DNA library preparation methods for mitochondrial DNA sequencing

Authors:

Y. Seo[1], **K. Ryu**[1], Y. Park[1], M. Kim[1], S. Cho[1], H. Lee[2], J-S. Lee[1], M. Kim[1], M-W. Seong[1]; [1]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of, [2]Chosun Univ. Hosp., Gwangju, Korea, Republic of

Background: Long-range PCR is widely used for preparation of mitochondrial DNA (mtDNA) libraries, which uses two pairs of mtDNA-specific primers, enabling Next-Generation Sequencing (NGS) with a small amount of mtDNA. We performed the probe capture enrichment for library preparation for whole exome and mtDNA and compared the NGS results with the conventional methods. **Methods**: DNA samples from thirteen patients with negative or positive results of long-range PCR based mtDNA sequencing performed by Illumina MiSeq and three patients with large deletion of mtDNA detected by multiplex ligation-dependent probe amplification (MLPA) were included. Library preparation was performed using a custom 1:100 mixture of Agilent SureSelect Human All Exon v8 and probes for mtDNA, and NGS was performed by Illumina Nova Seq 6000. Variant calling was done by Nextgene V2.4.0.1 and only single nucleotide variants (SNVs) were included, and variants from known artifact-prone sites, with a common low heteroplasmy flag sign, and with no passing filters were excluded, referring to gnomAD v.3.1.2 and Mitomap. Structural variants (SVs) were confirmed by Integrative Genomics Viewer (IGV). An allele frequency between 10% and 95% was considered heteroplasmy, while a frequency greater than 95% was considered homoplasmy. **Results:** In terms of SNV, total of 249 variants including 12 variants classified as variant of unknown significance, likely pathogenic, or pathogenic by the conventional method were detected, and 214 SNVs (86.0%) were detected concordantly, 20 (8.0%) were detected only in long-range PCR based NGS, and 15 (6.0%) were detected only in capture-based NGS. Among concordantly detected 214 SNVs, in respective of qualitative detection of homoplasmy/heteroplasmy, the agreement of the two methods was 99.1% (212/214). Conventional mtDNA sequencing identified 207 SNVs are homoplasmy, two of which were identified as heteroplasmy (allele frequency: 94.19% and 89.36%, respectively) in the capture-based mtDNA sequencing. In the Bland-Altman analysis, the mean bias was 0.20(%) and limit of agreement was [-10.0(%), 9.5(%)]. As for SV, capture-based NGS detected all known large deletion of mtDNA in three patients. The heteroplasmic levels detected through capture-based NGS were within the range of results determined by MLPA ratios in two of the three patients. **Conclusion**: Preparation of mtDNA libraries using the probe capture enrichment produces similar results with long-range PCR based NGS and more detailed information than MLPA. Capture-based mtDNA sequencing might be more beneficial because it has less risk for allele dropout and also enables simultaneous exome sequencing.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3183 Comprehensive variant analysis in clinical samples by cost effective whole genome sequencing.

Authors:

S. Pollock[1], P. Winer[1], D. Bogumil[1], T. Biniashvili[1], D. Shem-Tov[1], I. Soifer[1], S. Hussey[2], G. Krautz-Peterson[2], A. Kaplun[2], O. Barad[1], D. Lipson[1]; [1]Ultima Genomics, Newark, CA, [2]Variantyx Inc., Framingham, MA

We present a comprehensive clinical variant analysis study using the low-cost Ultima Genomics UG100 platform on a meticulously selected cohort of samples aimed at representing common pathogenic clinical variants. The dataset included 61 samples with annotated pathogenic variants, comprising of 18 cell-lines with clinical annotation and 45 patient saliva samples. We generated WGS data at an average coverage of 50X from these samples, with alignment percentage in the range of 62.2-99.9 due to microbiome contamination in the saliva samples. The primary objective of our study was to assess the recall on this clinical variant dataset. We achieved a detection rate of 100% for 32 expected pathogenic single nucleotide variants (SNVs), which included 20 SNPs and 12 indels of lengths 1-6 in genes such as MME, SYNE1, GALNS, PKHD1, OPA1. Additionally, we identified an average of 4.2 rare (population AF less than 0.01) candidate ClinVar pathogenic variants per sample (using the Ensembl Variant Effect Predictor on GENCODE v43 CDSs), demonstrating a low rate of false positives. Leveraging an optimized version of cn.mops we successfully detected all 20 expected pathogenic copy number variants (CNVs), encompassing 16 CNVs of length 134Kbs to 22.68Mbs and 4 CNVs spanning entire chromosomes (Trisomy 21, XXYY syndrome, XYY syndrome, and 90% mosaicism for Monosomy X). We additionally examined 5 pathogenic structural variations (SVs), including 2 inversions and 3 Alu insertions, and 14 cases with pathogenic short tandem repeat expansions (STRs). All 5 expected SVs were identified using GRIDSS and STRs were evident in the data through manual inspection, though optimized tools for classification of STR expansions samples and optimization of the SV detection in UG100 data are still currently in active development. By enabling variant detection across the entire genome, WGS allows for a more comprehensive understanding of an individual's genetic profile, offering valuable information for personalized healthcare. Cost-effective sequencing further enables WGS accessibility in clinical settings, enabling healthcare providers to harness the power of genomic information for improved disease diagnosis, treatment selection, and monitoring.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3184 D-2-hydroxyglutaric aciduria with enchondromatosis, severe vascular lesions and multiple cancers/growths,

Authors:

C-H. Tsai[1], c. hollas[2]; [1]Univ. of Illinois Chicago, Chicago, IL, [2]Univ. of oklahoma, Oklahoma city, OK

D-2-hydroxyglutaric aciduria (D2HA) with enchondromatosis is a disorder characterized by developmental delay, epilepsy, hypotonia, dysmorphic features, and multiple benign masses of hyaline cartilage in the medulla of metaphyseal bone. IDH1, IDH2 (mosaic) and D2HGDH gene changes are strongly associated with this condition. We report an 8-year-old male ascertained at 1 year of age with D2HA and enchondromatosis, unilateral cataract, hyper-hypo pigmented, segmental whorls and streaks on his abdomen which evolved into angiokeratoma circumscriptum. He was diagnosed with AML at age 3, relapsed at age 5 and received a hematopoietic stem cell transplantation. At 6 years of age, he was found to have more than 100 polyps from stomach to rectum. The skin lesions worsened over time and developed a tree bark like verrucous hemangioma. He is short (32 inch, 0%tile) with disproportionally large hands. WES on buccal smear revealed mosaic VUS in CREBBP3 p.V2109M (14.9% of 207 reads), and a VUS p.Y58C in IGF1R. No pathogenic variants were found in IDH1/2, D2HGDH, or SLC25A1 genes. Previous WES of Blood and skin sample showed a 7-10 % mosaic pathogenic R132C variant in the IDH1 gene. Pathogenic variants of the isocitrate-dehydrogenase (IDH) enzymes are one of the central research topics regarding gliomagenesis and tumorigenesis. Our patient has a very high level of 2-HG and D-2-HG, which promotes the cell cycle in cartilage bone marrow, skin, vessel, intestinal mucosa and face. This child has been published twice: Preston et al., 2019 and Srinivasan et al., 2020; there are lessons to learn. Review of 12 cases showed that our patient has the most severe cancers/growths. His CREBBP3 variant is mosaic, which could be related to the early mosaic skin pattern or could also be due to AML relapse (known strong association). The IGF1R variant may contribute to his extremely small size and the unique vascular malformations: angiokeratoma circumscriptum (AC) vs Verrucous hemangioma (VH**).** IGF1R enhances in situ endothelium regeneration. With a regeneration defect during rapid endothelial proliferation from the stimulation by D2HA, we hypothesize the vascular lesion may die/program death and appear as angiokeratoma circumscriptum instead of classic Maffucci type of hemangioma**.** VH and AC can only be distinguished histologically: in AC the vascular alterations are limited to the papillary dermis, VH extends deep into the dermis. Our patient has dermal involvement over the years which suggests the two conditions be a continuum.

PB3185 *De Novo* Germline Loss of the Distal End of the P-Arm of Chromosome 17 in an Individual with Intellectual Disability

Authors:

D. Sant, E. E. Pope, M. H. Huertas, A. A. Paul, B. R. Cunningham, M. R. Jennings, R. A. Perry, S. N. Chavez, J. A. Kriak, K. B. Bills; Noorda Coll. of Osteopathic Medic, Provo, UT

Purpose: In this report we present a case of a 20-year-old female with congenital intellectual disability, stunted growth, and hypothyroidism. Competitive genetic hybridization (CHG) revealed a loss of a portion of 17p13.3 at least 195 Kb in size, and the deletion was not present in either parent. This deletion has not previously been characterized, but mutations on the p-arm of chromosome 17 are responsible for Miller-Dieker Syndrome and Isolated Lissencephaly Sequence, both of which share symptoms in common with the patient.
Methods: Peripheral mononuclear cells (PBMCs) were used for karyotyping and competitive genetic hybridization (CGH) at Baylor College of Medicine. Further bioinformatic analysis was carried out using the Genome Data Viewer (ncbi.nlm.nih.gov/genome/gdv).
Results: Karyotype was found to be normal, but CGH revealed a deletion of the tail end of the p-arm of chromosome 17, 17p13.3. At least 134 genes are present in this genomic location, 35 of which are uncharacterized. Both Miller-Dieker Syndrome (MDS) and Isolated Lissencephaly Sequence (ILS) are characterized by a smooth cerebral cortex and intellectual disability, but the patient's symptoms more closely mirror MDS because muscle tone was normal. The patient was significantly shorter than peers, but growth hormone therapy over the course of several years allowed the patient to reach a normal height, albeit shorter than her siblings and parents. Genes in the deleted region that are possibly related to the condition include *HIC1, PAFAH1B1, YWHAE, DPH1, CCDC92B, RAP1GAP2, TAX1BP1,* and *SMG6*. Further work is needed to determine if one or more of these genes is likely contributing to the phenotype. Additionally, qPCR will be used to confirm deletion of genes determined to be of interest.
Conclusions: Here we present a patient with intellectual disability and a previously uncharacterized deletion on chromosome 17. Similar, though not identical conditions have been previously reported, but not well characterized indicating that the present patient could possibly have one of these conditions. Further directions include investigation of the deleted genes to determine a probable cause for the symptoms exhibited.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3186 † Deciphering Developmental Disorders in Central African setting (DDD-Africa): clinical characterization and molecular study

Authors:

G. Mubungu[1], P. Makay[2], D. Tshika[1], N. Louw[3], N. Carstens[3], H. V. Firth[4], M. E. Hurles[5], A. Krause[6], Z. Lombard[7], P. Lukusa[1], A. Lumaka[1,8]; [1]Université de Kinshasa, Kinhasa, Congo, Democratic Republic of the, [2]Université de Kinshasa, Kinshasa, Congo, Democratic Republic of the, [3]Univ. of the Witwatersrand, Johannesburg, South Africa, [4]Cambridge Univ. Hosp. NHS Fndn. Trust, Cambridge, United Kingdom, [5]Wellcome Sanger Inst., Cambridge, United Kingdom, [6]Div. of Human Genetics, Wits/NHLS, Johannesburg, South Africa, [7]Natl. Hlth.Lab. Service, Johannesburg, South Africa, [8]Service de Génétique Humaine, CHU de Liège, Liège, Belgium

Developmental Disorders (DD) affect about 1-3% of children globally. Clinical and genetic data related to DD in Central Africa are scarce. Given the broad genetic diversity in Africa and the fact that this continent has been understudied, we anticipate that the study of DD in Africa might yield novel insights.The aim was to recruit and characterize 150 families clinically and genetically with at least 1 individual presenting unexplained DD in DR Congo, as part of the DDD-Africa project. Patients were recruited through the collaborative network of the Centre for Human Genetics of the University of Kinshasa. A total of 149 probands were recruited, including 97 males and 52 females, recruited as Trio (n=79), Duo (n=56), Extended Duo (n=9), and Extended Trio (n=5). The mean age was 7.84±5.84 years (range 0-38.6). We excluded patients with clinically recognizable syndromes or strong suspicion of acquired causes. The clinical phenotype was determined and whole exome sequencing performed. Clinical information was deposited in Decipher using HPO terms. 130 cases (87.2%) were sporadic and 19 (12.8%) familial. In familial cases, autosomal recessive and X-linked inheritance were suspected in six cases each, autosomal dominant inheritance seven cases. This well-phenotyped cohort of 149 families with DD patients illustrates the very broad DD phenotype in patients from Central Africa. The molecular analysis of the first 68 families returned a definite diagnostic, likely pathogenic or pathogenic, in 32,4% (22 patients). Out of the 22 patients, the inheritance dominant de novo was in 36%. Many diagnosed patients represent the first to be reported with these syndromes in this community such as KBG syndrome, Stickler syndrome, GRIN2B-related neurodevelopmental disorder, Phelan-McDermid syndrome, Wolf Hirschhorn syndrome, Schinzel-Giedion midface retraction syndrome, Kaufman oculocerebrofacial syndrome, Pontocerebellar hypoplasia, type 1D, Intellectual disability and overgrowth, PPP2R5C-related, Kabuki syndrome, Myoclonic-atonic epilepsy/Developmental disorder, SLC6A1-related, Rett syndrome.

PB3187 Deletion *16P12.2* and small supernumerary marker chromosome (sSMC19) detected by array CGH in an adult patient with Goldenhar Syndrome.

Authors:

b. dikmen, B. Zhang, A. Iqbal; Univ. of rochester, rochester, NY

Goldenhar Syndrome (GS), also known as -Oculo auriculo vertebral spectrum (OAVS)- is a rare congenital condition characterized by impaired development of ears, eyes, nose, palate, lip, mandible and maxilla. Etiopathogenesis is multifactorial and dependent on genetic and environmental factors. The *16P12.2* recurrent deletion is inherited in an autosomal dominant manner from a carrier parent in most cases. It is linked to clinical manifestations that are frequently seen in probands, including developmental delay, speech delay, cognitive impairment, epilepsy, cardiac/skeletal malformations, and psychiatric and/or behavioral issues. The incidence of supernumerary marker chromosome (SMC) in newborn infants is about 0.044%. It generally presents in mosaic form. The patient, 31-year-old male, diagnosed with GS as an infant, has acute gastric volvulus, thrombocytopenia, splenomegaly, testicular cancer, systemic lupus erythematosus, cough, anxiety, chronic kidney disease, long term use of plaquenil, latent hypermetropia of both eyes, amblyopia in left eye, heart defect, bicuspid valve, pericarditis, long term use of immunosuppressant medication. On clinical examination, facial asymmetry is present with the right being more dominant than the left, down slanting palpebral fissures and microtia on left side, and surgically repaired cleft palate. In his upper extremity, he was noted to have left radial anomaly with short forearm and absent thumb. Chromosome microarray analysis (CMA) (4x180K CGH+SNP, Agilent technologies, USA), revealed 471kb loss at *16P12.2* from 21959891 to 22430592 base pairs and a mosaic 7.3 Mb gain at centromeric *19P12-Q12* from 22470583 to 29795821 base pairs. Interphase and metaphase FISH with dual color probe RP11-359H18 (*19P12*) and RP11-714C4 (*19Q11*) probes confirmed sSMC19 as a small ring chromosome. The level of mosaicism is approximately 80%. Genes of interest in these regions: *16P12.2: UQCRC2, EEF2K, POLR3E, CDR2. 19P12Q12: ZNF98, ZNF99, ZNF91, ZNF254, UQCRFS1.* Although many chromosomal abnormalities associated with GS have been defined, there are no specific genetic tests for diagnosis of GS. To the best of our knowledge, this is the first case report of an adult patient with GS who has *16P12.2* deletion and sSMC19. It can be challenging for clinicians to identify GS as it has a large variety of abnormalities and different severity of symptoms. This case underscores the importance of performing CMA in GS for genetic counseling and patient management.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3188 Detecting chromosomal aberrations with high sensitivity using an experimental model for mosaic copy number variation.

Authors:

J. McGirr[1], B. Bolstad[1], L. Wu[2], V. Huynh[2], S. Baral[2], N. Vegesna[2], D. Black[2], J. Wallace[2], A. Roter[1]; [1]Thermo Fisher Scientific, Emeryville, CA, [2]Thermo Fisher Scientific, Santa Clara, CA

Mosaicism is defined as the presence of two or more genetically distinct cell lineages within an individual derived from a single zygote. Post-zygotic mutations altering chromosome number or structure result in mosaic copy number variation. This type of mosaicism typically occurs due to errors in segregation during anaphase, causing the gain or loss of entire chromosomes, and non-allelic homologous recombination, which causes the loss, gain, or rearrangement of smaller genomic regions. Mosaic copy number variants have been implicated in a wide range of clinical phenotypes, including cancer, neurodegeneration, monogenic disease, and birth defects. Microarrays are routinely used to detect chromosomal aberrations and can also determine the relative abundance of an aberration that is present in a mosaic sample. However, it is challenging to detect the gain or loss of a small copy number variant in a mosaic sample, especially when it is present in only a small fraction of the total cell population sampled. We generated an experimental model for mosaic copy number variation by mixing genomic DNA from three pairs of cell-line samples, each harboring two known autosomal chromosome aberrations between 1.47 and 71.25 megabases. Sample pairs were titrated such that each mixture contained a copy number gain and a loss on different chromosomes at frequencies ranging from 15% to 85% of the total sample. These simulated mosaic samples were analyzed using the CytoScan HD Accel microarray to test whether structural variants as small as 1.47 MB could be detected in a sample mixture at a mosaic frequency as low as 15%. For each sample, probeset signal intensities were compared with a fixed set of reference intensities to calculate a log2 ratio. ROC curves showed that Smooth Signal (a probeset level metric resulting from a kernel smooth over a window of genomically contiguous log2 ratios) could reliably discriminate between integer copy number states at mosaic frequencies between 15% and 85% (AUC range 0.96-1.00). Furthermore, the Mosaic Segmentation Algorithm implemented in the Chromosome Analysis Suite software package correctly identified mosaic segments present between 15% and 30% with 95.8% sensitivity. This research provides a framework for using titration experiments to evaluate the sensitivity of automated detection of mosaic copy number variation. The CytoScan HD Accel microarray detected small structural variants (< 1.5 MB) at a low mosaic frequency (15%) with high sensitivity.

PB3189 Detection of *CFTR* polyT/polyTG variations by an NGS-based method

Authors:

Q. Zeng[1], Y. Cao[2], N. Russell[1], J. Smith[1], P. Okamoto[1], S. Letovsky[1], H. Zhu[1], N. Leach[1], A. Kenyon[1]; [1]Labcorp, Westborough, MA, [2]Labcorp, San Diego, CA

Pathogenic variants in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene have significant impact on the structure and functions of CFTR, resulting in cystic fibrosis (CF) and a range of other conditions. *CFTR* is one of the most studied human genes with many well characterized variants. Most of these variants can be detected with high accuracy by Next Generation Sequencing (NGS) technologies.
However, detecting variation in the *CFTR* polyTG/polyT tract is challenging for an off-the-shelf NGS method. PolyTG/polyT tract is located in the *CFTR* intronic region just six bases upstream of exon 10 and contains a string of TG-repeats followed by a polyT tract with (TG)11(T)7 being the most commonly observed. Shorter polyT tracts (5T or less) have been linked to reduced levels of *CFTR* mRNA and protein, which can potentially lead to *CFTR*-related disorders. Also, polyT status is of special consideration for R117H variant, where the polyT size and phase affect its clinical consequence. Because the lengths of polyTG and polyT tracts can vary between the two alleles, this region presents challenges in aligning and interpreting NGS data. In fact, variants in this region account for over 70% of all difficult pathogenic or likely pathogenic variants among the low-complexity regions in the human genome.
We have developed a computational strategy with a digital read-out for detecting variants in the *CFTR* polyTG/polyT region. Specifically, we generated simulated samples for over 13,000 different polyT and polyTG combinations and analyzed them in our bioinformatics pipeline to construct a comprehensive look-up table containing variant fingerprint profiles. The profiles were then used to match variant profiles in clinical specimens to determine the lengths of polyT and polyTG in each sample. The accuracy of our approach was confirmed by Sanger sequencing, which is generally considered the gold standard for variant detection but because it utilizes an analog signal, can be time-consuming and challenging to disentangle two alleles with varying polyTG/polyT lengths. Application of our NGS-based method to the analysis of polyTG/polyT regions in clinical samples not only offers an accurate and high-throughput solution, but also provides valuable insights into their patterns in the general population.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3190 Detection of putative dilated cardiomyopathy causing germline variants and DNA methylation by Nanopore sequencing

Authors:

Y-Y. Wang[1,2], S-H. Chen[1], D. Badescu[1], S. Oikonomopoulos[1], N. Giannetti[3], G. Thanassoulis[3], J. Engert, C.[4,3], R. Jiannis[1]; [1]McGill Genome Ctr., Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, [2]Kyoto-McGill Intl. Collaborative Program in Genomic Med., Kyoto, Japan, [3]Preventive and Genomic Cardiology, McGill Univ. Hlth.Ctr. and Res. Inst., Montreal, QC, Canada, [4]Dept. of Human Genetics and Div. of Experimental Med., McGill Univ., Montreal, QC, Canada

Dilated cardiomyopathy (DCM) is a disease of the heart muscle that is not due to an ischemic cause, valvular disease, or coronary artery disease. The inherited forms of DCM are most commonly autosomal dominant. Previous studies have reported causative mutations in more than 40 genes, including genes encoding structural components of the sarcomere and desmosome. Ten DCM patients had previously been subjected to genetic diagnosis by sequencing, but in only one of them was a causal variant identified. We produced Nanopore sequencing data and Illumina WGS data from the patients (nine with undetermined etiology based on the sequencing panel, and one control) and their relatives. We built a Nanopore analysis pipeline to investigate small variants, structural variants, and DNA methylation patterns at the haplotype level. Nanopore sequencing data was able to detect over 94% of SNPs called by Illumina WGS data. The known pathogenic variant (rs727505319 in TTN) in the control case was identified with Nanopore data alone, while likely-pathogenic variants (rs926741242 in TTN and rs727502851 in LAMA2) were identified in two additional cases by Nanopore data and Illumina WGS data independently. A 4.4Kb deletion across multiple exons in TTN could only be identified by Nanopore. Moreover, by phasing variants using the Nanopore data, the variants rs727505319 and rs926741242 in TTN were confirmed to be inherited from their affected parents. In addition, we observed different methylation patterns between haplotypes around DCM-associated genes and a deletion that may induce hypomethylation and confirmed their inheritance. Thus, Nanopore sequencing was successful in identifying and phasing haplotypes for both small and large variants, determining the methylation status of CpG islands, and integrating this information into haplotypes, with no need for additional methylation sequencing experiments. As a result, we have identified candidate mutations in TTN and LAMA2, as well as identified inherited, potentially deleterious variants in genes not associated with DCM so far.

PB3191 Detection of Trinucleotide Repeat Expansions and Uniparental Disomy by Whole Genome Sequencing.

Authors:

M. Hammer, B. Cao, D. Averbuj, M. Wright, M. Tokita, K. Watkins, K. Kelly, Y. Kwon, L. Guidugli; Rady Children's Inst. for Genomic Med., San Diego, CA

Background To diagnose genetic diseases accurately and promptly, it is critical to clinically validate a comprehensive rapid genomic testing with optimized diagnostic yield. A subgroup of genetic disease affecting the NICU population is composed by trinucleotide repeat expansion (TRE) disorders and imprinting disorders due to uniparental disomy (UPD). Trinucleotide repeat expansion (TRE) disorders are caused by an increase in the number of trinucleotide repeats exceeding the normal, stable threshold. These include Myotonic Dystrophy 1 (DM1) due to TRE in *DMPK* gene and Congenital Central Hypoventilation Syndrome (CCHS) caused by TRE in *PHOX2B*. Both diseases manifest severely at birth in presence of full penetrance, neonatal onset-associated repeat expansions. On the other end, imprinting disorders due to UPD manifest when both homologous chromosomes are inherited from one parent, with lack of contribution from the other parent and the affected chromosomes include clinically relevant imprinted genes.
Objective To develop and validate an accurate TRE and UPD analysis workflow to integrate into a comprehensive rapid whole genome sequencing (WGS) for improving clinical diagnostic yield in the NICU.
Methods TRE calling for *DMPK* and *PHOX2B* was performed via Expansion Hunter (EH) v4.0.2 (Illumina) on DRAGEN v3.10.4 (Illumina). UPD events were detected using an in-house developed algorithm. Concordance with external orthogonal assay, sensitivity, specificity, and precision were assessed, and a reporting workflow was established accordingly.
Results TRE Detection: 100% concordance with results generated by previous orthogonal methods. There was 100% agreement of all expected genotypes from all samples tested as assessed in the accuracy, precision, and reproducibility studies. UPD Detection: 100% concordance with results generated by previous orthogonal methods when the UPD algorithms were not restricted to identify UPD within the critical regions, rather expanded to call any region of UPD within the whole clinically relevant imprinted chromosome (chr 6, 7, 11, 14, 15, 20). For samples with more than one replicate tested, all replicates were concordant. Due to the lack of a reference gold standard with hetero and isodisomy details and the restrictions of UPD algorithms-based detection, the validated method has some limitations.
Conclusion The addition of TRE and UPD on rapid WGS testing is expected to increase diagnostic yield and possibly lead to a more precise appreciation of the prevalence of such disorders in the neonatal population. Additional prospective work will further enhance the detection of TRE and UPD on WGS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3192 Development of a rapid genotyping method for screening of RNF213 p.Arg4810Lys variant in patients with intracranial artery stenosis (ICAS).

Authors:

P-s. Lai, G. Tan, C. P. Liu, M. B. J. Ng, L. L. L. Yeo, V. K. Sharma, B. Y. Q. Tan; Natl. Univ. of Singapore, Singapore, Singapore

The ring finger 213 gene (*RNF213*; NM_001256071.2) encodes a 591kDa cytosolic E3 ubiquitin ligase with RING finger and AAA+ ATPase domains. It has been identified as the major susceptibility gene for Moyamoya disease in East Asian populations. More recently, it has been reported to be linked to other vascular diseases including intracranial artery stenosis (ICAS). ICAS is the most common cause of ischemic stroke in Asia, and has a much higher prevalence in Asian compared to Caucasian populations. In several Asian cohorts, patients with ischemic stroke secondary to ICAS have been observed to carry the *RNF213* p.Arg4810Lys (c.14429G>A, rs112735431) variant. Presence of this rare variant has been reported to be associated with recurrent cerebrovascular events in ICAS patients. About 1-2% of healthy individuals in some East Asian populations have been reported to carry this variant. Therefore, a rapid and cheap genotyping method to screen for *RNF213* p.R4810K would be clinically useful for investigating the association of this variant with ICAS. In this case-control study, we developed a simple one-step tetra-ARMS assay to screen *RNF213* p.Arg4810Lys in a cohort of 100 symptomatic ICAS patients prospectively recruited from a tertiary stroke centre in Singapore. ICAS patients were diagnosed using neurovascular imaging with either computed tomography angiogram or magnetic resonance angiogram of the brain and had involvement of either the terminal internal carotid artery or middle cerebral artery with at least moderate severity (>50% stenosis). Genotyping of *RNF213* p.Arg4810Lys (c.14429G>A) showed 3 patients carrying this variant (3%), while a control cohort of 100 healthy individuals were homozygous for the wild-type G allele. The results were confirmed using both RFLP and sequencing assays. We demonstrate the involvement of *RNF213* p.Arg4810Lys in ICAS patients in Singapore. Further large scale studies to investigate ethnic variations can be performed using similar assays targeted towards other *RNF213* variants.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3193 † Development of a region specific enrichment and long read sequencing strategy to phase de novo mutations in human genetic disease.

Authors:

J. Graham, J. Pitsch, M. Breuss; Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Next-generation sequencing (NGS) panels have greatly accelerated the detection of disease causing de novo mutations (DNMs) in prenatal and pediatric cases. Clinically, the term de novo is applied when the causal variant is not detected in the peripheral blood or saliva of either parent. However, recent research has shown that recurrence of a specific mutation in subsequent pregnancies is possible depending on the method of inheritance of the variant. The parent of origin of a DNM modifies its recurrence risk, and known paternal variants can be directly assessed in sperm for accurate recurrence risk detection. As a result, there is clinical benefit in performing haplotype phasing of DNMs to understand which parent transmitted the variant. This is done by identifying informative single nucleotide polymorphisms (iSNPs) near the mutation that are present in the proband as well as either parent. Once iSNPs have been identified on the same allele as the DNM, the haplotype can be phased to the parent of origin. Previously, this has required costly whole genome sequencing for iSNP identification and in most cases, short read NGS is unable to capture a DNM and iSNPs within one read to resolve the haplotype. To overcome this challenge, we combine nanopore long-read sequencing with a protocol for region specific enrichment (RSE) of the DNM to increase our target sequencing depth and ability to detect iSNPs directly without generating unnecessary genomic data. To develop our protocol, we tested two RSE approaches: biotinylated 120 base pair capture probes and a biotinylated, enzymatically dead Cas9 (dCas9). Both protocols then rely on binding to streptavidin magnetic beads for isolation of the target sequence. Recovered fragments are subjected to whole genome amplification prior to determination of fold enrichment (FE) by qPCR analysis. Enriched DNA fragments are then sequenced on the Oxford Nanopore MinIon. Our results have shown that the most promising approach is the use of the dCas9 protocol, as we have seen approximately 30 to 50 target FE with three different genomic targets. While the 120 bp oligos showed a similar level of target FE, the cost of these probes is significantly higher than the sgRNAs and dCas9, making it a less flexible targeted assay. Additionally, our nanopore sequencing of RSE products has revealed that we can, indeed, phase known variants of a proband sample to either parent, thus, demonstrating a proof of concept. Our future goals include employing our assay to phase human de novo mutations to provide clinicians with a better understanding of recurrence risk, determine cis or trans relationship of pathogenic variants, or determine DNM status in incomplete trios.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3194 Development of a targeted, low cost and high throughput single molecule molecular inversion probe based sequencing assay for rapid diagnosis of lysosomal storage disorders in low-middle income healthcare settings

Authors:

H. Sheth[1], A. Nair[1], C. Prabha[2], M. Joshi[3], C. Joshi[3], J. Sheth[1]; [1]FRIGE's Inst. of Human Genetics, Ahmedabad, India, [2]The Maharaja Sayajirao Univ., Vadodara, India, [3]Gujarat Biotechnology Res. Ctr., Gandhinagar, India

Lysosomal storage disorders (LSDs) are a collection of 70 monogenic disorders of lysosomal dysfunction with a combined incidence of 1:5000 in the general population. Current gold standard diagnostic strategy involves a sequential process of biochemical screening, followed by enzyme assays and gene sequencing. Due to the overlapping phenotypic features of some LSDs, the diagnostic pathway is expensive and time-consuming due to its iterative nature. Here, we describe a novel, low-cost and high-throughput targeted sequencing assay using single molecule molecular inversion probes (smMIPs) to carry out rapid genetic diagnosis of 29 common LSDs in India. 903 smMIPs were designed to target exon and exon-intron boundaries of 23 genes- *ARSA, ARSB, CLN6, GAA, GALC, GALNS, GBA, GLA, GLB1, GNPTAB, HEXA, HEXB, IDS, IDUA, NAGLU, NPC1, NPC2, PPT1, PSAP, SGSH, SLC17A5, SMPD1* and *TPP1*- using MIPgen and hg19 genome build. Pooled probes were used to generate sequencing libraries. Validation and diagnostic yield were assessed in a cohort of 49 patient samples with a known genetic diagnosis and 111 patient samples with clinical suspicion and/or biochemical diagnosis of LSD, respectively. The Illumina MiSeq platform was used for sequencing at a mean coverage of 200x. Data was analysed using a custom bioinformatics pipeline consisting of consensus calling using unique molecular barcodes. The average percentage of the coding region of the 23 genes covered by 903 smMIPs was 53.7kb (99.17%). A 98% (n=48/49) concordance was observed in the validation cohort with the discordance arising in 1 sample due to the lack of smMIP probes covering the exon 1 of the *GALNS* gene due to low sequence complexity. In the diagnostic yield cohort, 73.9% diagnostic yield (n=82/111) was observed. Crucially, 7 patients with Niemann-Pick type C and 1 patient with neuronal ceroid lipofucinosis-6 were identified, which can't be readily detected by enzyme testing. Additionally, the assay was able to detect p.L483P variant in the *GBA* gene in Gaucher disease patients with 100% accuracy. This is the most common variant observed in these patients but is currently difficult to detect by exome sequencing assays due to the presence of the pseudogene- *GBAP1*. Lastly, single and multi-exon heterozygous and homozygous CNVs were detected in 6 cases. Combined cost per sample including- reagents, sequencing on MiSeq platform and computational analysis is estimated to be US$60-85. Overall, the assay is robust in calling SNVs and CNVs together, thus obviating the need for MLPA. The proposed assay with its superior diagnostic yield and low cost makes it suitable for deployment in low-middle income healthcare settings.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3195 † Diagnosing challenging cases: Eight years of experience with the Undiagnosed Diseases Network (UDN) at Baylor College of Medicine (BCM).

Authors:

J. Rosenfeld, H. Bellen, L. S. Blieden, L. C. Burrage, H-T. Chao, I. Chinn, G. D. Clark, W. Craigen, H. Dai, B. C. Dawson, L. Emrick, C. M. Eng, S. Ketkar, F. Jamal, S. Lalani, R. Lewis, P. Liu, K. Machol, R. Marom, P. Moretti, D. Murdock, S. K. Nicholas, J. P. Orengo, J. Posey, L. Potocki, D. Scott, A. Tarakad, T. Vogel, M. Wangler, M. Weisz-Hubshman, K. Worley, S. Yamamoto, Undiagnosed Diseases Network, C. Bacino, B. H. Lee; Baylor Coll. of Med., Houston, TX

The UDN seeks diagnoses with multidisciplinary, in-depth phenotyping and innovative genetic testing technologies. Eight years of evaluations at the BCM UDN clinical site have yielded a 38% (107/284) diagnostic rate. Nearly all diagnoses are genetic (103/107), highlighting the importance of genetic testing technologies. While almost half of diagnoses were a result of newer medical genetic knowledge, including novel disease genes (23%), recently identified disease genes (9%), and phenotypic expansions for known disease genes (13%), many diagnoses were for known genetic disorders that remained undiagnosed prior to study enrollment, frequently despite extensive genetic testing. In at least two-thirds of all genetic diagnoses, disease-causing variants were detectable by exome sequencing (ES). In 15 diagnoses of a known genetic disorder, previous ES had not reported diagnostic variants that were observable in extant ES data: 40% intronic variants, 53% coding variants, and 7% a copy number variant (CNV) *in trans* with a coding variant. Analytic methods used to identify diagnostic variants from ES data include addition of parental ES and loosening of filters relating to intronic location, depth of coverage, and/or phenotype matching. CNVs (4-977kb) were part of 15 diagnoses. While some larger CNVs were detected via chromosomal microarray (CMA), many smaller CNVs were not found on CMA (due to array design) and/or ES (due to limitations and/or absence of CNV calling on clinical ES analyses). In addition to small CNVs, other diagnostic variants not detectable by ES included noncoding variants, mosaic findings, repeat expansions, and a balanced translocation. Genome sequencing (GS) is a powerful tool used to detect many of these diagnostic variants, but other technologies, including long-read sequencing and optical genome mapping, detected pathogenic variants in some cases. Regardless of the testing technology, simply identifying a genomic variant is frequently insufficient to establish a diagnosis. Additional functional evidence may be required. RNAseq has proven a useful tool: RNAseq was performed in samples from 72 subjects with genetic diagnoses and provided supporting data in 50%, including 14% in which RNAseq gave the first evidence for the diagnosis. Additional supporting data came from candidate gene-specific functional studies. Finally, particularly in cases of novel discovery, model organisms and patient matching platforms facilitated final diagnoses. Therefore, while GS can improve detection of genomic variants, challenging cases will likely continue to require additional tools to achieve diagnoses.

PB3196 Diagnostic Yield from Cardiogenomic Panel Testing for Inherited Cardiovascular Diseases

Authors:

R. Pyatt, J. Reiner, Z. Wolf, W. Xin, Z. Zhou, H. Zhu, N. Leach; Labcorp, Westborough, MA

Multiple organizations have issued practice guidelines and statements recommending genetic testing for heritable heart conditions. The American College of Medical Genetics and Genomics published a 2018 practice resource which recommended genetic testing using a 39 gene panel for patients with cardiomyopathy and at-risk relatives. The Heart Rhythm Society and European Heart Rhythm Association published a 2011 consensus statement which recommended a 9 gene panel for individuals with a suspected arrhythmic disorder. In a 2020 scientific statement on genetic testing, the American Heart Association reiterated the findings of the ClinGen Aortopathy Working Group which found definitive evidence associating 11 genes with heritable thoracic aortic aneurysms and dissections along with moderate/limited evidence for an additional 8 genes. Consequently, a retrospective analysis was conducted on the results from cardiogenomic testing in our laboratory to evaluate diagnostic yield. Panel based testing included 10 genes for aortopathy and the *MED12* c.3020A>G variant, 29 genes for arrhythmia, and 48 genes for cardiomyopathy. Disease-associated variants (Pathogenic and Likely Pathogenic) and variants of uncertain significance (VUS) were reported for all panels. Test results included 197 reportable variants across 1385 aortopathy panels, 333 variants across 596 arrhythmia panels, and 1,043 variants across 831 cardiomyopathy panels. Disease-associated variants were identified in 2% of aortopathy, 13% of arrhythmia, and 16% of cardiomyopathy panels. Only 1% of aortopathy panels identified more than one reportable variant, but significantly more of such scenarios were seen in arrhythmia (12%) and cardiomyopathy (35%) testing. One cardiomyopathy panel reported a single pathogenic *PKP2* gene variant along with seven VUS in the *DSP*, *MYH7*, *RYR2*, *SGCD*, and *TTN* genes. Only one panel had more than one disease-associated variant; a cardiomyopathy sample with a *FKTN* gene pathogenic variant and a likely pathogenic variant in the *DSP* gene. A majority of reportable variants for the aortopathy panel were identified in the *FBN1* (32%), *MYH11* (17%) and *COL3A1* (17%) genes, for the arrhythmia panel in the *KCNQ1* (13%), *SCN5A* (11%) *RYR2* (11%) and *KCNH2* (11%) genes, and for the cardiomyopathy panel in the *TTN* (37%), *ALMS1* (10%), *MYBPC3* (6%) and *MYH7* (6%) genes. Variants of uncertain significance were the most common group identified including 84% of aortopathy, 77% of arrhythmia, and 87% of cardiomyopathy reportable variants. These results reaffirm the diagnostic value of genetic testing for inherited cardiovascular diseases and illustrate challenges in result interpretation.

BACKGROUND: Next-generation sequencing (NGS) tests have become the primary diagnostic approach for rare diseases (RD) in the past decade. Common NGS approaches in clinical practice include targeted multi-gene panels (GP), exome sequencing (ES), genome sequencing (GS), and exome/genome-based panels (EGBP). While the value of NGS testing is well-established, determining the optimal implementation strategy remains debatable. Limited studies have reported on the additional diagnostic yield of reanalysis of ES and GS data in patients with unrevealing gene panels. Mayo Clinic's Program for Rare and Undiagnosed Diseases (PRaUD) offers genomic-based clinical services for RD, employing targeted GP or custom EGBP as the first-tier diagnostic strategy across various specialty divisions and departments. METHODS: ES/GS data of patients included in PRaUD was analyzed to determine if additional findings could enhance the diagnostic yield of previously performed genetic testing. The inclusion criteria consisted of patients evaluated at Mayo Clinic campuses in Minnesota, Florida, and Arizona between December 2018 and May 2023, who had non-diagnostic EGBP. RESULTS: ES data from 70 patients (53 adults, 42 females) and GS data from 13 patients (10 adults, 2 females) were analyzed. The mean age of patients is 41 years (range 3 to 81 years). Most patients were referred for suspicion of hereditary kidney disease (n=36), followed by auto-inflammatory syndromes (n=27), interstitial lung disease, and monogenic diabetes (n=10). After ES/GS data analysis, no additional relevant variants were identified in 80 cases (96.4%). In the remaining three cases (3.7%), a variant in a gene associated with a phenotype reported after the release of the original report (*RRAGD*), a variant in *COL4A3* not reported in the original panel testing, and a likely pathogenic variant in *HNF1A* related to part of patient's phenotype not targeted by the panel were found. Periodic automated re-analysis during the period flagged additional variants in 17 cases that were deemed not relevant for patient's phenotype after additional review. CONCLUSION: Based on our experience, ES and GS have similar diagnostic yield when compared to EGBP curated by a multidisciplinary team of experts. However, EGBP has limitations in identifying new gene-disease associations, which necessitates periodic updates to ensure their continued relevance.

Background & Aim: Genome sequencing (GS) may be used in the clinical context to solve diagnostic odysseys. However, GS may also be used as a screening tool or reveal secondary findings (SF) related to inherited predisposition to disease. In some cases, SF may explain a previously undiagnosed medical or family history of disease. Advancements in GS warrants exploration into how this technology may be used at scale. We aim to evaluate the diagnostic yield of GS in symptomatic adults within the general population. Methods: Adults with a prior diagnosis of COVID-19 were recruited for GS through the GENCOV study in Ontario, Canada. Medical history data was collected through an online intake survey. GS data was filtered and analyzed using frequency and database filters and variants were classified based on ACMG guidelines. Results counseling and clinical intake were initiated for participants with clinically significant findings requiring follow-up. Survey, intake and GS data were consolidated to identify those with self-reported history of disease and a pathogenic or likely pathogenic (P/LP) variant associated with personal disease risk. Results: To date, 656 genomes have been analyzed. Of these individuals, 652 (99%) responded to the intake survey. Sixty percent (n=393/652) reported at least one underlying medical issue or disease comorbidity at the time of intake (e.g. cancer, cardiac disease, diabetes, high blood pressure). Of participants reporting at least one underlying medical issue, 84 (21%) had at least one P/LP variant associated with personal disease risk(s). A P/LP variant identified by GS was consistent with a previously reported medical or family history in 21 cases for a diagnostic yield of 5%. Six participants were homozygous or compound heterozygous for variants associated with autosomal recessive or semi-dominant conditions. Thirty-eight participants indicated that they completed genetic testing prior to enrollment in the study, and 14 had a known previously diagnosed hereditary condition. Conclusion: GS identified risk for hereditary disease in 21% of adults with underlying medical issues. GS findings explained a previously reported history in 5% of cases. These findings illustrate the utility of GS to diagnose previously undiagnosed disease in the general population. Early diagnosis is crucial for reducing disease risk in the context of actionable conditions with known medical treatment, prevention, or screening, as well as solving undiagnosed symptoms in adults that may otherwise present undue costs to the healthcare system by way of unnecessary testing and treatment.

PB3199 Early use of whole exome sequencing (WES) informs lifelong medical management: case report.

Authors:

E. Dreikorn[1], C. Munro[1], N. Robin Berman[1], A. Kunovac[2], D. Bellissimo[3], M. B. Massart[1]; [1]Univ. of Pittsburgh, Dept. of Family Med., Pittsburgh, PA, [2]UPMC Genome Ctr., Pittsburgh, PA, [3]UPMC Clinical Genomics Lab., Pittsburgh, PA

Traditional medical management for patients with neurodevelopmental disorders (NDD) often involves the lengthy and expensive process of diagnostic testing, which puts immense burden on patients, their families, and the healthcare system. These barriers to diagnosis can often be overcome with the use of whole exome sequencing (WES), which provides the genetic resolution necessary to inform medical management now and throughout the patient's life. A 27-year-old patient was referred to the Primary Care Precision Medicine (PCPM) clinic with intellectual disability (ID), autism spectrum disorder (ASD), obsessive-compulsive disorder (OCD), tics, seizures, and PANDAS disorder. Previously, a microarray and single gene testing for *PTEN* were completed in 2009 and yielded no diagnostic results. The PCPM clinic ordered a WES duo, which revealed the presence of a missense SNV (c.2425-2A>G) in a splice acceptor site of the *HNRNPU* gene that was classified as pathogenic. Disruptions of *HNRNPU* can lead to HNRNPU-related NDD and developmental and epileptic encephalopathy-54 (DEE54), which suggests that this variant is causal for the patient's ID/ASD, seizure history, and encephalopathy. After WES and original diagnosis, two of the patient's physicians contacted the PCPM team with additional genetic questions. A UPMC physician requested reanalysis of WES to evaluate for hereditary hemorrhagic telangiectasia (HHT) as the patient's maternal aunt had recently been diagnosed. Reanalysis demonstrated no findings consistent with HHT and prevented the need for further diagnostic testing. Further, a UPMC hematologist contacted the PCPM team after suspecting the patient of having HFE-related hereditary hemochromatosis (HH). Indications were intermittent elevated iron levels and previous *HFE* sequencing in 2009 for HH that revealed a heterozygous missense variant in the *HFE* gene (p.C282Y), which leads to HH when the variant is homozygous. Reanalysis of the WES showed no compound heterozygous mutations that would support a full diagnosis of HH. WES is increasingly used to decrease the length of a patient's diagnostic journey for complex phenotypes; early use of WES can significantly decrease the number of tests and cost associated with identifying underlying causes for a patient's symptoms. As WES was used for the patient's initial presentation of ID/ASD, clinicians were able to reanalyze the sequencing data to inform two subsequent clinical indications for genetic data, shortening the length to diagnostic resolution. This case serves as an example of the clinical utility of WES across a patient's lifespan and the coordination of reanalysis through a primary care setting.

PB3200 Enhancement of Trophoblast purity through removal of maternal cells using CD45 and CD56 cell surface markers.

Authors:

H. Jang[1], J. Park[2], K. Kang[2], M. Go[3], H. Kim[2], S. Yang[2], J. Kim[4], S. Shim[5], D. Cha[6]; [1]CHA Univ., Seoul, Korea, Republic of, [2]CHA biotech, Seoul, Korea, Republic of, [3]CHA Univ., Seoul, Korea, Republic of, [4]CHA Biotech Inc., Seoul, Korea, Republic of, [5]Cha Univ., Seongnam, Korea, Republic of, [6]Gangnam CHA Hosp, Seoul, Korea, Republic of

Introduction Trophoblast retrieval and isolation from the cervix (TRIC) is an alternative method to non-invasively obtain fetal origin trophoblast cells that can be used for prenatal diagnosis. The most important thing in TRIC is how to remove maternal cells, mainly immune cells such as natural killer (NK) cells and white blood cells (WBC) from cervical fluid and to isolate only fetal cells. In this study, we tried to isolate fetal cells using maternal-cell-specific surface markers. **Materials and methods** The endocervical cells were collected from pregnant women between 5-20 weeks of gestational age. To remove maternal immune cells from endocervical fluid, the cells are separated using a magnet labeled with leukocyte common 45 (CD45) or leukocyte common 56 (CD56), which are maternal-cell-specific surface markers for maternal immune cells. CD45 or CD56 positive cells are removed from the endocervical fluid using a magnet. Human leukocyte antigen G (HLA-G) positive cells were separated from the supernatant from which immune cells were removed for trophoblast separation, and the HLA-G positive cells were counted. Slides are prepared to identify trophoblasts expressing CD45, CD56, HLA-G, cytokeratin 7 (CK7), and β-human chorionic gonadotropin (β-hCG) by immunofluorescence (IF). **Result** The cell counting rate(%) was compared with the expression of specific genes in trophoblast cells between with and without maternal immune cell sorting. The trophoblast cells with removed immune cells were decreased number of cells. The expression of maternal immune cell specific genes CD45 or CD56 was decreased in trophoblast cells with immune cell isolation, but the expression of trophoblast cell specific genes β-hCG and CK7 was increased. However, double gene isolation labeled CD45 and CD56 were aggregated endocervical cells and did not differ in trophoblast cells. **conclusion** In previous study, the trophoblast was detected in endocervical cells, and maternal immune cells were also identified. To isolate maternal immune cells, cells were sorted from cervical cells using maternal cell-specific markers, and the number of immune cells was reduced. Also, the trophoblast specific gene was increased in trophoblast cells with removed maternal immune cells. In conclusion, maternal immune cell isolation was suggested as a method to separate trophoblasts more purely from maternal endocervical cells.

PB3201 Enhancing Diagnostic Precision in Inherited Ocular Disorders: Insights from an iterative analytical approach.

Authors:

E. Ullah[1], B. Guan[1], A. Naik[1], C. Bender[1], R. Al Rawi[1], D. Blain[1], A. Agather[1], E. O'Heir[2], L. A. Huryn[1], W. M. Zein[3], C. A. Cukras[3], B. P. Brooks[1], A. O'Donnell-Luria[2], R. B. Hufnagel[1]; [1]Natl. Eye Inst., NIH, Bethesda, MD, [2]Ctr. for Mendelian Genomics, Broad Inst. of MIT and Harvard, Cambridge, MA, [3]Natl. Eye Inst., NIH, BETHESDA, MD

Introduction: Inherited ocular disorders are a diverse group of conditions affecting 1 in 1000 individuals worldwide, exhibiting clinical and genetic heterogeneity. These disorders can be isolated or syndromic, following any inheritance pattern. Over 500 genes have been implicated in causing these disorders. Genetic diagnosis is crucial for understanding disease mechanisms, improving patient counseling, potential therapies, and clinical trial eligibility. Current genetic testing has yielded diagnosis rates of 50-70% for inherited retinal dystrophies (IRDs) and 20-40% for developmental malformations (microphthalmia, anophthalmia, coloboma). Methods: This study used a systematic approach at the Ophthalmic Genomics Laboratory (OGL) to improve diagnostic yield in inherited ocular disorders. 479 patients underwent clinical evaluation and genetic testing on an exome/genome protocol. Gene panel-based testing with virtual Next Generation Sequencing (NGS) panels and exome-level Copy Number Variant (CNV) calling was performed. Exome data underwent re-analysis using an in-house pipeline. Unsolved cases underwent genome sequencing and analysis using the same pipeline. Results: The virtual panel-based approach identified pathogenic/likely pathogenic variants or high confidence Variants of Uncertain Significance (VOUSs) in 50% (242/479) of cases. Exome re-analysis resolved an additional ~2% of cases. Genome sequencing identified pathogenic/likely pathogenic variants or high-confidence VOUSs in 10 cases, contributing another 3% to the diagnostic yield, with around 100 cases pending genome data. ACMG secondary findings were found in ~5% of cases. Rare and damaging variants in over 30 previously unidentified genes may expand phenotypes for known disorders or establish new gene-disease relationships. Conclusion: Virtual exome-based panels are a powerful tool for diagnosing inherited ocular disorders, achieving a diagnostic yield of approximately 50%. Exome re-analysis captures additional disease-causing variants in lesser-known or new disease genes, as well as atypical variants in genes with a higher disease burden. Genome sequencing increases the diagnostic yield by identifying CNVs and deep intronic variants, primarily in known disease loci.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3202 Enhancing Fabry Disease Screening and Diagnostic Efficiency: Integration of Enzyme, LysoGb3, and Next-Generation Sequencing Testing

Authors:

Y. Pan[1], L. King[2], E. Vengoechea[2], S. Smith[1], Y. Wang[1], P. Chakraborty[1], E. Kallu[3], B. Nallamilli[1], T. Donti[1], A. Walter[2], S. Kazemi[2], M. Hegde[1]; [1]Revvity Omics, Pittsburgh, PA, [2]Sanofi, Cambridge, MA, [3]Lambert High Sch., Suwanee, GA

Fabry disease is an X-linked lysosomal storage disorder caused by a deficiency of alpha galactosidase A (α-Gal A) due to pathogenic variant in *GLA* gene. This study reports findings from Fabry disease data collected through The Lantern Project, sponsored by Sanofi, including α-Gal A enzyme assay from dried blood spots (DBS), globotriaosylsphingosine (LysoGb3) biomarker assay from DBS and next-generation sequencing (NGS). A total of 513 enzyme, 284 LysoGb3 and 994 NGS tests were conducted on 1380 individuals (708 female, 661 male, 11 sex-unknown) who participated in the project from December 2018-April 2023. Among these, 21% (103 male and 2 sex-unknown) had a low enzyme level (range 0.054-1.069 μM/h, Normal ≥ 1.10 μM/h), and 70% (79 female, 115 male and 2 sex-unknown) had a high LysoGb3 level (range 1.12-130.56 ng/mL, Normal ≤ 1.11 ng/mL). 379 cases had reportable *GLA* variants. The most frequently identified *GLA* variants in this cohort included c.427G>A (56), c.679C>T (23), c.1088G>A (19), c.593T>C (18), c.644A>G (17), and c.1087C>T (16). 76% (104/136) of the variants have only been identified in 1 or 2 cases. Novel *GLA* variants identified in this cohort included c.[351T>G;361G>C], c.370-558_370-1del, c.370G>T, c.548del, and c.1165C>T. Within 188 possibly affected female cases (with abnormal LysoGb3 or reportable *GLA* variant or both), 40% (72) are reported to have Fabry-related symptoms (excluding 9 newborn screening confirmation cases). The symptomatic rate is not age-related, as the same rate is observed for childhood, adolescent, and adult females. Among the 30 reportedly symptomatic females with normal or unknown LysoGb3 levels, 100% were identified by NGS to have reportable variants. The symptomatic rate is related to the LysoGb3 levels of female patients. 22% of the 36 female cases with normal LysoGb3 are reported to have symptoms, while 33% of the 18 cases with LysoGb3 levels between 1.15-1.96 ng/mL and over 60% of the 58 cases with LysoGb3 levels ≥2 ng/mL are reportedly symptomatic. Female cases with *GLA* pathogenic/likely pathogenic variants c.427G>A (24), c.1087C>T (11), c.644A>G (10), c.1088G>A (9), and c.593T>C (7) mostly lack symptom information. Whereas 57% (8/14) of the females with c.679C>T and 100% (3/3) with c.337T>C have reported symptoms. We present the largest-to-date comprehensive multi-testing Fabry cohort with demographic information and phenotypes from a single clinical laboratory. Our dataset provides important genotype-phenotype correlation in Fabry disease and demonstrates that the integration of enzyme, LysoGb3, and NGS testing can enhance the screening/diagnostic efficiency for Fabry disease, especially for female patients.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3203 Enhancing the power of NGS: Closing the diagnostic gap using short-read whole-exome sequencing.

Authors:

A. Haimovich[1,2], E. Javasky[1], N. Mor[1], Y. Khavkin[1], I. Bar-Joseph[1], O. Barel[3]; [1]Sheba Med. Ctr., Ramat-Gan, Israel, [2]Tel Aviv Univ., Tel Aviv-Yafo, Israel, [3]Sheba Med. Ctr., Ramat Gan, Israel

In recent years, whole exome sequencing (WES) has emerged as a groundbreaking tool for uncovering pathogenic variants and diagnosing genetic diseases. While WES has significantly enhanced our ability to provide accurate and efficient diagnoses, it does have certain limitations. One particular challenge arises when mutations occur in pseudogenes and homologous regions. These regions often pose difficulties during analysis, leading most Next-Generation Sequencing (NGS) computational tools to exclude reads with multiple alignments. Unfortunately, this exclusion can result in missed genetic diagnoses, leaving patients without proper answers. To overcome this hurdle, we have developed multiple modifications to our WES pipeline, focusing on detecting mutations in these intricate regions. By combining our understanding of these complex regions with the patients' clinical phenotype, we have successfully provided genetic diagnoses for individuals who would have otherwise received negative WES results. Notably, we have identified significant genes such as *HBA2*, *NSF*, *IKBKG*, and *CBS* using our tailored methodology. Our approach aims to surpass the limitations of standard short-read WES by ensuring the accurate detection of mutations in pseudogenes and homologous regions. By implementing these pipeline adjustments, we aspire to increase the identification of disease-causing variants, ultimately assisting clinicians in delivering precise genetic diagnoses. This novel methodology holds the potential to greatly enhance diagnostic outcomes, meeting a critical need in the field of clinical genetics, and improve patient care and outcomes.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3204 Evaluation of diagnostic utility of custom array CGH for identification of copy number variants in patients with epilepsy and epileptic encephalopathies.

Authors:

A. Kucinska[1], W. Hawuła[1], M. Piotrowicz[1], L. Przesór[1], T. Chilarska[1], L. Kępczyński[1], K. Połatyńska[2], L. Przysło[2], A. Gach[1]; [1]Dept. of Genetics, Polish Mother's Mem. Hosp.-Res. Inst., Lodz, Poland, [2]Dept. of Dev.al Neurology and Epileptology, Polish Mother's Mem. Hosp.-Res. Inst., Lodz, Poland

Epilepsy is characterised by occurrence of recurrent, unprovoked epileptic seizures. This common neurological condition affects over 70 million people worldwide, accounting for about 1% of the total population. Epileptic encephalopathies encompass severe and drug-resistant form of epilepsy associated with cognitive and neurodevelopmental disorders. Genetic etiology of epileptic syndromes is complex and heterogeneous. With the development of genetic diagnostics, an increasing number of genes associated with epilepsy are being identified. Currently, several hundreds of such genes have already been reported. The contribution of genetic factors is estimated at approximately 70% of which about 5-12% are copy number variants (CNVs). The aim of this study is to demonstrate the clinical usefulness of dedicated array Comparative Genome Hybridization (aCGH) in patients with epilepsy and epileptic encephalopathies.

The tested group included 36 pediatric patients diagnosed with epilepsy, epileptic encephalopathy or epileptic syndrome and consisted of 24 males and 12 females. Prior to recruitment, patients tested negative using commercial targeted sequencing panels. DNA was extracted from peripheral blood. Array CGH was performed using 4x180k CytoSure Custom Array (OGT; UK). This microarray has specific coverage in 264 genes with both exonic and intronic sequences of proven and probable clinical significance in epilepsy and epileptic encephalopathies.

Overall, the strategy allowed for the identification of seven non-polymorphic relevant CNVs. Three of them were classified as pathogenic and four as variant of uncertain significance (VUS). Among these reported variants were six deletion and one duplication with the size range of 9.25 kb to 1.63 Mb. Importantly, four out of six variants would not be detected by standard microarray in routine testing. One of these cases is an intragenic deletion in CPA6 gene, which was not previously reported in the available databases or described in the literature.

The cases of patients with epilepsy presented here raise the question of whether routinely used standard microarrays are sufficient to continue genetic diagnostics in patients with normal sequencing-based test results.. Our results on a relatively small group encourage to study a much larger number of patients. We should consider the need to implement more targeted methods including dedicated chromosome microarrays for more efficient diagnosis in epilepsies and epileptic encephalopathies. This diagnostic tool may allow to expand the knowledge of genetic determinants and genotype-phenotype relationships in this group of neurological disorders.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3205 Evaluation of missing disease-causing variation in autosomal recessive conditions using long-read sequencing

Authors:

K. Patterson, M. Galey, J. Goffena, University of Washington Center for Rare Disease Research, E. Eichler, M. Bamshad, J. Chong, D. Miller; Univ. of Washington, Seattle, WA

Conventional clinical genetic testing fails to provide a precise genetic diagnosis in ~50% of individuals with suspected Mendelian conditions. Individuals without a precise molecular diagnosis undergo more diagnostic tests than those with a diagnosis and are limited in their ability to participate in clinical trials or benefit from N-of-1 therapies. In individuals in which clinical testing identified only one variant in a gene associated with a suspected autosomal recessive (AR) condition, emerging technologies like long-read sequencing (LRS) can provide details about variant types that may have been missed.

We performed LRS of 23 individuals with a suspected AR condition who had either one variant (N=22) or no variants (N=1) identified after clinical evaluation. LRS identified a pathogenic (P) or likely pathogenic (LP) variant in 13/23 cases (53%), a variant of uncertain significance (VUS) in 5/23 cases (22%), and no second candidate variant in 5/23 cases (22%). Among the 18 cases with second variants classified as P/LP or VUS, we identified eight structural variants (SVs) (44% of cases), including single- and multi-exon deletions, transposable element (TE) insertions, and one large intronic deletion. Splice variants were identified in 7/18 (39%) cases, missense variants in two cases, and a promoter variant in one case.

While short-read genome sequencing (srGS) is expected to identify all splice, promoter, and missense variants identified by LRS, only 4/8 SVs would likely be detected due to inherent challenges posed by TE insertions or variant calling in repetitive genomic regions. Because it remains unclear what the next best test is after nondiagnostic clinical testing, we are performing in-silico simulations of the events to more concretely assess their detectability using srGS. Even if srGS can detect the variants found by LRS, the utility of LRS should not be underestimated as its additional benefits include better phasing of distant variants (e.g., when parental samples are unavailable or for de novo variants), the ability to more fully resolve complex SVs, simultaneous acquisition of methylation information, and higher sensitivity in complex genomic regions. These technical advantages can help increase confidence in excluding a candidate gene from consideration, evaluating pathogenicity, or in concluding that a heterozygous candidate variant is likely explanatory due to an unexpected mode of inheritance (e.g., dominant when AR inheritance is typical). Our findings suggest LRS as a potential next best test for recessive missing variant cases. Larger studies directly comparing the sensitivity and specificity of srGS and LRS are needed.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3206 Exome reanalysis in a cohort of patients with inborn errors of immunity

Authors:

E. Vorsteveld, C. van der Made, A. Simons, S. Smeekens, Radboudumc multidisciplinary immune-exome team meeting, M. Netea, A. Hoischen; Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Background/Objectives: Inborn errors of immunity (IEI) comprise a group of immune defects that display significant clinical and genetic heterogeneity. Exome sequencing has been fundamental in the understanding of these diseases and has led to a sharp increase in the number of genes associated with these disorders. The diagnostic yield of IEI remains low compared to other rare monogenic disorders. We aimed to improve the diagnostic yield of exome sequencing through a systematic reanalysis.**Methods:** We have collected exome data of 1300 patients with (suspected) IEI that were sequenced and analysed between 2013 and 2021 at the Radboud University Medical Center. We filtered for rare variants in 484 genes comprising the latest *in silico* gene panel for IEI. **Results:** Diagnostic exome sequencing provided a molecular diagnosis in 11.7% in our patient cohort. Through the systematic reanalysis of the exome data, we identified variants in genes added to the gene panel after the initial genetic analysis (n=36), or through addition of novel disease mechanisms to known IEI genes (n=4). Further diagnostic yield was attained through variant reinterpretation based on current insight (n=24), the addition of CNV analysis (n=4), diagnostic whole exome analysis (n=10) or through variant reannotation (n=1). Exome reanalysis yielded 79 additional variants in 74 patients (5.7%), leading to the diagnosis of an additional 24 patients.**Conclusion:** We have performed a systematic reanalysis of exome sequencing data from 1300 patients with IEI. We show additional disease causing variants in 5.7% of patients, increasing the diagnostic yield. There remains continued value in diagnosing individuals with rare (immune) diseases through systematic reanalysis of exome data.

PB3207 Exome sequencing from urinary epithelial cells - exploring the potential role in rare disease discovery

Authors:

K. Ounap[1,2], K. T. Oja[1,2], K. Reinson[1,2], K. Muru[1,2], T. Reimand[1,2], U. Samarina[2], S. Pajusalu[1,2]; [1]Univ. of Tartu, Inst. of Clinical Med., Tartu, Estonia, [2]Tartu Univ. Hosp., Genetic and Personalized Med. Clinic, Dept. of Clinical Genetics, Tartu, Estonia

Increasing the diagnostic rate of rare diseases (RD) is extremely important. Current clinical practice will detect the exact etiology in 30-50% of RD cases. It has been previously shown that some neurodevelopmental disorders, like *SLC35A2* defect, can be caused by somatic mosaicism in brain tissue. Moreover, among mitochondrial disorders, the heteroplasmy of the pathogenic variant is variable in tissues, and urinary epithelial cell analysis corresponds in the best way to the impairment of the brain. In this study, we hypothesized that we could increase the detection rate by performing exome sequencing (ES) from different tissues and analyzing these data together. The initial study group consisted of 116 individuals; in all of them, a reanalysis of ES data was performed using Seqr platform. Among cases that remained negative after ES reanalysis, trio/quad genome sequencing was performed in 56 families, RNA sequencing in 53 individuals, and untargeted metabolome analysis in 51 individuals. We previously identified the disease cause in 70/116 (60%) individuals. In this study, we selected 25/116 (22%) unsolved individuals with neurodevelopmental phenotypes. In all of them, a fresh urinary sample was collected, and the DNA was extracted. The amount of DNA varied extensively (14-197 ng/µl). The new ES analysis was performed, and results were analyzed in quadruple (blood and urinary from the patient and blood from both parents). In the initial quadruple ES analysis, we tagged a *de novo* gene candidate in 16 cases in the urinary sample. Most of the tagged variants were located in low-covered regions of the exome. After thorough consideration, we determined four gene candidates worth validating in a new urinary sample. However, three of these variants were not confirmed in the new sample, and in one case, validation was not possible due to the region's complexity. Post-zygotic mosaicism is one etiological cause which is very difficult to confirm in the routine diagnostic clinical setting. We assumed to specify RD diagnosis by performing ES from different tissue sources. However, we could not prove our hypothesis due to the low DNA concentration extracted from urinary epithelial cells and not persistent findings in different samples. Funding: Estonian Research Council grants PRG471 and PSG774.

PB3208 Exon-level copy number variants detected by CytoScan XON microarray in patients with genetic disorders

Authors:

c. nam, E. Seo, S. Min, B. Lee; Asan Med. Ctr., Dept. of Lab. Med., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, seoul, Korea, Republic of

Background Copy number variants (CNV) have been increasingly linked to various pathologies. Intragenic CNVs spanning one or two exons are more common in Mendelian disorders than previously thought. Although whole exome sequencing (WES), whole genome sequencing (WGS), or chromosomal microarray (CMA) can be used to detect CNVs, a confirmatory test is essential. Multiplex Ligation-dependent Probe Amplification (MLPA) is commonly used for confirmation. However, it requires a control group test and new probes need to be made for candidate genes. We performed CytoScan Xon array for 24 patients to evaluate its clinical performance. **Methods** The twenty four subjects who showed pathogenic CNV in high-resolution chromosomal microarray (CytoScan Dx) and MLPA were analyzed. The subjects had small CNVs which involved single to multiple exon deletions or duplications as follows; six *NF1* deletions, four homozygous *SMN1* deletions, three *DMD* deletions, two *H19-IGF2* duplications, gene deletions of *ANKRD11 and SPG7, COL4A3, CREBBP, GAA, MAOA and MAOB, SHANK3 and ACR, SNTG2, TSC2, VHL.* CytoScan XON array is designed to cover 21,844 genes, including 7,000 clinically relevant genes associated with genetic diseases and OMIM morbid genes. The array combines whole-genome amplified DNA with 6.85 million probes to integrate single-nucleotide polymorphism genotypes and copy number calls. We compared the results with CytoScan Dx or MLPA. **Results** The CytoScan Xon array was able to detect all chromosomal imbalances of 24 patients that were identified by CMA or MLPA. It was able to detect small CNVs as single exon deletion of *DMD* exon 44, *DMD* exon 45, and *MAOA, MAOB* 90 kb loss. Loss of heterozygosity of GAA gene in Pompe's disease was able to be detected. Especially, a muscular dystrophy case was difficult to determine *DMD* exon 51 deletion by CytoScan Dx while CytoScan Xon array clarified exon 51 deletion, as MLPA detected. **Conclusion** Our data shows that the CytoScan Xon array can detect exon level copy number variants more clearly. However, this array detected too many variants to be evaluated, as 100-300 variants per specimen. In conclusion, CytoScan XON array can serve as a complement to mutation analysis performed by WES/WGS, especially for inconclusive result or multiple gene analysis. It can be used in cases with only one heterozygous pathogenic mutation in highly suspicious autosomal recessive genes. Also, it can be used in cases with one homozygous mutation in gene to rule out uniparental disomy, homozygous mutation, and mutation with exon deletion.

PB3209 † Exploring Blindspots in Genetic Diagnosis of Leukodystrophies: Integrating State-of-the-art Methodologies and HiFi Long-read Genome Sequencing for Undiagnosed Pediatric Patients

Authors:

I. Thiffault[1], E. Farrow[1], A. Cohen[1], J. Macintosh[2], T. Zion[1], E. Boillat[1], J. Johnston[1], S. Younger[1], J. Means[1], W. Cheung[1], C. Schwendinger-Schreck[1], S. Perrier[2], T. Truong[3], G. Evrony[3], J. Bonkowsky[4], G. Bernard[2], T. Pastinen[1]; [1]Children's Mercy, Kansas City, MO, [2]McGill Univ., Montreal, QC, Canada, [3]New York Univ. Sch. of Med., New York, NY, [4]Primary Children's Hosp. and the Univ. of Utah, Salt Lake City, UT

Leukodystrophies are a group of heterogenous genetic diseases leading to progressive disabilities and often associated with poor prognostic. Collectively, their incidence is ~ 1:5000 births. Although some subtypes of white matter disease (WM) have a high diagnostic rate by short-read exome (srES), other forms with more complex presentation (neuro+) remain mostly unsolved even by short-read genome sequencing (srGS). Beyond increased diagnostic yield by AI-driven reanalysis, we hypothesize that variations in "srES/srGS blindspots" (repeat expansions, structural variants (SV), intronic/regulatory variants) account for missed molecular diagnoses. Furthermore, HiFi-GS can be utilized for interrogation of non-coding/regulatory variation via methylation detection as well as RNA (HiFi-IsoSeq) and can overcome limitations of reference genomes by *de novo* assembly. We recently demonstrated that up to 3% of functional genomes can be missed by a reference genome as compared to *de novo* assembly. **Methods:** In the context of a collaborative genomic medicine program "Genomic Answers for Kids" with >5000 families with suspected genetic disorders; we have developed one of the largest HiFi-GS data resources by integrating an enhanced HiFi-GS workflow for unsolved pediatric cases. To determine the utility of HiFi-GS in WM diseases, we established a cohort of ~300 patients from three sites: McGill University Health Center, Children's Mercy Kansas City, and Primary Children's Hospital and the University of Utah. All patients entering the program have had srES/srGS performed. Prior to deploying HiFi-GS, existing srES/srGS data of unsolved leukodystrophy cases are systematically reanalyzed by AI-driven methods. **Results:** As previously reported, subtypes of WM (i.e., hypomyelinating, mitochondrial, or metabolic) have a high (70%) diagnostic rate versus neuro+ (22%). In neuro+, blended phenotypes among patients with dual diagnoses are observed, along with a higher rate of gene discovery. For non-trio cases, if VUS(s) detected by srES/srGS are confirmed *de novo* or *in trans* configuration, the genotype would be diagnostic (~20%). Using HiFi-GS, we identified diagnostic genotypes undetected by srES/srGS. We also identified a private hypermethylated "GCC" expansion in a non-OMIM gene. **Discussion:** We are pursuing full genome profiling of unsolved WM cases by leveraging HiFi-GS, *de novo* assembly, methylation, and IsoSeq. Moreover, the findings will be validated in patient-derived cells (iPSCs) to systematically study the impact of RNA or myelination (oligodendrocytes).

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3210 Extended chromosomes after ICRF-193 treatment in human peripheral blood lymphocytes: An aid in the study of the mitotic chromosome.

Authors:

L. Prouty; Louisiana State Univ. Hlth.Sci. Ctr. Shreveport, Shreveport, LA

The study of the mitotic chromosome has been greatly enhanced by advances in electron and superresolution microscopy. The work presented here combines structured illumination microscopy with modified cytogenetic techniques which lengthen chromosomes in mitotic spreads, for the purpose of making FISH and immunofluorescence targets more accessible and clarifying spatial relationships between imaged structures. Normal peripheral blood lymphocytes are synchronized to select for long mitotic chromosomes with an established high-resolution technique. At harvest, a topoisomerase II alpha inhibitor, ICRF-193, is added to the cultures, markedly slowing chromosome compaction. Chromosomes captured in early prometaphase can be nearly twice the length of chromosomes in conventional high-resolution preparations. After hypotonic treatment of cells, two methods of fixation are used. The first, conventional acid/alcohol (Carnoy's) fixation, is a harsh, protein denaturing fixative, but its action enhances a segmented appearance in individual chromatids. In early prometaphase, rounded chromatin "beads" (mean dia. 260 nm) alternate with more diffuse segments, and, in regions free of stretching artifacts, the segmental structure of sister chromatids is nearly identical, giving rise to the hypothesis that individual segments contain the same DNA in succeeding mitoses. This hypothesis is testable with oligo-FISH probing. The second fixation method is an aqueous one, with detergent release of chromosomes, paraformaldehyde fixation, and "drying down" of spreads on slides. With the preservation of proteins, chromatin fiber structure is improved and segmentation is less pronounced. In addition to DNA probing, proteins are targeted with immunofluorescence technique, broadening the research potential to the many outstanding questions, such as the details of mitotic chromosome structure and compaction, including the positioning of condensins; histone modifications of the same loci in interphase and metaphase; with Click technology, transcription in mitosis; and others. Progress in the analysis of the mitotic chromosome is bound with microscopy, including imaging in live cells, an approach typically confined to relatively compacted chromosomes. Extended, fixed chromosomes in spreads offer a complementary approach and chromosomal configuration.

PB3211 † Facing the challenges of the diagnostic odyssey: diagnostic genome sequencing in 501 patients with rare diseases from Colombia.

Authors:

H. VELASCO[1], A. Bertoli-Avella[2], J. Espinosa[3], D. Cardona[1], A. Gonzalez[1], M. Naranjo[1], J. Valencia[1], C. Buitrago[1], J. Gutierrez[4], J. Marcello[5], P. Bauer[6], C. Jaramillo[3]; [1]SURA, BIOSci. CENTER, MEDELLIN, Colombia, [2]Centogene AG, Rostock, Germany, [3]SURA, GENETIC UNIT, MEDELLIN, Colombia, [4]Centogene, Rostok, Germany, [5]CENTOGENE, Rostok, Germany, [6]CENTOGENE, Rostock, Germany

Exome and genome sequencing (ES GS) are routinely used for the diagnosis of genetic diseases in developed countries. However, their implementation is limited in countries from Latin America, affecting millions of patients living in the continent. In this work, we describe the results of GS in 501 patients from Colombia. GS was performed in the index cases using dried blood spots. Multiomic testing was performed in cases that needed further clarification on the clinical relevance of the identified variants (biomarker, enzymatic activity, RNA-seq). All tests were carried at an accredited genetic laboratory (CENTOGENE, Germany). Ethnicity prediction confirmed that 401 patients were mainly of Amerindian origin. A genetic diagnosis was established for 142 patients with a 28.3% diagnostic yield (101 pathogenic/likely pathogenic variants). The highest diagnostic yield was achieved for pathologies with a metabolic component, followed by syndromic disorders (p. minus 0.001). Patients with genetic syndromes have spent more than 75% of their life without a diagnosis, while for patients with neurologic and neuromuscular diseases, the time of the diagnostic odyssey tended to decrease with age. Previous testing, specifically karyotyping or chromosomal microarray (CMA) were significantly associated with a longer time to reach a definitive diagnosis (p minus 0.01). Furthermore, 1 out of 5 patients that had an ES before could be diagnosed by GS. In conclusion, we present the results of GS in a large cohort of patients from Colombia and demonstrate the value of GS as first tier test for the diagnosis of genetic diseases.

PB3212 Furthering WGS/WES results: clinical implementation of RNA-based functional assessments of coding and intronic variants with potential loss-of-function

Authors:

J-L. Blouin[1,2], A. VANNIER[3], C. MARCONI[1], F. Masclaux[3], M. ABRAMOWICZ[1,2], T. Rio Frio[4]; [1]Univ. Hosp. of Geneva, GENEVA, Switzerland, [2]Univ. of Geneva-Sch. of Med., Geneva, Switzerland, [3]Univ. Hosp. of Geneva, Geneva, Switzerland, [4]Geneva Univ. Hosp., Geneva, Switzerland

Background: The introduction of NGS in clinical practice has improves dramatically the rate of elucidated cases, but has also created a paradoxal increase of variants of unknown significance (VUS). Current ACMG guidelines for variant interpretation focus on amino-acid level identified but filter out other non-coding or synonymous variants that may however have a clinical significance. **Methods**: After selection by an interdisciplinary team of variants pre-filtered on a compound of in silico predictors, fast and affordable molecular investigations on targeted transcript regions were performed on RNA extracted from patients' blood. **Results**: Besides confirmation of predicted impact on splicing for variants localized in critical regions of canonical splicing sites, missense variants of uncertain significance (relative to their impact on protein function) and rare deep intronic variants were shown to critically impact the splicing of genes they lie in. For example, missense VUS in *ATP8B1* and *MYBPC3* genes were found to create stronger donor or acceptor splice site than the canonical one, leading to abnormally spliced mRNAs degraded by nonsense-mediated mRNA decay (NMD). Also, a deep intronic variant localized at position 337 in an intron of 1212 nucleotides in *MYBPC3* gene and other intronic variants IVS-19 in *CHD7*, IVS-18 in *NUP93* and IVS+9 in *NEB* genes were found to create cryptic intronic splice sites leading to abnormally spliced mRNA degraded by NMD or leading to non-functional protein. We also demonstrated the utility of RNA analysis in prenatal diagnosis in the context of ultrasonography abnormalities using RNA from fetal amniocentesis cells for a IVS+5 variant of *FBN1* and a IVS-19 variant in *CHD7* that were upgraded to class 5 and 4, respectively. **Conclusion**: We have translated to diagnostics an analytical pipeline to assessing VUS predicted to impact gene transcript with the aim to decipher their pathogenicity. We demonstrated that combination of *in silico* predictors and such targeted RNA-based analytical approach is able to clarify a number of DNA-based interpretation of variants. It appears to be far-more cost-effective than total RNAseq that needs complex analytical process and would not be necessary in a number of such situatiosn where VUS are identified and could explain the phenotype. All variants, within several genes, analyzed through this pipeline so far had been re-classified, either upward (to pathogenic or to likely pathogenic) or downward (to benign) following the ACMG guidelines. We found also that nearly all assessed genes until now could be analyzed in RNA from blood even when a low expression in this tissue was reported according to GTEx database.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3213 GenDiseak: Automated platform for human genetic variant interpretation based on ACMG guidelines.

Authors:

T-H. Yuan[1,2], Y-A. Chen[3], Y-B. Wang[1], J-H. Huang[1], C-Y. Chen[1,2,4], J-J. Hsu[3], P-L. Chen[2,3,5,6,7]; [1]TAIGenomics Co., Ltd., Taipei, Taiwan, [2]Genome and Systems Biology Degree Program, Academia Sinica and Natl. Taiwan Univ., Taipei, Taiwan, [3]Graduate Inst. of Med. Genomics and Proteomics, Coll. of Med., Natl. Taiwan Univ., Taipei, Taiwan, [4]Dept. of Biomechatronics Engineering, Natl. Taiwan Univ., Taipei, Taiwan, [5]Dept. of Med. Genetics, Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [6]Div. of Endocrinology and Metabolism, Dept. of Internal Med., Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [7]Graduate Inst. of Clinical Med., Coll. of Med., Natl. Taiwan Univ., Taipei, Taiwan

The application of Next-Generation Sequencing (NGS) technology in molecular genetic testing has greatly improved the research and diagnosis of genetic disorders in clinical practice. In 2015, the American College of Medical Genetics and Genomics (ACMG) published updated standards and guidelines for the clinical interpretation of sequencing variants associated with human diseases. However, there are challenges in the identification and interpretation of variants when translating high-throughput genetic sequencing into clinical practice. These complications arise due to variability in interpretation among individuals and the lack of standardized interpreting algorithms. To address these issues, our team has developed GenDiseak, an automatic interpretation tool. GenDiseak offers a user-friendly interface and provides users with custom bioinformatic workflows, coupled with automatic variant classification and prioritization based on the 2015 ACMG guidelines for clinical significance. We assessed the performance of GenDiseak using benchmark datasets from the DEAFNESS VARIATION DATABASE (DVD) and BRCA Exchange. Remarkably, GenDiseak achieved an F1 score of 89.98% for the classification of Pathogenic and Likely Pathogenic single nucleotide variants (SNVs) and InDels in the DVD dataset, and an impressive F1 score of 99.96% for the same Pathogenic categories of SNVs and InDels in the BRCA Exchange dataset. Furthermore, GenDiseak integrates pubmedKB, a novel literature understanding tool for extracting semantic relations between biomedical entities. This enables rapid and intelligent search through vast amounts of biomedical literature, providing valuable knowledge and insights. Given its features, GenDiseak has the capacity to assist professionals in variant identification and interpretation, leading to substantial enhancements in efficiency, precision, and the general standard of healthcare and genomic research.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3214 Genetic causes of neurodevelopmental disorders.

Authors:

A. Mohamed[1,2], O. Eid[3], A. kamel[2], E. Ashaat[1], G. El Houseiny[1], M. Farid[4], R. Mahrous[1], P. Erian[1], M. Zaki[1], N. Meguid[1]; [1]Natl. Res. Ctr., Cairo, Egypt, [2]Natl. Res. Ctr., Cairo, Egypt, [3]Natl. research centre - Egypt, Giza, Egypt, [4]Natl. Res. Ctr., Cairo, Egypt, Cairo, Egypt

The aim of this research was to detect genetic causes in three groups with NDDs. Autism spectrum disorder (ASD), intellectual disabilities (ID) associated with multiple congenital abnormalities (MCA), and imprinted disorders. This paves the way for personalized medicine in some NDDs. Methods: chromosomal microarray (CMA), multiple ligation probe amplification (MLPA), and whole exome sequencing (WES) were performed. The 1st group included 80 child suffering from ASD, CMA applied on 40 patients showed pathological structural copy number variance (CNV) in 17.5%, this involved mainly chromosomes 15q13,16p11.2, 22q11.2 and 7q11.23.Whole exome sequencing (WES) was performed for 20 ASD patients, they showed frameshift and missense variants associated to ASD in 6 patients, there was one identical twin who had nonsynonymous SNV in AGTR2 gene, which is a strong candidate for ASD, the variant was inherited as X-linked trait from their mother. The 2nd group is the patients with ID associated with MCA (80 patients). The molecular karyotype revealed 44% structural CNV in these patients. The 3rd group is the patients with clinical manifestations of imprinting disorders (80 patients). This cohort revealed 2 patients with Beckwith- Wiedemann syndrome due to hypomethylation of KCNQ-CR, two patients with Silver-Russel syndrome, one due to uniparental disomy (UPD)in chromosome 7 with hypermethylation of MEST-1, the other one due to mutation in the imprinting centre, one patient with Prader-Willi syndrome due to UPD of chromosome 15, and with hypermethylation of SNPRN. This research indicates the great importance of conducting MLPA, CMA and WES for all neurodevelopmental delay patients. These tests must be carried out under the umbrella of health insurance, and this is the only way to give sound genetic advice, proper prenatal diagnosis, personalized medicine with Possibility of gene therapy for NNDs depending on accurate molecular diagnosis.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3215 Genetic etiology analysis of 216 patients of infantile epileptic spasm symdrome with unknown cause

Authors:

Z. Pan[1,2], H. Tang[3], C. Chen[3], J. Peng[1,2]; [1]Dept. of Pediatrics, Xiangya Hosp. of Central South Univ., Changsha, China, [2]Clinical Res. Ctr. for Children Neurodevelopmental Disabilities of Hunan Province, Xiangya Hosp., Central South Univ., Changsha, China, [3]Ctr. for Med. Genetics & Hunan Key Lab. of Med. Genetics, Sch. of Life Sci., Central South Univ., Changsha, China

Background: The genetic etiology of Infantile epileptic spasm syndrome (IESS) is an important predictor of prognosis, however, nearly one-third to one-fifth of IESS patients have an unknown cause. Reanalysis of trio whole-exome sequencing (WES) data can improve the genetic diagnostic yield. Whole-genome sequencing (WGS) is believed to increase variant detection, especially non-coding region variants, and transcriptome sequencing (TS) can improve the interpretation of non-coding region variants. **Objectives:** To explore the genetic etiology of patients with IESS of unknown cause and to improve the diagnostic yield by WES reanalysis, and WGS combined TS. To investigate the utility of machine learning in the identification of candidate causative IESS genes. **Methods:** IESS patients meeting inclusion criteria were recruited from the Department of Pediatrics, Xiangya Hospital, Central South University from January 1, 2010 to June 1, 2021. Trio-WES data was pre-processed and re-analyzed according to the virtual epilepsy gene panel. Different epilepsy-causative variant prediction models were built base on GTEx and ClinVar database. An optimal prediction model was selected to identify candidate disease-causative genes from trio-WES data. WGS was performed on WES reanalysis-negative patients. TS were used to verify the functional impact of non-coding region variants from WGS to inform pathogenicity rating. **Results:** Reanalysis of WES data from 17 patients identified disease causative variants, with a positive diagnosis rate of 7.8%. The diagnostic yield of reanalysis after three years was higher than those analyzed at less three years. Forty-one candidate disease causative genes were detected by the random forest variant prediction model. 103 IESS patients with negative WES reanalysis were prospectively enrolled to perform WGS with TS analysis, which identified three patients with pathogenic disease-causative variants, including a *de novo* missense variant of *ATP6V0A1* and complex heterozygous intronic variants of *AFG3L2*, and a de novo missense variant of *MT-ATP6*, resulting in positive diagnosis rate of 2.9%. **Conclusions:** Periodic re-analysis of trio-WES, or trio-WGS with TS can improve genetic diagnostic yield of IESS with unknown cause and provide clues for further identifying candidate IESS-causative or risk gene variants. Further, the prediction model of random forests based on gene-tissue expression feature can be used to identify more candidate IESS-causative genes.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3216 Genome sequencing uncovers a 8,8 kb deletion between L1CAM and AVPR2 in a boy with Hirschsprung disease and nephrogenic diabetes insipidus

Authors:

I. Bader, S. Beck-Wödl, K. Buder, P. Stöbe, M. Sturm, O. Riess, T. Haack; Univ.sklinikum Tübingen, Tübingen, Germany

Pathogenic loss-of function variants and missense-variants in AVPR2 (Arginine Vasopressin Receptor 2) are a known cause of X-linked nephrogenic diabetes insipidus. Pathogenic loss-of function variants and missense-variants in L1CAM (L1 Cell Adhesion Molecule) are a known cause of X-linked hydrocephalus with or without Hirschsprung disease. A contiguous-gene-deletion syndrome with a clinical picture that comprises nephrogenic diabetes insipidus and hydrocephalus with or without Hirschsprung disease, has been described in two male patients that harbor deletions (approx. 62 kb and 29 kb respectively) that affect coding regions of both adjacent genes (AVPR2 and L1CAM) (PMID: 18553546, 17318848). Here we describe a 1,5 year old boy with Hirschsprung disease and nephrogenic diabetes insipidus that harbors an 8,8 kb Deletion in Xq28 (NC_000023.11:g.[153883503_153892327del];[0]) located in between the two adjacent genes L1CAM and AVPR2. The deletion affects the 5' UTR exon 1 of L1CAM but no annotated protein coding exons of L1CAM. The deletion terminates 11 kb before the 5'-end of the nearest annotated AVPR2-trancript (NR_027419.2). The deletion does not affect any annotated coding or non-coding transcripts of AVPR2; that is why the deletion was uncovered only by whole genome sequencing and was undetectable in whole exome sequencing data of the patient. The unusual combination of the specific and rare symptoms of the patient raises the hypothesis that this 8,8 kb deletion affects chromosomal material that regulate the expression of both genes. Our data indicate that whole genome sequencing can uncover potentially disease causing CNVs in non protein-coding regions in patients with a specific clinical picture. Further analyses, i.e. RNA-expression of AVPR2 and L1CAM in blood and fibroblasts of the patient need to be performed to demonstrate dysregulation.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3217 Going the extra mile for rare diseases: Feasibility and challenges of setting up a pilot Undiagnosed Disease Program (UDP) in Iowa

Authors:

J. Ginter[1], A. Paulson[1], B. Darbro[1], N. Niu[1], J. Nagy[1], H. Major[1], A. Wetzel[1], K. Coleman[2], B. Chandra[1]; [1]Stead Family Dept. of Pediatrics, Iowa City, IA, [2]Holden Comprehensive Cancer Ctr., Iowa City, IA

Undiagnosed rare diseases (URD) remain common despite comprehensive clinical evaluations and advances in next generation sequencing. The proportion of URD after trio exome sequencing (ES) is about 70-85% depending on parameters. As such, genetics services at University of Iowa Hospitals and Clinics (UIHC) have many patients with URD. UIHC houses the only comprehensive genetics center for a population of 3.19 million in Iowa, with 1.27 million living in rural areas. Travel to Undiagnosed Disease Network (UDN) sites has not been possible for some Iowa patients with URD. Through internal philanthropic funding, the Division of Medical Genetics and Genomics at UIHC initiated a pilot Undiagnosed Disease Program (UDP) in January 2023, led by a core team of a neurogeneticist and two genetic counselors (GCs). The UDP was modeled on the UDN framework. Participants with non-diagnostic ES or comprehensive genetic testing are eligible. GCs review the chart to abstract human phenotype ontology (HPO) terms and summarize past studies. These are reviewed by the physician and included in clinic notes as part of deep phenotyping. Appointments are a hybrid of clinical testing, such as global metabolomics, and research testing that insurance is unlikely to cover, like genome sequencing and RNA sequencing and interpretation. Participants provide specimens for the IRB approved UI rare disease biorepository (UIRDB) for research testing. The GCs or physician consent for the UIRDB. The physician conducts a detailed physical and neurological exam for participants. To remain cost effective, we perform research-based genome sequencing in-house through Shivanand R. Patil Cytogenetics and Molecular Laboratory. RNA extraction and sequencing with analysis are performed locally at our center through our collaboration with tissue procurement core at UIHC Holden Comprehensive Cancer Center and the Iowa Institute of Human Genetics. The Chandra laboratory performs induced pluripotent stem cell(iPSC)-based disease modeling. Challenges we experience include lack of a coordinator, no dedicated bioinformatician, and limited access to trio samples. Our UDP service recently hired a 0.5 FTE bioinformatician. Also, iPSC reprograming from peripheral blood had limited success and we are considering skin biopsy in the future. Our program has received 24 referrals through May 2023. Of these, 17 individuals have been evaluated. All have undergone deep phenotyping using HPO terms and genome sequencing. RNA sequencing is in process for 8/17 (47%). In conclusion, we have successfully initiated a UDP service with limited funding in the state of Iowa.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3218 High fidelity copy number detection from difficult sample types using an accelerated chromosomal microarray assay.

Authors:

V. Huynh, V. Alford, A. Baker, S. Baral, C. Chen, A. Goyal, J. Law, K. Padamata, N. Vegesna, J. Wallace, B. Bolstad, L. Wu, J. McGirr, D. Black, A. Roter; Thermo Fisher Scientific, Santa Clara, CA

Chromosomal Microarray (CMA) has been widely used for studying genomic imbalances for over a decade and is currently recognized as a first-tier research tool for CNV detection. The application of molecular karyotyping to blood samples is often considered the “gold standard” test, but there is increasing interest and clinical research applications to enable accurate detection of copy number changes in alternative sample types such as oral and prenatal samples. These sample types present multiple challenges around adequate yields of high quality gDNA as well as contamination with extraneous sources of DNA, such as from the oral microbiome for saliva and buccal samples or maternal cell contamination often associated with detection of chromosomal aberrations in prenatal samples. To support robust detection of copy number changes, we built a diverse Reference Model by incorporating over five hundred samples of multiple tissue types (blood, buccal, saliva, amniocentesis, chorionic villi, and POC) to enable genome-wide detection of copy number variation on the CytoScan HD Accel microarray. Principal Component Analysis (PCA) illustrates that most, but not all, genomic DNAs are equal. Specifically, buccal and saliva sample types cluster separately from the other sample types. These sample batch effects can be corrected by incorporating buccal and saliva samples into the copy number reference model. The copy number reference model contains the expected log2 signal intensity for each probe at the diploid state and enables detection of copy number variants. A large reference model built from a variety of sample types and under a variety of processing conditions captures normal variation of process and sample type and is robust to these variations. Furthermore, we demonstrate passing array QC metrics with up to 25% maternal cell contamination and ability to detect copy number changes associated with a trisomy with up to 30% maternal cell contamination using a sample mixing cell-line model.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3219 High-resolution karyotype reveals a maternally inherited complex chromosome rearrangement involving chromosomes 4p, 5p, and 12q with an inverted insertion and a 12q21.31q21.32 loss identified by SNP array.

Authors:

V. Stinnett[1], J. Biscoe[1], N. DeMetrick[1], J. Murry[2]; [1]Johns Hopkins Hosp., Baltimore, MD, [2]Johns Hopkins Sch. of Med., Baltimore, MD

Background: Complex chromosome rearrangements (CCRs) are defined as rearrangements involving three or more chromosomes or as having more than two breakpoints. CCRs can be further classified into subgroups based on their complexity. Unbalanced CCRs are often associated with phenotypic findings. Here we present lab findings for a 19-year-old patient referred for autoimmune hemolytic anemia. An outside karyotype performed on a bone marrow specimen identified an apparently balanced novel translocation between chromosomes 4 and 12 present in all cells examined, implicating a constitutional aberration.
Results: A karyotype performed on cultured fibroblast cells confirmed a germline origin and revealed chromosomal aberrations for 4p14, 5p15.1, and 12q14, raising a high suspicion for a rearrangement involving an insertion of 12q14q21 material into the 5p15.1 locus. Metaphase FISH performed using subtelomeric probes for all three chromosomes revealed a reciprocal translocation between 4p and 12q. A normal hybridization pattern for chromosome 5 supported an interstitial insertion of 12q material into 5p, as suggested by karyotype. The only genomic imbalance identified by SNP microarray (Illumina® 850k BeadChip) was a 234 kilobase (kb) interstitial loss of 12q21.31q21.32, classified as a variant of uncertain significance. A high-resolution maternal karyotype and SNP array performed on peripheral blood showed the same results confirming the CCR in our patient was maternally inherited.
Discussion: The high-resolution maternal karyotype clarified the cytobands and rearrangement orientation by identifying that insertion of 12q13.3q21.31 material at chromosome 5p14.3 is inverted. This report highlights the continued utility of high-resolution (greater than 550 band level) karyotypes in assessing CCRs. It is possible the small deletion on chromosome 12 occurred secondary to the CCR formation. As other small deletions or gene disruptions from the CCR cannot be excluded, emerging laboratory methods may assess this possibility. Here, we confirm prior literature reports that inherited CCRs are often maternal in origin. As carriers of CCR are at an increased risk of abnormal pregnancy outcome and infertility, genetic counseling is recommended to discuss recurrence risk. Other family relatives may be carriers of this CCR and should be evaluated using complementary cytogenomic methods.

PB3220 HLA typing using capture-based next-generation sequencing

Authors:

S-K. Lai[1,2], M-J. Lin[3], C-S. Chen[4], P-L. Chen[1,5]; [1]Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [2]Graduate Inst. of Genome and Systems Biology Degree Program, Taipei, Taiwan, [3]Dept. of Computer Sci., Johns Hopkins Univ., Baltimore, MD, [4]TBG Biotechnology Corp., Taipei, Taiwan, [5]Graduate Inst. of Med. Genomics and Proteomics, Taipei, Taiwan

Accurate and reliable HLA typing is crucial in various immunological applications, such as disease diagnosis and transplantation compatibility assessment. However, achieving precise and reliable HLA typing remains challenging due to the complexity and extensive polymorphism of HLA genes. In this study, we aimed to develop a set of capture probes and evaluate their performance using four distinct software programs: HISAT-genotype, HLA-VBseq, T1K, and QZtype. To accomplish this, we designed and utilized HLA capture probes specifically targeting our desired HLA loci and conducted NGS sequencing on a set of 38 samples from Human Pangenome Reference Consortium (HPRC). Subsequently, the generated NGS data were subjected to HLA typing analysis using the aforementioned software programs. In order to establish a benchmark, we aligned the HLA allele sequences obtained from the IPD-IMGT/HLA database to the HPRC publicly available whole-genome assemblies. The HLA alleles exhibiting the least sequence variations were selected as the HLA_annotate benchmark. Comparative analysis showed different performance characteristics among the software programs. T1K achieved a perfect concordance rate of 100% for HLA class I typing. For HLA class II typing, T1K demonstrated concordance rates ranging from 96% to 100% except for the challenging HLA-DRB1 region, where it achieved an 86% concordance rate. QZtype and HISAT-genotype exhibited comparable accuracy, with minor discrepancies compared to T1K. Inconsistencies with the HLA_annotate benchmark were attributed to intronic repeat regions and variations in exon weighting criteria used by different software programs. In conclusion, this study provides insights into the performance of HISAT-genotype, HLA-VBseq, T1K, and QZtype software programs for HLA typing. The designed HLA capture probes were effective, and no loss of heterozygosity was observed during typing. This approach has potential for precise and comprehensive HLA typing in research and clinical applications, improving immunological analyses and transplantation procedures.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3221 Host and microbial determinants of cutaneous lesions detected simultaneously via RNA-Sequencing: Biallelic pathogenic CORO1A sequence variant, Mycobacterium tuberculosis, and Staphylococcus aureus Identification.

Authors:

L. Youssefian[1], F. Palizban[2], A. Saeidian[3], H. Hakonarson[4], E. Jouanguy[5], J-L. Casanova[6], H. Vahidnezhad[7]; [1]UCLA, Los Angeles, CA, [2]IBB, Tehran, Iran, Islamic Republic of, [3]Children s Hosp. of Philadelphia, Philadelphia, PA, [4]Children's Hosp. of Philadelphia, Philadelphia, PA, [5]Lab. of Human Genetics of Infectious Diseases, Necker Branch, INSERM U1163, Necker Hosp. for Sick Children,, Paris, France, [6]The Rockefeller Univ., New York, NY, [7]Univ. of Pennsylvania, Philadelphia, PA

Biallelic mutations in the CORO1A gene result in severe combined immunodeficiency (SCID) and susceptibilities to multiple infections, including granulomatous tuberculoid leprosy, epidermodysplasia verruciformis, human herpesvirus 4 (HHV-4), molluscum contagiosum, mucosal HHV-1, HHV-3, HHV-8, and visceral leishmaniasis. We report a novel association between COROA1 homozygosity, late-onset cutaneous tuberculosis (CTB), and Staphylococcus aureus infection. The immunophenotype of SCID was supported by clinical and immunological evaluations, including fluorescence-activated cell sorting and lymphocyte transformation tests. With a novel bioinformatic pipeline, we utilized whole-transcriptome sequencing (RNA-Seq) to concomitantly detect pathogenic viral and bacterial agents, the causal human pathogenic variant, and the consequences of detected sequence variants in the host. The proband, a 17-year-old male, was found to be homozygous for *CORO1A*: NM_007074:exon3:c.248_249del: p.P83Rfs*10, this variant was located inside the 26 Mb of runs of homozygosity on 16p11. RNA-Seq confirmed the deleteriousness of the *CORO1A* variant in four skin biopsies, revealing significant downregulation of *CORO1A*. Reads unaligned to the human genome were applied to a catalog of 926 different viruses and about 1500 pathogenic bacteria. β-HPV5, Mycobacterium tuberculosis (TB) H37Rv, and Staphylococcus aureus were detected. Collectively, we describe a previously unrecognized inborn error of immunity to CTB, indicating that it is autosomal recessive. Whole-transcriptome sequencing allows for the simultaneous detection of host and microbial determinants of widespread cutaneous lesions. A CORO1A deficiency can underlie EV and CTB. In addition, we innovatively harnessed the RNASeq data to detect abnormal microbiota underlying recalcitrant skin lesions.

PB3222 Identification of Contiguous Gene Deletions of *SLC6A8*, *BCAP31*, and *ABCD1* in a Korean Infant Presenting with Hypotonia, Failure to Thrive, Hearing Loss, and Hepatitis

Authors:

Y-M. Kim[1], E. Kim[1], Y. Kwon[1], H. So[1], B. Lee[1], M. Kim[1], J. Min[1], Y. Lee[1], B. Kim[1], G. Seo[2], G-H. Kim[3], B. Lee[3], H-W. Yoo[4,3]; [1]Chungnam Natl. Univ. Sejong Hosp., Sejong, Korea, Republic of, [2]3billion, Seoul, Korea, Republic of, [3]Asan Med. Ctr., Seoul, Korea, Republic of, [4]CHA Bundang Med. Ctr., Seongnam-si, Gyeonggi-do, Korea, Republic of

Contiguous gene deletions involving *SLC6A8*, *BCAP31*, and *ABCD1* are associated with X-linked cerebral creatine deficiency syndrome-1 (MIM#300352), Deafness, dystonia, and cerebral hypomyelination (DDCH, MIM#300475), and X-linked adrenoleukodystrophy (MIM#300100), respectively. These deletions can result in severe clinical phenotypes, including significant failure to thrive, hypotonia, developmental delay, hepatic dysfunction, and hearing loss. We report the case of an 11-month-old boy presenting with growth failure, congenital deafness, muscle hypotonia, and hepatic dysfunction caused by de novo contiguous gene deletions of *SLC6A8*, *BCAP31*, and *ABCD1*. The patient, born to non-consanguineous parents at 40 weeks of gestation with a birth weight of 3.0 kg, exhibited failure to thrive and hypotonia. Congenital hearing loss and persistent elevation of liver enzymes were observed. The patient's height, weight, and head circumference were below the 3rd percentile. The laboratory findings showed persistent elevation of liver enzymes (ALT 81-138 U/L). At 3 months of age, hepatitis workup revealed positive urine and blood cytomegalovirus (CMV) PCR. Congenital CMV infection was diagnosed, and a hearing aid was provided. Metabolic evaluation, except for mild elevation of very long-chain fatty acids (VLCFA), was normal, and *ABCD1* sequencing was unremarkable. Brain magnetic resonance imaging (MRI) revealed a 2.3 cm arachnoid cyst in the left side of the cisternal magna and delayed myelination. Chromosome microarray, methylation tests for Prader-Willi syndrome, mitochondrial sequencing, and whole exome sequencing yielded negative results. At 22 months of age, the patient's development had halted at 10 months. Reanalysis of whole exome sequencing identified an 82.6 kb deletion at the Xq28 region, encompassing *SLC6A8*, *BCAP31*, and *ABCD1*. Mild elevation of VLCFA (C24/C22 1.642, C26/C22 0.045) was observed. Multiplex ligation-dependent probe amplification confirmed the deletions of *ABCD1*, *BCAP31*, and exons 12-14 of the *SLC6A8* gene. The mother did not have the same deletion. MR spectroscopy was consistent with cerebral creatine deficiency syndrome. Treatment with creatine monohydrate (200 mg/kg/day), glycine (150 mg/kg/day), and arginine (400 mg/kg/day) was initiated, resulting in the patient achieving independent walking after 3 months of treatment. Over 2 years, brain MRI showed no interval changes. In conclusion, we present a case of infancy with global developmental delay, failure to thrive, hepatic dysfunction, and hearing loss caused by rare contiguous gene deletions involving *SLC6A8*, *BCAP31*, and *ABCD1*.

PB3223 Implementation of clinical genome sequencing-based panel testing: Experience and results from over 400 patients with suspected inherited cardiovascular diseases

Authors:

C. Hale[1], J. Platt[2,3], K. Dumas[1], D. Fisk[1], M. E. Grove[4], H. Ison[2], M. Kawana[2,5], A. Klinder[2], J. W. Knowles[2,5], J. N. Kohler[2], T. Moscarello[2], R. Murtha[2], T. Nguyen Dolphyn[1], M. Pariani[2], V. N. Parikh[2,5], M. V. Perez[2,5], C. Reavey[1], C. M. Reuter[2], K. Sallam[2,5], E. E. Smith[1], K. S. Weymouth[1], M. T. Wheeler[2,5], S. White[6], E. Spiteri[1,7], W. Qiao[1,7], Y. Yang[1,7], E. A. Ashley[2,5], S. A. Scott[1,7]; [1]Clinical Genomics Lab., Stanford Med., Palo Alto, CA, [2]Stanford Ctr. for Inherited Cardiovascular Disease, Stanford, CA, [3]Dept. of Pediatrics, Div. of Med. Genetics, Stanford, CA, [4]Color Hlth., Burlingame, CA, [5]Dept. of Med., Div. of Cardiovascular Med., Stanford, CA, [6]Fabric Genomics, Oakland, CA, [7]Dept. of Pathology, Stanford, CA

Although high-throughput sequencing is widely implemented for enrichment-based multigene panel diagnostic testing, enrichment-based exome sequencing is increasingly employed as a single platform for clinical panel testing. However, given that genome sequencing has less bias and more consistent coverage across coding regions and improved capacity to detect copy number variants (CNVs) compared to enrichment-based sequencing, in 2021 we validated and launched six genome-based diagnostic panels for inherited cardiovascular diseases [combined cardiomyopathy and arrhythmia (CMA), comprehensive cardiomyopathy (CCM), hypertrophic cardiomyopathy (HCM), aortopathy/familial thoracic aortic aneurysm/dissection (FTAAD), familial hypercholesterolemia, and comprehensive arrhythmia (CA)]. Five genome-based panels (CMA, CCM, HCM, FTAAD, and CA) include optional limited evidence genes for inclusion, and in total, 194 genes and 102 non-coding variants are interrogated across all six panels. To date, 431 genome-based panels (≥40X coverage) have been resulted, with the majority being CMA (73%) and CCM (14%). Outpatients and inpatients represented 69% and 31%, respectively, and most patients (81%) had not previously had prior genetic testing. The majority of patients were adults (97%) and the overall diagnostic rate across all six panels was 17%, which likely was influenced by age distribution as 76% of patients were ≥40 years of age. Inpatients had a higher diagnostic rate than outpatients (20% vs 15%; $p<0.0001$), and among patients that previously had a negative panel result (n=74), 3% had a new positive result by genome-based CMA panel testing, including pathogenic variants in the autosomal dominant *DSP* and *MAP2K1* genes. Among all patients subjected to genome-based panel testing, two patients had positive findings in two independent disease genes, and the spectrum of all reported diagnostic variants included frameshift (30%), missense (23%; including one mosaic), nonsense (19%), in-frame deletions (7%), and CNVs (6%). Importantly, genome-based panel testing across all patients reported 13 CNVs (3%; eight uncertain significance, two likely pathogenic, and three pathogenic), which included the ability to precisely identify most breakpoints. These results underscore the feasibility and utility of implementing genome-based diagnostic panel testing for Mendelian diseases, including improved coverage and accuracy, flexibility in content and design, CNV breakpoint interrogation, mosaic variant detection, a single laboratory workflow, and the opportunity to subsequently leverage non-diagnostic genome content for translational research.

PB3224 Improved technical noise correction in integrated functional genomics datasets with application to pathogenic variant discovery in rare diseases

Authors:

C. Smail[1], R. L. Biswell[1], B. Koseva[1], J. C. Means[1], E. Grundberg[2], S. Younger[1], T. Pastinen[3]; [1]Childrens Mercy Kansas City, Kansas City, MO, [2]Childrens Mercy Res. Inst., Kansas City, MO, [3]Childrens Mercy Hosp. and Clinics, Kansas City, MO

The use of functional genomics resources (such as RNA-sequencing) has emerged as a powerful tool in the diagnosis of rare diseases where DNA-based methods are unsuccessful. This approach is used to measure the downstream molecular consequences of candidate pathogenic variants, revealed using outlier detection methods. Identification of outlier signals from rare disease patient cohorts requires a background distribution of gene function contributed from large-scale healthy/control data. This reference data is often sourced from external sources and the detection and removal of technical/non-biological noise is first required. However, a key limitation of standard noise correction methods is in the handling of non-linear effects when combining samples from imbalanced datasets, where rare disease samples are vastly outnumbered by controls. This creates a paradox central to the research described here; namely, large-scale control data should increase power for uncovering pathogenic functional profiles among rare disease samples, but in fact can substantially increase noise as statistical modeling is biased by the larger cohort. To enable accurate detection and removal of technical noise in imbalanced datasets, we developed a statistical method called SplineSeq. SplineSeq robustly models both linear and non-linear covariates using regression splines, removing confounding technical noise but retaining important biological outlier signal. Applied to a large-scale RNA-sequencing rare disease cohort, we observed that SplineSeq significantly improved technical noise reduction across 20% of all genes (mean increase in model fit (R2) = 4.8%). We applied SplineSeq to a patient case of affected siblings enrolled in the NIH Undiagnosed Diseases Network (UDN) presenting with microcephaly and quadriplegia, observing a 66% improvement in outlier rank in candidate gene *RARS2*. Applied to an additional UDN patient case presenting with diverse clinical phenotypes (including global developmental delay, acute metabolic decompensation, hyperketotic hypoglycemia, rhabdomyolysis) and subsequent intractable candidate gene list, we identified an under expression outlier event in the gene *TANGO2*. Repeating both analyses using standard noise correction approaches failed to identify any clear outlier signal in both cases. SplineSeq is applicable to multiple functional genomics modalities, including short-read Illumina RNA-sequencing and long-read PacBio Iso-Seq.

PB3225 Improving the genetic diagnosis of patients with Congenital Hypogonadotropic Hypogonadism through the integration of genomics and transcriptomics data.

Authors:

A. Boizot[1,2], J. ZHAI[2,1], Y. Zouaghi[1,2], F. De Azevedo Correa[1,2], J. Meylan[1,2], C. Xu[1,2], L. Bartoloni[1,2], M. Adamo[1], G. Papadakis[1], A. Jacobs[1], N. Vionnet[1,2], N. Pitteloud[1,2], F. Santoni[1,2]; [1]Univ. Hosp. of Lausanne CHUV, Lausanne, Switzerland, [2]Univ. of Lausanne, Lausanne, Switzerland

Congenital Hypogonadotropic Hypogonadism (CHH) is a complex genetic disorder causing impaired gonadal development and function and absent puberty. More than 50 genes are nowadays considered to be causative for this disease, but our current knowledge of its etiology is incomplete. In general, more than 50% of CHH cases remain without genetic diagnosis.
To improve the diagnostic outcomes, we investigated the blood transcriptome of 40 CHH patients as a complementary approach of the standard genetic testing based on WES/WGS.
We developed a pipeline based on STAR integrated with custom designed modules to detect introns retentions caused by specific splicing variants. First, we utilized our pipeline to analyze the known CHH genes expressed in the blood.We found one CHH patient with a heterozygous synonymous variant in *CHD7*:c.2442G>A (p.Gln814=). This variant is not present in population databases, it is benign for the splicing predictors and it is classified as VUS by ACMG criteria. Our pipeline discovered that the variant creates an unannotated exon junction consequent to the skipping of exon 6, as frequent in reads as the normal junction. Sanger sequencing confirmed the splicing alteration. Subsequently, we decided to extend this analysis to the entire transcriptome.
An intriguing finding from this analysis was the observation that, on top of unannotated exon-exon junctions and intron retentions, several intra-exonic deletions were not detected by the standard genomic analysis but captured through our transcriptomics based approach. These deletions are mostly, but not only, located in repeated exonic regions and the reads covering the junctions (split-reads) are either unmapped or partially mapped by state-of-the-art DNA aligners (soft clipping). This suggest that the current clinical WES/WGS pipelines have a limited ability to align split-reads and an RNA-based complementary analysis is necessary not only to discover clinically relevant variants in known genes but also for the identification of novel causative genes. A clear disadvantage is the tissue-specificity of gene expression combined with the limited availability of human tissues that practically restrict this complementary approach to genes expressed in blood.
In conclusion, we have developed a comprehensive strategy to detect potentially clinically relevant variants that are undetectable or overlooked by standard clinical or research pipelines. By combining standard WES/WGS processing with the identification of aberrant junctions, intron retentions and exonic deletions, our pipeline improves the diagnostics yield in our cohort of CHH patients.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3226 In search of "hidden" variants in craniofacial microsomia: benchmarking ultra-low frequency mosaic variants in deep exome sequencing

Authors:

N. Parmalee[1], C. T. Myers[2], P. Cliften[3], C. Heike[4], D. M. Jensen[1], M-H. M. Pham[1], N. Au[5], K. A. Loy[6], J. Perkins[1], J. T. Bennett[1]; [1]Seattle Children's Res. Inst., Seattle, WA, [2]Seattle Children's Hosp., Seattle, WA, [3]McDonnell Genome Inst., Washington Univ. Sch. of Med., St. Louis, MO, [4]Univ. of Washington, Seattle, WA, [5]Seattle Children s Res. Inst., Seattle, WA, [6]Univ. of Washington Sch. of Med., Seattle, WA

Structural birth defects (SBD) affect 3-6% of live births in the United States, accounting for >20% of deaths in the first year of life. Although genetic factors have been identified, the etiology of most isolated SBD remains unknown. Explanations could include 1) low variant allele fraction (VAF) that is missed by standard sequencing, or 2) absence of the variant in blood/saliva. The goal of our HiddenSeq project is to identify mosaic variants missed by conventional sequencing by performing ultra-deep (>2500X) exome sequencing of affected tissue from a patient with craniofacial microsomia (CFM), a common SBD.

To establish precision and recall of our ultra-low (<1% VAF) variant detection approach, we made two dilutions of HapMap samples (NA18517 into NA12878) to create pseudo-mosaic variants with VAFs of 0.5%, 1%, 2.5%, and 5%. These two benchmark samples were sequenced to >2500X coverage, aligned to hg38 and variants called using Dragen and MosaicHunter. Error correction using dual UMIs was performed. Truthsets were established by standard 100X exome coverage and called on the same pipeline. We defined the truthset as the 16,093 SNP and indel variants present in NA18517 that were not present in NA12878. We also sequenced DNA from affected tissue (pre-auricular skin tag) and blood from an individual with CFM and both parents, to identify variants present only in CFM affected tissue.

We detected 93% (n=15,012) of the truth set variants at low VAFs (5 and 2.5%), and 73% (n=11,698) of the truth set variants at ultra-low VAFs (1 and 0.5%.). 2,208 false positive variants were called in the low VAF dilution and 2,096 false positive variants were called in the ultra-low dilution, representing a false discovery rate of 12.8% and 15.2%, respectively. Application of filtering based on summary statistics of true and false positive reduced the number of false positives by 46% while removing 2-8% of true positives. Application of this pipeline to the ~25K variants called in the CFM samples, identified 611 variants private to CFM tissue. Applying the same filters from our benchmarking samples resulted in 303 variants of interest private to preauricular tag tissue. Manual inspection of these variants revealed >90% to be artifacts. ~25 candidates did not appear artifactual and await orthogonal validation.

Calling mosaic variants exome-wide from bulk tissues at VAFs nearing 1% or lower remains challenging. Ongoing work includes examining other callers and comparing alignment to the T2T CHM13 reference. Results of this work will have direct relevance to the broader field of calling somatic mutations genome-wide, as a part of the NIH Somatic Mosaicism across Human Tissues (SMaHT) Consortium.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3227 Increasing clinical throughput: Automated DNA extraction of cultured cells.

Authors:

A. C. W. Brand, MS, A. S. Berlyoung, PhD, D. A. Johnson, MS, S. C. Lynch, J. Noya, MS, J. Spangler, MS, S. Yusuff, PhD, J. M. Devaney, PhD; GeneDx, Gaithersburg, MD

In genetic testing, quickly producing accurate and reliable data is vital to helping clinical providers communicate test results with patients. This process begins with DNA extraction, which is used for primary downstream testing as well as secondary confirmations of potential molecular variants of interest. Depending on sample type, manual DNA extraction using salting-out pellet precipitation can take 24 to 72 hours due to the length of the protocol and pellet rehydration times. We describe the implementation of an automated KingFisher Flex DNA extraction method for direct and cultured cell types at GeneDx that (1) reduced average DNA extraction time to three hours, (2) eliminated viscosity issues that exist with manual processes, (3) stabilized DNA concentrations post-extraction with the utilization of inverse magnetic particle processing, and (4) maintained downstream success for a wide range of clinical assays. 476 cell pellets were cultured and extracted, 90% of which passed GeneDx extracted DNA quality standards (≥10ng/μL). Compared to original specimen data, average DNA yield and nucleic acid purity slightly decreased using the KingFisher method; however, the average extraction time decreased by 87.5% (from 24 hours to 3 hours). Samples were not viscous, and concentration changed an average of 0.1 ng over 14 days. For downstream analysis, a subset of 82 DNAs were selected with the following cell types: One direct amniotic fluid, 28 cultured skin punches, 48 amniocytes, and five cultured chorionic villi. Extracted DNAs were distributed among 24 tests most common to GeneDx direct and cultured cell samples. Testing included Next-Generation and Sanger sequencing, Multiplex Ligation-dependent Probe Amplification, analysis of repeat expansions, arrays for the detection of copy number variants/regions of homozygosity, and maternal cell contamination. Datasets were generated for each test method comparing original specimen data to validation results, and no statistical difference ($p<0.05$) in data quality was observed. Downstream quality of test results was consistent with the manual extraction method, supporting automated KingFisher Flex DNA extraction of direct and cultured cell sample types as an efficient alternative to manual salting-out precipitation in high throughput clinical settings.

PB3228 Insights from Cohesin Complex and Beyond: A single-center experience for cohesinopathy-related/like disorders

Authors:

J. Alaimo[1], V. Paolillo[1], F. Del Viso[2], A. Cohen[1], E. Farrow[1], S. Starling[1], C. Schwager[1], L. Bartik[3], K. Engleman[1], L. Cross[1], H. Welsh[1], E. Rush[1], S. M. Amudhavalli[1], M. Baig,[1], B. Sullivan[1], D. Zhou[1], E. Shaffer[1], T. Zion[1], E. Boillat[1], T. Pastinen[1], C. J. Saunders[1], I. Thiffault[1]; [1]Children's Mercy, Kansas City, MO, [2]Children's Mercy, kansas City, MO, [3]Children's Mercy, Kansa City, MO

Introduction: Cornelia de Lange syndrome (CdLS) is a well-characterized developmental disorder that is associated with genes encoding the cohesin complex. While a significant proportion is attributed to *NIPBL*, other components of the cohesin complex, combined with broader sequencing testing have led to the identification of individuals who have milder or atypical CdLS features. Moreover, CdLS-like phenotypes have been associated with defects in chromatin-associated proteins, such as *KMT2A, AFF4, EP300, TAF6, SETD5, SMARCB1, MAU2, ZMYND11, MED13L, PHIP, ARID1B, NAA10, BRD4* or *ANKRD11*, most of which have limited or no association with CdLS. Our study sought to identify cases for CdLS genotype/phenotype expansion along with the identification of novel genes. **Methods:** We queried our clinical genetics laboratory and research program "Genomic Answers for Kids" at Children's Mercy, Kansas City, for potential CdLS patients. This retrospective study included >5300 families who received genomic testing. A diagnosis of CdLS was established in a proband with heterozygous pathogenic variants in *NIPBL, RAD21, SMC3, or BRD4*, or hemizygous pathogenic variants in *HDAC8 or SMC1A*. We further extended the analysis to other components and regulators of the cohesin complex, which included many genes of unknown significance (GUS). The medical records were retrospectively reviewed for clinical and phenotypic assessment. **Results:** A total of 51 patients harbored private variants in the selected genes (absent in public datasets): 26 (51%) were *de novo* in origin (when a trio was performed), 35 (68%) had a diagnostic genotype, of which 15 (43%) were in "classic" CdLS genes. The proportion of cohesinopathies attributed to pathogenic variants in established CdLS genes was similar to the reported incidence. Highly suspicious variants of uncertain significance (VUS) were detected in 4 patients with "classic" CdLS. Ten individuals (20%) had deleterious variants in other components/regulators of the cohesin complex, not previously associated with disease. Moreover, we identified two patients, including one with classic CdLS features, with *JADE2* deficiency. Genotype/phenotype assessment suggests that additional factors are contributing to the phenotypic variability and severity. **Conclusion:** In conclusion, our study has successfully broadened our understanding of the genetic and phenotypic diversity observed in CdLS-like disorders. Our findings emphasize the importance of conducting pathway analysis to identify potential causal variants beyond the established CdLS genes. Furthermore, our results support the emerging concept of CdLS-related/like disorders**.**

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3229 In-silico genotyping for Gaucher Disease using Gauchian: The good, the bad, the complex.

Authors:

J. Lichtenberg, E. Hertz, E. Sidransky, N. Tayebi; NIH, Bethesda, MD

Biallelic mutations in *GBA1* result in Gaucher disease (GD), the inherited deficiency of the lysosomal enzyme glucocerebrosidase. Variants in *GBA1* are also the most common genetic risk factor for Parkinson disease (PD). While multiple centers screen for mutant *GBA1* alleles when genotyping patients with parkinsonism, detecting of pathogenic variants, including recombinant alleles resulting from crossover events between *GBA1* and its homologous nearby pseudogene *GBAP1*, remains a challenge.

Recently, a new software tool named Gauchian was introduced to identify *GBA1* variants in whole genome sequencing studies and to detect recombinant alleles. It has been integrated into automatic diagnostic pipelines such as Illumina's Dragen4 to facilitate high-throughput detection of *GBA1* mutations in large cohorts. Using sequencing read depth across a 10kb region between *GBA1* and *GBAP1*, Gauchian employs a Gaussian mixture model to call copy number variants, with losses and gains presumed to represent potentially pathogenic fusion genes consisting of *GBA1* and *GBAP1* fragments. A database of a third of the known *GBA1* mutations is used to classify the cases further.

While Gauchian correctly classified the majority of Gaucher patients in a cohort of 96 individuals previously characterized by Sanger sequencing, it often failed to identify rare mutations and was unable to characterize de novo mutations. By relying on the identification of copy number changes in the intergenic region, the software runs the risk of misreporting the correct number of gene and fusion gene fragments in recombinant alleles. While Gauchian provides a step towards confident in-silico genotyping (sensitivity: 0.9, specificity 1.0), it still reports false positives and negatives that preclude its use in high-throughput variant screening in diagnostic laboratories. Another identified concern stems from an analysis of data from the 1000 Genomes project. Gauchian identified 28 cases out of 1435 individuals with *GBA1* variants. Most of the identified genotypes predicted severe GD that would present in infancy or childhood. suggesting that these were false positive cases.

Because of the significant number of misannotations, future studies should specifically compare the results of Sanger sequencing and copy number analyses with Gauchian predictions in a larger cohort including individuals known to carry complex alleles. While Gauchian may have value in a research setting, we recommend that prior to clinical use, all results be validated with Sanger sequencing and that Gauchian should not be used as a blackbox in larger diagnostic genotyping pipelines.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3230 Integrating machine learning tools into a cloud based NGS platform to facilitate molecular diagnosis of Mendelian disorders.

Authors:

X. Wang[1], H. Yu[2], T. Zhuang[1], W. Xu[2], Y. Yang[1]; [1]AiLife Diagnostics, Pearland, TX, [2]Shandong Normal Univ., Jinan, China

Genome-wide sequencing has been growing rapidly in recent years, driven by advancements in sequencing technology and increasing demand for personalized medicine. In the meantime, clinical laboratories are overwhelmed with huge amounts of raw data but lack comprehensive tools for accurate and efficient clinical interpretations of NGS data. We have developed a cloud based NGS platform (AilisNGS®) with machine learning (ML) features that incorporates all components needed for clinical NGS, including LIS, HPO auto generation by natural language processing (NLP), knowledgebase buildup, secondary data analysis, data annotation, ML supported data interpretation, and clinical reporting.

The ML model for variant prioritization in AilisNGS® was established using a cohort of 657 symptomatic individuals previously referred to our lab for clinical exome sequencing. The exome data was initially processed in the AilisNGS® pipeline for secondary analysis and variant annotation. Clinical interpretation and reporting had been performed using rule based and manual methods according to our SOPs. About 26% of the cases were found to be positive cases with definitively contributing variants identified. For ML, fully annotated variants based on multiple public and internal databases, together with NLP generated HPO terms were fed into a multivariate regression model for training on variant ranking. The trained ML model was then applied to sets of testing data for evaluations. Cross validation data from the 657 samples (2/3 training and 1/3 testing) showed that an average of 94% and 98% of the positive variants rank within the top 5 and top 10 lists of the ML generated candidate variants respectively. While manual variant review can be time consuming, it takes only 36 seconds for the ML algorithm to perform training and testing for the 657 samples. The ML feature is being incorporated into our AilisNGS® pipeline for continuous and automatic learning and optimization of the ML model.

Our study showed that ML based models trained from well-annotated genomic data can accurately prioritize variants and enable efficient and accurate genomic data interpretation and molecular diagnosis. It should be noted that although ML can be a useful tool in NGS data interpretation, final manual review by trained professionals is still needed for clinical NGS cases at the current stage of ML implementation.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3231 Integration of genomic and transcriptomic data for rare disease diagnosis.

Authors:

J. Major-Mincer[1], B. Moore[1], L. Botto[1], R. Mao[2], P. Bayrak-toydemir[2], A. Quinlan[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]ARUP Lab., Salt Lake City, UT

Millions of individuals worldwide are affected by a rare disease. Typically, individuals with a rare disease will undergo a variety of clinical and diagnostic tests to try to provide a diagnosis. Though an estimated 80% of rare diseases have a genetic etiology, genetic diagnoses are lacking due to a myriad of factors. Genetic variant and phenotype association studies are statistically underpowered due to difficulties in assembling sufficiently large cohorts for rare disease. Evaluating the biological significance of genetic variants is challenging and many variants are left classified as “variant of unknown significance” (VUS). Lastly, patients presenting with complex phenotypes may necessitate the investigation of many variants across many genes to determine a correct diagnosis. While whole genome sequencing (WGS) has been transformative in determining the genetic cause of rare disease cases, the diagnostic rate remains at approximately 50% due to the detailed challenges. Clinical laboratories have begun to utilize RNA sequencing (RNA-seq) to identify candidate genes and functionally validate the effect of such VUSs. Diagnostic laboratories typically rely on manual investigation of VUSs with paired RNA-seq expression events, including aberrant total expression, alternative splicing, and allelic imbalance, for confirmation. Even with the rich information RNA-seq can provide, rare disease diagnostics presents unique interpretation challenges. The relevance of proximal or distal variation to combinations of such expression events may entail the ascertainment of tens to hundreds of potentially relevant VUS, leading to scalability challenges when there is no clear prior genetic candidate. We will present our progress in developing a computational framework to automate the integration of paired WGS and RNA-seq data to identify and prioritize gene/variant candidates that are statistically supported by a multi-omics perspective. An emphasis will be placed on concise representation that reduces the interpretation burden on the reviewing clinical team. We will validate our approach on diagnosed patients in collaboration with the Undiagnosed Diseases Network and the Utah NeoSeq Project, which develop and apply state-of-the-art methodologies to diagnose individuals with rare diseases. The tools will then be applied to undiagnosed individuals from the same cohorts to evaluate cases that remained undiagnosed after WGS analysis.

PB3232 Intentionally degenerate probe design for genotyping multiallelic variants

Authors:

B. Main, B. Wong, J. Gollub; Thermo Fisher Scientific, Santa Clara, CA

The Applied Biosystems™ Axiom™ genotyping microarray platform uses a two-color, hybridization- and ligation-based assay. Biallelic and multiallelic SNPs and indels can be genotyped. Multiallelic genotyping is less robust compared to biallelic because it relies on more probe sequences and a complex calling algorithm with more degrees of freedom. In many applications, such as research in inherited diseases, only pathogenic alleles need to be detected and distinguishing non-pathogenic alleles is not necessary. Here, we present the intentionally degenerate probe design (IDPD) method that simplifies multiallelic genotyping by reducing the number of alleles to distinguish. To accomplish this, IDPD probes ambiguously detect two or more non-pathogenic alleles in the same channel. To estimate the scale of pathogenic markers that are amenable to IDPD, we applied IDPD to a set of 20,232 multiallelic variants in ClinVar. Probe designs were successful for 12,452 (62%) of the variants. The next step would be to compare concordance of IDPD versus standard multiallelic probe design (MA) on an array. However, DNA samples with pathogenic alleles are not readily available. We therefore applied IDPD to a set of 48,497 complex multiallelic variants that have alleles observed in 1000 Genomes Project samples. After standard QC filtering, IDPD outperformed MA with 60% more markers achieving high call rate and concordance (>0.95) to 1000 Genomes Project reference calls. Thus, IDPD is an important new tool that can be used to substantially increase the number of complex pathogenic variants that can be interrogated by the Axiom platform.

PB3233 *Investigating the molecular mechanism of a complex genomic rearrangement causing 6X amplification at 13q33.3*

Authors:

P. Kaur[1], C. M. Grochowski[1], H. Du[1], P. J. Hastings[1], K. Machol[2,3], J. R. Lupski[1,3,4,5,6]; [1]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [2]Dept. of Molecular and Human Genetics, Baylor Coll. Med., Houston, TX, [3]Texas Children's Hosp., Houston, TX, [4]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [5]Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, [6]Baylor Genetics, Houston, TX

Copy number variation (CNV) leading to gene dosage changes are associated with several genomic disorders. When found within a complex genomic rearrangement (CGR), these deviations from diploid state pose a challenge to clinical interpretation partly due to current sequencing technology limitations such as short read lengths and computational challenges of mapping to repetitive sequences. Herein, we present a CGR at 13q33.2 in a 2-years-old male with developmental delay, recurrent infections, hypergammaglobulinemia, laryngeal cleft, thrombocytopenia, fatty liver and splenomegaly. Whole exome sequencing and chromosomal microarray revealed an apparent 6x amplification of LIG4, inherited from phenotypically normal father, however its boundaries could not be ascertained. No other clinically significant variants were identified. In order to better delineate this higher order amplification, we enrolled the family in our IRB approved research protocol and employed short read whole genome sequencing (WGS) followed by read depth analysis using VizCNV plotting tool (https://github.com/BCM-Lupskilab/VizCNV). This revealed a more complex genomic structure than previously detailed on clinical testing. Five copy number changes were seen in an apparent duplication-triplication-6xAmplication-triplciation-duplication event at 13q33.2. All five segments were in positive orientation with length ranging from 5,805 to 240,926 bp. Within these copy number changes, three junctions (blunt fusion, 4 bp insertion and 2 bp deletion) were mapped to nucleotide level resolution. The largest segment had 6X copy number and spanned LIG4, ABHD13 and TNFSF13B. MYO16, was located in region of copy number change truncating this amplified copy of the gene. These findings were confirmed by long read WGS with reads spanning more than one junction. Cohort analysis of over 60,000 individuals who underwent clinical CMA testing revealed four additional patients with CNVs in same relative region affecting the gene LIG4 who had developmental delay, autism, sensory dysfunction and seizures among other findings. The clinical significance and molecular mechanism(s) of gains within 13q33.3 remain to be established. To further resolve this CGR and its clinical significance, we will employ WGS in the four additional patients with gains of LIG4, optical genome mapping to visualize the structure in a linear fashion and expression studies of involved genes. This study emphasizes the complexity of structural mutagenesis and interpretive challenges for clinical genomicists. Understanding CGRs in human disease paves path for evidence based clinical practice.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3234 † Lessons learned from the nationwide 10K rare disease genome project.

Authors:

G. Seo[1], H. Han[1], D-W. Kim[1], R. Khang[1], E. Lee[1], J. Han[1], J. lee[1], H. Lee[1], M. Kim[2], B. Lee[3]; [1]3billion, Seoul, Korea, Republic of, [2]Seoul St. Mary s Hosp./The Catholic Univ Korea, Seoul, Korea, Republic of, [3]Asan Med Ctr, Seoul, Korea, Republic of

As part of the pilot study for the South Korea National Project of Bio-big Data supported by the Korea National Institute of Health (KNIH), ~10,000 suspected rare genetic disease patients (4,657) and family members (5,306) were recruited through 17 hospitals between 2021 and 2022. Whole genome sequencing (WGS) was performed on all participants using TruSeq PCR-free library preparation kit and NovaSeq6000 (Illumina). SNV/INDELs and structural variants (SV) including CNVs, inversions, translocations, and repeat expansions were called and interpreted using a custom developed AI-based system, EVIDENCE, that adopts the ACMG variant classification guideline. Once the variants were annotated, filtered, and prioritized, each patient data was manually curated by medical geneticists for reporting of the diagnostic variants and the results were reviewed by the clinical committee to confirm the genotype-phenotype correlation before the return of results to the patient. Overall, 31.6% of the patients received a conclusive molecular diagnosis. Patients with at least one family member sequenced yielded higher diagnostic rate (DR) of 40.8% compared to patients without family members (25% DR). The DR varied by disease categories, and the two groups with the highest DR were ‘neurology/neurodevelopmental disorders (47.3%)’ and ‘dysmorphic/congenital abnormality syndromes (42.9%)’. The lowest DR of 9.2% was observed for ‘cancer’ and the overall DR without ‘cancer’ increased to 37.8%. Of all diagnosed patients, 28.3% were diagnosed with at least one SVs. Most of them had CNVs (97.2%), 1.5% had repeat expansions, and the rest had other SVs including LINE-1 insertions and UPD. Importantly, 3.9% of the diagnosed patients could not have been diagnosed by WES or CMA as the variants were deep intronic or copy-neutral/complex SVs. Additional 5.2% of the patients received inconclusive results and 16 of them had deep intronic variants that were predicted to alter splicing, requiring further study. An essential component of the successful completion of this project within just a year was cost-effective distribution of the tasks across multiple sites and a highly streamlined process including the automated and accurate analytical system handling large genomic dataset. Although further workup such as re-evaluating the patients, reanalyzing the WGS data, integrating RNAseq data and/or performing long-range sequencing is warranted for the undiagnosed patients, this study demonstrates that WGS is a preferred first-line genetic diagnostic tool for a large portion of the patients with suspected rare genetic diseases yielding high diagnostic rate while being fast and accessible.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3235 Long-Chain Fatty Acid Oxidation Disorder Gene Variants and Newborn Screening Results from a Sponsored Gene Panel Program

Authors:

V. Rangel Miller[1], H. Gutierrez[1], O. Japalaghi[1], L. Konczal[2], D. Marsden[1], D. McKnight[3], M. Mcnutt[4], M. Vela-Amieva[5], N. Miller[1]; [1]Ultragenyx Pharmaceutical Inc., Novato, CA, [2]Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH, [3]Invitae Corp., San Francisco, CA, [4]UT Southwestern Med. Ctr., Dallas, TX, [5]Natl. Inst. of Pediatrics, Mexico City, Mexico

Introduction: Long-chain fatty acid oxidation disorders (LC-FAOD) are rare, life-threatening but treatable autosomal recessive conditions that result from impaired utilization of long-chain fatty acids for energy production. Clinical signs may include hypoglycemia, cardiomyopathy, cardiac arrhythmias, retinopathy, and rhabdomyolysis. LC-FAOD may be detected through newborn screening (NBS) or plasma/dried blood spot acylcarnitine (AC) analysis. Genetic testing can aid diagnosis, but access to follow-up genetic testing has historically been limited.
Methods: Clinicians suspecting LC-FAOD accessed a no-charge gene panel consisting of the LC-FAOD genes (*ACADVL*, *CPT1A*, *CPT2*, *HADHA*, *HADHB*, *SLC25A20*) plus 19 genes associated with disorders having a similar presentation or overlapping AC profiles. Samples were submitted to Invitae® for clinical testing sponsored by Ultragenyx. De-identified results and optional clinical data were used for this analysis.
Results: As of APR2023, 84 of 1060 patients tested received a presumed LC-FAOD molecular diagnosis (a combination of 2 or more pathogenic variant(s), likely pathogenic variant(s) or VUS): 62% *ACADVL*, 19% *CPT2*, 11% *HADHA*, 4% *HADHB*, 2% *CPT1A*, 2% *SLC25A20*. NBS results were provided for 526 patients as positive (suggestive of increased risk of LC-FAOD) or negative (suggestive of no increased risk of LC-FAOD). A positive NBS and a presumed molecular diagnosis were identified in 58/526 patients. Among 468/526 patients without a molecular diagnosis, NBS results were 95% positive, 5% negative. AC analysis results were provided for 503 patients as positive (suggestive of LC-FAOD), inconclusive (neither normal nor suggestive of LC-FAOD), or negative (normal). A presumed molecular diagnosis was found in 51/503 patients, and AC results were 65% (33/51) positive, 35% (18/51) inconclusive. Among 452/503 patients without a molecular diagnosis, AC results were 73% (331/452) inconclusive, 21% (93/452) positive, 6% (28/452) negative. Additionally, 103 patients had only one LC-FAOD variant identified (83% *ACADVL*). 84/103 patients had NBS results provided: 99% (83/84) positive. 54/103 patients had AC results provided: 78% (42/54) inconclusive, 15% (8/54) positive, 7% (4/54) negative.
Conclusion: Diverse genetic findings were observed among patients tested through this gene panel. VUS and single heterozygous variants were frequent, highlighting the diagnostic challenges for patients with abnormal NBS for LC-FAOD and/or abnormal AC profiles. These data demonstrate the value of gene panel testing to aid LC-FAOD diagnosis and highlight the need for clinical and biochemical evidence to resolve VUS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3236 † Long-read sequencing addressed clinically unsolved problems remained by expanded carrier screening: thalassemia as an example.

Authors:

Y. Zheng[1], M. Chau[2], Y. Cao[1], E. Dong[1], C. CHAN[3], A. LIAUW[4], S. TONG[5], S. LAU[1], A. KWAN[1], M. SHI[1], S. JIANG[1], Y. Kwok[1], T. Leung[1], K. Choy[6]; [1]The Chinese Univ. of Hong Kong, Hong Kong, China, [2]Baylor Coll. of Med., Houston, TX, [3]Hong Kong Maternal & Fetal Med. Clinic, Hong Kong, China, [4]Union Hosp., Hong Kong, China, [5]United Christian Hosp., Hong Kong, China, [6]Chinese Univ. of Hong Kong, Hong Kong, China

Background: Widespread next-generation sequencing- (NGS) based expanded carrier screening (ECS) could support an informative reproductive decision. However, it is limited by a short-read sequencing strategy, and thus could not adequately evaluate several prevalent conditions related to low sequence complexity or repeat regions. This study aimed to assess the utility of long-read sequencing (LRS) in solving these challenges by taking homologous α- and β-globin gene clusters as examples. **Methods:** We retrospectively reviewed NGS-based ECS results of 782 individuals from 2019-Mar to 2021-Sep, among which 14.1% (110/782) cases were screened positive as thalassemia carriers. Inconclusive results were obtained for 0.3% (2/782) of cases. There were 4/476 (0.8%) hemoglobin (Hb) Bart's hydrops at-risk couples (ARCs), and 1/476 (0.2%) Hemoglobin H-constant spring (Hb H-CS) ARC identified. However, alpha-thalassemia deletion subtypes cannot be delineated for future genetic workup. Targeted LRS was applied to 104/774 (13.4%) of the selected cases with sufficient samples, including 1) Ten cases in the unsolved group: The two inconclusive cases, the four Hb Bart's ARCs, and one Hb H-CS ARC and 2) Ninety-two other thalassemia carrier cases in the validation group. Variant analysis was blinded from previous testing results. **Results:** LRS resolved all (12/12) cases in the unsolved group: phased one case with both *HBA1* deletion and *HBA2* triplication as HKαα (Hong Kong αα) allele, thus clarifying the non-carrier status; revealed ECS missing variant Hb Quong Sze for another case with abnormal hemoglobin parameters; delineated deletion subtype as SEA for all four Hb Bart's ARCs; and THAI for Hb H-CS ARC. For the validation group, all 97 events detected by the NGS-based ECS panel were validated by LRS. Overall, 2.8% (3/108) additional events missed by the NGS-based ECS panel were revealed by LRS, leading to a change of thalassemia carrier status for 1.9% (2/104) cases after internal curation. **Conclusions:** LRS is more comprehensive for thalassemia screening. The potential of LRS acting as a supplement of NGS-based ECS panel for challenging genes for reducing residual risk deserves further investigation.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3237 Making the call: Trends among successful strategies to conclude the diagnostic odyssey for participants at the Pacific Northwest Undiagnosed Diseases Network clinical site.

Authors:

E. Blue[1,2], S. Sheppeard[1], A. Allworth[1], E. Kaitryn[1], J. Chen[1], D. Miller[1,2,3], E. Rosenthal[1], A. Stergachis[1,2], S. Strohbehn[1], N. Dargie[1], D. Doherty[1,3,2], A. Folta[1], M. Gillentine[3], M. Horike-Pyne[1], G. Mirzaa[4], J. Ranchalis[1], U. Schwarze[1], M. Bamshad[1,3,2], P. Byers[1], S. Chanprasert[1], I. Glass[1,2], K. Leppig[5], W. Raskind[1], V. Sybert[1], M. Wener[1], F. Hisama[1,2], K. Dipple[3,1,2], G. Jarvik[1,2], University of Washington Center for Mendelian Genomics (UW-CMG), Undiagnosed Diseases Network (UDN); [1]Univ. of Washington, Seattle, WA, [2]Brotman Baty Inst., Seattle, WA, [3]Seattle Children's Hosp., Seattle, WA, [4]Seattle Children's Res. Inst., Seattle, WA, [5]Group Hlth.Cooperative, Kaiser Permanente Washington, Seattle, WA

The Undiagnosed Diseases Network (UDN) offers comprehensive clinical and multiomics profiling to individuals with rare disorders who have exhausted local resources during their long diagnostic odyssey. The Pacific Northwest UDN clinical site has provided diagnoses to dozens of individuals since 2018 through our interdisciplinary approach and deep, diverse range of expertise. Here, we offer metrics and trends among our successes and obstacles to diagnosis, each supported by an example case.

We performed a comprehensive review of the 258 applications reviewed by our center over the last five years, up to May 5, 2023. Through our careful review of existing medical records, we diagnosed 25 (10%) applicants without admitting them to our program. The overwhelming majority of these were adults (88%), and only 16% involved genetic diagnoses.

Among the 134 participants enrolled in our study (52% of applicants), we diagnosed 26 (27%) of the 95 participants evaluated to date. We are pursuing strong candidates for another 18 (19%), while evaluations are pending or ongoing for the remaining participants. Most evaluated participants with new diagnoses are pediatric (58%) and most have a genetic diagnosis (88%). A "genome-first" approach would have provided many (35%) of these genetic diagnoses while avoiding costly chart review, as pathogenic or likely pathogenic variants were identified in the original clinical exome or genome analysis.

Our program emphasizes that the value of reanalysis and fresh clinical and molecular perspectives cannot be overstated. Our depth of clinical expertise applied to medical records across time and providers benefited all applicants and directly led to 24 diagnoses (47%), while reanalysis of clinical sequence data led to 10 molecular diagnoses (38%). Atypical phenotypic presentations could be explained by multiple rare disease diagnoses in a single participant (n >= 2) or novel disease mechanisms (n = 2) or genes (n = 3). Two cases of mosaicism required sequencing of multiple tissue sources, while research technologies including long-read DNA sequencing and transcriptomics resolved the boundaries and phenotypic consequences of pathogenic structural variants (n = 3).

Despite our best efforts, diagnostic rates were slowed by common obstacles in rare disease research, including the "n of 1" problem requiring patient-specific experiments in model systems and the patience to wait for matches within gene- and phenotype-based patient networks. These results emphasize the need for precise data sharing among networks of experts who are then provided time and targeted experimental resources tailored to individual patient needs.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3238 Measuring genome wide sensitivity for detecting copy number variations (CNVs) using a sampling methodology.

Authors:

A. Roter[1], B. Bolstad[1], J. Schmidt[2], L. Wu[2]; [1]Thermo Fisher Scientific, Healdsburg, CA, [2]Thermo Fisher Scientific, Santa Clara, CA

Chromosomal Microarrays are the first tier research tool for chromosomal abnormalities. But measuring the sensitivity to detect CNVs for all 3 billion base pairs of the human genome using real samples is an impossible task. As a reasonable proxy, we use a sampling method on microarray data generated on chromosome aberration cell lines from the National Institute of General Medical Science Chromosome Abnormality Human Genetic Cell Repository. These cell lines have large chromosomal aberrations due to aneuploidy, triploidy and unbalanced translocations that create large regions of non-neutral copy number across a large portion of the genome. Genomic DNA from 41 chromosome aberration samples was processed and run 3 to 7 replicates on the CytoScan HD Accel microarray, using the accelerated 2-day protocol using 100µg of input DNA. This generated a data set of 195 microarrays with large aberrations covering ~ 50% of the genome. Stretches of log ratio data with lengths of 25 to 150 markers were sampled from the aberration regions and inserted into 100 marker stretches of log ratios randomly sampled from copy number neutral regions. These stretches of marker data were run through a Hidden Markov Model copy number segmentation and calling algorithm and scored as detected if 90% of the markers were called as the correct copy number by the algorithm. This was repeated for every 25 bp sliding window in the aberration regions, resulting in a test of over 130,000 sampled regions. For regions of copy number loss, the average sensitivity for detecting 25 marker segments of at least 25kbp was 97.4%. For regions of copy number gain, the average sensitivity for detecting 50 marker segments of at least 50kbp was 96.5%. Analysis of the large chromosome aberrations showed that the mean reproducibility for detecting losses or gains of ≥ 100kbp was 100% (95% confidence interval of 98.8 to 100%). In addition, the false discovery rate for 400kbp segment with ≥50 markers was 2.3% (2.7% for gains and 1.8% for losses), corresponding to a PPV of 97.7%.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3239 Minimizing uncertainty and increasing equity in genetic testing: the role of machine learning tools in the classification of genetic variants

Authors:

F. Facio[1], A. Colavin[1], B. Johnson[1], S. Aradhya[1], J. Reuter[1], S. Padigepati[1], T. Manders[1], J. Nicoludis[2], D. Stafford[1], A. Wahl[1], Y. Kobayashi[1], R. Nussbaum[1], K. Nykamp[1], L. Fresard[1]; [1]Invitae, San Francisco, CA, [2]Genentech, San Francisco, CA

INTRODUCTION: Variants of uncertain significance (VUS) remain a challenge in the translation of genetic information to clinical care. This study describes an Evidence Modeling Platform (EMP) designed to validate and integrate novel variant evidence sources. This EMP combines clinical genomics expertise with machine learning (ML) models built from various types of input data (e.g. evolutionary conservation, population frequency, protein structure) to provide evidence for a variant's pathogenicity. Here we present the **validation** and the **impact** of the EMP models on variant classification (VC) for individuals undergoing testing for diverse hereditary conditions.
METHODS: EMP was validated by calculating the concordance in VC with and without the input of its models for novel variants observed at Invitae® from May 2022 to May 2023. Impact was measured by assessing the proportion of individuals with ≥1 variants classified as Benign (B), Likely Benign (LB), Likely Pathogenic (LP), Pathogenic (P) after the application of EMP evidence. For each clinical area and clinician-reported ancestry group analyzed, 10 subsets of 5,000 individuals were sampled.
RESULTS: **Validation**: 27,477/496,209 novel variants were eligible for validation, as they received evidence from at least one EMP model and had reached a non-VUS classification without that evidence. Across 8,517 pathogenic variants and 14,960 benign variants, the EMP models achieved 98% Negative Predictive Value and 90% Positive Predictive Value. **Impact**: Overall, 22.3% of individuals had at least one variant classified based on the input from EMP models (21.6% from VUS to B/LB, 1.4% to P/LP). Impact varied by clinical area, being the greatest among individuals tested for immunology (60.5%) and neurology (48.5%). Impact also varied by ancestry, with the greatest impact seen among individuals of Asian (33.7%) and Black (28.7%) ancestries compared to White individuals (18.5%, two-sided t-test p<1e-10).
CONCLUSION: A systematic approach to integrating ML models into VC yields highly accurate interpretations, allowing a significant proportion of individuals with a VUS to receive a more definitive result. EMP models are largely informed by biologically-grounded hypotheses, not biased by the ancestral origin of the evidence, leading to more equity in VC.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3240 Mitochondrial dysfunction detected by peripheral blood mononuclear cells analysis in patients with Williams-Beuren syndrome

Authors:

I-C. Ling[1], T-L. Liao[2], D-M. Niu[1,3,4], Y-J. Chen[1,3,2]; [1]Dept. of Pediatrics, Taipei Veterans Gen. Hosp., Taipei, Taiwan, [2]Dept. of Life Sci. and Inst. of Genomic Sci., Natl. Yang-Ming Chiao Tung Univ., Taipei, Taiwan, [3]Inst. of Clinical Med., Sch. of Med., Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan, [4]Genetic Counseling Ctr., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Williams-Beuren syndrome (WBS) is a rare genetic disorder caused by the deletion of about 28 genes on chromosome 7q11.23. Secondary mitochondrial dysfunction frequently accompanies genetic disorders and plays a significant role in their pathogenesis even without major mitochondrial gene defects. Previous studies have implied that individuals with WBS might have decreased mitochondrial function. However, practically, there are no feasible methods for screening mitochondrial function in WBS patients.

Peripheral blood mononuclear cells (PBMCs) analysis through Seahorse XFe analyzer and flow cytometry were used to evaluate mitochondrial function in this study. For XFe analyzer, cellular respiration, and bioenergetics are measured, where mitochondrial mass, reactive oxygen species (ROS), and membrane potential are estimated via flow cytometry.

PBMCs from 30 healthy individuals (HI) and 15 WBS patients were collected. In the bioenergetic analysis by Seahorse XFe analyzer, a significant reduction of mitochondrial respiration was found in WBS patients, including decreased maximal respiration, decreased spare respiratory capacity, and increased proton leakage. The overall bioenergetics health index (BHI) was lower in WBS than in normal healthy individuals. BHI were 1.20±0.44 and 1.93±0.29 for patients with WBS and HI, respectively. In flow cytometry, ROS and mitochondrial mass were higher in WBS than in HI; while the mitochondrial membrane potential was lower in WBS than in HI. All of these could imply that WBS patients have decreased mitochondrial function even though they have more mitochondria.

In conclusion, bioenergetic analysis and flow cytometry were performed on blood samples of patients with WBS and HI. Our results revealed patients with WBS had lower BHI, lower mitochondrial membrane potential, and higher ROS. All of these indicate mitochondrial dysfunction in WBS patients and enhancement of mitochondrial function may improve WBS clinical manifestation.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3241 Molecular and phenotypic characterization of a group of Colombian patients with clinical suspicion of a RASopathy.

Authors:

M. Suarez Rubiano[1], S. Bello Uyaban[1], J. Lores Espinosa[2], H. Pachajoa[3], M. Galvez[4]; [1]Gencell – Genuino Res. Group, Bogotá, Colombia, [2]Pontifical Javeriana Univ., Cali, Colombia, [3]Icesi Univ. - Valle de Lili Fndn.., Cali, Colombia, [4]Gencell – Genuino Res. Group, Bogota, Colombia

Purpose: RASopathies are rare diseases with a worldwide incidence of 1 in 1.000 live births. This group of diseases present common clinical characteristics, secondary to germline variants in the RAS-MAPK pathway. In Colombia, there is only one study characterizing Noonan Syndrome (a RASopathy) in a specific geographic region of the country. A wider knowledge of these diseases' spectrum in our country is needed.
Objective: To perform a genotypic and phenotypic characterization in a group of Colombian patients with a clinical suspicion of a RASopathy.
Methodology: Observational, retrospective, cross-sectional study including subjects who underwent next-generation sequencing (NGS) analysis of genes related to RASopathies. Two groups were defined based on clinical suspicion: 1) Neurofibromatosis and 2) Other RASopathies. The analysis includes a description of pathogenic (P) and likely pathogenic (LP) variants, as well as a general phenotypic description of the two groups.
Results: A total of 127 subjects, distributed among the five Colombian geographic regions (Andean, Pacific, Orinoquia, Caribbean and Amazon) were included. Fifty-four percent were male. The most frequent diagnosis suspicion was Neurofibromatosis in 77 (60.6%) subjects, who had a median age of 10 years (IQR: 3-16) at the time of molecular testing. P or LP variants were identified in 29 (37.6%) of these patients, with NF1 being the most affected gene (96.5%) and null variants (frameshift, nonsense and deletions) being the most frequent (75%). We found 50 (39.3%) cases with clinical suspicion of other RASopathies, with a median age of 7.5 years (IQR: 3-15) at the time of genetic testing. P or LP variants were identified in 21 (42%) of these cases. PTPN11 mutations were predominant (52.3%) and missense variants were the most frequent in this group (85.71%). Overall, 50 subjects had a confirmed molecular diagnosis of a RASopathy, 56% with Neurofibromatosis type 1 and 30% with Noonan syndrome. Other less frequent syndromes included Leopard, cardiofaciocutaneous, Schwannomatosis and Noonan-like.
Conclusions: We describe the largest known genotypic-phenotypic characterization in a Colombian group of patients with a suspected RASopathy. NGS is an useful tool for molecular confirmation of RASopathies, given the genetic heterogeneity of this spectrum. We observed a delayed median age for molecular diagnosis, which in the era of precision medicine could impact access to personalized therapies.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3242 Molecular characterization of a colombian group of patients with clinical suspicion of dystrophynopathies.

Authors:

M. Galvez[1], S. Bello Uyaban[2], A. Eslava[1], S. Castellar[3]; [1]Gencell-Genuino Res. Group, Bogota, Colombia, [2]Gencell-Genuino Res. Group, Bogotá, Colombia, [3]Univ. Natl. de Colombia-Inst. Roosevelt, Bogota, Colombia

Purpose:
Dystrophynopathies are the most common inherited muscular dystrophy (incidence 19.5/100.000 live male births). These are caused by mutations in the *DMD* gene. Some of these lead to milder manifestations, known as Becker, and the severest form known as Duchenne. Initial clinical features should be suspected by primary physicians, but in low-income countries as Colombia they are commonly suspected by clinical specialists. There are a limited number of studies concerning dystrophynopathies in our country. Therefore, understanding the underlying genetic causes and the health professionals requesting molecular testing in Colombia is relevant.
Objectives:
To describe the molecular findings in a group of Colombian male patients who underwent molecular testing of the *DMD* gene within the context of a personal and/or family history of a suspected distrophinopathy.
Methodology:
Retrospective, descriptive, cross-sectional study analyzing the results of *DMD* molecular testing and the medical specialty requests, between 2019 and 2022. Initially, a multiplex ligation-dependent probe amplification (MLPA) was carried out, and when negative, followed by next-generation sequencing (NGS). The molecular results were analyzed considering only pathogenic and likely pathogenic variants.
Results:
We included 346 male patients, of which seven were familial cases, belonging to three families. Median age at the moment of molecular testing was 9 years (IQR 6-14) and the demographic analysis showed a distribution of subjects in four out of the five Colombian geographic regions (Andean, Pacific, Orinoquia and Caribbean). Health professionals requesting the genetic test included pediatric neurologists (31.2%), clinical geneticists (26.6%), physiatrists (16.7%), pediatricians (12.2%) and others (13.3%). A pathogenic or likely pathogenic variant was identified in 41% of cases, confirming a dystrophinopathy in 142 patients. Copy number variants (CNV) were identified in 91 (64%) individuals, 82.4% of them corresponded to deletions. Single-nucleotide variants were found in 51 cases (36%), of which nonsense were the most frequent (54.9%), followed by frameshift (25.5%) and splicing site (17.6%).
Conclusions:
CNV were the most frequently identified variants, accordingly to worldwide genotypic description associated with *DMD* gene, which highlights the importance that health professionals should consider first a MLPA-based diagnosis strategy, and only in negative cases, requesting a sequencing technique during primary attention. We found a low proportion of molecular requests by primary care programs, which could impact early diagnosis and treatment.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3243 Molecular diagnosis for patients with autism spectrum disorder

Authors:

N. Miyake[1], T. Yoshinori[2], R. Fukai[3], E. Koshimizu[3], S. Miyatake[3], A. Takata[4], N. Matsumoto[3]; [1]Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, [2]Sagami Women's Univ., Sagamihara, Japan, [3]Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan, [4]RIKEN Ctr. for Brain Sci., Wako, Saitama, Japan

Autism spectrum disorder (ASD) is a heterogenous neurodevelopmental disorder characterized by persistent deficits in social communication and interaction across multiple contexts, and restricted, repetitive pattern of behavior, interests, or activities, with onset during the first year of life. Monogenic and polygenic causes have been indicated. We investigated monogenic factors in 405 individuals (351 trios, 24 quads, and 2 quintet families) affected with ASD using trio-based whole exome sequencing (WES). We reached the molecular diagnosis in 66 affected individuals (16.3%). Total 55 causative variants including 45 single nucleotide variants (SNVs) and 10 small insertion deletions (indels) were classified “Pathogenic” (28 variants) and “Likely pathogenic” (27 variants) based on the American Collage of Medical Genetics/Association for Molecular Pathology guidelines. They were confirmed by Sanger sequencing. We also analyzed copy number variants (CNVs) using WES data by eXome Hidden Marcov Model, and reached molecular diagnosis in 13 affected individuals (3.2%). 13 CNVs were confirmed by quantitative PCR. The molecular diagnostic rate in our cohort was higher in females than in males, which is consistent with “female protective effect” as previously reported. We analyzed familial cases (24 quads and 2 quintets), and contrary to expectations, we found only one family shared the pathological variant. Interestingly, the molecular diagnostic rate in familial cases (4/54, 7.4%) was lower than simplex cases (62/351, 17.7%), which might indicate a difference in genetic architecture between simplex and multiplex families. As one attempt, we simulated the diagnostic yield of WES data using known disease-related aberrant genes for each year since 1992, and calculated that the average percentage of newly resolved cased was 0.63% (0%~2.5%) per year in our ASD cohort. We re-recognized the importance of re-analysis using the latest annotation data.

PB3244 Molecular Diagnostic Yield of Exome Sequencing and Chromosomal Microarray in Short Stature: A Systematic Review and Meta-analysis

Authors:

Q. Li[1], Z. Chen[1], J. Wang[1], K. Xu[1], X. Fan[2], C. Gong[3], Z. Zhao[1], G. Li[1], J. Cai[1], Z. Wu[4], T. Zhang[1], N. Wu[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]Dept. of Pediatric, The second affiliated Hosp. of Guangxi Med. Univ., Guangxi, China, [3]Dept. of Endocrinology, Genetics and Metabolism, Beijing Children's Hosp., Capital Med. Univ., Natl. Ctr. for Children's Hlth., Beijing, China, [4]Peking Union Med. Coll. Hosp., Chinese Academy of Med. Sci., Beijing, China

Background: The diagnostic yield of exome sequencing (ES) and chromosomal microarray analysis (CMA) for short stature cohorts is currently uncertain, despite their widespread use. A definitive diagnostic yield has not been established.
Methods: A systematic literature search was conducted in three databases (PubMed, Embase, and Web of Science) in February 2023 to investigate the diagnostic yield of ES and CMA in short stature. Eligible studies for meta-analysis were those that had at least 10 participants with short stature who were diagnosed using either ES or CMA, and the number of diagnosed patients was reported. Out of 5,222 identified studies, 20 were eventually included in the study. Two independent investigators extracted relevant information from each study, which was then synthesized using proportional meta-analysis to obtain the overall diagnostic yield of ES and CMA.
Results: The overall diagnostic yield of ES among the cohorts (10 study cohorts comprising 1,350 individuals) and CMA among the cohorts (14 study cohorts comprising 1,070 individuals) was found to be 27.1% (95% CI, 18.1%-37.2%) and 13.6% (95% CI, 9.2%-18.7%), respectively. A subgroup meta-analysis was also performed to assess if the diagnostic yield varied depending on whether ES was used as a first-tier or last resort test. Although no statistically significant difference was observed between the first-tier and last resort groups, a slightly higher diagnostic yield was observed in the former. Furthermore, a meta-regression was carried out to investigate how the diagnostic yield varied over time. There was an increase in the percentage of positively diagnosed patients over time, although this was not statistically significant.
Conclusions: The results of this systematic review and meta-analysis suggest that ES and CMA may be warranted to identify molecular disorders of children with short stature. The diagnostic yield of ES was higher than that of CMA, and there was a slightly higher diagnostic yield when ES was used as a first-tier test. Although there was no statistically significant increase in diagnostic yield over time, the trend suggests that these tests may become even more effective in the future. These findings have important implications for clinical practice, as they suggest that ES and CMA should be considered as diagnostic tools for children with short stature.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3245 Molecular genetic analysis of patients with skeletal disorders: Identification of ultra-rare monogenic diseases.

Authors:

L. Dvorakova[1], M. Reboun[1], R. Bakalar[1], P. Slavikova[1], R. Svacinova[1], V. Todorovova[1], K. Peskova[1], A. Baxova[2], T. Honzik[1]; [1]Dept. of Pediatrics and Inherited Metabolic Disorders, Gen. Univ. Hosp. and 1st Faculty of Med., Charles Univ., Prague, Czech Republic, [2]Inst. of Biology and Med. Genetics, Gen. Univ. Hosp. and 1st Faculty of Med., Charles Univ., Prague, Czech Republic

Background: Monogenic skeletal disorders are a heterogeneous group of disorders affecting the development, growth and homeostasis of bone and/or cartilage. They remain a diagnostic challenge due to their phenotypic diversity.**Methods:** Sequencing of 334 genes was performed using a custom enrichment system (Roche) and the MiSeq platform (Illumina). Variant calling was performed using an in-house pipeline including the ANNOVAR annotation tool and the CNV kit. **Results:** Molecular genetic analysis was performed in 109 patients, the causative mutation was found in 36 of them. Low diagnostic yield is observed mainly in children with isolated short stature (height below -2.5 SD) and isolated osteoporosis (Z-score below -3). Some of the diagnosed patients had specific signs leading to a high suspicion of the disease and molecular genetic analysis confirmed the diagnosis. For example, Aarskog-Scott syndrome (*FGD1*, two probands), fibrodysplasia ossificans progressiva (*ACVR1*, one proband), hypophosphatemic rickets (*PHEX*, three probands), multiple epiphyseal dysplasia (*SLC26A2*, four probands). The other patients had less specific signs, in three of them an extremely rare diagnosis was confirmed. In one patient, two undescribed variants (c.82+2T>G and c.258G>C, which may lead to missense and/or splicing mutation) were identified in *B3GAT3*. The clinical symptoms were fully compatible with this finding and led to the diagnosis of glycosaminoglycan linkeropathy (osteoporosis, repeated fractures, radioulnar synostosis, valve involvement, joint dislocation, hypermobility). In the second patient with IUGR/SGA, growth failure (-2.9 SD), microcephaly and delayed speech development a deletion of the distal part of the long arm of chromosome 15 including *IGF1R* was identified. We conclude that haploinsufficiency of *IGF1R* is a highly probable cause of the patient's phenotypic symptoms. The third patient was a newborn with craniosynostosis, prominent forehead, midface hypoplasia, proptosis, limb contractures, clubfoot, long toes, genital anomalies (originally thought to be female, normal male profile was found by array CGH). Two previously described mutations in *POR* confirmed the diagnosis of Antley-Bixler syndrome.**Conclusions:** Skeletal disorders show a wide variety of phenotypic manifestations and a high degree of heterogeneity in the genetic basis. Next-generation sequencing is the method of choice to confirm the diagnosis. One of the reasons why some patients remain undiagnosed is a mutation in a gene not included in the panel. We are now testing the yield of whole exome sequencing in undiagnosed patients.Support: MH CR-RVO-VFN00064165

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3246 Molecular genetic testing of congenital adrenal hyperplasia due to 21-hydroxylase deficiency should include comprehensive chimera analysis.

Authors:

Q. Lao[1], S. Kollender[1], D. Burkardt[1], A. Schulman[1], A. Moon[1], D. Merke[1,2]; [1]NIH Clinical Ctr., Bethesda, MD, [2]The Eunice Kennedy Shriver Natl. Inst. of Child Hlth.and Human Dev., Bethesda, MD

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive diseases of steroid hormone biosynthesis with 21-hydroxylase deficiency CAH due to defects in *CYP21A2* accounting for 95% of the cases. Both neonatal screening and diagnosis are based on biochemical testing. Molecular genetic testing is a vital second tier means of CAH diagnosis and is essential for genetic counseling, but is not suitable for massive parallel sequencing methodologies due to the pseudogene interferences across the genome locus where *CYP21A2* is mapped, and chimeric genes due to large gene conversions or unequal crossovers (also called 30-kb deletions) during meiosis commonly exist. Most commercial molecular tests detect pathogenic CAH alleles of minor pseudogene conversions and chimeric genes but rarely analyze the latter in detail. In our large CAH cohort at the U.S. National Institutes of Health Clinical Center (n=420), chimeric genes account for 28% of the CAH alleles (242 of 850), and a comprehensive analysis of the chimeric genes is clinically meaningful in 20% (39/197) of patients carrying a chimeric allele. *CYP21A1P-TNXA/TNXB*, or CAH-X chimeras, are associated with hypermobility type Ehlers-Danlos syndrome manifestations. The vast majority of known *CYP21A1P/CYP21A2* chimeras are null 38/197mutations, but attenuated chimeras corresponding to a milder phenotype also exist and have been historically under-detected. Identification of attenuated chimeras may resolve some common genotype-phenotype discrepancies because they are misdiagnosed as either a P30L variant associated with the nonclassic mild phenotype or a null chimera associated with the most severe salt-wasting phenotype by current methodologies, but in fact attenuated chimeras are often associated with a moderate simple virilizing phenotype. Although, in general, we agree with the European Molecular Genetics Quality Network practice guidelines for molecular genetic testing of CAH due to *CYP21A2* defects, comprehensive chimera analysis should be included. Early diagnosis of *CYP21A1P-TNXA/TNXB*, or CAH-X chimeras, is especially valuable because monoallelic presence is associated with the Ehlers-Danlos phenotype including possible cardiac anomalies regardless of CAH status. A genetic diagnosis thus offers valuable early awareness.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3247 Monosomy 7 in Philadelphia-PositiveCML

Authors:

N. Abdelmoula, S. Aloulou, B. Abdelmoula, S. Kammoun; Genomics of Signalopathies at the service of medicine UR17ES36, Med. Univ. of Sfax, Sfax, Tunisia

Background: Chronic myeloid leukemia (CML) is a clonal hematopoietic stem cell disorder, characterized by reciprocal translocation t(9,22)(q34;q11). Occasionally, CML patients harbor additional chromosomal anomalies during the chronic phase. While some additional chromosomal aberrations are common such as trisomy 8, others such as monosomy 7 (5 percent) are rare. The additional chromosomal aberrations may be factors of prognostic significance. Our aim was to report a rare case of association of an additional monosomy 7 in a Ph+ CML patient. In this cytogenetic CML presentation, we described related hematologic characteristics as well as the clinical course. Methods: A 43-year-old Tunisian female patient was diagnosed with CML at the chronic phase based on peripheral blood and bone marrow examination. She was treated by Busulfan therapy for 13 months. At the clinical level, she was in remission. Hematological assessment was carried out using blood cell count, peripheral blood smears, bone marrow aspirate and biopsy, as well as bone marrow cytogenetic analysis. Results: Blood cell count revealed aregenerative normocytic normochromic anemia, impaired production of red blood cells with punctate basophilia (the presence of numerous basophilic granules that are dispersed through the cytoplasm of erythrocytes) in peripheral blood smear, as well as reticulin myelofibrosis on bone marrow biopsy. There were also abnormalities of the megakaryocytic cell lineage at sternal puncture. Megakaryocytic dysplasia consisted of numerous micro-megakaryocytes and hypo-lobed nuclei in megakaryocytes. Cytogenetic analysis revealed the Philadelphia translocation associated with monosomy 7 in all 30 analyzed metaphases: 45,XX, t(9,22)(q34;q11), -7. The clinical course was fatal and the patient died in the context of severe infection one month after the evaluation and 14 months after the CML diagnosis. Conclusion: Abnormalities involving chromosome 7 are one of the most frequent chromosomal abnormalities in myeloid disorders including myelodysplastic syndromes and acute myeloid leukemia, and they are associated with an adverse prognosis. In the Ph+ CML patient reported here, we identified additional monosomy 7 at the chronic phase. This rare additional abnormality suggested an acceleration of the CML or a myelodysplastic syndrome secondary to alkylating agent treatment. The aggressive clinical course in the reported patient confirms that the monosomy 7, as an additional chromosomal abnormality, indicates CML transformation/progression.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3248 Mosaic: A multiplexed in-vivo drug screening platform at the intersection of single-cell RNA sequencing and small molecule oncology.

Authors:

K. Jin; Vevo Therapeutics, San Francisco, CA

Herein we present MOSAIC, a multiplexed in vivo drug discovery platform. MOSAIC combines advances in single-cell RNA sequencing with in-vivo xenograft model systems. The core principle behind the platform is combining cells from tens to hundreds of cell lines or patient-derived xenograft models into a single MOSAIC tumor and then implantation of that multiplexed tumor into 3D organoid or in-vivo mouse models. Tumors are then treated appropriately in the model system over an extended time course with small molecule oncology drugs and then post-treatment, dissociated and prepared for single-cell RNA sequencing. Cells are deconvolved according to patient of origin, mouse identity, and drug treatment without the need for barcoding of models. This allows for simultaneous interrogation of multiple model systems in a single mouse, dramatically reducing the scale of experimentation needed while simultaneously increasing the scale and data output by way of high-throughput transcriptome based readouts. We demonstrate utility and scalability of the MOSAIC method in this abstract by presenting data from many models across many compounds.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3249 Multimodal sequencing approaches to end the diagnostic odyssey of patients with suspected rare monogenetic diseases.

Authors:

J. A. Madden[1], W. Shao[2], C. A. Genetti[1], H. Li[3], D. A. Johnson[4], K. McWalter[4], J. Noya[4], K. Arvai[4], V. Gainullin[4], K. Schmitz-Abe[1], V. D. Ustach[4], S. Rockowitz[2,1], P. B. Agrawal[1], C. A. Brownstein[1], S. Newman[4], J. Chin[5], J. M. Devaney[4], P. Kruszka[4], A. H. Beggs[1]; [1]The Manton Ctr. for Orphan Disease Res., Div. of Genetics and Genomics, Boston Children's Hosp., Harvard Med. Sch., Boston, MA, [2]Res. Computing, Boston Children's Hosp., Boston, MA, [3]Dept. of Data Sci., Dana-Farber Cancer Inst., Boston, MA, [4]GeneDx, Gaithersburg, MD, [5]GeneDx, Gaithersburg, MA

Despite multi-year diagnostic odysseys, many individuals with neuromuscular and developmental disorders never receive a genetic diagnosis. To develop best practices for comprehensive, multimodal, genomic diagnostic evaluations, we combined Illumina-based short-read genome sequencing (GS), with PacBio HiFi long-read GS, and RNA sequencing to investigate six trio/quad families enrolled by The Manton Center for Orphan Disease Research at Boston Children's Hospital. Each case had a strong suspicion of monogenic disease and had extensive phenotyping and genetic testing but remained undiagnosed. DNAs were extracted from either fresh peripheral blood or previously frozen and banked whole blood specimens, both of which yielded high-quality data by short and long-read GS technologies. Short-read GS data were processed through a DRAGEN Bio-IT Platform and VExP and long-read data were analyzed via the PacBio Human Whole Genome bioinformatics workflow, with results of both integrated and delivered through Genuity Sequence Miner via custom scripts. De novo long-read genome assemblies with Hifiasm were compared with the recent draft human pangenome with PGR-TK and structural variants (SVs) and CNVs of interest were identified with a novel kmer counting approach. Candidate genes for focused variant evaluation were prioritized based on a novel machine-learning phenomics algorithm, "Multiscore", as well as clinical domain expert input based on comprehensive clinical phenotyping. SV analysis of the long-read data identified variants of interest in three of the six families. Notable findings include a de novo 119 kb intragenic deletion of *TTN* predicting in-frame loss of exons 34-152 (NM_001267550) that was confirmed on RNAseq of skeletal muscle mRNA in a proband with neuromuscular disease, and copy number gain of the triplicated region of *NEB* that may be responsible for nemaline myopathy in another proband. A novel duplication within the 15q13 region in a 26-year-old male with a complex neurodevelopmental disorder is also under further study. Short-read analysis also identified candidate single nucleotide variants in this and other cases. RNAseq is pending to evaluate the potential impact of a de novo splice region variant in *UBA6* in this proband as well as the impact of a *ZEB2* deletion in two brothers with intellectual disability, psychiatric disorders, and connective tissue abnormalities. These results demonstrate the potential of multimodal and 'next generation' genomic approaches to generate new candidate variants for patients previously unable to receive a diagnosis through traditional short-read sequencing methods alone.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3250 Nanopore long-read sequencing analysis in patients with congenital malformations and balanced chromosomal abnormalities

Authors:

H. Murakami[1,2], Y. Enomoto[2], T. Sakashita[1], T. Kumaki[2], N. Aida[2], A. Imamura[1], K. Kurosawa[2], H. Kaneko[1]; [1]Gifu Prefectural Gen. Med. Ctr., Gifu, Japan, [2]Kanagawa Children's Med. Ctr., Yokohama, Japan

Accurate evaluation of breakpoints is crucial for analyzing balanced chromosomal abnormalities in patients with congenital anomalies. However, conventional chromosome analysis methods face difficulties in precisely pinpointing breakpoints of structural abnormalities that do not involve copy number variations. In this study, we employed Nanopore long-read sequencing to perform breakpoint analysis in two patients presenting with multiple malformations and developmental delay. These patients exhibited a *de novo* inversion of chromosome 3q and a complex balanced translocation t(9;17;20), respectively. The first patient presented with bicoronal craniosynostosis, characteristic facial features, and cerebellar malformation. Breakpoint analysis revealed a breakpoint in the distal centromere of 3q24, located 7 kb downstream of the 3′ untranslated region of *ZIC1*. *ZIC1*, a member of the Zic family, encodes a transcription factor with zinc finger domains that is essential for the normal development of the cerebellum. Loss-of-function of *ZIC1* causes Dandy-Walker malformation, while gain-of-function leads to a multiple congenital anomaly syndrome. On the basis of the clinical similarities, we concluded that the abnormalities in this patient were caused by the transcriptional dysregulation of *ZIC1*. We hypothesize the underlying molecular mechanisms of transcriptional dysregulation of *ZIC1* such as the abnormalities in topologically associated domains encompassing *ZIC1* or abnormal transcriptional extension of 3'-terminus of *ZIC1*. The second patient presented hydrocephalus, esophageal atresia, and developmental delay. Through the analysis, we identified 12 breakpoints and 4 microdeletions. Notably, a breakpoint at 20q12q13.11 cleaved *PTPRT* gene, which has been associate with developmental delay resulting from haploinsufficiency. These findings demonstrate the clinical utility of long-read sequencers in analyzing balanced chromosomal abnormalities.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3251 National Validation of Long-read Whole Genome Sequencing for Characterizing Chromosomal Genomic Rearrangements in Sweden

Authors:

A. Lindstrand[1], F. Lenner[2], J. Eisfeldt[1], A. Ameur[2], M. Ek[1], H. Ehrencrona[3], L. Lovmar[4], M. Melin[2], L. Feuk[2], Genomic Medicine Sweden - Rare Diseases; [1]Karolinska Inst, Stockholm, Sweden, [2]Uppsala Univ., Uppsala, Sweden, [3]Lund Univ Hosp, Lund, Sweden, [4]Sahlgrenska Univ. Hosp., Gothenburg, Sweden

Clinical cytogenetic laboratories often require comprehensive analysis of chromosomal genomic rearrangements (CGRs) which can range from gross chromosomal events such as translocations and inversions to supernumerary ring/marker chromosomes, and small deletions or duplications. In order to fully understand the complexity of a specific event and its associated clinical consequences, it is imperative to locate the breakpoint junctions and to resolve the derivative chromosome structure. This task, however, often surpasses the capabilities of conventional short-read sequencing technologies. In contrast, emerging long-read sequencing techniques present a compelling alternative for clinical diagnostics. In Sweden, the Genomic Medicine Sweden (GMS) rare diseases consortium has validated PacBio Revio long read whole genome sequencing (lrWGS) for clinical digital karyotyping of unresolved CGRs nationwide. The first 20 samples included in this validation study were collected from six of the seven Swedish university regions. For most cases new blood samples were not available, and DNA extracted by standard clinical protocols stored for years in the clinical biobanks was used. The sequencing yield ranged from 65-111Gb of HiFi data per sample, correlating with extraction protocols and storage time for samples. We have established a national analysis pipeline and a shared database for variant calling and filtering, which enables both reference-based and *de novo* assembly analysis. Additionally, tools for analysis and filtering of differential methylation will be incorporated. The findings include a balanced translocation between 17p and the 19 centromere, previously undetected by both short read sequencing and optical mapping. Both derivatives were fully assembled after *de novo* analysis. The included validation samples also encompass inversions and complex CGRs. In conclusion, the GMS rare diseases consortium has successfully validated PacBio Revio lrWGS as a clinical analysis for chromosomal rearrangements.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3252 † Neuron-specific chromatin disruption at CpG islands and aging-related regions in Kabuki syndrome

Authors:

L. Boukas[1], T. Luperchio[2], A. Razi[3], K. Hansen[4], H. Bjornsson[5]; [1]Children's Natl. Hosp./Johns Hopkins Univ., Washington, DC, [2]Johns Hopkins Sch. of Med., Ellicott City, MD, [3]Johns Hopkins Sch. of Med., Baltimore, MD, [4]Johns Hopkins Univ, Baltimore, MD, [5]Univ. of Iceland/Johns Hopkins Sch. of Med., Reykjavik, Iceland

Many Mendelian developmental disorders caused by coding variants in epigenetic regulators have now been discovered. Epigenetic regulators are broadly expressed, and each of these disorders typically exhibits phenotypic manifestations from many organ systems. An open question is whether the chromatin disruption - the root of the pathogenesis - is similar in the different disease-relevant cell types. This is possible in principle, since in all these cell-types the causative gene has the same kind of function (e.g. methylates histones) and is disrupted by the same germline variant. In particular, because intellectual disability is the most prevalent phenotype of these disorders and blood is easily accessible, the blood/brain comparison is of major interest. The blood/brain comparison can also shed light upon another question of much recent interest: whether the same locations that comprise blood-derived diagnostic episignatures can inform the chromatin basis of abnormal neurodevelopment, as has been hypothesized. Here, we focus on mouse models for Kabuki syndrome types 1 and 2, and characterize genome-wide chromatin accessibility changes using ATAC-seq in a well-powered experiment (12 mutant vs 11 wild-type mice). We find that the chromatin accessibility changes in neurons are mostly distinct from those in B or T cells from blood. Zooming into the KS1 blood episignature locations, we see that they are no more likely to be disrupted in neurons than random locations. By contrast, they are significantly disrupted in B/T cells, suggesting that this result is not due to human-mouse differences.

We find that the discrepancy between neurons and B/T cells is not because the neuronal abnormalities occur at regulatory elements that are only active in neurons. Neurons, but not B or T cells, show preferential chromatin disruption at CpG islands and at regulatory elements linked to aging, such as promoters of genes regulating the IGF1-receptor and mTOR pathways. This is true in both Kabuki syndrome types, pointing towards a unified pathogenesis at the chromatin level downstream of the distinct causative genes. Moreover, the accessibility changes in the mutant neurons suggest they are epigenetically “older” than their wild-type counterparts.

Our findings reveal that the same variant, in the same epigenetic regulator, has cellular-context-specific effects. They also provide novel insights into the molecular pathogenesis of Kabuki syndrome. Finally, they suggest that blood-derived episignatures, while accurate as a diagnostic tool, may not be well-suited for understanding the mechanistic basis of neurodevelopment in Mendelian disorders of the epigenetic machinery.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3253 Next generation sequencing in the clinical setting: four years' experience from a private laboratory in Brazil.

Authors:

N. Sobreira[1,2], A. Planello[2], D. Alencar[2], D. Bermeo[2], J. Sobreira[2], M. Gomes[2], T. Cavalcanti[2], L. de Castro[2], E. Palmero[2], H. Galvão[2], R. Martin[3], C. Scapulatempo-Neto[2]; [1]Johns Hopkins Univ, Crownsville, MD, [2]Diagnósticos da América S.A., DASA, São Paulo, Brazil, [3]Johns Hopkins Univ, Crownsville, MA

Introduction: Next generation sequencing (NGS) technology has been progressively incorporated to clinical laboratory testing in Brazil. Current applications include detection of either germline or somatic variants, and laboratories may focus their analysis on single gene, multi-gene panels, exome or whole-genome sequencing. Objectives: In this study, we aimed to report the implementation of NGS tests in the DASA laboratory in Brazil, and discuss the types of NGS tests ordered per year and the diagnostic yield by disease group and by test type.Methods: We retrospectively analyzed the NGS results from 3025 patients investigated in our laboratory between 2018 and 2021. NGS methods included single gene, multi-gene panel and WES. A descriptive statistic was used to evaluate the diagnostic yield of NGS tests results, which were categorized as positive, inconclusive, or negative. The clinical indications were: neurodevelopmental disorders, late-onset neurological disorders, neuromuscular disorders, syndromic disorders, skin/hair disorders, hematological/immunologic disorders, endocrine disorders, ophthalmologic disorders, inborn errors of metabolism (IEM), skeletal disorders, cardiovascular disorders, reproductive planning, cancer, genitourinary disorders, gastrointestinal disorders, and hearing disorders. Results: Out of the total 3025 NGS tests, 420 were single gene, 1158 were multi-gene panel, and 1447 were WES. From 2018 to 2020, the most frequently ordered test was muti-gene panel, followed by WES. However, in 2021, WES became the most frequently ordered test in our laboratory routine. The primary clinical indication for WES were syndromic features (76.2%) and neurodevelopmental disorders (74%). In terms of diagnostic yield, WES had the highest detection rate (32.7%), the highest inconclusive rate and the lowest negative rate; nonetheless, the diagnostic yield remained relatively constant, and the negative results decreased with time. Among the clinical feature groups, hearing disorders (50%) and skeletal disorders (43.15%) had the highest diagnostic yield. When stratified by WES, skeletal and hearing disorders had 55% and 50% detection rate, respectively. The rate of positive secondary findings in WES was 3%, and regarding the detected variants, predicted protein-truncating accounted for 25% of the P/LP variants and 7% of VUS.Conclusion: Our data show that in a short period of time WES already became the most frequently order test clinical routine of DASA, a private laboratory in Brazil, for being more cost-effective due to its ultra-high throughput, scalability, speed, and higher diagnostic yield.

PB3254 Non mosaic trisomy 22. A case report.

Authors:

C. Mutinda[1,2], J. Wachira[3], N. Gachara[4], T. Mutinda[3], W. Sikolia[5]; [1]Univ. of Nairobi, Nairobi, Kenya, [2]Pumwani Maternity Hosp., Nairobi, Kenya, [3]Paediatrician, Mp Shah Hosp., Nairobi, Kenya, [4]Paediatrician and Paediatric Cardiologist, Univ. of Nairobi, Nairobi, Kenya, [5]Obstetric Gynecologists and fetal maternal medicine, Aga Khan Univ. Hosp., Nairobi, Kenya

Background: Majority of trisomy 22 zygotes end up as spontaneous abortions. Postpartum survival ranges from 3-4 days to a maximum of 3 years. Most trisomy 22 errors occur in oogenesis, predominantly in the first meiotic division. We present a case of a complete trisomy 22 that lived for 52 days.Methods: A case report Results: Live female neonate born via caesarean section at 37 weeks gestation of nonconsanguineous parents who had 2 sons. Pregnancy was flagged by an ultra sound at 30 weeks that showed severe intrauterine growth restriction and unspecified cardiac anomalies. Amniotic Fluorescence In Situ Hybridization (FISH) ruled out T13, T18, T21 and sex chromosomal aneuploidy. Apgar score at birth was 6 1, 7 5, 910, birth weight was 1710g (<2.5th centile), length 40 cm (<3rd centile) and head circumference of 31cm (10th centile). Physical exam, the neonate had dolichocephaly, sparse hair, flat square face, full cheeks, short columella, depressed wide spaced nasal bridge, long and smooth philtrum, macrotia, low set ears posteriorly rotated with preauricular pits, short neck, narrow shoulders and widely spaced nipples. A cardiac echo revealed Double Outlet Right Ventricle (DORV) with normally related great arteries and an interrupted aortic arch type B. A chromosomal microarray reported Arr [GRCh37] 22q11.1q13.33(17153988_51178264) x3. A follow up karyotype confirmed Karyotype 47, XX, +22 Complete, not mosaic. Parental karyotype results Father 46, XY Mother 46, XX, 21ps+. The child had poor weight gain and respiratory distress. The parents gave a Do Not Resuscitate order on day 48 of life, the child died at the age of 52 days. Conclusion: Trisomy 22 though rare can be diagnosed in utero. Access to comprehensive prenatal genetic services are paramount to enable parents make informed reproductive decisions.

PB3255 † Not just one: the utility of whole genome sequencing for making a dual molecular diagnosis

Authors:

M. Chau[1,2], C. Settler[2], W. Bi[1,2], H. Dai[1,2], C. Eng[1,2], P. Liu[1,2], L. Meng[1,2], N. Owen[1,2], R. Rigobello[1,2], L. Vossaert[1,2], C. Wu[1,2], F. Xia[1,2], X. Zhao[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics Lab., Houston, TX

Introduction: Whole genome sequencing (WGS) offers a comprehensive solution for genetic investigation by capturing a wide range of genomic variations in a single test. Conventional phenotype-driven and stepwise genetic testing is time-consuming and may yield inconclusive results. Moreover, the genetic investigation paradigm often stops at the point of identifying a single diagnosis, potentially overlooking additional underlying genetic etiologies. WGS is now often utilized as a first- or second-tier test for patients with multiple congenital anomalies (MCA), developmental delay and intellectual disability (DD/ID). Limited data exist on the frequency of patients receiving multiple genetic diagnoses pertaining to their phenotype.
Methods: This is a retrospective evaluation of WGS results at Baylor Genetics. Demographic data, clinical history, diagnostic findings and the frequency of patients who had multiple reportable molecular findings were investigated.
Results: Reportable multilocus findings were detected in 48 cases; including 13 cases with dual molecular diagnoses (pathogenic or likely pathogenic variants); 24 cases with one diagnosis in conjunction with reportable finding(s) in another locus [2 variants in an autosomal recessive (AR) locus or 1 variant in an autosomal dominant (AD) locus]; 7 cases with one molecular diagnosis and one reportable variant in an AR locus; and 4 cases with one molecular diagnosis and an actionable secondary finding. Among the 13 cases with dual diagnoses, the most common clinical indications included MCA (n=10), DD/ID (n=4), seizures (n=3), and failure to thrive (n=1). All 13 cases involved at least one AD gene(s) (AD+AD=3, AD+AR gene with two variants=7, AD+X-linked=2, AD+mitochondrial DNA=1) among the dual diagnoses. Copy number variants contributed to a high impact finding in 8 of the 13 cases. Parental samples were available in 8 cases which revealed that *de novo* findings accounted for at least one of the diagnostic variants in 7 trios.
Conclusion: This study demonstrates the utility of WGS to provide reportable multilocus findings. This finding is significant not only in ending diagnostic odysseys but also in demonstrating the need to account for heterogenous variant types and multiple molecular etiologies associated with complex patient phenotypes. In addition, WGS can also aid in optimizing management and expediting diagnoses of critically ill patients with complex phenotypes. Multiple molecular diagnoses will also improve the understanding about the clinical effects of multiple variants at more than one locus.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3256 Novel deletion 19(q13.31q13.32) with syndromic presentation.

Authors:

J. Pappas[1], E. Moran[2]; [1]NYU Clinical Genetic Services, New York, NY, [2]NYU-Hosp Joint Diseases, New York, NY

19q13.32 microdeletion syndrome has been reported in four cases in the medical literature (Castillo A et al, 2014). Common features of these cases were facial asymmetry, ptosis, oculomotor paralysis, orofacial clefts, micrognathia, kyphoscoliosis, aortic defects and colonic atony. There is a ClinVar entry [VCV000057097.1] of a pathogenic deletion in 19q13.32 presenting clinically with genu valgum, impaired language development and ostium primum atrial septal defect (Kaminsky EB et al, 2011). We describe a 19 year old female with a del19(q13.31q13.32). The deletion in our case overlaps a portion of the deletion in the reported cases and includes the deletion in ClinVar. Our case was referred to us at 32 months because of macrocephaly, hypotonia, developmental delay, dysmorphic features, surgically repaired cleft soft palate, multiple resolving VSDs, G-tube, history of aspiration pneumonia and bilateral hip dysplasia. She was born full term via NSVD to a 15.5 year old primigravida after uncomplicated pregnancy. Birth weight was 3.295 kg and length 48 cm, appropriate for gestational age. Delayed developmental milestones prompted early intervention therapies and included: sitting at 9 months, cruising 31 months and no words at 32 months. We periodically followed the patient and at age 19 our case presented with minimal expressive language, obesity (BMI 32.39 kg/m^2), short stature (0.03 centile, Z = -3.42), obstructive sleep apnea, hyperphagia and aggressive oppositional behavior. She had menarche at 12 but amenorrhea since. She had right hip dislocation and left epiphysiodesis for leg length discrepancy. Her features were distinctive: short neck, small and low set ears with right preauricular pit, flat face, bilateral microphthalmia, exotropia with history of nystagmus, lateral eyebrow flaring, sparse scalp hair, tented upper lip, inverted nipples, left accessory nipple, small hands and feet, sacral dimple and thick nails with rapid growth. None of these features were familial. Whole genome CN/SNP microarray revealed arr19q13.31q13.32(49,662,092-52,484,949)x1 (NCBI36/hg18). Phenotyping similarities between our case and the cases in Castillo A et al, 2014 included developmental delays, behavioral disorders, congenital heart defects, orofacial clefts and skeletal abnormalities. These abnormalities are likely associated with deletion of the overlapping segment and further support their association with the 19q13.32 microdeletion syndrome. The facial features and minor malformations appear to be different in our case and the cases with del19q32.2 and suggest a unique syndromic association with the deletion 19(q13.31q13.32).

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3257 Optical genome mapping as a potential routine clinical diagnostic method.

Authors:

H. Barseghyan[1,2,3], D. Eisenreich[1], H. Erdmann[1], A. Hallermayr[1], E. Lindt[1], K. Sendelbach[1], U. Koehler[1], T. Neuhann[1], A. Abicht[1,4], E. Holinski-Feder[5,6]; [1]MGZ - Medizinisch Genetische Zentrum, Munich, Germany, [2]Childrens Natl. Res. Inst., Washington, DC, [3]Dept. of Genomics and Precision Med., The George Washington Univ., Washington, DC, [4]Dept. of Neurology, Ludwig-Maximilians-Univ., Munich, Germany, [5]MGZ - Medizinisch Genetisches Zentrum, Munich, Germany, [6]Dept. of Med. IV, Ludwig-Maximilians-Univ., Munich, Germany

Both cytogenetics and molecular genetics methods have helped to identify genetic diagnoses for many disorders. However, despite this success, many remain undiagnosed due to our inability to sensitively identify structural variants (SVs) with currently available technologies, that are limited in resolution (karyotype), detection of only unbalanced events (microarray), targeted nature (FISH) or utilization of short reads (genome sequencing). Optical Genome Mapping (OGM) promises to address these limitations by capturing patterns of fluorescent labels within long DNA molecules (>150kbp) that allow for accurate identification of SVs starting from 500bp in size even in highly repetitive regions of the human genome.

We have performed validation of OGM using 72 samples for which diagnoses had been achieved with orthogonal methods. In total, OGM was 98% concordant with previous diagnoses only missing one translocation case due to breakpoints being in centromere and one mosaic variant in an FSHD case. We also tested 25 undiagnosed cases for which microarray and exome sequencing were uninformative to investigate the increased diagnostic yield provided by OGM.

To select for potential clinically significant variants, we filtered SVs based on quality, size, frequency, and gene overlap. We identified two likely pathogenic deletions involving two clinical genes, *CLTC* and *DHX30*. We also identified several potentially interesting insertions in disease causing genes needing further investigation. Lastly, we identified a translocation involving *SON* gene and mosaic deletion involving *TSC2* gene. Both SVs were diagnostic and were validated via targeted long-read sequencing. In summary, we show that OGM detects large SVs, has high concordance with other cytogenetic methods and can provide diagnosis in negative cases.

PB3258 Optical genome mapping identified a *KMT2C* exonic deletion in a Kleefstra syndrome subject resulting from maternal mosaicism.

Authors:

B. Brassell, A. Ortega, C. Bilancia; Bionano Lab., Salt Lake City, UT

Recent advances in genomic technology have significantly increased diagnostic yield in patients with genetic disorders. Here, optical genome mapping (OGM) was used to further investigate an apparently de novo deletion in *KMT2C*. The proband is an 8-year-old male presenting with clumsiness, drooling, sensory disorder, speech articulation and developmental coordination disorder, fine motor delay, hyperactivity, facial weakness with asymmetry, and hypotonia. Family history indicates that both parents are apparently healthy, a maternal uncle presents with attention deficit hyperactivity disorder (ADD) and learning disabilities, and the proband's younger twin siblings were born prematurely at 30 weeks.

In the proband, OGM revealed a heterozygous 338 kbp deletion (within hg38 chr7:152,245,774-152,590,586 window) affecting exons 1-14 of *KMT2C* (NM_170606.3), which was previously reported as likely pathogenic by chromosomal microarray (CMA) in 2018. Disease-causing variants in *KMT2C* are associated with autosomal dominant Kleefstra syndrome (MIM: 617768). Further examination by a geneticist determined that the deletion is explanatory for his symptoms and is consistent with a diagnosis of Kleefstra syndrome. Parental testing by qPCR indicated this deletion to be de novo. However, OGM testing in the maternal sample revealed the 338 kbp *KMT2C* deletion with a lower variant allele frequency (VAF) of 0.28, suggesting mosaicism. A confirmatory CMA was performed on both the proband and maternal sample. This testing both confirmed the deletion in the proband and the deletion present in the mother that was not called by the CMA interpretation software and was identified by manual review by expert geneticists. Further follow-up studies are ongoing in this family and the younger twin siblings will be tested to determine the effect of the *KMT2C* deletion in this family.

In conclusion, this case demonstrated that OGM, as an advanced genomic technology, can be used to reveal the genetic etiology of diseases caused by structural variations (SVs) even with lower-level mosaicism. Mosaicism in unaffected parents of children with Kleefstra syndrome has been reported for the *EHMT1* gene (PMID: 29416845, 34357686), but not for *KMT2C*. Thus, the variant reported here is the first published for this gene.

PB3259 Optimization of ORACollect buccal sample extraction for clinical molecular analysis.

Authors:

A. Berlyoung, A. C. Brand, S. C. Lynch, D. A. Johnson, J. Noya, J. Spangler, S. Yusuff, J. Devaney; GeneDx, Gaithersburg, MD

As a patient-centered health intelligence company, GeneDx continually focuses on improvements to laboratory processes. Efforts to streamline methods, reduce costs, and improve turnaround times provide critically important answers to patients. This will facilitate rapid diagnosis, leading to swift treatment and significantly improved prognosis. We recently launched a novel extraction method for our highest quantity sample, ORAcollect buccal (OCB), based on a commercially available kit (ThermoFisher Scientific).

The extraction utilizes automation for plate setup with the OCB samples and reagents. The entire method is performed in under two hours, requires no by-hand steps, and is of minimal cost ($3.70/sample). To measure quality and quantity of the DNA extraction, we utilized a UV method that determines the amount of DNA and any contaminants. To further scrutinize the quality of the extracted DNA, we analyzed the samples on massively parallel sequencing (gene panels, exomes, and genomes), microarrays, multiplex-ligation dependent probe amplification reactions, repeat expansion assays, and sanger sequencing. For all lab techniques, we used current measures of quality for each method to determine if the extracted DNA would pass in our clinical lab. The pass rate for the extracted samples was >95%.

With our modifications to the extraction method, we were able to consolidate resources and limit reagent waste. This modified laboratory procedure created a novel instrument protocol for extraction of OCBs that produces high quality DNA that is usable for all of our current molecular laboratory techniques. This protocol serves as a model archetype for future works to improve laboratory efficiency, simplify workflows, and provide rapid answers for patients.

PB3260 Pathogenic tandem splice acceptor variants escape screening by*in silico*tools

Authors:

F. Frost[1], S. Gu[2,3], A. Elbert[4,5], M. Malicdan[1,6], C. Boerkoel[4,5], P. Cherukuri[2,3]; [1]NIH, Rockville, MD, [2]Imagenetics, Sanford Hlth., Sioux Falls, SD, [3]Sanford Sch. of Med., Sioux Falls, SD, [4]Dept. of Med. Genetics, Univ. of British Columbia, Vancouver, BC, Canada, [5]Provincial Med. Genetics Program, B.C. Women's Hosp. and Hlth.Ctr., Vancouver, BC, Canada, [6]Human Biochemical Genetics Section, Med. Genetics Branch, Natl. Human Genome Res. Inst., NIH, Bethesda, MD

Introduction. Tandem splice acceptor sites are a known mechanism of alternative splicing. Such tandem sites serve as loci of transcriptional regulation by modulation of either the transcript abundance or the function of the resulting protein. Previous literature has demonstrated that variants modifying existing tandem acceptor sites or creating novel sites can cause mendelian disease. Despite recent advances in *in silico* splicing prediction tools and understanding of tandem splice acceptors, predicting the pathogenicity or deleteriousness of variants remains difficult and, as a result, are rarely contextualized in clinical reporting. **Methods.** In this study we characterize the prevalence of variants creating novel tandem acceptor sites in healthy (gnomAD) and disease (ClinVar) reference populations. To characterize tandem splice acceptor variants further in the context of Mendelian disease, we screened for such variants among 1236 individuals from the NIH Undiagnosed Diseases Program (UDP). To evaluate the pathogenicity of those variants among130 individuals who had available RNA sequencing data, each novel tandem splice acceptor variant was assessed for evidence of function and pathogenicity. **Results.** Assessment of nucleotide trimer frequency at the exon-intron boundary showed a depletion of AG-containing trimers from position -3 to -14, a region that often overlaps the polypyrimidine tract, an acceptor site enhancer motif. SpliceAI scores of AG-gain variants in both ClinVar and gnomAD showed that acceptor gain scores are higher in the AG-depleted region compared to the rest of the intron and exon window. AG-gain variants within that same window showed similarly high SpliceAI acceptor gain scores in the UDP cohort but occur infrequently (mean = 10 per case). Evaluation of empirical RNASeq data for novel acceptor site usage in UDP cases showed that variants with verified usage were more abundant in the -3 to -14 window compared to the rest of the intron. Furthermore, although variants verified to create utilized novel acceptor sites tended to have high SpliceAI acceptor gain scores, they had a PPV of 0.344, demonstrating the incomplete ability of *in silico* tools to assess AG-gain variants.**Conclusions.** The pathogenicity of variants affecting splicing are difficult to assess. We show that a subset of those variants, those which create tandem splice acceptor sites, frequently lead to the usage of a novel acceptor site. Predicting the function of those variants using *in silico* tools is inconsistent. This supports the use of empirical evaluation of AG-gain variants by RNA sequencing.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3261 PDIVAS: Pathogenicity predictor for Deep-Intronic Variants causing Aberrant Splicing

Authors:

R. Kurosawa[1], K. Iida[2], M. Ajiro[3], T. Awaya[1], M. Yamada[4], K. Kosaki[4], M. Hagiwara[1]; [1]Kyoto Univ., Graduate Sch. of Med., Kyoto, Japan, [2]Kindai Univ., Faculty of Sci. and Engineering, Osaka, Japan, [3]Natl. Cancer Ctr. Res. Inst., Tokyo, Japan, [4]Keio Univ. Sch. of Med., Tokyo, Japan

Deep-intronic variants that alter RNA splicing were ineffectively evaluated in the search for the cause of genetic diseases. Determination of such pathogenic variants from a vast number of deep-intronic variants (approximately 1,500,000 variants per individual) represents a technical challenge to researchers. Thus, we developed a Pathogenicity predictor for Deep-Intronic Variants causing Aberrant Splicing (PDIVAS) to easily detect pathogenic deep-intronic variants. PDIVAS was trained on an ensemble machine-learning algorithm to classify pathogenic and benign variants in a curated dataset. The dataset consists of manually curated pathogenic splice-altering variants (SAVs) and commonly observed benign variants within deep introns. Splicing features and a splicing constraint metric were used to maximize the predictive sensitivity and sensitivity, respectively. PDIVAS showed an average precision of 0.92 and a maximum MCC of 0.88 in classifying these variants, which were the best of the previous predictors. Genome sequencing analysis using PDIVAS with 95% sensitivity identified an average of 27 pathogenic candidates per individual. Furthermore, the causative variants were more efficiently prioritized than the previous predictors in simulated patient genomes. Incorporating PDIVAS into variant interpretation pipelines will enable efficient detection of disease-causing deep-intronic SAVs and contribute to improving the diagnostic yield. PDIVAS is publicly available at https://github.com/shiro-kur/PDIVAS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3262 Performance of Copy Number Variant Detection Tools in Clinical Applications: A Comparative Benchmark for Short-Read Whole Genome Sequencing

Authors:

F. De La Vega[1], S. Irvine[2], P. Anur[1], K. Potts[1], L. Kraft[1], R. Torres[1], S. Truong[3], Y. Lee[3], S. Han[3], V. Onuchic[3], J. Han[3], P. Kang[1]; [1]Tempus Labs, Inc., Chicago, IL, [2]Real Time Genomics, Ltd., Hamilton, New Zealand, [3]Illumina, Inc., San Diego, CA

As whole genome sequencing (WGS) becomes cheaper, it is set to become a standard approach in clinical settings due to its superior copy number variant (CNV) detection. Current tools for short-read WGS CNV calling need to be evaluated in clinical settings where orthogonal confirmation of CNVs may be required and there is a higher priority placed on sensitivity over specificity compared to research uses. We evaluated several CNV detection tools designed for short-read WGS data, including Delly, DRAGEN™ 4.0, CNVkit, CNVpytor, Lumpy, Manta, and Parliament2, as well as two newer tools: Cue, a machine learning-based method, and DRAGEN 4.2's integrated CNV caller that combines breakpoint and depth-based calls. We used data from independent PCR-free libraries of the HG002 reference cell line, sequenced to a mean depth of 50X using paired-end 2x150bp reads on Illumina NovaSeq™ 6000 and X-Plus instruments. Benchmarking CNVs is often aimed to evaluate event-level similarities, but in clinical contexts, the primary concern is whether a variant disrupts protein structure. Thus, to calculate accuracy we evaluated CNV overlaps with coding exons, defining a match as an event intersecting an exon with the same dosage direction as the truth set. The event's contribution is adjusted by the number of exons spanned to account for events overlapping multiple exons. Using GRCh37-defined exon boundaries, we confined our analysis to exons intersecting the HG002 GIAB v0.6 SV truth set for events of 1-100kb, including 13 deletions and 4 duplications that overlap 45 and 8 exons, respectively. Given the limited examples in the truth set, we placed simulated gene models across the truth set to increase deletion and duplication exon overlaps to 125 and 20, respectively. We show that all callers struggle with detecting single-exon events (typically <5kb) and duplications. However, DRAGEN 4.2 and Parliament2 demonstrated the highest combined sensitivity (86% and 94%, respectively), with the former showing superior specificity (66% vs 22%, respectively). Remarkably, despite a reduction in specificity (down to 42%), DRAGEN's v4.2 "high sensitivity mode" achieved 96% and 100% combined sensitivity for events >1kb and >5kb, respectively. This could be advantageous in clinical settings where sensitivity is paramount and confirmatory tests are performed.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3263 Phenotypic Variations of a Novel TRMT10A Gene Mutation in a Consanguineous Malian Family

Authors:

M. Barros Perez, J. Lee, R. Vela Sosa, N. Khardoush, M. Banikazemi; NYC H+H/Metropolitan Hosp. Ctr., New York, NY

Microcephaly, short stature, and impaired glucose metabolism 1 (MSSGM1) (OMIM #616003) is a rare autosomal recessive condition caused by TRMT10A gene variations. MSSGM1's clinical manifestations include impaired glucose homeostasis or non-autoimmune diabetes, microcephaly, epilepsy, cognitive impairment, and failure to thrive. Less frequently, delayed puberty and joint laxity have been reported. To the best of our knowledge, a total of 20 cases within 13 families have been documented. In this report, we describe the variable phenotypic manifestations of the MSSGM1 syndrome in three siblings from one family, with a variation in the TRMT10A gene. Our case involves three of the six children from a family of African descent from Mali with third-degree consanguinity. The eldest sibling was referred for genetic evaluation at 4 years of age due to developmental delay, failure to thrive, and microcephaly. Initial genetic work-up including karyotype, SNP microarray, FISH, and metabolic testing resulted normal. In 2016, at 13 years of age, a repeat SNP microarray showed ROH of 233 MB. The middle sibling, also with microcephaly and developmental delay, had an SNP microarray with multiple ROH, and between these, the mutual ROH was located in Chromosome 4q21.23q24. After reviewing genes in this locus, only the gene TMRT10A was a candidate for sequencing, which revealed an autosomal recessive homozygous nonsense mutation c.483G>A (p.Trp161*), which had not been reported previously. Soon after, the middle sibling was found to have the variation, and eight years later, the youngest sibling, who had intrauterine growth restriction and microcephaly, also tested positive for the homozygous mutation. The affected siblings, a currently 20-year-old female, a 17-year-old male, and a 10-month-old female, demonstrated intrauterine growth restriction, microcephaly and progressed to have failure to thrive. Microcephaly has been seen in around 85% of reported individuals. Short stature was observed in the elder two siblings, reported in approximately 94% of the cases. All of the siblings exhibited developmental delay. Glucose homeostasis disturbances observed were neonatal hypoglycemia and type 2 diabetes mellitus in the eldest and neonatal hypoglycemia in the youngest sibling. The middle one was not affected by diabetes. Delayed puberty was observed in the older two siblings. Unique features of the eldest sibling were seizure, central hypothyroidism, and joint laxity.
We discuss the variability of the MSSGM1 phenotypes within the members of a family. The scarcity of reported cases underlines the need for further exploration of this rare genetic condition.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3264 Physical linkage to resolve complex variants in the X-chromosome opsin locus

Authors:

A. Naik[1], B. Guan[1], D. Elul[2], E. B. Haggerty[3], W. Zein[1], C. Lwin[1], Z. Li[1], D. Blain[1], B. P. Brooks[1], S. J. Tumminia[1], G. Kerry[1], D. H. Brainard[4], G. K. Aguirre[5], R. B. Hufnagel[1]; [1]Natl. Eye Inst., NIH, Bethesda, MD, [2]2Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA, [3]3Dept. of Neurology, Univ. of Pennsylvania, Philadelphia, PA, [4]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA, [5]Dept. of Neurology, Univ. of Pennsylvania, Philadelphia, PA

The X-opsin array encodes for red and green opsin and is associated with X-linked color vision deficiencies, high grade myopia, Bornholm eye disease (BED), X-linked cone dystrophy (XLCD), and blue cone monochromacy (BCM). The X-opsin array consists of highly homologous *OPN1LW* (L) and *OPN1MW* (M) genes arranged in multiple tandem copies, increasing the probability a gene conversion event or that unequal crossover occurs. Current gold standard sequencing technologies are unable to resolve the variation between gene copies that may contribute to disease. Here we present a novel method to resolve complex genotypes of the X-opsin array. We designed a tiered approach to assess copy number, structural, and sequence variants to comprehensively genotype the X-opsin array. The test involves digital droplet PCR (ddPCR) copy number analysis for the locus control region (LCR), L and M genes, the recurrent inactivating variant c.607T>C p.(Cys203Arg) (C203R), and exon-3 haplotypes. Proximal and distal gene(s) are genotyped separately by long-range PCR followed by nested PCR and Sanger sequencing or next-generation sequencing. The ddPCR milepost assays were employed to determine gene order. Nanopore long-read sequencing was used for validation. Male patients (n=31) with X-opsin array disorders from 29 families were used to demonstrate the utility of the test. Pathogenic genotypes of 100% (29/29) probands with X-opsin array disorders were resolved. Of these, seven required milepost assays to determine gene arrangement. Of 17 males with color discrimination disorder, 14 deutans and three protans were molecularly confirmed by haplotype and spectrally sensitive amino acid residues. Three probands with BED, XLCD, or cone-rod dystrophy had splice-altering exon-3 haplotypes. Of nine BCM probands, six had LCR deletions, and three had p.C203R in expressed gene copy(s), including two brothers harboring p.C203R in three of four gene copies in which the C203= allele could not be resolved by long-read sequencing alone. The ddPCR-centered diagnostic test provides an economical and efficient tool for genotyping the X-opsin array, elucidating genotype-phenotype correlations, and informing future gene-directed therapies. The milepost assay is critical for the determination of genotypes of expressed genes on the array in a subset of patients. The applicability of the assay, however, is dependent on DNA quality and integrity. The ddPCR milepost approach could be applied to other genomic regions that are difficult to genotype with current technologies.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3265 Precise and reliable detection of regions of homozygosity and copy-neutral loss of heterozygosity in the human genome

Authors:

L. Wu, B. Bolstad, J. McGirr, A. Roter, D. Black, J. Wallace; Thermo Fisher Scientific, SANTA CLARA, CA

Human genome often harbors regions that are in allelic imbalance or homozygosity without an associated DNA copy-number change. This type of genomic events can occur in somatic cells or in the germline. In the absence of a copy number variation, this is referred to as copy-neutral loss of heterozygosity (CN-LOH) or as a region of homozygosity (ROH). In this study, for simplicity, we use the term of loss of heterozygosity (LOH) to stand for both ROH and CN-LOH. Genome-wide detection of LOH with high accuracy and reproducibility plays a vital role in understanding tumorigenesis in neoplastic disorders and unravelling genetical causes of constitutional disorders. We employed a newly developed chromosomal microarray analysis (CMA) platform to ascertain LOH at a genome-wide scale. This new CMA has a shorter laboratory turnaround time of two days and expanded genomic content. It provides a whole-genome copy-number profile of a sample that includes neutral copy numbers and genome-wide SNP genotyping, which allows an effective LOH detection. The sensitivity of the new array platform was measured on 49 HapMap cell line samples. These samples have 200 known LOH regions with reportable length greater than 3 megabases (MB). We conducted LOH calling and visual confirmation using B-allele frequencies (BAF) in version 4.4.1 of the Chromosome Analysis Suite (ChAS) software. The LOH-calling algorithm in ChAS is based on a binomial statistical test that adapts to SNP call rate in the sample. The new array platform reaches 98.5% sensitivity in detecting LOH greater than 3MB in length and demonstrates very high reproducibility. DNA from sample NA18550 with twelve reportable LOH regions was run by two different operators on different instruments and dates. ChAS analysis shows that the results of both runs target the same set 12 LOH regions with 100% concordance. In addition to these results on cell line DNA, the accuracy of LOH calling of the new array platform using prenatal samples will be reported.

PB3266 † Precision Genomics in 9p Minus Syndrome

Authors:

T. Turner, E. Sams, K. Valle, S. Couteranis, R. Slaugh, J. Neidich, X. Cui, F. Cole, P. Dickson, R. Mitra, J. Milbrandt; Washington Univ. Sch. of Med., St. Louis, MO

Complex structural variation underlies several rare syndromes. One example is 9p minus syndrome, which is caused by deletions on the p-arm of chromosome 9 with co-occurring translocations in 50% of affected individuals. In collaboration with the Chromosome 9 p minus network, we have used several strategies to assess the genomic features of 9p minus syndrome including our published results on karyotypes in >700 individuals with 9p minus syndrome and our unpublished results on short read whole genome sequencing (WGS) in 42 individuals, PacBio HiFi long-read WGS in 10 individuals, and Illumina Complete Long Read WGS in 14 individuals. It is known that the deletions in 9p minus syndrome do not share one specific set of breakpoints. In our large-scale karyotype analysis, we found that the most common deletions include the 9p24 locus and the second most common include 9p24 to 9p22. Furthermore, by assessing translocation information from the karyotypes, we found that there is no preference for a specific chromosome arm; rather, there are examples of individuals with 9p minus syndrome with structural variants involving several different chromosome arms, respectively. By WGS and overlapping deletion assessment, we have identified one of at least two hypothesized critical region(s) for 9p minus syndrome. This region encompasses the gene RFX3, deleted in 80% of individuals with 9p minus syndrome. We also utilized a machine learning based approach to evaluate gene dosage-phenotype correlations among individuals with 9p minus syndrome, compared with control individuals from the 1000 genomes project. This analysis also revealed *RFX3* as the top gene implicated in 9p minus syndrome. Previously, *RFX3* has been implicated in autism, and we hypothesize that it may be involved in the developmental delay phenotype in 9p minus syndrome. Beyond the identification of genes shared across all individuals with 9p minus syndrome, we have also utilized long read WGS to precisely catalogue all genomic variation within individuals with 9p minus syndrome. This includes complex variation involving translocations, deletions, and mosaic duplications within single individuals. Combining several modern genomic technologies may yield insights into 9p minus syndrome and may be broadly important for the genomic study of syndromes with complex structural variation.

PB3267 Proteome-scale probabilistic modeling of human genetic variation discovers novel developmental disorder genes

Authors:

R. Orenbuch[1], J. Frazer[2], M. Dias[2], H. Spinner[1], D. Franceschi[1], D. Marks[1]; [1]Harvard Med. Sch., Boston, MA, [2]Ctr. for Genomic Regulation, Barcelona, Spain

Our inability to identify causal variants across patients' genomes is a major limitation in genome sequencing for diagnostics. This is especially problematic for variants in genes not previously associated with disease. To overcome this issue, we introduce the first unified model of genetic variation across the full human proteome. Our model, popEVE, enables us to rank all variants according to their pathogenicity and to obtain a measure of missense constraint at variant-level resolution. We find this model to significantly outperform all other models, including meta-predictors, at distinguishing patients with developmental disorders from unaffected individuals, based on their de novo mutations, while also achieving state of the art performance at predicting readouts from deep mutational scanning experiments. Finally, we argue that our model can play a valuable role in identifying many rare genetic disorders which may never be discoverable with burden tests. We provide evidence that there are likely thousands of such disorders, some of which are present in the 31k trio meta-cohort, partially explaining the current low yield of patient sequencing in the context of rare disease.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3268 Rapid DNA extraction from buccal swab samples: enhancing efficiency and performance.

Authors:

L. Willing[1], N. Seip[2], M. Salazar-Rondon[2], L. Torres-Benito[2]; [1]BioEcho Life Sci., Inc, Wouburn, MA, [2]BioEcho Life Sci. GmbH, Cologne, Germany

The extraction of high-quality DNA from buccal swab samples is of utmost importance in various fields of genetic research, forensic science, and medical diagnostics. However, conventional DNA extraction methods often involve time-consuming protocols and provide suboptimal results in terms of DNA concentration, yield, and integrity. This can significantly hinder downstream applications such as PCR testing, short tandem repeat (STR) analysis, and genetic sequencing. In this study, we present a novel and efficient method for rapid DNA extraction from buccal swab samples: a tailored lysis, followed by a single purification step. The primary objective of this research was to streamline the DNA extraction process while maintaining high-quality DNA suitable for subsequent approaches. Dry buccal swab samples were collected from a diverse set of individuals, and DNA extraction was performed with our novel method and with a silica-based technique. Our results demonstrated significant improvements in multiple aspects of DNA extraction. Firstly, the total processing time was reduced by 85 % compared to the conventional method, allowing for faster sample throughput. Secondly, the DNA extraction using our method resulted in comparable DNA concentration and superior yield. Notably, our technology ensured better preservation of DNA integrity, as evidenced by higher DIN values obtained. To validate the extracted DNA for downstream applications, we performed STR analyses. The results obtained from the DNA extracted with our method exhibited concordance with a standard DNA extraction method, demonstrating the suitability of the extracted DNA for molecular genetic analysis. In conclusion, the presented EchoLUTION technology presents a significant advancement in the extraction of DNA from dry buccal swab samples. The reduction in processing time, coupled with the enhanced efficiency of our technology, ensures increased sample throughput and enables more accurate and reliable downstream applications, such as STR analysis, genetic investigations, and further microarray analysis, and sequencing.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3269 Relative contribution of variant prioritization and phenotype similarity to performance of automatic genome analysis algorithms

Authors:

S. Khanam[1], A. J. Marcello[1], Z. Soens[2], V. Ustach[2], J. X. Chong[1,3]; [1]Univ. of Washington, Seattle, WA, [2]GeneDx, Gaithersburg, MD, [3]Brotman-Baty Inst., Seattle, WA

Genome analysis algorithms (GAAs) attempt to automate analysis of patient phenotype and sequence data to identify pathogenic variants in individuals with suspected Mendelian conditions (MCs). Most successful GAAs such as XRare, LIRICAL, and Exomiser combine variant-driven and phenotype-driven prioritization, in which patient phenotypic similarity is compared to a reference set of known MCs. Performance is assessed in small cohorts, typically obtained from gene discovery or clinical diagnostic research programs or in sets of published cases. For example, the performance of LIRICAL was assessed in a 100,000 Genomes Project cohort (N=116) and XRare was assessed in a Melbourne Genomics Health Alliance Cohort (N=59). These cohorts may not be representative of the heterogeneous set of individuals receiving genetic testing. Most affected individuals worldwide lack access to similar clinical expertise, even in high resource settings, especially as genetic testing makes inroads into diverse areas of medicine in which clinicians do not necessarily have explicit genetics training (e.g., neurology, cardiology). Moreover, phenotype data available to diagnostic testing laboratories may be extracted computationally, with variable accuracy, from a diverse set of sources such as medical records and notes, test requisition forms, etc. We assessed GAA performance in >20,000 individuals with a wide variety of categorical phenotypes (e.g., autism, skin disorders, seizures, deafness) in whom diagnostic testing identified a Likely Pathogenic or Pathogenic (LP/P) variant(s) that was likely explanatory. We used phenotype data submitted during testing and considered the gene with the reported LP/P variant to underlie the correct diagnosis. Because variant-driven prioritization in all algorithms relies on pathogenicity predictors, a fast-evolving area of research, GAAs may differ in performance purely due to external factors (e.g., date of last update). To understand the impact of phenotype detail and the efficacy of GAAs operating on phenotype alone, we analyzed our cohort without including sequence data. GAAs ranked the correct gene highest in only ~0.3-3% of cases and among the top 10 genes in ~3-13% of cases. We are in the process of assessing performance when GAAs use sequence data simultaneously with phenotype. Our analyses highlight a gap in performance by GAAs that seemingly perform well in small cohorts with phenotype data collected in ideal conditions but are compromised when heterogeneously collected phenotype data are used, as well as their dependency on variant prioritization to achieve good performance.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3270 Reporting the common African PMS2 variant c.2182_2184delACTinsG results with 100% confidence.

Authors:

T. Wijesuriya[1], A. Smith[1,2], L. Huang[1,2], W. Qin[1]; [1]Children's Hosp. of Eastern Ontario, Ottawa, ON, Canada, [2]Univ. of Ottawa, Ottawa, ON, Canada

The *PMS2* gene has 15 exons and encompasses ~37 kb of genomic sequence on chromosome 7. A partial duplication of the *PMS2* gene, as a part of a larger repeat element, results in a transcribed pseudo copy of *PMS2*, termed *PMS2CL*. *PMS2CL* consists *PMS2* exons 9 and 11-15, whereas exon 10 is missing due to an Alu-mediated deletion. Sequencing analysis of *PMS2* is extremely difficult due to these highly homologous regions between *PMS2* and *PMS2CL*. Currently in our lab, we use a custom designed Next Generation Sequencing (NGS) panel (Roche, KAPA HyperPlus) as the initial test for all patients referred for hereditary cancer testing. Read alignment, single nucleotide variants and small insertion/deletions calling are performed using NextGENe software. This can be technically challenging for genes like PMS2 that are prone to misalignment Due to the presence of high sequence homology, any variants detected by NGS within exons 11-15 of *PMS2* are confirmed by long range PCR (LR-PCR) amplifying *PMS2* exons 11-15 followed by Sanger sequencing. Only variants confirmed by *PMS2* LR-PCR and Sanger sequencing are reported. Variants that are not confirmed are assumed to be in *PMS2CL*. However, we haven't confirmed that these variants are in fact in *PMS2CL* using a LR-PCR assay targeting the pseudogene. We have detected c.2182_2184delACTinsG variant by NGS, which is in exon 13 of either *PMS2* or *PMS2CL*. This is a truncating variant with an allele frequency of ~2.5% in African population (gnomAD). Distinguishing the origin of this variant is very important as if it is detected in the *PMS2* gene, it is considered to be pathogenic; however, if it is in the *PMS2CL* pseudogene it is considered as having no clinical impact. This variant was not confirmed by our *PMS2* LR-PCR and Sanger sequencing analysis, suggesting it is a variant in *PMS2CL*. In order to further verify this variant is in *PMS2CL*, we designed highly specific LR-PCR primers that only amplify the *PMS2CL* pseudogene. We were able to confirm this c.2182_2184delACTinsG variant is indeed in the *PMS2CL* pseudogene using the *PMS2CL* LR-PCR and Sanger sequencing analysis in 8 patients in which the variant was detected by NGS but was not confirmed by the *PMS2* LR-PCR and Sanger sequencing. Being able to perform LR-PCR for both *PMS2* and *PMS2CL* simultaneously for variants detected by NGS allows us the added confidence in distinguishing the origin of any variants discovered in these highly homologous exons and to report them appropriately.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3271 Resolution of non-coding variants by RNA sequencing in rare disease.

Authors:

A. Marshall[1], G. Del Gobbo[1], Y. Liang[2], M. Couse[2], K. M. Boycott[1], K. D. Kernohan[3]; [1]Children's Hosp. of Eastern Ontario Res. Inst., Univ. of Ottawa, Ottawa, ON, Canada, [2]Ctr. for Computational Med., The Hosp. for Sick Children, Toronto, ON, Canada, [3]Children's Hosp. of Eastern Ontario Res. Inst., Univ. of Ottawa; Newborn Screening Ontario, Ottawa, ON, Canada

The clinical implementation of next-generation sequencing has revolutionized genetic diagnostics of rare disease, yet many exome and genome analyses remain inconclusive. This is due in part to challenges with variant prioritization and interpretation, particularly for intronic variants. The accuracy of *in silico* tools to predict the effect of a variant on RNA expression and/or splicing outside the canonical splice site remains low and therefore these variants are almost always variants of uncertain significance (VUSs).

Following inconclusive genetic testing, families affected with undiagnosed rare disease consented to enrollment in the Care4Rare Canada research program and RNA sequencing (RNA-Seq) analyses were performed on affected individuals and has been useful for resolution of VUSs in a number of projects we have analyzed. For example, an affected individual with suspected short-rib thoracic dysplasia 3 (SRTD3) had clinical genetic testing which identified a likely pathogenic frameshift variant and an intronic VUS in *DYNC2H1* in trans. Research RNA-Seq investigations revealed significantly decreased *DYNC2H1* gene expression in the proband as well as a novel splice junction as a result of the intronic variant, which again allowed reclassification of the variant to LP. In a second study, an individual with medium-chain acyl-coenzyme A dehydrogenase (MCAD) deficiency had only one likely pathogenic variant detected in *ACADM* by clinical sequencing. RNA-Seq detected a novel intron inclusion in this gene; an SNV was detected within this intron inclusion, was confirmed to be heterozygous in the individual's genomic DNA and was classified as likely pathogenic. Finally, in two siblings with suspected Joubert syndrome, RNA-Seq was also able to identify their second causative variant. This variant was intractable to detection by routine exome and genome sequencing analyses as it is a 57 bp deletion in a repetitive intronic region, but was detectable by RNA-Seq as it leads to novel intron inclusion in the resulting transcript.

These studies highlight the benefits of RNA-Seq in obtaining a diagnosis for patients with rare disease where additional data is required after inconclusive clinical testing, especially for variants with a potential mRNA splice impact. While we recognize that non-coding variants play a role in disease, we currently lack robust tools to accurately interpret and classify them. RNA-Seq can assess the impact of these non-coding variants via their effect on gene expression, RNA stability and RNA processing and therefore could be considered as a follow up clinical test in the future.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3272 RNA Sequencing as a Routine Diagnostic Tool in Medical Genetic Practice, Solving A Case with Gaucher Disease

Authors:

H. Onay[1,2], E. Goksoy[3]; [1]Multigen Genetic Diseases Diagnosis Ctr., Izmir, Turkey, [2]Gene2Info Sag.Hiz., Istanbul, Turkey, [3]Dept. of Pediatry, Pediatric Metabolic Diseases Subdivision, Adnan Menderes Univ., Faculty of Med., Aydın, Turkey

In routine medical genetic practice sequencing is the main molecular genetic technique for diagnosis of the genetic disorders and sequencing of the coding exons and exon-intron boundaries is the main sequencing approach. DNA is the main genomic material used in sequencing in routine practice. In recent years RNA sequencing was began to use as a diagnostic tool in limited number of diagnostic genetic laboratories for limited number of genetic disorders. The main barriers for RNA sequencing in routine practice are rapid degradation of RNA and expression of the RNA in certain tissues. In metabolic genetic disorders such as Gaucher, Pompe and Fabry RNA sequencing can be performed from the blood because there is limited expression of the genes responsible for metabolic genetic disorders in the blood. A 6-year-old girl was referred to our laboratory due to bicytopenia. Her motor and mental milestones were normal. She had suffered from hepatosplenomegaly since the age of 2 years. Physical examination revealed a pale appearance, distended abdomen, palpable liver and spleen up to the groin, and prominent veins on the anterior abdominal surface. She had anaemia, thrombocytopenia, moderate elevation in liver function tests and high ferritin. In metabolic tests; chitotriosidase level (809.8 µmol/L.hr; NR 200.0) and lyso-GB1 level (832.1 ng/mL; NR <14.0) were quite high. Leukocyte beta-glucosidase levels were found to be low (0.40 nmol/mg/hr; NR 1.00). Ultrasound revealed massive hepatosplenomegaly. With all these findings, the patient was clinically diagnosed with Gaucher disease type 1. *GBA* sequencing from DNA was performed. Heterozygous c.1126A-G [p.N409S-N370S)] pathogenic variant was detected. GBA Whole Gene Sequencing (including all introns) and MLPA tests were performed in order to find the second causal variant in the patient but turned to be negative. Then the RNA sequencing was performed from the blood. Interestingly second causal pathogenic variant, c.475C-T (p.R159W), was detected in the RNA in heterozygous state. Heterozygous c.1126A-G [p.N409S-N370S)] variant was also detected in the RNA. Segregation analysis was performed. Father is carrier for the c.1126A-G [p.N409S-N370S)] variant but mother is carrier for the c.475C-T (p.R159W) variant in RNA. After re-analyses of the sequencing data from DNA obtained from blood, c.475C-T (p.R159W) variant was detected but allele frequency is 5%. Eventually, the patient was genetically diagnosed and received treatment. This patient shows the importance of RNA sequencing in routine practice. Single step RNA sequencing from the blood might be an optimal solution for metabolic genetic disorders.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3273 RNA-based diagnosis of a child with SMA disease

Authors:

S. Durmus[1], U. Guven Gulhan[1], C. Kolakoglu[1], O. Akdas[1], I. Ovali[1], E. Evin[2], F. E. Sevilgen[1], E. Nikerel[1], P. Pir[1], M. Adli[3], E. Unsal[2], L. Ozer[2], S. Aktuna[2], A. Ulgenalp[4], U. Yis[4], V. Baltaci[2], A. O. Caglayan[4], T. Cakir[1]; [1]PhiTech AS, Kocaeli, Turkey, [2]Mikrogen Ltd, Ankara, Turkey, [3]PhiTech Inc, Chicago, IL, [4]Dokuz Eylul Univ., Izmir, Turkey

Monogenic rare diseases challenge the patients, families, and healthcare systems with approximately 5 years spent on average to achieve a successful diagnosis. The conventional methods are based on the detection of disease-causing mutations using gene panels or exome sequencing, and still, they fail to provide a successful diagnosis for more than 50% of the patients.

Here, we report a case for which diagnosis was not possible using the conventional methods for years after the emergence of the abnormality in muscle functions. Whole Exome Sequencing was previously applied to the blood samples from the family, consisting of healthy parents and the diseased child. A homozygous variant with uncertain significance (VUS) was detected in the *SMN1* gene of the child. The same variant was detected in the mother as heterozygous, while the father had a deletion in the related variant region. However, evidence of loss of function was needed to demonstrate the pathogenicity of the detected VUS. RNA sequencing (RNA-Seq) provides information on the genes with aberrant expression, which is not possible to obtain via genome sequencing. Therefore, RNA-Seq was applied to the blood samples from the family, and expression levels were identified at the gene and transcript levels. Transcript level expression analysis showed that, in the mother and father, no significant loss of expression was observed in the transcripts of the *SMN1* gene. However, there was a 100% loss of expression in the canonical and biologically relevant transcript of the gene in the child. Functional analysis via RNA-Seq demonstrated the pathogenic effect of the identified VUS in the function of SMN1 protein, leading to SMA disease. A muscle biopsy from the child was further subjected to RNA-Seq and transcript-level expression analysis, confirming the complete loss of expression of the *SMN1* gene in the muscle tissue. Consequently, the RNA-based diagnosis of the patient was approved by the clinical committee, and drugs for treatment were prescribed. While DNA holds genetic code, the functional effects of genetic variants can only be detected through the functional genome, and we here demonstrated that RNA has the power to capture the functionality of the protein coded by the candidate gene, *SMN1*.

We propose the use of our approach in rare disease diagnosis, particularly for patients who could not be diagnosed with genome profiling. In the near future, we expect to demonstrate the success of our approach with many other cases.

PB3274 RNA-seq based rare diseases diagnostics at the Pan-European consortium Solve-RD

Authors:

V. Yepez[1], C. Mertes[1], K. Ellwanger[2], R. Luknarova[1], C. Doornbos[3], A-S. Denomme-Pichon[4], A. Vitobello[4], D. Beijer[5], M. Synofzik[5], D. Mei[6], R. Guerrini[6], B. Estévez-Arias[7], D. Natera-de Benito[7], A. Segarra[8], J. Müller[9], A. Topf[8], L. Matalonga[10], G. Demidov[2], S. Beltran[10], A. Hoischen[3], P-B. t'Hoen[3], A. Esteve-Codina[10], J. Gagneur[1]; [1]Technical Univ. of Munich, Garching bei München, Germany, [2]Univ. of Tübingen, Tübingen, Germany, [3]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [4]CHU Dijon Bourgogne, Dijon, France, [5]Hertie Inst. for Clinical Brain Res., Tübingen, Germany, [6]Meyer Children's Hosp. IRCCS, Florence, Italy, [7]Hosp. Sant Joan de Déu, Barcelona, Spain, [8]Newcastle Univ. and Newcastle Hosp. NHS Fndn. Trust, Newcastle, United Kingdom, [9]Univ. Coll. London, London, United Kingdom, [10]CNAG-CRG, Ctr. for Genomic Regulation (CRG), Barcelona, Spain

RNA sequencing has emerged as a powerful complementary approach to DNA sequencing to discover disease-causing gene regulatory defects in individuals affected by genetically undiagnosed rare disorders. However, as large rare disease research consortia are implementing RNA-seq-based diagnostics, new data analysis challenges arise to cope with the heterogeneity of diseases, various tissues and sample sizes, and the multiplicity of interpreters. Here we present new algorithms and methodologies that have been developed by the RNA-seq working group of the Pan-European consortium Solve-RD to address these issues. The Solve-RD RNA-seq dataset consists of >450 RNA-seq samples collected from 4 different tissues, from individuals tested at more than 20 clinics belonging to 6 European Reference Networks. The vast majority of the samples also have matching whole exome or whole genome sequencing. The samples were analyzed using the workflow DROP v1.3.3, which includes the recent release of the aberrant splicing caller FRASER 2.0 to call aberrant events in RNA-seq data. Two new RNA-seq quality control modules were added to DROP to confirm sex and tissue annotations. Both helped to detect a handful of mislabelled samples. To identify candidate genes and variants, we considered i) a DNA-first approach, in which candidate variants from DNA sequencing are functionally validated by RNA-seq and ii) an RNA-first approach in which candidate genes are first identified by aberrant expression or splicing and DNA data is then re-examined. The two approaches proved to be complementary and reported on average, a handful of candidates per sample. The DNA-first approach benefits from a much reduced multiple testing burden. It falls under the ACMG guidelines, whereby the RNA-seq is considered as a functional assay. We devised annotation guidelines for the RNA-first approach that integrates scoring of an aberrant expression or splicing event at four levels: i) raw data support of the outlier calls, ii) gene function, iii) identification of a variant with a plausible regulatory mechanism, and iv) variant segregation. To further increase the consistency of our annotations, we have conducted an in-presence workshop named Solvathon, combining training and collective data inspection sessions, and offered weekly consultancy hours. As of June 2023, the RNA-seq analysis has led to 5 new solved cases (4 harboring a deletion and 1 a deep intronic variant missed by exome sequencing), and a handful of strong candidates. Extensive case-by-case analysis is ongoing. Altogether, our new algorithms and processes contribute to improved methodologies for RNA-seq-based rare disease diagnostics.

PB3275 Selected aspects of the process of implementation of tandem repeats characterisation into routine laboratory testing processes based on massively parallel sequencing

Authors:

I. Lojová[1,2,3], M. Kucharik[2,4], Z. Pös[1,2,4], A. Zatkova[1,4], E. Tothova Tarova[1], J. Budis[4,2,5], T. Szemes[2,3,4], J. Radvanszky[2,3,1,4]; [1]Inst. of Clinical and Translational Res., BioMed. Res. Ctr. of the Slovak Academy of Sci., Bratislava, Slovakia, [2]Comenius Univ. Sci. Park, Bratislava, Slovakia, [3]Dept. of Molecular Biology, Faculty of Natural Sci., Comenius Univ., Bratislava, Slovakia, [4]Geneton Ltd., Bratislava, Slovakia, [5]Slovak Ctr. of Scientific and Technical Information, Bratislava, Slovakia

Introduction: The introduction of massively parallel sequencing (MPS) methods initiated the rapid development of methods for genotyping sequence variants at the genomic level. The evaluation of tandem repeat (TR) motifs has become possible with some delay, mainly due to their high variability and complexity. We are reporting on specific qualitative and quantitative measures of reliability in the context of characterizing TR motifs in genomic diagnostics. **Material and Methods:** Whole genome sequencing data, using short-read MPS, were generated for 62 individuals. For characterisation of appr. 50 clinically relevant TR loci we used the modified version of a TR dedicated tool Dante. **Results:** According to us, for efficient genotyping of TR loci there are certain aspects of quality management, which may yet differ from the actual recommendations for SNVs. The most important parameters include: 1) uniformity of locus definition and nomenclature (may be more complex than for SNVs); 2) sufficient depth of locus coverage (higher than for SNVs); 3) the possibility of visual verification (dedicated tools with more complex functions); and 4) laboratory validation of relevant findings (may be still necessary, using alternative methods, in certain specific cases). **Conclusion:** The MPS is currently an advanced methodology, which in the case of SNVs has been refined and translated into clinical practice. The characterization and assessment of TRs presents multiple challenges in both secondary and tertiary data analysis, which means that the official guidelines currently applicable to SNVs will need to be extended to include interpretation and reporting of TRs. **Grants:** This work has been supported by the PANGAIA project H2020-MSCA-RISE-2019 (Grant agreement ID: 872539) funded under H2020-EU.1.3.3. Programme; by the ALPACA project H2020-MSCA-ITN-2020 (Grant agreement ID: 956229) funded under H2020-EU.1.3.1. Programme; by the Operational Program Integrated Infrastructure within projects ITMS: 313011F988 and ITMS:313021BUZ3, co-financed by the ERDF; and by the Scientific Grant Agency (VEGA_2/0146/23).

PB3276 † Semiautomated Interpretation of Genomic Disease Contribution to Unknown Causes of Infant Mortality.

Authors:

L. Protopsaltis[1,2], R. Baer[3,4], M. Bainbridge[1,2], B. Cao[1,2], Y. Ding[1], K. Ellsworth[1,2], L. Forero[1,2,3], E. Frise[5], L. Guidugli[1,2], Y. H. Kwon[1,2], J. Le[1,2], E. Ontiveros[1,2], M. J. Owen[1,2], E. Sanford[1,2], L. Van Der Kraan[1,2], M. Wright[1,2], M. Yandell[1,5], L. Jelliffe-Pawlowski[4], G. Bandoli[3], C. Chambers[3], S. F. Kingsmore[1,2]; [1]Rady Children's Inst. for Genomic Med., San Diego, CA, [2]Rady Children's Hosp., San Diego, CA, [3]Dept. of Pediatrics, Univ. of California San Diego, San Diego, CA, [4]California Preterm Birth Initiative, Univ. of California San Francisco, San Francisco, CA, [5]Fabric Genomics, Oakland, CA

Quantitative understanding of the causes of infant mortality shapes public health, surveillance, and research investments. However, the contribution of single-locus genetic diseases to infant mortality is poorly understood. We recently reported that 46 (41%) of 112 infant deaths within a large pediatric hospital system in San Diego County (SD), CA, were associated with genetic diseases using whole genome sequencing (WGS) and semiautomated interpretation. Subsequently, we performed post-mortem WGS (>30-fold, Illumina) of de-identified, archived, newborn dried blood spots collected from 2005-2018 in an additional 914 SD infant deaths. Here we report initial results of diagnostic analysis of the first 211 of these infant deaths. Death certificates listed ICD-10 code R95 (sudden infant death syndrome) as the cause of death in 175 (83%) of 211 infants, and R99 (ill-defined and unknown cause of mortality) or W75 (other accidental threats to breathing) in the remaining 36 (17%). Variants identified with DRAGEN v3.9 underwent semiautomated interpretation with Fabric Genomics' Artificial Intelligence Classification Engine (ACE) and GEM with the HPO phenotype "death in infancy". Variant diplotypes in disease-associated genes with positive Bayesian GEM scores were reviewed manually according to ACMG classification guidelines. 71 (34%) of 211 infant deaths were associated with at least one pathogenic (P) or likely pathogenic (LP) variant, of which <5 were assessed to have had autosomal dominant (AD) disorders associated with infant mortality, such as Left Ventricular Noncompaction (OMIM IDs 615396, 615092). The remaining 69 infant deaths either had P/LP variants in genes associated with later-onset AD disorders or represented carrier status for autosomal recessive (AR) disorders. Analysis of variants associated with AR, mitochondrial, and X-linked disorders in addition to copy number and structural variants is ongoing and will be reported together with results of manual curation of variants where ACE or GEM did not report. We will also evaluate this cohort for likely deleterious variants that occur recurrently and that have biologic plausibility as novel causes of infant mortality. It is much more difficult to identify genetic disorders that potentially contributed to infant mortality in WGS of de-identified samples than in the previous cohort with deep phenotypes derived from electronic health records. However, ACE and GEM are effective for automated prioritization of P and LP variants in disease-associated genes. Together these studies should clarify the contribution of single-locus genetic diseases to infant mortality in Southern California.

PB3277 Single exonic CNV analysis uncovers masked complex genome rearrangements in recessive disorder

Authors:

T. Naruto, Y. Kuroda, Y. Saito, Y. Enomoto, K. Kurosawa; Kanagawa Children's Med. Ctr., Yokohama, Japan

Advances in next-generation sequencing and genome capture technologies have made exome sequencing a cost-effective approach for mutation detection in inherited diseases. However, computationally predicting copy number variants (CNVs) from exome sequence data is a challenging task. Numerous programs are available, but with varying sensitivities and less sensitivity to detect smaller single-exon CNVs. Bardet-Biedl syndrome (BBS) is a genetically heterogenous disorder characterized by retinopathy, obesity, polydactyly, urogenital abnormalities, and intellectual disability. BBS is a multisystemic disorder requiring lifelong medical care and support. Because of the variable expressivity of BBS, a molecular genetic approach combined with clinical diagnosis is crucial. The proband was an 11-year-old boy. He was born at 39 weeks of gestation to nonconsanguineous parents. At birth, he was noted to have bilateral postaxial polydactyly. From the age of three years, he developed progressive vision loss and night blindness and was diagnosed clinically with Bardet-Biedl syndrome. Whole exome sequencing revealed a pathogenic SNV of ClinVar in BBS9. Since it was consistent with the patient's clinical symptoms and recessive inheritance, we searched for a causative variant in the other allele. three CNV detection programs (XHMM, CoNIFER, and CNVnator) failed to find CNV in BBS9. A detailed investigation of the CNVs of each exon converted from read depth log 2 ratio, we identified a deletion of exon 17 as a candidate variant. To elucidate the deletion interval, we employed Nextera XT (Illumina) sequencing of a PCR product of approximately 22 kb containing exons 16 to 18. We identified a deletion of 3.6 kb and insertions of uncertain origin in the adjacent 239 bp and 22 bp. From this result, it was inferred that exon 17 was skipped, resulting in a codon stop and causing the onset of BBS. These results indicated that the deletions of exons may have potential complex rearrangements around them.

PB3278 Somatic genetic rescue in a patient with RUSAT2 syndrome carrying a *MECOM* LoF variant

Authors:

A. Buijs[1], S. Holwerda[1], R. Bladergroen[2], L. Suurenbroek[2], L. van Vulpen[1], M. Bartels[1], R. Kuiper[2], M. Jongmans[1]; [1]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands, [2]Princess Máxima Ctr. for Pediatric Oncology, Utrecht, Netherlands

We present a unique case of clonal hematopoiesis of indeterminate potential (CHIP) by means of copy neutral loss-of-heterozygosity (CN-LOH) of the long arm of chromosome 3, potentially resulting in a rescue mechanism for MECOM loss-of-function (LoF) in radioulnar synostosis with amegakaryocytic thrombocytopenia-2 (RUSAT2) syndrome (OMIM 165215). A 20 years-old woman was diagnosed with RUSAT2 syndrome, caused by a *de novo* heterozygous missense variant in the *MECOM* gene. Since diagnosis, mild cytopenias remained stable (hemoglobin 7.0-8.4 mmol/L; leukocytes 3.2-5.1x10^9/L; platelets 127-161x10^9/L). Routine bone marrow (BM) analyses showed decreased cellularity. Single nucleotide polymorphism (SNP) array analyses on BM DNA samples were performed for surveillance of genomic alterations associated with progression and/or malignant transformation, requiring stem cell transplantation. We detected acquired CN-LOH of 66 Mb of the long arm of chromosome 3 (band 3q22.1->3qter) including *MECOM*, with an increasing percentage of mosaicism in time up to ~10%. Locus-specific amplicon-based deep sequencing (4,500X) demonstrated an identical quantitative shift in time in favor of the wildtype *MECOM* allele. Our data indicate that the expanding clone in the BM cells has undergone mitotic recombination resulting in wildtype *MECOM* on both alleles. Somatic genetic rescue has been reported in other bone marrow failure (BMF) syndromes, conferring selective advantage of cells that lost the germline pathogenic variant(s) over cells carrying the pathogenic allele(s). We are, for the first time, witnessing expanding CHIP in RUSAT2 syndrome, suggesting somatic genetic rescue for MECOM LoF. We will continue to follow the course of the CN-LOH 3q and its consequences in relation to the mild cytopenias in this case. Our study underscores the importance of periodic genomic screening of BM in BMF syndromes in clinical decision-making.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3279 Spontaneous induction of Chromosome 1 Trisomy in reprogrammed iPSC line is associated with accelerated growth and Proliferation.

Authors:

C. Pearce[1], S. Borrowman[1], S. Ternes[2], A. Kamath[2], J. Nagy[1], M. Schultz[1], M. Tung[1], B. Chandra[1]; [1]Univ. of Iowa, Iowa City, IA, [2]Cellular Engineering Technologies, Coralville, IA

Induced pluripotent stem cell (iPSCs)-based model systems allow for a wide array of studies, and especially the direct reprogramming of patient-derived cells into iPSCs further enables the implementation of personalized medicine through their broad applications in drug discovery, regenerative medicine, and disease modeling. Although iPSC reprogramming methods have been well established and highly reproducible over the past decade, reprogrammed iPSC cell lines must be grown and maintained in artificial culture media supplemented with multiple growth factors for an extended time period, which may result in cellular or genetic aberrations, such as spontaneous differentiation of the cells or a spontaneous gain or loss of chromosomes. Here we report a rare occurrence of spontaneous gain of an extra copy of chromosome 1 in a patient derived Gaucher disease iPSC line. The parent fibroblasts were successfully reprogrammed using Episomal reprogramming factors, and pluripotency was confirmed by both immunohistochemistry and Flow Cytometry. This gain of chromosome 1 was discovered after 15 passages when the cell line was sent for karyotyping. A karyotype performed on the parent of origin fibroblasts was normal. The mechanisms of these cellular and genetic aberrations are not well studied but are typically attributed to suboptimal culture techniques and replication stress. Replication stress can lead to replication fork stalling, which results in double-strand DNA breaks. iPSCs also undergo rapid replication by avoiding certain cell cycle checkpoints, which is also a likely cause of the genetic aberrations the cells could acquire, particularly when compared to somatic cell lines. In humans, trisomies and other aneuploidies are known to cause multiple congenital anomalies and developmental delays and, depending on the chromosome, can often lead to miscarriages. Pathogenic mechanisms of certain trisomies are known or are being studied, such as trisomy 21 (down syndrome), 18 (Edwards syndrome), and trisomy 13 (Patau syndrome), and are believed to be due to maternal meiotic non-disjunction. However, there is limited information available on Trisomy 1, due to its constitutional non-viability. Our reprogrammed iPSC cell lines grew rapidly with a significantly faster doubling time in comparison to the other lines that were being grown concurrently, leading us to believe that trisomy 1 has some effect on growth. This may allow for further investigation into the pathogenic mechanisms and consequences of trisomy 1 in somatic disorders such as cancers.

PB3280 Subtle Cellular Phenotypes Inform Pathological and Benign Genetic Mutants in the Iduronidase-2 Sulfatase Gene

Authors:

W. Buchser[1], S. Elia[1], S. Hurt[1], A. Viswanathan[1], S. Le[1], K. Kelley[1], B. Doray[1], P. Dickson[2]; [1]Washington Univ. in St Louis, Saint Louis, MO, [2]Washington Univ. Sch. of Med., Saint Louis, MO

BackgroundInterpreting the pathogenicity of genetic variants in molecular DNA testing for inherited conditions presents significant challenges, leading to many "variants of uncertain significance" (VUS). Mutations in the IDS gene, implicated in mucopolysaccharidosis type II (Hunter syndrome), where deficiency of the lysosomal enzyme iduronate-2-sulfatase (I2S) impairs the degradation of specific glycosaminoglycans, requiring enzyme replacement therapy. Despite available biochemical assays, numerous IDS VUS remain unclassified, highlighting the need for innovative classification methods. MethodsWe devised an evaluative platform, Deep Cellular Phenotyping, leveraging high-content imaging and machine learning to generate composite phenotypes based on cellular morphology. This platform enables individual cell sequencing after imaging to identify cellular variants. The approach was applied to the IDS gene for functional variant classification.ResultsAfter introducing a dozen IDS mutations into the A549 cell line, imaging revealed distinct differences in lysosomal structures, dye accumulation in intracellular vesicles, and the distribution of a LAMP1-GFP reporter. These image-based features facilitated differentiation between known mutant and wild-type cells. Notably, cells with pathogenic IDS mutations showed a reversal of these anomalies upon exposure to recombinant I2S enzyme. Only a fraction of the cells was rescued after 72-96 hours, implying some long-term damage to the organelles in these particular cells.ConclusionOur findings suggest image-based screening as a promising tool for detecting subtle distinctions, potentially paving the way for new methods of variant classification and elucidating a broader spectrum of variant effects.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3281 Targeted sequencing of 50+ pathogenic repeat expansions using Twist target enrichment and PacBio HiFi sequencing.

Authors:

T. Han[1], H. Corbitt[1], E. M. Lampraki[2], F. Tornos[1], S. Holt[2], D. Stucki[2], E. Toro[1], S. Kingan[2], C. Locklear[1]; [1]Twist BioSci., South San Francisco, CA, [2]Pacific BioSci.s, Menlo Park, CA

Background/objectives: The expansion of unstable genomic short tandem repeats (STRs) has been identified as the causal DNA mutation in more than 30 Mendelian diseases. PCR-based DNA fragment analysis, short-read sequencing, or legacy molecular genotyping methods like Southern blot are frequently used to analyze STR expansions, but are not capable of determining the exact length and sequence composition. Targeted sequencing allows for high-resolution characterization of dozens to thousands of gene regions at a scale and cost that is more accessible than whole genome sequencing. **Methods:** Here we describe the performance of a Twist target enrichment panel sequenced with PacBio long HiFi reads to measure the size of STR expansions with base-pair resolution. Using a proprietary algorithm, we designed a gene panel targeting 50+ regions with known pathogenic repeat expansion alleles in human samples. We started with 200 nanograms of fragmented gDNA. After end-repair, A-tailing, and adapter ligation, unique dual indices for sample barcoding were added during PCR. Every 8 samples were pooled for an overnight hybridization. After capture and wash, the post-capture libraries were then amplified and converted into SMRTbell library and sequenced on PacBio Sequel IIe system (also compatible with the Revio system) with resulting HiFi read lengths of ～5 kilobases. We genotyped repeat copy numbers using Tandem Repeat Genotyping Tool (TRGT) and visualized reads spanning repeats using TRVZ. **Results:** We benchmarked performance of the long-read capture workflow in reference samples, of which 7 have characterized pathogenic repeat expansions alleles with diverse repeat base composition. Preliminary analysis showed two CAG repeats in the *HTT* and *AR* genes, a CTG repeat expansion in *DMPK*, a GAA repeat expansion in *FXN*, and GC-rich expansions in several other genes could be captured and sequenced. We also tested four different commercially available PCR polymerases and compared sequence coverage across the samples and targets for each condition. We found concordance between observed and expected repeat number for the genes *HTT*, *DMPK*, *AR*, and *PABPN1*. Optimizing the coverage of a few genes and testing on clinical samples with expanded alleles are ongoing. **Conclusion:** From this pilot study, we provide design and workflow guidance to researchers interested in targeted long-read sequencing for scalable and cost-efficient hybrid capture of 50+ different repeat expansions with long read lengths, minimizing coverage bias, and maximizing accuracy to fully capture all variant types. *[For Research Use Only. Not for use in diagnostic procedures.]*

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3282 The diagnostic yield of plasma-based cell free DNA in individuals with matched tissue-based venous and arteriovenous malformations

Authors:

D. Jensen[1], N. Au[1], M-H. M. Pham[1], N. Parmalee[1], V. Dmyterko[1], T. T. Cook[1], K. Zenner[2,1], S. Wilcox[1,3], C. T. Myers[4], M. A. Gillentine[4], G. Strub[5,6], R. A. Bly[2,7], G. M. Shivaram[8], G. Richter[9,6], J. A. Perkins[2,7], J. T. Bennett[10,7,11]; [1]Seattle Children's Res. Inst., Seattle, WA, [2]Dept. of Head & Neck Surgery, Univ. of Washington, Seattle, WA, [3]Univ. of Michigan, Ann Arbor, MI, [4]Seattle Children's Hosp., Seattle, WA, [5]Arkansas Children's Res. Inst., Seattle, AR, [6]Univ. of Arkansas, Fayetteville, AR, [7]Vascular Anomalies Program, Seattle Children's Hosp., Seattle, WA, [8]Dept. of Radiology, Univ. of Washington, Seattle, WA, [9]Arkansas Children's Res. Inst., Little Rock, AR, [10]Seattle Childrens Res. Inst., Seattle, WA, [11]Dept. of Pediatrics, Div. Genetic Med., Univ. of Washington, Seattle, WA

Purpose: Most venous and arteriovenous malformations (VeM and AVM) are caused by somatic activating mutations in oncogenes. Molecular diagnosis currently requires surgically excised tissues, but there is increasing demand for non-invasive molecular diagnostics due to the development of targeted medical therapies. Here we report the diagnostic yield of cfDNA in a cohort of 61 individuals with matched tissue and plasma samples. We also compared diagnostic yield of peripheral blood and "lesional" blood collected directly from the vascular malformation. **Methods:** We included only individuals with known tissue-based pathogenic mutations in *PIK3CA*, *TEK*, *MAP2K1*, *BRAF*, or *KRAS*. cfDNA was extracted from the plasma and mutations were assayed using digital droplet PCR or high depth custom NGS panel. **Results:** Mutations were identified in plasma based cfDNA in a third of the cohort (21/61 individuals). The diagnostic yield was higher in VeM (16/36 individuals) than in AVM (5/25 individuals). Surprisingly, the diagnostic yield of intralesional plasma samples was higher (10/17 VeM and 1/3 AVM) than peripherally collected plasma (8/35 VeM and 4/25 AVM). All plasma samples were also compared to matched cellular "pellets," where mutations were detected in 5/36 individuals with VeM and in 0/25 individuals with AVM. In a single individual with an AVM, the mutation was not detected in plasma collected prior to glue embolization, but was detected in a peripheral sample collected immediately post-embolization. **Conclusion:**In a cohort of 61 individuals with known tissue-based somatic mutations as gold-standard comparators, we demonstrate the utility of plasma based cfDNA as a non-invasive diagnostic analyte. Overall, mutations were detected in cfDNA in 44% of our VeM cohort and 20% of our AVM cohort. The detection rate in plasma cfDNA is superior to that in the cellular ("blood pellet") fraction (13% VeM and 0% AVM), likely reflecting an enrichment of endothelial cell derived DNA in the plasma. Direct sampling of intralesional plasma increased the diagnostic yield (58% VeM and 1/3 AVM) over peripheral plasma, which is also consistent with an endothelial cell origin of these mutations. Although the diagnostic rates in cfDNA are inferior to that in tissues, our results suggest a route to molecular diagnosis, and companion targeted medical therapy, in individuals with VeM or AVM for whom surgical tissues are unavailable. Our results also support the collection of plasma for diagnostic testing during embolization or sclerotherapy procedures.

PB3283 The first case of a Korean patient with the *WAC* germline mutation c.451C>T(p.Arg151*)

Authors:

C. Cheon, I. Kim; Pusan Natl. Univ. Children's Hosp., Yangsan-si, Korea, Republic of

Backgrounds: DeSanto-Shinawi syndrome is an autosomal dominant genetic condition caused by loss-of-function mutations in *WAC* and is characterized by a multitude of dysmorphic features along with behavioral abnormalities, and intellectual disability. Congenital heart defects associated with DeSanto-Shinawi syndrome were rarely reported in patients with pathogenic variants in *WAC*. **Methods:** We performed WES on DNA obtained from the peripheral blood of the patient and his parents, and variants found were compared and filtered. The coding and flanking intronic regions were enriched using Agilent solution (Agilent Technologies) and sequenced using the HiSeq 2500/4000 system (Illumina). Conventional Sanger sequencing was used to sequence at least 1 causative or rare variant for a second, independent confirmation. **Results:** Here, we report a case of a 13-year-old Korean girl patient with dysmorphic facial features such as a prominent forehead, high arched palate, anteverted nares, low nasal bridge, long philtrum, micrognathia, and intellectual disability. She was born at 40+3 weeks, 3.14kg via cesarian delivery. She underwent coartoplasty and mitral valve valvotomy with papillary muscle splitting. She had medullary nephrocalcinosis, VUR (left grade III), and epilepsy. Brain MR revealed several small microbleeds in the cerebrum on the SWI image and left mild periventricular leukomalacia. Whole exome sequencing revealed a novel heterozygous variant, c.451C>T (p.Arg151*), in the *WAC* gene. **Conclusions:** To the best of our knowledge, this is the first case of DeSanto-Shinawi syndrome in Korea, which expands the phenotypic and genotypic spectrum of this rare syndrome and provides deeper insights by delineating the clinical features of our patient.

PB3284 The NIH INCLUDE Project: Transforming research for people with Down syndrome across the lifespan.

Authors:

M. Parisi[1], S. Bardhan[1], M. Brown[2], L. Garcia[1], **H. Li**[2], A. Mazzucco[3], G. Pearson[2], L. Ryan[4], C. Schramm[2], B. Schwartz[2], E. Tarver[4]; [1]NICHD/Natl. Inst.S OF HEALTH, Bethesda, MD, [2]NHLBI/Natl. Inst.S OF HEALTH, Bethesda, MD, [3]Office of Director/Natl. Inst.S OF HEALTH, Bethesda, MD, [4]NIA/Natl. Inst.S OF HEALTH, Bethesda, MD

Introduction: In response to a Congressional directive in fiscal year (FY) 2018, the NIH launched the INCLUDE (INvestigation of Co-occurring conditions across the Lifespan to Understand Down syndromE; https://www.nih.gov/include-project) Project. INCLUDE is studying conditions that affect those with Down syndrome (DS) and the general population, such as Alzheimer's disease, autism, celiac disease, congenital heart disease, and diabetes, and expanding the number of investigators engaged in DS research. Methods: The INCLUDE Project supports DS research through three major components: (1) Conduct targeted, high-risk, high-reward basic science studies on chromosome 21; (2) Assemble a large study population of individuals with DS; and (3) Include individuals with Down syndrome in existing and future clinical trials. There are currently 19 active Funding Opportunities, including five focusing on career development and fellowship awards, and several focusing on increasing diversity. The INCLUDE Data Coordinating Center (DCC; https://includedcc.org/) is promoting data sharing through its cohort-building efforts and by creating tools for data visualization and analysis through the INCLUDE Data Hub (https://portal.includedcc.org/login). The DCC has launched a training initiative for diverse data scholars through a summer internship program. In addition, the DS-Connect® registry (https://dsconnect.nih.gov/) is enhancing research participation by connecting families with research opportunities of interest to them. Results: NIH has invested $258 million in the past 5 years on 269 new INCLUDE projects. In FY2022, the INCLUDE investment was $75 million for total NIH DS funding of $113 million. Over three dozen trainees have been supported during the past 5 years. DS-Connect® has over 5800 registered participants and has promoted research enrollment for 100 projects, 18 INCLUDE-funded, and 5 clinical trials. The INCLUDE DCC launched the INCLUDE Data Hub with clinical and 'omics data from multiple studies, and currently includes over 2600 whole genomes. A DS Research Plan was recently published outlining goals and objectives for the next 5-10 years of DS Research. Conclusions: The INCLUDE Project has stimulated DS research funding since its launch, while the DS-Connect® registry and INCLUDE DCC are facilitating subject recruitment. A major cohort and biobanking initiative will be launched in FY24. Efforts to increase the diversity of research participants and investigators through community outreach are essential to create a more representative cohort that will lead to improved treatments and quality-of-life for those with DS.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3285 The Role of Large Copy Number Variants in The Etiology for Chronic Kidney Disease Revealed through A Commercial Next-Generation Renal Gene Panel (Renasight™)

Authors:

F. Fang[1], J. Fierro[1], B. Sapra[1], J. Choi[1], S. Punj[2], **Y. Xue**[1]; [1]Fulgent Genetics, Temple City, CA, [2]Natera, Inc, San Carlos, CA

Introduction Disease-causing genetic variants are present in ~10% of adults and ~20% of children with chronic kidney disease (CKD). Large copy number variants (LCNVs) are associated with Mendelian disease, common traits, and sporadic diseases, including CKD. However, the role of LCNVs in the etiology for CKD in clinical practice is not yet well characterized. **Method:** A commercially available next-generation sequencing (NGS)-based 385 gene kidney disease panel test was performed for clinical purposes on patients seeing general and transplant nephrologists in the US. We used an in-house developed algorithm for CNV analysis. 1103 consecutive unique patient samples with deletion/duplication of >100kb and chromosomal aneuploidies were analyzed. CNVs were classified and Pathogenic (P) and Likely Pathogenic (LP) variants were reported. Positive findings included a monoallelic P/LP variant in an autosomal dominant or X-linked gene and biallelic P/LP variants in autosomal recessive genes and well-documented large chromosomal structural alterations. **Result:** Positive LCNV findings were identified in 26% (287/1103) of cases. A total of 42 positive results were identified across 18 chromosomes. Most frequently occurred positive results were: 17q12 microdeletion (12.7%, 140/1103, including *HNF1B*), 47, XXY (2.63%, 29/1103), 4q22.1 microdeletion (1.81%, 20/1103 including *ABCG2, DMP1, PKD2*), 45, X (1.09%) and 47,XXX (1.09%). Multiple diagnosis due to large CNV were identified in 3.35% (37/1103) of cases. Trisomy 12p, trisomy 13, trisomy 15 and trisomy 18 have been identified in 1, 3, 2, and 1 case respectively. Some of them were detected as mosaic trisomy and were reported as incidental findings. **Conclusion:** LCNV plays an important part in attributing to inherited kidney diseases. Detecting LCNVs in clinical exome-based broad kidney disease panel benefits the diagnosis, prognosis and management of CKD patients.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3286 Transcriptional landscape of *MLIP* in pediatric and adult myopathy patients.

Authors:

A. Gagné[1,2], S. Audet[1,2], J. Mezreani[1,2], L. Hamilton[1], V. Triassi[1], A. Rihoux[1,2], E. O'Ferrall[3], J. Karamchandani[4], S. Donkervoort[5], C. Bonnemann[5], M. Tetreault[1,2]; [1]CHUM Res. Ctr., Montreal, QC, Canada, [2]Dept. of NeuroSci.s, Univ. of Montreal, Montreal, QC, Canada, [3]Dept. of Neurology and Neurosurgery, Montreal Neurological Inst., Montreal, QC, Canada, [4]Dept. of Pathology, Montreal Neurological Inst., Montreal, QC, Canada, [5]Neuromuscular and Neurogenetic Disorders of Childhood Section, Neurogenetics Branch, Natl. Inst. of Neurological Disorders and Stroke, Natl. Inst.s of Heallth, Bethesda, MD

Progress in genomic research has been driven by technological innovation, such as high-throughput sequencing. Despite great progress, there is a significant number of patients without a molecular diagnosis. One reason for this diagnostic shortfall is the challenge associated with interpretation of clinically relevant variants. To address this, *in vivo* or *in vitro* validation is required. Recently, bi-allelic variants in the gene *MLIP* (Muscular LMNA-interacting protein) were identified. Little is known about the biological role of MLIP, except the fact it interacts with *LMNA* (Lamin AC) a known muscle disease gene. *MLIP* has a complex transcriptional architecture with at least 7 isoforms with a tissue-specific expression pattern. Thus, the interpretation of MLIP variant is even more difficult and requires functional validation. Using long-read sequencing we uncovered unannotated transcripts of MLIP as well as a compensatory alternative event in an adult patient affected with a distal myopathy. Since biallelic variants have been identified in both pediatric and adult patients, we believe that difference in transcriptional landscape could explain, at least partially, the variability in age-of-onset and disease severity. To answer this question, we performed long-read sequencing on pediatric patients and compared the different splicing events. A better characterization of MLIP isoforms in muscle will contribute to our understanding of disease variability and ultimately will increase our understanding of MLIP's function in muscle.

Papadakis[1], N. Niederlander[1], A. Messina[1,2], F. Santoni[1,2], J. Acierno[1], I. Habibi[1], N. Pitteloud[1,2]; [1]Service of Endocrinology, Diabetology and Metabolism, Lausanne Univ. Hosp., Lausanne, Switzerland, [2]Faculty of Biology and Med., Univ. of Lausanne, Lausanne, Switzerland, [3]Dept. Translational & Clinical Res. Inst., Univ. of Newcastle-upon-Tyne, Newcastle-upon-Tyne, United Kingdom, [4]Dept. of Endocrine and Metabolic Diseases and Lab of Endocrine and Metabolic Res., IRCCS Istituto Auxologico Italiano, Milan, Italy, [5]Dept. of Med. Biotechnology and Translational Med., Univ. of Milan, Milan, Switzerland, [6]Dept. of Pediatric Endocrinology and Diabetology, Univ. Children's Hosp. Basel, Univ. of Basel, Basel, Switzerland, [7]Dept. of Clinical Res., Univ. Hosp. Basel, Univ. of Basel, Basel, Switzerland, [8]"Iuliu Hatieganu" Univ. of Med. and Pharmacy Cluj-Napoca, Cluj-Napoca, Romania

Background: Congenital Hypogonadotropic Hypogonadism (CHH) and Kallmann Syndrome (KS), an anosmic subtype of CHH (MIM147950), constitute rare genetic disorders defined by delayed puberty, infertility and GnRH deficiency. Despite the identification of numerous disease-associated genes, the genetic etiology remains elusive in approximately 25% of cases. **Objectives**: The aim of this study was to investigate the genetics of CHH in a cohort of well-characterized trios (n=21) using whole-genome sequencing (WGS). **Methods**: The WGS data from all trios were processed through a Sentieon-empowered pipeline, which included sequence alignment, variant calling, and subsequent annotation by ANNOVAR. Prioritization of candidate variants was conducted using VariantMaster. **Results**: So far, we have identified 4 heterozygous *de novo* variants in known CHH genes: one in *FGF17* and three in *FGFR1*. In addition, we have identified two putative *de novo* mutations in *BICRA* and *BARHL1*, genes not previously know to be associated with CHH.In a patient with KS, we found a *de novo* variant in *BICRA*, a gene involved in chromatin remodeling complex-associated protein. *BICRA* mutations have been previously implicated in Coffin-Siris Syndrome. In addition, we identified a *de novo* variant in *BARHL1* in a CHH patient. *BARHL1* is a homeobox gene, that is known to promote neurogenesis, neural survival and neuronal migration in developing brain and is a candidate gene for Joubert Syndrome. To investigate the potential involvement of these novel genes, we performed variant analysis in a cohort comprising 483 CHH patients. Remarkably, we identified 2 CHH patients harboring rare heterozygous variants in *BARHL1* and 1 CHH patient harboring a heterozygous rare variant in *BICRA* . **Conclusion**: Trio analysis has been fruitful to identify *de novo* variants in CHH using WGS. To validate these two putative candidate genes, further studies including functional analysis is required.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3288 Trisomy of 4p and partial monosomy of 15q due to unbalanced translocation in an infant with multiple congenital anomalies - A case report.

Authors:

K. KARAKUS GULEN, N. Hara, X. Tang, C. Kumar; Westchester Med. Ctr., Valhalla, NY

Derivative chromosomes are often caused by unbalanced chromosome rearrangements that appear spontaneously or may be inherited from healthy parents carrying balanced reciprocal translocations. Trisomy 4p has been reported sporadically in the literature with variable phenotypes such as neurodevelopmental disorders, intellectual disability, poor growth, microcephaly, musculoskeletal anomalies and dysmorphic features. Deletion of 15q26 is a relatively rare chromosomal disorder, and it is described only in few cases. The severity of the 15q deletion phenotype depends on the size and location of the deletion that may include developmental delay, intellectual disability, dysmorphic features and skeletal abnormalities. Here we present a new case of a male infant born at 35 weeks gestation to a 25-year-old mother. The infant's birth weight was 1.67 kg (~3rd percentile) and birth length was 42.5 cm (~1st percentile) with multiple congenital anomalies, tracheomalacia VSD, PTO, bicuspid aorta and aortic coarctation, hypospadias, vertebral and digital anomalies. The chromosomal microarray and the cytogenetic investigations were indicated. Chromosome analysis was performed on GTG banded metaphases prepared from cultured lymphocytes that revealed a derivative chromosome 15 with an additional unidentified material at 15q region and the infant's karyotype as 46,XY,add(15)(q26.?1). The microarray analysis performed on whole blood showed a 48.8 megabase duplication from 4p16.3 to 4p11 and a 2.8 megabase terminal deletion of 15q26.3. The FISH studies using 4p and 15q subtelomere probes identified an unbalanced translocation between 4p and 15q regions. These findings confirmed that the additional material at 15q was from chromosome 4p representing the trisomy of the 4p region and the terminal deletion of 15q represented partial monosomy of 15q region. The duplicated interval from 4p16.3 to 4p11 involves 396 genes, 225 of that are protein-coding. The deleted interval at 15q26.3 involves 33 known genes, 20 of which are protein-coding. While none of these genes is individually known to have haploinsufficient phenotypes, this deletion may further modify the clinical phenotype of this case. Clinical correlation and genetic counseling were recommended. To the best of our knowledge, this unbalanced translocation between chromosome 4p and 15q is the first report of this combination of chromosomal abnormalities. Parental chromosome analyses were suggested to determine whether this abnormality is inherited or de novo in origin. In conclusion, this case demonstrates the effective use of cytogenetics, microarray and FISH studies for patient's diagnosis and care.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3289 Unveiling the Cellular Landscape of Monogenic Genes of Kidney Stones: A Secondary Analysis of Single-cell RNA-seq Data.

Authors:

E. Eam[1,2], **J-e. Lo**[1], J. Chang[1,2], K. Lovrenert[1,2], D. Bodner[2], M. Baum[3,4], F. R. Schumacher[1], F. Hildebrandt[3,4], A. J. Majmundar[3,4], C-H. W. Wu[1,2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Univ. Hosp., Cleveland, OH, [3]Boston Children's Hosp., Boston, MA, [4]Harvard Med. Sch., Boston, MA

Kidney stones (nephrolithiasis) is an increasingly prevalent condition causing worldwide morbidity with a multitude of complex factors. In particular to the genetic factors, our previous review identified 57 causal monogenic genes; however, the mechanism of kidney stones formation is not completely understood.
Here, we performed a secondary analysis of kidney stone genes using the single-cell RNA sequencing (scRNA-seq) data from Park et. al (2018). We expanded the number of genes applied to their whole kidney scRNA-seq data from adult mice. The data matrix was downloaded from the Gene Expression Omnibus (accession number GSE107585), and we subset the 57 monogenic genes of kidney stones. The 16 distinct cell types, including kidney-specific and non-kidney-specific cells, were identified in alignment with the original authors.
The matrix was normalized, zero-adjusted, and z-scored. Unsupervised clustering of gene expression was performed by their z-scores using k-means. NbClust was used for clustering and optimization. ComplexHeatmap visualized the resultant expression matrix by a heatmap.
The results showed there were 8 distinct groups of genes that were expressed in different cell types. For example, SLC3A1 and SLC7A9, causal genes of cystine stones, were found to be exclusively overexpressed in the proximal tubule among the other kidney cell types. CLDN16 and CLDN19 were exclusively overexpressed in the ascending loop of Henle, whereas XDH and MOCS1 were overexpressed in neutrophils, a non-kidney-specific cell type.
The resultant heat map revealed that monogenic kidney stone genes are not universally expressed in the kidney but in specific cell types. This implies the pathogenesis started in that specific cell type. There were some genes showing overexpression in non-kidney-specific cell types, indicating that the primary pathogenesis is not from the kidney.
Our results suggest that future genetic research on kidney stones should identify the specific cell type where the gene is overexpressed. Functional studies investigating the novel gene mechanism or the drug development should target the specific cell types that greatly express the desired gene. In addition, our results reveal a new classification system for monogenic genes of kidney stones.

PB3290 Unveiling the Significance of Copy Number Variations & Mitochondrial Mutations via a Single Next-Generation Sequencing Test

Authors:

P. Kamdar, T. Vaishnani, M. Haque, E. Jajodia, N. Arora, S. Chaudhary, J. Suthar; Unipath Speciality Lab. Ltd, Ahmedabad, India

Introduction Next-generation sequencing (NGS) has revolutionized our understanding of genetic variations, but detecting copy number variations (CNVs) and mitochondrial DNA mutations still remains a challenge and the incorporation of such variant detection may not be encompassed within a standard analytical framework. However, our study underscores the critical significance of incorporating the identification of copy number variation (CNV) and mitochondrial DNA mutations in standard next-generation sequencing (NGS) pipelines. **Methods** Samples referred to Unipath Speciality laboratory from March 2023 to May 2023 underwent exome sequencing using Sophia, enabling coverage of CNVs and mitochondrial DNA mutations. Library was prepared as per instruction manual of Sophia Exome Solution kit and sequencing was performed using Illumina NovaSeq 6000 platform. Variant calling, annotation and prioritization were carried out through machine learning approach used by Sophia DDM software. Relevant variants were reported based on ACMG 2015 guidelines. Maternal cell contamination was ruled out in case of prenatal samples. **Results** In our study, we found that 9 out of 230 patients exhibited either copy number variations or mitochondrial mutations. Our analysis unveiled pathogenic deletions encompassing a size range of 2.54 kilobases (affecting a single gene) to 15.4 megabases (involving over 100 genes). These deletions play a pivotal role in diagnosis of various disorders such as Duchenne muscular dystrophy, Methylmalonic aciduria, Turner syndrome, Krabbe's disease, osteosarcoma, DiGeorge syndrome, and Bartter syndrome. Furthermore, we identified a wide range of duplications, spanning from a few kilobases to entire chromosomes, such as Trisomy 18. Additionally, the identification of mutations in the mitochondrial DNA has proven instrumental in understanding and deciphering complex disease conditions like MELAS. **Conclusion** Our study highlights the significance of integrating CNV analysis and mitochondrial mutation assessment with SNV and small indel analysis to enhance the precision, effectiveness, and cost-efficiency of diagnostics. Unlike microarray, next-generation sequencing (NGS) has higher resolution to detect copy number variation lesser than 150 kb including a single exon.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3291 † Update to the CLIA diagnostic procedure using optical genome mapping for the diagnosis of facioscapulohumeral dystrophy.

Authors:

J. Jang[1], H. Sung[1], J. Lee[1], S. Jo[1], J-S. Lee[1], M. Kim[2], M-W. Seong[1]; [1]Dept. of Lab. Med., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of, [2]Dept. of Genomic Med., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Background: Facioscapulohumeral muscular dystrophy (FSHD) is a rare progressive muscular dystrophy. The expression of the causative gene, DUX4 relies on the contraction or hypomethylation of the D4Z4 repeat sequence on chromosome 4q35 and a permissive haplotype. Currently, type 1 FSHD can be partially diagnosed in Korea. Cases with complex mechanisms such as hybrid or mosaicism, or type 2 FSHD is undiagnosable due to limitations in methods. Optical genome mapping (OGM) is an approach to detecting structural variations (SV) in whole genomes. As the base-specific fluorescent-labelled DNA flows through the nanochannel, the fluorescence pattern is captured by the camera. The imaged DNA is compared to a standard genome and SVs are detected by the different patterns. It can also be applied to detect contractions in repetitive sequences such as FSHD. The performance of OGM in simple FSHD caused by repetitive contractions is known, but not in FSHD involving complex mechanisms. We evaluate the diagnostic value of OGM in complex FSHD and propose an integrated diagnostic strategy.
Methods: We reviewed the test results of 218 patients with suspected FSHD at Seoul National University Hospital from 2017 to 2021, including 30 patients with complex FSHD. Complex FSHD includes hybrid, mosaic, 4 on 10, and type 2 FSHD that is not diagnosed by D4Z4 repeat contractions. OGM was performed in 26 patients, and the results were compared with SB using linear regression and the Blend-Altman method.
Results: A total of 226 alleles were identified for the 26 patients. The 10 hybrid cases showed the greatest discrepancy in the number of D4Z4 repeats between the two methods. Linear regression analysis showed that mosaics had an adjusted R^2 and p-value of 0.89 and < 0.01 respectively, whereas hybrids had -0.10 and 0.81, indicating a significant difference for hybrids. In the Blend-Altman analysis, the bias (confidence interval) was -0.096 (-1.632 to 1.441) for mosaics and 1.041 (-8.337 to 10.419) for hybrids, indicating a similar mean but a more variable distribution for hybrids.
Conclusions: We evaluated the diagnostic value of OGM for complex FSHD, which involves structural complexity beyond simple repeat contractions. Neither SB nor OGM alone could diagnose hybrid FSHD, and the combination of both was required. Here, we propose a modified Clinical Laboratory Improvement Amendments (CLIA) procedure in which OGM is performed first for suspected FSHD, followed by SB based on additional criteria, as a rapid and reliable method of diagnosing FSHD. However, both are repeat count methods, further studies using sequencing and epigenetic analysis are needed to better understand the pathogenesis of FSHD.

PB3292 Vector copy number detection for CAR-T Therapy using a Droplet Digital PCR system.

Authors:

Y. Ding[1], Y. Wang[1], F. Tu[1], Z. He[2], H-J. He[2], Z. Zhu[1], S. Smirnov[1], A. Jadali[1], J-E. Lee[1], E. Stevenson[1], M. Sheldon[1], S. Nahas[1], R. Grimwood[1]; [1]Sampled, Piscataway, NJ, [2]Natl. Inst. of Standards and Technology, Gaithersburg, MD

Chimeric Antigen Receptor (CAR) T cell therapy has evolved and proven to be an effective regimen for individuals diagnosed with certain types of hematologic malignancies and solid tumors. Managing CAR-T cell therapy doses, monitoring safety and potency of CAR-T cell drug products and vector transduction rate is a challenge clinicians and CAR-T cell manufacturing facilities face. Vector Copy Number (VCN) detection by Droplet Digital PCR has been reported to be a valuable tool in assessing VCN and quality control of CAR-T cell products. Here, we report a method feasibility design and results using ddPCR system to detect VCN at Sampled. To do this, five DNA samples with well characterized lentiviral vector copy numbers extracted from transduced clonal Jurkat cell lines (provided by the NIST) were blinded at Sampled and run using the Bio-Rad QX200 ddPCR system, utilizing the Bio-Rad ddPCR Supermix (no dTUP) with assay on the target coupling with RPP30 (a house keeping gene) reference assay. Input DNA ranging from 0.005 ng to 20 ng per reaction were attempted with triplicates within same runs and repeated multiple times on the different days to estimate lowest possible input that could detect a target. Linearity between DNA input vs vector copy concentration was plotted. Only data with R^2 (coefficient of determination)>0.99 was accepted and used to estimate lowest input for target detection. Our results demonstrated that four samples detected VCN with expected concentrations (100% accuracy), and one showed no target detected, as expected. Limit of blank (LOB) was identified as 0 with 95% confidence. The lowest input for target detection was estimated as 4.54 copies per reaction at 95% confidence level. Our results demonstrated that a target was detected when input DNA was equal and higher than 0.005 ng per reaction. On average, with 10 ng input per reaction, CV% (Coefficient of variation) of intra-runs (repeatability) and inter-runs (reproducibility) of VCN concentration were 1.39% and 1.65% across samples respectively. In conclusion, VCN detection by the ddPCR system demonstrates high accuracy, precision and detection resolution applying low DNA input with less than 1ng per reaction. This workflow is suitable for a clinical laboratory to develop a LDT (Laboratory Developed Test) and to provide services for monitoring CAR-T production and clinical applications for individuals with CAR-T therapy.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3293 WES CNV Filtering and Curation in Epilepsy and Obesity for Medically Reportable Secondary Findings per ACMG Guidelines

Authors:

S. Torkamandi, J. Glessner, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA

Copy number variants (CNVs) are important contributors to the genetic causes of epilepsy and obesity disorders. Whole-exome sequencing (WES) is a valuable tool for identifying CNVs associated with these conditions. This study aimed to enhance CNV calling accuracy in WES data using the XHMM protocol, while adhering to ACMG guidelines for medically reportable findings. To improve computational efficiency, we replaced the read depth calculation step with the mosdepth tool, yielding comparable results to the computationally intensive GATK. Normalization of read depth using PCA was crucial in reducing potential biases caused by the exome capture kit. XHMM CNV calling was performed on WES data from epilepsy (n=3,333) and obesity (n=9,533) patients. CNV calls were intersected with a curated list of 140 genes, including 65 CNV-specific genes. Out of 6,049 overlapping CNVs, 333 exhibited a 50% reciprocal overlap. Additionally, 18 CNVs intersected with reported CNV-specific gene locations. CNV counts per gene of interest and unique CNV numbers were generated for further analysis. Obesity CNVs and a syndromic list were processed across four cohorts. Filtering strategies were applied to 348,801 CNVs overlapping genes with a 50% query gene overlap, revealing distribution patterns based on length, genotype quality (GQ), and gene overlap frequency. A filtering strategy was proposed, restricting CNVs to deletions (DEL) or duplications (DUP) with length <10 Mb, GQ >500, and FILTER=PASS annotation. Applying these filters yielded 14,580 CNVs. Further applying a 50% reciprocal overlap criterion with entire gene boundaries and GQ >500 reduced the CNV count to 16. ClassifyCNV algorithm, following ACMG standards, categorized DEL or DUP rows. In conclusion, this study improved the accuracy and reliability of CNV calling in WES data using the XHMM protocol, following ACMG guidelines. The analysis identified CNVs associated with epilepsy and obesity disorders, highlighting specific genes of interest. The proposed filtering strategy allowed for refined CNV selection. This research provides valuable insights into the genetic etiology of these disorders and contributes to the understanding of CNVs in clinical applications.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3294 WGS improves detection of Duchenne and Becker Muscular Dystrophy: Case studies

Authors:

S. Gessay[1], **E. Bend**[1], A. Gruber[1], S. Bianconi[2], A. Cooper[2], R. Peretz[3]; [1]PreventionGenetics LLC, Marshfield, WI, [2]Kaiser Permanente, San Diego, CA, [3]Harbor-UCLA Med. Ctr., Los Angeles, CA

Duchenne and Becker Muscular Dystrophy (DMD and BMD, respectively) are among the most common inherited neuromuscular conditions in children. The allelic disorders are caused by variants in *DMD*, located on Xp21.2, but efficient detection of variants has been difficult given the high percentage of causative intronic and copy number variants (CNVs). Traditional cytogenetic techniques, including karyotype and chromosomal microarray (CMA), lack sufficient resolution to identify sequence variants; and sequencing approaches, including Sanger and exome-based next-generation sequencing (NGS), offer limited detection of sequence variants and CNVs outside the exome. Whole genome sequencing (WGS), in contrast, covers both intronic and intergenic regions and is able to detect CNVs all with one test. We present three cases where relevant findings were discovered by WGS that escaped detection by another platform. 1) A 7-year-old male's clinical history was notable for Gower sign and progressive muscle weakness. Previous NGS panel analysis was inconclusive, leading the care team to pursue single gene testing on a WGS platform. The intronic variant c.5739+362A>G was detected and classified as likely pathogenic given descriptions from published case studies and its absence in population databases. 2) A 5-year-old male presented to clinic given his combined history of Gower sign, bilateral mid-calf hypertrophy, elevated CK levels, and positive muscle biopsy results. Genetic testing, including MLPA and unspecified sequencing analysis, were uninformative. Panel analysis performed on a WGS platform identified a complex rearrangement resulting in a duplication at 2q21.1q22.1 near the splice acceptor site of intron 23 in *DMD*. The location of the event led to a likely pathogenic classification given reports of large insertions altering splicing and disrupting gene expression. 3) A preadolescent biological male was evaluated for a years-long history of muscle pain and weakness. The patient's CK levels were significantly elevated, but results from sequencing analysis with del/dup were non-diagnostic. WGS run on his sample identified a hemizygous ~35.9 kb duplication in tandem encompassing exons 10 and 11 within *DMD*. Similar published case reports contributed to its pathogenic classification. These cases demonstrate that WGS can offer genetic confirmation in previously negative cases, which has the potential to provide patients with access to targeted therapeutics and inform recurrence risk for reproductive decisions.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session II

PB3295 Whole exome sequencing for prolonged neonatal/infantile intrahepatic cholestasis discovered a definitive molecular genetic diagnosis.

Authors:

S. Ito[1], T. Togawa[1], T. Tanimura[1], K. Imagawa[2], H. Hayashi[3], K. Ito[1], T. Endo[1], T. Sugiura[1], S. Saitoh[1]; [1]Nagoya City Univ., Nagoya, Japan, [2]Univ. of Tsukuba, Tsukuba, Japan, [3]The Univ. of Tokyo, Tokyo, Japan

Genetic liver diseases, such as cystic fibrosis, alpha-1 antitrypsin deficiency, and progressive familial intrahepatic cholestasis (PFIC), can cause intrahepatic cholestasis, leading to fibrosis and cirrhosis. The majority of these conditions manifest as direct hyperbilirubinemia, commencing in the neonatal or infantile period, commonly referred to as neonatal/infantile intrahepatic cholestasis (NIIC). Despite advancements in liver transplantation and the advent of emerging pharmaceutical agents, clinicians encounter challenges in establishing a precise diagnosis due to overlapping and extensive clinical manifestations. In a previous publication, we documented a conclusive molecular diagnosis in 27% of the patients enrolled in our targeted 61-gene panel study, utilizing the Ion Personal Genome Machine system (Thermo Fisher Scientific) in conjunction with bioinformatics pipelines. Nevertheless, approximately 70% of the patients remained with no definitive genetic diagnosis. Consequently, we have resolved to perform whole exome sequencing (WES) to enhance the diagnostic yield for cholestatic patients. Of the NIIC patients who were examined with the 61-gene panel between May 2013 and March 2023 and had prolonged cholestasis with no definitive genetic diagnosis, 18 probands, and their parents were included in the study. We performed WES with trio analysis and bioinformatic pipelines on the Illumina platform. Five of 18 (27.8%) probands received a definitive molecular genetic diagnosis; they carried causative variants in *ABCB11* (PFIC type2), *SLC25A13* (neonatal intrahepatic cholestasis due to citrin deficiency), *SLCO1B1* and *SLCO1B3* (Rotor syndrome), *MYO5B* (PFIC type 10), or *MTM1* (severe X-linked myotubular myopathy) in each. Out of the 6 identified genes, *ABCB11, SLC25A13, SLCO1B1*, and *SLCO1B3* were included within our 61-gene panel. We had already found one pathogenic variant on a single allele of *ABCB11* and *SLC25A13* in an autosomal recessive manner. Because WES discovered a wider range of the targeted region than that of our previous targeted 61-gene sequencing, we additionally detected one more causative pathogenic variant on the other allele of the 2 genes. Regarding *SLCO1B1* and *SLCO1B3* in a digenic recessive manner, we newly detected 4 pathogenic variants due to the same reason. Consequently, WES possessed the capability to uncover variants not only in genes that were previously unexamined but also in genes that were previously confirmed through panel analysis.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session III

PB3296 Whole exome/genome sequencing with rapid automated judgment algorithm for diagnosis of difficult-to-diagnose hereditary hearing impairment patients

Authors:

C-Y. Tsai[1,2], Y-S. Lu[2], Y-T. CHIANG[1,2], C-J. Hsu[3,2], J. Hsu[1], C-C. Wu[2], P-L. Chen[1,4,5]; [1]Graduate Inst. of Med. Genomics and Proteomics, Natl. Taiwan Univ. Coll. of Med., Taipei, Taiwan, [2]Dept. of Otolaryngology, Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [3]Dept. of Otolaryngology, Taichung Tzu Chi Hosp., Taichung, Taiwan, [4]Dept. of Med. Genetics, Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [5]Inst. of Molecular Med., Natl. Taiwan Univ. Coll. of Med., Taipei, Taiwan

Background: Hereditary hearing impairment (HHI) is a common inherited disorder characterized by genetic heterogeneity. However, the genetic etiologies of many unconfirmed HHI families remain elusive. Next-generation sequencing (NGS), specifically whole genome/exome region sequencing (WGS/WES), provides a powerful solution to explore broader genomic regions for hidden pathogenic variants. To effectively apply NGS in the clinical genetics of HHI, it is crucial to develop and package an expanded collection of HHI-related genetic information and an efficient method to identify causative variants from the vast amount of WGS/WES data.Method:
We employed WGS/WES assays based on the capture-based NGS approach using the Illumina platform. In addition, we developed a "virtual panel" consisting of 728 deafness genes, which integrates our NTUH targeted NGS panel (216 genes) and four other academic databases (Hereditary Hearing Loss, Deafness Variation database, clinical genomic database and PanelApp). Furthermore, we designed a Python-driven algorithm that rapidly and automatically evaluates NGS data based on multiple metrics, including the reported inheritance model of targeted genes, the genotype of each variant, and the cosegregation analysis of multiple samples. This algorithm generated all possible causative genotypes and identified the genetic etiologies based on the ACMG guideline.**Result:**We recruited a total of 46 multiplex families for the WGS/WES assays. The automated judgment process, which output all candidate genotypes from the annotated variant file of each family, took less than one minute. We identified a total of 31 pathogenic variants in 22 families (diagnostic rate = 47.8%), including 15 novel variants accounting for 41.9% of all confirmed variants. Among the 31 variants, 15 (48.4%) were categorized as null variants. Additionally, two intronic variants (*GSDME*: c.1883+5G>A and *MITF*: c.1013+5G>A), which exhibited high predicted scores for abnormal splicing, were considered potentially deleterious based on cosegregation analysis in the affected members within multiplex families.**Conclusion:**Compared to conventional panel-based NGS assays, WGS/WES assays coupled with the virtual panel of 728 HHI-related genes demonstrated a high diagnostic rate for causative variants in challenging multiplex HHI families. Furthermore, the development of a rapid algorithm for automated judgment of causative HHI variants is feasible for further clinical applications, alleviating the time-consuming and laborious manual pathogenicity assessment pipeline.

Session Title: Molecular and Cytogenetic Diagnostics Poster Session I

PB3297 Whole Genome Sequencing in Adults with Chronic Kidney Disease or End-Stage Kidney Disease in the Million Veteran Program

Authors:

J. Triozzi, H-C. Chen, R. Tao, A. Hung; Vanderbilt Univ. Med. Ctr., Nashville, TN

Background: As the utilization of diagnostic genetic testing in nephrology increases, genetic causes of kidney disease are identified at significant rates in the adult population. A molecular diagnosis has numerous advantages for patient care, including facilitating treatment decision-making, enabling familial testing, providing information for safe kidney allograft donation, as well as uncovering insights into the pathogenesis of kidney diseases. In this study, we report whole-genome sequencing results among patients with chronic kidney disease or end-stage kidney disease.

Methods:

We selected genes associated with Mendelian kidney and genitourinary disorders compiled in a previous study by Rasouly et al (PMID: 30476936). We performed a secondary analysis of whole genome sequencing data of patients with chronic kidney disease (CKD) or end-stage kidney disease (ESKD) available from the Department of Veteran Affairs Million Veteran Program (MVP) pilot study. CKD was defined as eGFR < 60 mL/min/1.73 m2 on two occasions 90 days apart. ESKD was defined by diagnosis or procedure codes for chronic dialysis, kidney transplant or eGFR < 15 mL/min on two occasions 90 days apart. The prevalence of genetic variants for CKD or ESKD was tabulated by category.

Results:

A total of 4236 patients met criteria for CKD (n = 3411, 81%) and ESKD (n = 825, 19%) with a mean age of 68 (SD 9.56) years. There were 37% African, 57% European, 3% Hispanic, and <1% Asian ancestry individuals. There was a high prevalence of diabetes (63%) and hypertension (99%). There were urinary markers of kidney disease including hematuria (n=542, %), proteinuria >1+ (N=1,013, %), and proteinuria >=2+ (N=602, %). A total of 431 genetic variants related to kidney disease were identified. These genetic variants were related to cystic and tubulointerstitial kidney disease (24%, PKD1, PKD2, PKHD1), complement-related diseases (17%, CFH, C3, CFI, ADAMTS13), tubular disorders (6%, HBB), and glomerular diseases (4%, COL4A3, COL4A4, CUBN). Notably, we identified multiple rare genetic causes of nephrolithiasis, such as cystinuria, primary hyperoxaluria, and hypophosphatemic rickets.

Conclusion:

Genetic variants for actionable disorders were identified in this cohort of patients with CKD or ESKD in the MVP. In contrast to previous reports, our findings identified rare nephrolithiasis variants among patients decreased kidney function, highlighting their clinical significance and potential impact on outcomes. More detailed phenotyping of our cohort is underway to better understand the clinical implications of these variants.

Session Title: Omics Technologies Poster Session I

PB3298 A clinical and molecular approach for the classification of *KANSL1* variants as a strategy to solve pitfalls of genome-wide investigations.

Authors:

G. Marangi[1], F. F. L'Erario[1], S. Maietta[1], S. Frangella[1], D. Pasquetti[1], A. G. Renzi[1], M. Carapelle[1], A. Panfili[1], A. Gazzellone[1], D. Orteschi[2], S. Bigoni[3], G. Zampino[2], M. Zollino[2]; [1]Università Cattolica Del Sacro Cuore, Rome, Italy, [2]Università Cattolica del Sacro Cuore, Rome, Italy, [3]Azienda Ospedaliero-Univ.ria di Ferrara, Ferrara, Italy

The development of high-throughput sequencing (HTS) methods has led to an extensive implementation of a genome-wide approach in routine genetic investigations. As a result, this has had a massive impact on the diagnostic yield, also enabling the rapid identification of new Mendelian disease genes. The dramatic increase in the number of variants that need to be interpreted constitutes the main drawback of the use of HTS as first-tier genetic test in diagnostic settings. Koolen-de Vries syndrome (KdVS) can be considered a paradigmatic example of the effect of the use of genome-wide approach in medical genetics. The recurrent 17q21.31 deletion has been firstly identified by means of array-CGH, while exome HTS in non-deleted patients allowed for the definition of *KANSL1* as the causative gene. Thereafter, potential loss-of-function variants in *KANSL1* detected in patients with syndromic intellectual disability have been routinely classified as pathogenic. However, common duplication polymorphisms involving the first two exons of the NM_015443.4 “MANE Select” transcript of *KANSL1* are found in about the 40 % of alleles in European populations. Hence, it is crucial to consider these polymorphisms in the evaluation of genetic variants. We propose a gene-specific strategy for *KANSL1* variant interpretation based on the architecture of the 17q21.31 region, the evaluation of consequences at mRNA level and a precise clinical characterization of patient phenotype.We report five genomic abnormalities of *KANSL1*: one case of exons 1-2 deletion detected by array-CGH, and four cases of variants affecting exon 2 (c.540delA and c.985_986delTT, in three cases) identified by exome sequencing. Our clinical and molecular evaluation included: 1) deep clinical evaluation of patients; 2) parental analysis; 3) MLPA of *KANSL1*, specifically devised to distinguish the benign duplication polymorphism form other CNVs; 4) cDNA sequencing of *KANSL1*. While we could classify as pathogenic the c.540delA variant found in a patient with a phenotype fully consistent for KdVS, we categorized both the exon 1-2 deletion and all the three c.985_986delTT variants as benign, since they affected the duplicated, non-functional copy of exons 1-2. Nonetheless, this classification cannot always be assumed as true, since the validation strategy we propose should be applied for any single patient carrying a potentially pathogenic variant in the first two exons of *KANSL1*. This report highlights the pivotal role of clinical genetics in precise diagnosis of syndromic neurodevelopmental disorders.

Sch., Univ. of Texas Hlth.at Houston, Houston, TX, [9]Dept. of Pediatrics, Stanford Univ., Stanford, CA, [10]Dept. of Orthodontics & The Iowa Inst. for Oral Hlth.Res., Univ. of Iowa, Iowa City, IA, [11]Dept. of Pediatrics, Univ. of Iowa, Iowa City, IA, [12]Dept. of Oral and Craniofacial Sci., Univ. of Pittsburgh, Pittsburgh, PA

Short tandem repeats (STRs) are a class of structural variation characterized by the expansion or contraction of repeat motifs of 1-6 bp. STRs have been associated with a number of diseases and recent bioinformatic advances have facilitated accurate genotyping of known disease STRs in short-read whole genome sequencing data (srWGS). Despite these advances, there has been little success in discovering pathogenic STR loci outside these predefined lists due to technical challenges in novel STR detection from srWGS. Taking advantage of the current genotyping strength of STRs in srWGS, we developed a novel genome-wide STR discovery approach using a cloud-based pipeline for the Expansion Hunter (EH) tool. We applied the pipeline to genome wide STRs derived from application of TandemRepeatFinder on GRCh38 obtaining all STRs with 3 or more repeats that spanned ≥ 9bp in the reference (n = 3,281,006). We reduce genotyping cost by focusing on plausible functional regions by overlapping at least one of the following annotations: genic, TAD boundaries, non-coding constrained regions, VISTA enhancers, ultraconserved elements, HACER enhancers, human accelerated regions or constrained STR loci (Gymrek et al. 2017) leaving a total of 2.1M sites. We benchmarked this pipeline against 3 samples from the 1000 Genomes Project with matched srWGS and long-read sequencing data (Pacbio HiFi, STR calling with TRGT) and found an average of concordance of 86.9%.

We applied our STR pipeline to a cohort of 437 case-parent trios with probands affected with isolated cleft palate (CP), performing the first assessment of the effect of genome-wide STR variation on CP risk. Taking advantage of our trio structure, we primarily focused on the influence of *de novo* variants and found an average of 236 *de novo* variants per proband across 62,420 total sites. Upon checking for enrichment of *de novo* STR alleles in CP cases across the functional relevant annotations described above, we observed two significant categories (HACER enhancers - p = 9.7e-05; constrained STR loci - p=1.1e-61). Among the constrained STR, we observed an interesting locus with a single TTTG expansion in an intronic repeat of *PIEZO2* (chr18:11010608). This gene is associated with Marden-Walker Syndrome, which often features a cleft or high-arched palate. Interestingly, we found an additional intronic STR upstream in *PIEZO2* (chr18:10759203) that had a *de novo* expansion in 3 CP cases, providing further evidence that STR variation may influence this gene. Further functional studies are necessary to confirm these findings, but these results demonstrate the promise of investigating STRs in CP and potentially other birth defects.

Session Title: Omics Technologies Poster Session III

PB3300 A comprehensive single-cell RNA sequencing analysis evaluating the role of T-lymphocytes in idiopathic and genetic Parkinson's disease.

Authors:

M. Rosen[1], O. Narcis[1], A. Allan[1], T. Khashan[1], E. Mejia[1], C. Argyru[1], S. Frucht[2], R. Saunders-Pullman[3,1], G. Riboldi[2], T. Raj[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]New York Univ. Langone Hlth., New York, NY, [3]Mount Sinai Beth Israel, New York, NY

Parkinson's disease (PD) is a devastating neurodegenerative disease characterized by a loss of dopaminergic neurons in the substantia nigra, movement abnormalities, and in some cases the accumulation of α-synuclein (α-syn) as fibrils or Lewy bodies. It is well established that T-cells are involved in PD pathology, shaping the inflammatory cascade from the periphery into the brain. Moreover, genetic studies have linked the human leukocyte antigen (HLA) class II and the risk of developing PD, which suggests that CD4 T-cells may have a crucial role in their interaction with antigen-presenting cells. We explore the role of T-cells in PD by rigorously characterizing their transcriptional profile and T-cell receptor (TCR) repertoire during disease progression.Our aims are to (i) characterize immune cell expression and repertoire in PD patients, prodromal patients (subjects with elevated risk of developing PD, including GBA/LRRK2 genetic carriers and patients with rapid eye movement (REM) sleep behavior disorder) and control donors; (ii) assess the clinical relevance and antigen specificity of clonal T-cells; and (iii) explore the functional impact of human leukocyte antigen (HLA) risk and protective alleles on T-cell biology and PD pathogenesis. We are performing a large-scale, comprehensive single-cell RNA-seq analysis on a well-characterized cohort (n=150) to control for biological heterogeneity. We are planning to obtain gene expression, V(D)J immune receptor gene expression and genetic information for each donor. We perform standard single-cell data processing using an in-house pipeline utilizing the Seurat package. We perform differential expression analysis using both single-cell and pseudobulk methods. Our preliminary results (n=24) demonstrate differences in CD4 and CD8 T-cell proportions between PD patients and control donors (p=0.05 and p=0.1, respectively). Furthermore, we have observed distinct V(D)J gene expression patterns indicating clonal expansion in CD8 activated T-cells in PD. These novel insights shed light on the involvement of T-cells and their potential impact on PD development and progression.We are currently increasing our sample size to reach our target cohort. Further, we are processing genotype data so that we can impute HLA class II alleles. We will investigate the association between HLA alleles and TCR gene usage and the hypervariable complementarity determining region 3. Overall, the results of these experiments will further our understanding of the role of T-cells in PD, lead to mechanistic discovery and determine the potential for targeted immune-based therapeutic interventions or biomarker capabilities.

Session Title: Omics Technologies Poster Session I

PB3301 A consensus algorithm for genetic demultiplexing of scRNA-seq from pooled iPSC cultures of multiple subjects for cohort-scale analysis

Authors:

M. Fiorini, R. Thomas, S. Farhan, S. Amiri; McGill Univ., Montreal, QC, Canada

Induced pluripotent stem cells (iPSCs) and single-cell RNA sequencing (scRNA-seq) can be used to model the transcriptome of unique cell types in neurodegenerative disease *in vitro*. However, iPSC-based scRNA-seq remains costly and low throughput, restricting the feasibility of cohort-scale study designs, which is required for therapeutic exploration. Multiplexing iPSC lines bypasses the costly parallel growth of individual iPSC lines by pooling batches of lines in a single dish. Demultiplexing algorithms can then resolve the sample identity of each cell based on genetic differences. However, the accuracy of available demultiplexing software for cohort-scale study designs remains questionable, as benchmarking has been predominantly based on small sample sizes. To facilitate cohort-scale iPSC-based scRNA-seq, we are developing a consensus demultiplexing software that assigns sample identities to individual cells based on the predictions of four currently available demultiplexing algorithms. We are testing our consensus algorithm on multiple synthetically pooled iPSC-derived dopaminergic neuron scRNA-seq transcriptomes from control and Parkinson's disease (PD) patients generated by the FOUNDIN-PD project. In silico pools ranging from 4 to 80 iPSC lines will be produced and tested in our pipeline to ensure our algorithm remains accurate for cohort-scale cell batches. Preliminary results have shown that our consensus algorithm outperforms all four other demultiplexing algorithms for cell pools comprising three different iPSC lines, and we expect this improvement to increase for larger pools as individual algorithms struggle to maintain accuracy. Eventually, as proof of principle, we will harness our consensus demultiplexing algorithm to test the hypothesis that multiplexed iPSC lines and scRNA-seq can be used to screen for transcriptional responses to chemical compounds in dopaminergic neurons in PD patients. Our novel demultiplexing algorithm will facilitate the application of cohort-scale iPSC-based scRNA-seq across neurodegenerative diseases, allowing for cell-type specific transcriptional responses to chemical compounds to be explored and elucidate novel therapeutics.

PB3302 A deep learning model for predicting probeset performance of genotyping microarrays

Authors:

F. Lin[1], A. Mittal[1], J. Gollub[2]; [1]Thermo Fisher, SANTA CLARA, CA, [2]Thermo Fisher Scientific, Santa Clara, CA

Genotyping microarrays are a high-throughput tool for measuring genetic variation across the genome. Accurate prediction of probeset performance is crucial for optimizing the array design strategy and maximizing accuracy and call rates. Probeset performance is impacted by various factors including hybridization specificity, secondary structure propensity, sequence similarity or identity to off-target loci, and sequence complexity. Deep learning algorithms have proven effective in identifying complex local patterns within the sequences. In this work, we built a deep learning model to predict probeset performance using probe sequence to capture the sequence composition and local sequence patterns and additional features, such as sequence similarity and the number of copies of the probeset on the array that can impact the robustness of signal intensities. The model is comprised of a bi-directional recurrent neural network fused with a deep neural network to incorporate sequence and numerical features. The model was trained using the performance information of over 3 million probesets. A binary probeset performance label was assigned based on the frequency with which the probeset passed the stringent Axiom genotyping QC metrics. The performance data was split into training, validation and testing set in an 8:1:1 ratio. The training and validation performance are similar, around an AUC-ROC of 0.75. The testing performance slightly decreased, with an AUC-ROC of 0.74. We also evaluated the contribution of each feature to the predictions and found both probe sequence and the two numeric features impacted the performance prediction, with sequence homology exhibiting the highest contribution to performance prediction.

Session Title: Omics Technologies Poster Session III

PB3303 A graph clustering algorithm for detection and genotyping of structural variants from long reads.

Authors:

J. Duitama, N. Gaitán; Univ. de los Andes, Bogotá, Colombia

Structural variants (SV) are genomic polymorphisms defined by their length (more than 50 bp). The usual types of SVs are deletions, insertions, translocations, inversions, and copy number variants. SV detection and genotyping is fundamental given the role of SVs in phenomena such as phenotypic variation and evolutionary events. Thus, methods to identify SVs using long-read sequencing data have been recently developed. We present an accurate and efficient algorithm to predict SVs from long-read sequencing data. The algorithm starts collecting evidence (Signatures) of SVs from read alignments. Then, signatures are clustered based on a Euclidean graph with coordinates calculated from lengths and genomic positions. Clustering is performed by the DBSCAN algorithm, which provides the advantage of delimiting clusters with high resolution. Clusters are transformed into SVs and a Bayesian model allows to precisely genotype SVs based on their supporting evidence. This algorithm is integrated into the single sample variants detector of the Next Generation Sequencing Experience Platform (NGSEP), which facilitates the integration with other functionalities for genomics analysis. Benchmark experiments show that our approach outperformed state-of-the-art tools on SV calling and genotyping, especially at 20x depth, on a simulated dataset with an F-score of 99.1%, and on the HG002 GIAB PacBio HiFi sample with an F-score of 94.5% and 96% GT-Accuracy. These experiments show that our algorithm reliably detects and genotypes most SV events. We believe this work significantly contributes to the development of bioinformatic strategies to maximize the use of long-read sequencing technologies.

Session Title: Omics Technologies Poster Session I

PB3304 A haplotype-aware framework for detecting differentially methylated regions using Oxford Nanopore sequencing.

Authors:

M. Ahsan, K. Wang; Children's Hosp. of Philadelphia, Philadelphia, PA

DNA methylation is an important biological marker that affects a range of physiological processes, such as aging and carcinogenesis, and cellular processes, such as differentiation and pluripotency. Analysis of differentially methylated regions can provide crucial insights into how certain genomic regions or biological pathways are affected by different biological or medical conditions. For instance, detection of differentially methylated regions between cancer-normal paired samples can lead to more accurate cancer subtyping and identification of therapeutic targets. Similarly, identification of differentially methylated regions between haplotypes of the same sample can lead to identification of novel imprinted regions, which can provide a better understanding of imprinted disorders. In recent years, Oxford Nanopore Technologies (ONT) sequencing has emerged as a reliable and direct technology in DNA methylation detection through the analysis of ionic current signal. However, recent studies aimed at differential methylation analysis from ONT sequencing use methods and tools designed for short-read bisulfite sequencing, such as DSS or Methylkit. To enable the use of short-read methods, these studies reduce all methylation probabilities from a single molecule into statistically independent counts of cytosines and thymidines. As a result, such analyses ignore the rich long-range information provided by Nanopore reads that cover multiple CpG sites whose methylation levels are linked together. This can reduce the statistical power and sensitivity of such analyses. Here we present a haplotype-aware framework for detecting differentially methylated regions using ONT sequencing. Our method exploits the dependence between methylation levels of CpG sites on the same reads to more accurately detect regional differences between samples. We evaluated our framework on paired-tissue samples and HG002 genome from Oxford Nanopore open datasets and found that incorporating haplotype information improves differential methylation detection.

Session Title: Omics Technologies Poster Session II

PB3305 † A high-throughput, automated ATAC-seq reveals quantitative regulatory effects of transcription factor dosage.

Authors:

B. B. Liu[1], S. Vermeulen[1], S. H. Kim[1], T. Clark[2], N. Iremadze[2], D. Lipson[2], Z. Shipony[2], W. J. Greenleaf[1]; [1]Stanford Univ., Stanford, CA, [2]Ultima Genomics, Newark, CA

Transcription factors (TFs) regulate gene expression by binding to accessible DNA regulatory regions. However, a quantitative understanding of the effects of TF dosage on the chromatin accessibility and gene expression landscape for most TFs remain unclear. A systematic investigation of the effects of varying TF levels on accessibility and gene expression is challenging to carry out across a large panel of TFs as current accessibility assays are time, labor, and cost-intensive and often lack reproducibility when manually repeated across small batches. To address this challenge, we developed roboATAC, an automated, scalable plate-based ATAC-seq platform that replaces rate-limiting centrifugation steps with bead-based solutions and validated roboATAC against the gold-standard omniATAC method. Using roboATAC and RNAseq, we assayed genome-wide chromatin accessibility and gene expression changes induced by variable overexpression of individual and pairs of five TFs (GATA1, GATA2, TAL1, KLF1, SPI1) in HEK293T cells across a total of 88 samples. We sequenced both ATAC and RNA libraries with Ultima Genomics. Our analysis showed significant enrichment of TF motifs associated with overexpressed TFs within accessible regions. We also see dosage-dependent effects on accessibility that are TF specific, with increasing TF footprint depths and increasing accessibility flanking TF binding motifs as a function of increasing TF expression. In addition, we identified thousands of differential genes with increased expression in each condition, enriching for pathways relevant to the TF function (e.g. SPI1 induced expression of genes involved in T cell activation and lymphocyte differentiation absent in wild type HEK293T cells) and exhibiting dosage-dependent effects consistent with those observed in the open chromatin. Furthermore, our data revealed diverse dynamics in TF dosage response, with the majority of motif-containing peaks exhibiting limited sensitivity to TF dosage, while a small percentage (e.g. 8% in SPI1 samples) showed linear or hill dynamics. We also observed that peaks with higher TF binding affinity reached accessibility and linked gene expression saturation at earlier dosages, highlighting the role of TF-DNA interactions in governing transcriptional outcomes. Overall, this dataset is a valuable resource for generating mechanistic hypotheses on how transcription factor level regulates gene expression, as well as developing strategies to utilize those mechanisms for reversing disease states.

Session Title: Omics Technologies Poster Session III

PB3306 A joint model of cell-type-specific RNA and protein expressions in the human brain.

Authors:

D. Bai[1], P. Emani[2], M. Gerstein[3]; [1]Yale Univ., New haven, CT, [2]Yale Univ., New Haven, CT, [3]Yale Univ, New Haven, CT

Recent advances in single-cell technologies have provided unprecedented insights into our understanding of transcriptional diversity at the single-cell level. However, despite the importance of quantifying proteins at a cellular level, there are no proteomic amplification methods to do so at the same resolution as RNA. To address this, we have leveraged information from single-cell RNA-seq (scRNA-seq) to aid in the identification of cell-type-specific proteomic signatures by incorporating the stochastic nature of gene expression for better understanding of the biological variation between mRNA and protein distributions in human brain tissue samples. First, we introduce a zero-inflated Beta Poisson distribution to model cell-type specific mRNA distributions from scRNA-seq data. This model allows us to capture information about underlying transcriptional parameters that give rise to stochastic gene expression. To separate technical noise from biological components, we incorporated a binomial distribution noise model. Next, we applied deconvolution of tissue-level RNA-seq to obtain cell type fractions within each tissue sample. Finally, we used matching proteomics data from the same individuals, as well as mathematical relationships between the expected protein levels, translational rates and transcriptional rates to impute cell-type specific protein signatures. We subsequently identified genes and cell types that show significant variation between mRNA and protein levels. We compared our results to experiments on RNA and protein variations. In summary, our framework circumvents the unavailability of single-cell proteomics by using models of stochastic gene and protein expression, thus offering better insights into the biological discrepancies between cell-type-specific mRNA and protein levels.

Session Title: Omics Technologies Poster Session I

PB3307 A new hybrid method provides robust analysis for clustered data, with applications to single-cell transcriptomics data.

Authors:

M. Du, Z. Yu, V. Berrocal, X. Xu; Univ. of California, Irvine, CA

Technological developments in quantifying molecular profiling characteristics, such as transcriptomics, proteomics, microbiome data, have gone through multiple breakthroughs. As a result, we can now measure the whole gene profiles of each individual cell. Identifying differentially expressed genes across various conditions remains challenging due to small sample sizes, non-normal distributions of transcriptomic counts, and repeated measurements from the same biological unit. Existing methods often focus on only a subset of these issues. Here we propose a novel computationally feasible hybrid method that takes advantage of the robustness of rank-based methods and the statistical efficiency of parametric methods for small sample sizes. Simulation studies suggest that our method achieves optimal statistical properties compared to existing methods. Importantly, our new method effectively controls Type I error rate at the nominal level while achieving a good statistical power of detecting differentially expressed genes. Furthermore, our method readily extends to differential analysis involving multiple conditions and enables adjustment for potential covariates. We applied our method to a spatial transcriptomics dataset of Alzhimer’s disease mouse model. The differentially expressed genes identified through our method align with known genes associated with Alzheimer's disease, further validating our approach. In conclusion, our novel hybrid method effectively tackles key challenges simultaneously and offers a new computationally and statistically efficient framework for analyzing complex molecular profiling data.

Session Title: Omics Technologies Poster Session II

PB3308 A new tool for enhancing the interpretability of machine learning prediction models leveraging '-omics' data.

Authors:

X. Loffree[1,2], H. Yun[1,3], J. Li[4,5], L. Liang[1]; [1]Dept. of Biostatistics, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Dept. of Statistics and Actuarial Sci., Univ. of Waterloo, Waterloo, ON, Canada, [3]Dept. of Epidemiology, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [4]Div. of Preventive Med., Dept. of Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [5]Dept. of Nutrition, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Background: When using high-dimensional data in prediction analysis, the trade-off between the predictive power and interpretability of machine learning models is important. Greater predictive power comes at the expense of interpretability. The model interpretability is pivotal in medical settings, especially for healthcare providers, clinical consulting, and pharmaceutical discovery. To objectively assess the interpretability for prediction models based on large-scale data, we have designed a Python tool to enhance the interpretability of machine learning models using omics data. Methods: We examined three interpretability metrics: Permutation Feature Importance (PFI), Local Interpretable Model-agnostic Explanations (LIME), and SHapley Additive exPlanations (SHAP). Each employs a different mathematical principle to determine the individual contribution of a feature to the prediction of a black box model. Our Python tool applies these metrics to a machine learning model, evaluates the distributions of these metrics, and identifies the most influential features in determining predictions. Additionally, we propose the Robust Interpretability Metric (RIM) - a new interpretability metric calculated by aggregating results from LIME, PFI, and SHAP. In a previous study, we established metabolomic signatures (MS) for 8 dietary patterns including the DASH diet, using elastic net regression in the Lifestyle Validation Study (LVS, n=1134). As a case study, we applied our tool to facilitate the interpretations of these MS. Results: Applying our tool to interpret the MS models, we identified the most influential metabolites in determining dietary index alignment. Using the DASH diet as an example, among the 286 metabolites used to train the model, RIM values revealed 4 glycerophospholipids as the most important feature for prediction: lyso-phosphatidylcholine (PC) 22:5 (RIM=5.61), PC 34:0 (RIM=5.09), PC 38:3 (RIM=4.49), and phophatidylethanolamine 18:0 (RIM=3.94). The distribution of the 286 RIM values was skewed slightly to the right and most were close to zero. In general, only a small number of metabolites contributed greatly to the model prediction. The RIM values of the 4 aforementioned metabolites accounted for 20.92% of the sum of the total RIM value from all 286 metabolites. We further demonstrated that, the RIM, together with LIME, PFI, and SHAP, identified robust metabolite predictors for the MS of other dietary patterns, thus prioritizing top predictors that could greatly facilitate the biological interpretation of the MS.

PB3309 A novel method for hepatocyte isolation combined with cell size agnostic single cell RNA sequencing enables scalable analysis of liver cells

Authors:

C. Emery[1], M. Gallina[1], D. Loh[1], B. Davis[2], A. Sapre[2]; [1]Miltenyi Biotec Inc., San Diego, CA, [2]Parse BioSci.s, Seattle, WA

The successful application of single cell RNA sequencing (scRNA-seq) heavily relies on the isolation of high-quality, viable single cells from heterogeneous tissues. The difficulty of obtaining viable single cells in some tissues is so great that sequencing nuclei has become the default strategy since it is traditionally a faster, easier process. Single nuclei RNA sequencing (snRNA-Seq) is also the default for especially large cells such as hepatocytes and cardiomyocytes, which are often not compatible with droplet based single cell sequencing instruments. While snRNA-Seq is a well-accepted substitute for scRNA-Seq, it results in the loss of cytoplasmic transcripts and cellular context for binucleated cells, which is commonly seen in hepatocytes. Dissociation of liver tissue into a viable single cell suspension poses challenges due to the unique characteristics of hepatocytes, the main functional cells of the liver. Current methods for the isolation of viable hepatocytes typically require two-step manual perfusion and suffer from limitations such as low throughput, a lack of standardization, and complexity, thereby compromising the scale, reproducibility, and quality of scRNA-seq data for liver. To overcome these challenges, we developed a semi-automated approach for ex vivo liver perfusion of up to 8 rodent livers in parallel that yields intact, viable liver cells suitable for cell culture, flow cytometry, and scRNA-seq analysis. To validate the performance of our method, we conducted flow cytometry and scRNA-seq on isolated liver cells using Parse Biosciences Evercode™ Whole-Transcriptome technology. This instrument free approach based on split-pool combinatorial barcoding is cell size agnostic which allowed us to successfully capture the transcriptomic diversity within the hepatic cell and non-parenchymal cell populations. The resulting scRNA-seq data demonstrated high-quality gene expression profiles, enabling the identification of known liver cell types.This semi-automated method for liver cell isolation complemented with Evercode cell fixation could be scaled up to process dozens of rodent livers in a single day resulting in scRNA-seq data from up to 96 samples and a million cells. In conclusion, we present a novel, scalable method for the gentle, rapid isolation of liver cells ideal for scRNA-seq applications. This method holds great promise for furthering our understanding liver diseases, drug discovery, metabolism, and biodistribution.

Session Title: Omics Technologies Poster Session I

PB3310 A novel method for nucleic acid extraction from FFPE tissue: high compatibility and enhanced convenience with NGS applications.

Authors:

L. Torres Benito[1], T. Schughart[1], I. Rose[2], T. Hess[1]; [1]BioEcho Life Sci. GmbH, Cologne, Germany, [2]Reference Med. Inc., Phoenix, AZ

Formalin-fixed paraffin-embedded (FFPE) tissue samples are invaluable resources for retrospective studies as well as routine diagnostic procedures. However, the extraction of high-quality nucleic acids from FFPE tissues poses significant challenges due to the chemical modifications and degradation caused by formalin fixation. Here, we introduce a novel method for DNA and RNA extraction from FFPE tissues, designed to improve convenience and prove compatibility with downstream applications commonly used in diagnostic and research settings. The EchoLUTION technology addresses key issues encountered during the process. After tissue decrosslinking, paraffin and detergent removal, the DNA is extracted in a single step. The DNA passes through the purification matrix without further interaction while impurities are held back and thereby removed. The workflow leads to a protocol that is up to 70 % faster than with established kits. Further, the novel method does not use xylene or other organic solvents like ethanol, thereby reducing hazardous reagents to a minimum. The performance of the technology was validated by extracting nucleic acids from a spectrum of standardized human FFPE samples. Results determined that high DNA yield, and suitable integrity were obtained with the new method. Additionally, we assessed the compatibility of the nucleic acids extracted with the new method via sequencing downstream applications. For this, we selected tumor-normal sample pairs from brain, breast, colon, and kidney, as well as a commercial FFPE reference standard. We performed targeted gene sequencing using an in-house tumor panel comprising a conventional hybridization capture covering 40 onco- and tumor suppressor genes. Next-generation sequencing (NGS) confirmed all variants expected to be found in the reference standard. Furthermore, somatic driver mutations were identified in all tumor-normal sample pairs, which could be further validated using Sanger sequencing. In summary, our results demonstrate that the new extraction technology offers improved convenience in handling FFPE samples while maintaining compatibility with downstream applications. The streamlined workflow reduces processing time and provides high-quality nucleic acids. The availability of high-quality DNA from FFPE tissues enables comprehensive genomic analyses, facilitating discoveries in molecular pathology, personalized medicine, and beyond.

Session Title: Omics Technologies Poster Session II

PB3311 A novel single-cell *in situ* WGS library preparation method is compatible with target enrichment.

Authors:

K. Zobeck, H. W. Richards, S. F. Sanchez, D. O. Vasquez, A. Campos, X. C. Chen, M. R. Malinas, B. A. Novak, J. D. Wells; Factorial Biotechnologies, San Carlos, CA

Single-cell sequencing has been dominated by methods for detecting RNA expression. In cancer, the source for these expression changes remains difficult to assess with existing single-cell technologies. Two predominant methods currently exist to detect genomic variants in single cells: directly assaying the genome using a single-cell amplicon method and computationally mining variants from single-cell RNAseq data. Both methods have inherent limitations: 1) amplicon panels are limited is the number of targets they can interrogate; 2) current amplicon methods have minimal cell recovery; 3) genomic variant detection in RNA data is limited to coding regions, missing important variants in promoters and introns; 4) expression differences and 3'-bias can exacerbate variant detection limits in RNA data. We describe an *in situ* DNA library prep method that can be combined with existing single-cell technologies to sequence the whole genome. On its own, and with sufficient sequencing, our in situ whole genome sequencing (WGS) library prep could be used to detect large CNVs, structural rearrangements, and SNPs. However, the amount of sequencing needed for sufficient coverage of human WGS data at single-cell resolution is excessively high. We therefore developed our in situ WGS library prep method for compatibility with existing target enrichment technologies. Here, we show how the output of our single-cell WGS library prep can be used with hybrid capture to detect variants in specific target regions of each cell. This method will provide a scalable approach for identifying genomic variants in single cells.

Session Title: Omics Technologies Poster Session III

PB3312 A Protein Signatures-Based Decoy Framework For Improved Protein Identification In Target-Decoy Search Approach

Authors:

T. Bensellak[1], A. Moussa[2,3]; [1]UAE, Tetouan, Morocco, [2]ENSATg, Tangier, Morocco, [3]UAE, Tangier, Morocco

The primary objective of the target-decoy strategy is to estimate the false discovery rate (FDR) for reported peptide or protein matches during a protein database search. Various strategies, such as decoy database generation methods and search engine combinations, have been explored. Earlier research investigated the influence of decoy construction models and showed stochastic/statistic methods to be more promising and accurate than basic sequence reversal or shuffling methods.In this paper, we propose a novel decoy creation framework based on proteins' significant biological signatures, patterns, and profiles, using stochastic models such as Markov. As part of the proposed approach's flexibility, decoy sequence generation can be adapted to digestion sites and be peptide-based or protein-based. For comparison and benchmark purposes, we investigated a standard MS/MS data set of two well-known protein pools based on E. coli peptide fragments to compare the proposed approach to standard methods by assessing the false discovery rate and identification correctness.When compared to default methods, the false discovery rate was quite high. The imbalanced number of discovered patterns in the two pools has resulted in an improved accuracy and specificity for sequences with the most signatures. For certain examined samples, the proposed method improved the correct and incorrect identification ratios by 12.3 percent and 7.7 percent, respectively.

Session Title: Omics Technologies Poster Session I

PB3313 A sequence variation graph-based approach to genotype immunoglobulin genes using short read sequencing data

Authors:

D. Duchen, S. H. Kleinstein; Yale Univ. Sch. of Med., New Haven, CT

Despite the important role our antibodies play in the adaptive immune response to infection, genetic variation across the genes encoding their components remains poorly characterized as most are located in highly repetitive loci with an underappreciated amount of structural variation. For example, within the human immunoglobulin heavy chain locus (IGH) on chromosome 14 there are over 140 functional or pseudogene immunoglobulin heavy chain variable region genes (IGHV), of which many have high sequence similarities, lie within structural variants, or are highly polymorphic with many potential alleles. The characterization of these loci is therefore difficult, especially when using widely available short-read sequencing data. As a result, the genetic variability across the IGH locus is often excluded from host genome-wide association studies. Building upon the limited number of tools able to genotype IGH-related genes at allelic resolution using high-throughput sequencing data, we developed an approach which leverages a whole genome sequence variation graph containing sequences from the International ImMunoGeneTics (IMGT) and other databases for read mapping and alignment. We then infer the observed alleles across the IGH genes using a graph-based approach originally designed to estimate the relative abundance of individual haplotypes/strains from a viral quasispecies. Leveraging available sequencing data from 1000 Genomes Project individuals with a fully-resolved IGH locus for benchmarking, we find our graph-based approach successfully infers the correct IGHV alleles for the majority of IGHV genes using solely short-read Illumina sequencing data.

Session Title: Omics Technologies Poster Session II

PB3314 A Statistical Testing Framework for Structural Difference and Similarity of Multiple Proteomics Networks based on Gaussian Graphical Models

Authors:

J. Chen[1], J. Murabito[2], K. Lunetta[3]; [1]Boston Univ. Sch. of Publ. Hlth., Boston, MA, [2]Boston Univ. Sch. of Med., Framingham, MA, [3]Boston Univ SPH Crosstown Ctr, Rm 313, Boston, MA

Proteomic networks, representing interactions among proteins, play a crucial role in understanding biological pathways and their regulation under different conditions. Differential network analysis aims to identify differences among network components for multiple disease or phenotype states. The Gaussian Graphical Model (GGM) is a statistical network model approach that represents the partial correlations among components. There are several methods for estimating group differences in sparse GGMs, but most apply only to comparisons between two groups, and statistical tests that can rigorously examine similar and differential edges across groups are still underdeveloped: the challenging problem of multiple testing related to the differential and similar structures of multiple GGMs persists. Thus, we propose a new two-step statistical framework that controls the false discovery rate (FDR) in testing structural differences and similarities for multiple groups. We conduct simulations considering GGMs under several common network structures and different proportions of samples across groups to evaluate our proposed framework's performance and compare it with existing methods. We find that our method outperforms existing methods for identifying both group differences and similarities under several network structures such as random and hub graphs. Differential edges in band-structure graphs are more difficult to detect for all methods; for this structure, the joint graphical lasso approach performs better than our proposed method and moderated network models. Based on our simulations we suggest modeling strategies tailored to different network structures. We apply our method to 68 inflammatory biomarkers and three cognitive domain scores measured on a sample of 708 individuals from the Framingham Heart Study categorized into three groups based on Apolipoprotein E (APOE) genotypes. We find 374 similar edges across all the APOE subgroups and 2 edges that are significantly different across the groups. All edges between cognitive scores and proteins were similar across the three APOE groups. Two differential edges: edges between AXIN1 and STAMBP and between CXCL10 and STAMBP, are identified as potentially differential pathways related to neuroinflammation, in that APOE E2 shows positive relationships between CXCL10 and STAMBP whereas negative relationships for APOE E4 and E3E3 subgroups, and different negative strengths between AXIN1 and STAMBP were observed across groups. By applying our framework to high-throughput protein data, we provide a valuable tool for joint comparisons of multiple proteomics networks.

Session Title: Omics Technologies Poster Session III

PB3315 A transformer model for accurate genotype imputation.

Authors:

M. Mowlaei[1], C. Li[1], J. Chen[2], B. Jamialahmadi[3], S. Kumar[4], T. Rebbeck[5], X. Shi[6]; [1]Temple Univ., Philadelphia, PA, [2]Harbin Inst. of Technology, Shenzhen, China, [3]Univ. of Waterloo, Waterloo, ON, Canada, [4]Temple Univ, Philadelphia, PA, [5]Harvard T. H. Chan Sch. of Publ. Hlth., Boston, MA, [6]Temple Univ., Philadephia, PA

Recent advances in Next-Generation Sequencing enable researchers to sequence a whole genome within a day. However, differences in sequencing platforms, assay failures, and genotype calling errors can lead to untyped and missing genotypes. This negatively affects the accuracy of downstream analysis in disease association studies and causal inference. Genotype imputation addresses this problem by predicting missing genotypes based on the patterns found in the reference samples.

Here, we present a transformer model for imputation (STI), which can accurately predict bi-allelic and multi-allelic missing genotypes. Transformers, such as Generative Pre-trained Transformer 4 (GPT4), have shown outstanding performance in many natural language processing and computer vision tasks in recent years. Considering each genotype sequence can be treated similar to a sentence in natural language, we decided to develop STI to tackle genotype imputation. Specifically, our STI model breaks down a sequence into smaller windows and forms a separate deep neural network composed of convolutional and transformer blocks for each window. In STI, we apply convolution blocks to conserve locality in SNP-SNP correlations that create linkage disequilibrium blocks. Although transformers use the attention mechanism to attend to important segments of the input at a global scale, they are costly to apply to long sequences as in human genomes. To address the memory cost of implementing transformers, we used a splitting strategy, like Minimac4 and many other tools, to make the model scalable and efficient in memory and computation cost. The combination of transformers and convolution blocks thus enables STI to outperform other deep learning and classical imputation methods.

We use the yeast and the human 1000 Genomes Project datasets in different settings to extensively evaluate the STI model. Our experimental results showed that STI is competitive with or better compared to the existing imputation models, including Minimac4 and other deep learning methods, in terms of accuracy and imputation quality score metrics. Additionally, our model can impute multi-allelic SNVs with higher accuracy than existing deep learning methods. In summary, we develop a new deep learning-based model for genotype imputation, with potential to be applied to predict missing genotypes in disease association studies and meta-analysis.

Session Title: Omics Technologies Poster Session I

PB3316 Advancing the pace of omics research and discovery

Authors:

E. Floden; Seqera, Barcelona, Spain

Increasingly, multiple omics disciplines are being combined to study biological processes in a more comprehensive manner. Multi-omics techniques are used in everything from personalized medicine and dosing control to population-level studies to the development of new therapeutics. Traditionally, techniques used for large-scale genomic analysis in research and clinical settings have been plagued with technical and procedural challenges, including complexity, reproducibility, auditability, ensuring data provenance, and integrating with public datasets. Bioinformaticians also face a variety of practical challenges, such as marshaling and managing necessary compute resources for analysis, monitoring pipeline execution, managing costs, and maximizing the use of various sequencing platforms. In this talk, the author will discuss his organization's efforts to address many of these large-scale analysis problems. The author will discuss Nextflow, an open-source project for multi-omics data analysis pipelines, and introduce nf-core, a community effort to build a high-quality set of curated analysis pipelines. The author will provide specific examples of pipelines and how they address a wide range of omics disciplines and provide specific examples of how pharmaceutical, biotech companies, and public health authorities are using these open science pipelines and techniques to automate end-to-end analysis. Attendees will learn how they can advance their research and improve productivity and efficiency by leveraging reusable open science pipelines and modules.

Session Title: Omics Technologies Poster Session II

PB3317 † Age-related transcriptional regulation in blood revealed by long-read sequencing

Authors:

M. Tomlinson, K. Small, A. Hodgkinson; King's Coll. London, London, United Kingdom

Ageing is characterised by physiological decline and a growing susceptibility to disease. While the cellular and molecular hallmarks of ageing are well known, emerging evidence suggests altered transcriptional processes play a vital role in cellular ageing. Here, we utilised long-read Oxford Nanopore Technology in a longitudinal design to sequence the transcriptomes of 19 females at two time points approximately ten years apart, enabling high-resolution analysis. Specifically, we focused on two age groups: middle-aged (age at first visit: 52.04±2.19) and older adult (age at first visit: 73.52±2.67). Full-length cDNA sequencing was performed, followed by bioinformatic processing using the 'nanoseq' pipeline, which allowed detailed characterisation of the changing transcriptional landscape during ageing. Comparing transcriptomes between time points, we found decreased transcript usage across samples, accompanied by a corresponding decline in the relative abundance of alternative transcripts. Using paired samples, we found significant differences in transcript usage (FDR 5%) for 55 genes between time points. These genes were enriched in cellular stress response pathways (adjusted $p < 0.05$). We found 122 differential alternative splicing events that were enriched in genes involved in immune processes including negative regulation of NIK/NF-kappa B signalling (adjusted $p = 0.01$) and T-cell receptor signalling (adjusted $p = 0.01$). Moreover, we observed 7 differential intron retention events, which predominantly occurred in genes implicated in reduced natural killer cell count ($p = 0.0064$). Notably, we identified 1104 genes between time points and 735 genes between age groups with significant changes in transcript diversity, measured by Laplace entropy ($p < 0.05$). Functional enrichment analysis revealed these genes were associated with age-related processes, including neurodegenerative pathways ($p = 0.00039$). Importantly, we observed a genome-wide decrease in transcript diversity with age and this effect was most pronounced in older adults ($p = 0.035$). In summary, this study utilising long-read sequencing data provides enhanced resolution and comprehensive profiling of the transcriptional changes associated with ageing in blood. These findings shed light on the dynamic alterations occurring in the transcriptome during the ageing process and the role of alternative splicing.

PB3318 Alternative Therapeutics for Breast Cancer: An Assessment of Promising Anticarcinogenic Plants Derived from Traditional Medicinal Use; Persimmon Leaf Extract (*Diospiros kaki*), Marjoram Extract (*Origanum majorana*) and Thyme Extract (*Thymus vulgaris*) on *In Vitro* and *In Vivo* systems

Authors:

A. Mattingly[1], D. Ivankovic[2], Z. Vickery[1], J. Spencer[1], L. Boccuto[1], A. Broom[3], HCG SON Laboratory Undergraduate Student Aids; [1]Clemson Univ., Clemson, SC, [2]Clemson Univ., Clemson, SC, SC, [3]Anderson Univ., Anderson, SC

Overview Despite the advancements in targeted radiation and chemotherapy, these treatments still have limitations and pose risks to healthy tissue. However, alternative therapies, including the use of persimmon leaves and Mediterranean herbs like marjoram and thyme, offer potential solutions in the fight against breast cancer. Through our observations, these natural remedies have demonstrated a range of beneficial properties, including anticarcinogenic, apoptotic, pro-metabolite, and antioxidant effects.
Methodology Preparation of Persimmon, Marjoram, and Thyme: The extraction and preparation of alternative therapeutics was completed using microwave-assisted ethanol extraction (ETHOS-X) and subsequent rotary evaporation, followed by a drying period. Cell Culturing and Selection: Cell cultures were maintained according to ATCC guidelines with evidence-based modifications for healthy breast MCF-12A and MCF-12F as control lines, triple-negative HTB-26 and HCC-38, hormonal positive BT-483, and MCF7. Metabolomics: Biolog plates PMM1-PMM8 (Phenotype Mammalian Microarray) were used to collect metabolomics data in the form of normalized spectra and absorbance readings. This measures the amount of NADH produced in the presence of different molecules such as metabolic effectors, amino acids, hormones, ions, and various others. Enrichment, Pathway, and Metabolic Analysis: Used to validate pathway interactions in alternative therapeutics, human cancer cells, and zebrafish biological systems. Metabolism and metabolic analysis are useful to determine which components are causal to therapeutic effect. MTS assay: Conducted to evaluate cell viability, cytotoxicity, and proliferation after treatment with all 3 alternative therapeutics at set concentrations. *In vivo* Zebrafish Injections and Treatment: 5D, Tg(fli1:EGFP), zebrafish (*Danio rerio*) are raised, bred, and kept according to ZIRC and Clemson IACUC husbandry standards. Six breast cancer cell lines are fluorescently labeled in culture, incubated, prepared, and subsequently injected into zebrafish embryos. The embryos are treated to remove pigmentation, allowing for visualization and quantification of metastasis, tumor growth, vasculature, and response to treatment. Gene expression profiles are created using tail digests with detection via qRTPCR and the pathways of interest are investigated.
Future Direction Our preliminary findings indicate high potential for the use of natural compounds in treatment protocols for breast cancer: future studies on mammalian *in vivo* models and human subjects are necessary to validate and expand these results.

PB3319 Amplicon based NGS using mostly natural sequencing-by-synthesis.

Authors:

J. Sinson[1], M. Pena[1], S. Li[1], S. Zhao[1], P. Liu[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX

The recent advancement in next-generation sequencing (NGS) technology produced unique platforms that aim to lower the cost and time of sequencing while improving quality. These advances led to an increase in the use of whole genome sequencing (WGS) and whole transcriptome analysis with total RNA sequencing (RNASeq). While we are moving towards a time where WGS is the first diagnostic test to be performed, most clinical laboratories are currently offering targeted NGS panels or whole exome sequencing (WES) along with WGS. Here, we aim to highlight the importance of other NGS assays using one of the newly developed sequencing platforms.Utilizing the UG 100 sequencer created by Ultima Genomics, we were able to develop and sequence our own amplicon based NGS assay that accompanies our WGS. The amplicon based NGS assay was developed as an identification tool to confirm the identity of the WGS samples. It was designed to enable genotyping of 53 SNP loci across the human genome. The 53 loci consist of 49 autosomal and 4 allosomal SNPs with redundancy to ensure the gender of the sample if allelic drop out were to occur. All 53 primer pairs were designed to produce a 600 base pair amplicon and were pooled accordingly to set up in one multiplex polymerase chain reaction (PCR). The addition of the Ultima NGS barcodes to the amplicons was done through a secondary PCR that targets a linker sequence added at the end of each primer. The assay was tested on 12 Coriell samples which consist of 9 lymphoblastoid cell lines and 3 fibroblasts. Using our identification assay, we were able to match the 53 SNPs found in our assay against the same SNPs in the WGS data. Using a similar approach, we developed another assay that verifies low level somatic variants by PCR amplicon sequencing.As the focus in the industry shifts towards generating large amount of data in a short period of time, targeted NGS testing remains a necessity for most clinical laboratories to implement in their operations. Here we highlighted the importance and feasibility of sequencing targeted NGS assays in a newly developed sequencing platform.

Session Title: Omics Technologies Poster Session II

PB3320 An integration of common disease GWAS and omics to fuel rare disease target discovery.

Authors:

Y. Wu, S. Berasi, L. Shang, S. Li, H. Yang, Y-C. Cheng, M. Tadin-Strapps, K. Loomis; Pfizer, Cambridge, MA

Autosomal dominant polycystic kidney disease (ADPKD) is a rare renal disease which leads to end-stage renal disease following enlargement of the kidneys due to the growth and expansion of fluid-filled cysts. ADPKD affects over 300,000 patients in the US. Tolvaptan is the only approved therapy, but the marginal efficacy and hepatotoxicity lead to a large remaining unmet medical need. Human genetics is recognized as an 'experiment of nature' model for drug development. Drug targets with human genetic support are estimated to be nearly twice as likely to result in approved drugs. ADPKD is a ciliopathy caused by mutations in the *PKD1/2* genes; however, the causal genes remain undruggable. To identify genetic modifiers as potential therapeutic targets while being unable to utilize ADPKD specific genome-wide association studies (GWAS) as a starting point, we focused on the ~800 candidate genes possibly associated with renal function from published eGFR GWAS (CKDGen, MGI-HUNT, and Kidney biobank). In addition, as cilia function is a mechanism relevant to ADPKD, we next merged ~950 known/predicted ciliary genes cataloged in CiliaCarta, SysCilia and CilioGenics, and identified 34 overlapping genes. The omics integration further prioritized 16 genes with colocalized eQTLs or SNP-CpG -gene associations by kidney meQTL and eQTM. Eight are predicted targetable using small molecules or antibodies based on tractability assessment. *CDKL5* was identified as a target of interest given a robust eGFR-associated signal (p=1.4x10^{-9}). The same SNP also led the association with blood urea nitrogen (BUN) in a meta-analysis of BioBankJapan, UK Biobank and FinnGen. A kidney-specific eQTL for *CDKL5* was colocalized with the GWAS locus (COLOC PP4=0.96) in GTEx kidney cortex (p=0.0012; not significant in other ~50 tissues) and NEPTUNE tubulointerstitium (p=6.9x10^{-12}). The risk allele for reduced eGFR was associated with higher *CDKL5* mRNA expression, indicating antagonism as a potential direction of treatment. Further supporting our hypothesis, a previously published phosphoproteomic screen demonstrated that CDKL5 kinase substrates are enriched in protein clusters modulating cilium function. Given the GWAS and omics support, target validation experiments evaluated the biological role of CDKL5 in ADPKD using *in vitro* and *in vivo* models. In summary, our multi-omics integrative approach translated GWAS of common diseases/related phenotypes into a novel target hypothesis for a rare kidney disease following the incorporation of known disease biology. This example provides a therapeutic target identification paradigm for rare diseases where direct GWAS are not feasible.

Session Title: Omics Technologies Poster Session III

PB3321 An integrative approach to detect potential blood-based biomarkers for frailty.

Authors:

M. Suganuma[1], M. Furutani[2,1], T. Hosoyama[3], S. Akiyama[1], R. Mitsumori[1], R. Otsuka[4], M. Takemura[5], Y. Matsui[5], Y. Nakano[2], S. Niida[6], K. Ozaki[1,2,7], S. Satake[8], D. Shigemizu[1,7]; [1]Med. Genome Ctr., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [2]Dept. of Cardiovascular Med., Hiroshima Univ. Graduate Sch. of BioMed. and Hlth.Sci., Hiroshima, Japan, [3]GeroSci. Res. Ctr., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [4]Ctr. for Gerontology and Social Sci., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [5]Ctr. for Frailty and Locomotive Syndrome, Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [6]Core Facility Admin., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [7]7RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [8]Dept. of Frailty Res., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan

Frailty is a common geriatric syndrome characterized by age-associated declines in function across multiple physiologic systems and cognitive reserves. The number of people with frailty is increasing with the current rapid population aging, especially in developed counties. A recent meta-analysis reported estimated incidences of frailty and prefrailty of 43.4 and 150.6 new cases per 1000 person-years, respectively. Frailty is associated with a high risk for adverse health outcomes such as physical disabilities and hospitalizations and mortality, but it is reversible and preventable with appropriate interventions. Thus, promising novel biomarkers for the diagnosis of frailty are urgently required. Here, we performed a comprehensive analysis of clinical data, messenger RNA sequencing (RNA-seq), and aging-related factors to detect candidate biomarkers of frailty by using a total of 104 older adults aged between 65 and 90 years, representing 61 frail subjects and 43 robust subjects. We identified two candidate biomarkers of frailty from the clinical data analysis, nine from the RNA-seq analysis, and six from the aging-related factors analysis by logistic regression analysis adjusting for age, sex, and body mass index (BMI). Risk prediction models were then constructed by using combinations of the candidate biomarkers and clinical information (age, sex, and BMI) with a random forest classifier. As a result, the best models used combinations of five biomarkers achieved a high area under the curve (AUC) of 0.95 in an independent validation cohort (95% confidence interval: 0.79-0.97). Our risk prediction models afforded significantly higher AUC than did models constructed using only basic clinical information (Welch's *t*-test $p < 0.001$). All five biomarkers also showed statistically significant correlations with components of the Japanese version of the Cardiovascular Health Study (J-CHS) frailty diagnostic criteria. We believe that further refinement may lead to future clinical use.

Session Title: Omics Technologies Poster Session I

PB3322 Analysis of public long-read transcriptome datasets reveals a putative SINE-VNTR-Alu-intrinsic antisense promoter.

Authors:

A. Lorenzetti[1], T. A. Evans[1,2], J. A. Erwin[1,2], A. Paquola[1,2]; [1]Lieber Inst. for Brain Dev., Baltimore, MD, [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

SINE-VNTR-Alu elements (SVAs) are non-autonomous hominid-specific retrotransposons present at approximately 2,700 copies within the human genome. SVAs greatly contribute to the estimated GC-rich tandem repeat differences between humans and other hominids and are considered a potential source underlying divergence of some human-specific traits. Here, we aim to gain insights into their function and impact by analyzing SVA-derived transcripts in long-read sequencing data. SVAs generally comprise five distinct regions, such as i) a 5' (CCCTCT)n tandem repeat, ii) an inverted Alu-like region, iii) a variable number tandem repeat, iv) a SINE-R region, and v) a Poly-A tail. SVA insertions may be pathogenic, causing several diseases, which include but are not limited to Fukuyama congenital muscular dystrophy, autosomal recessive hypercholesterolemia, and X-linked dystonia-parkinsonism (XDP). In XDP, a neurodegenerative movement disorder, the 5' tandem repeat length has been associated with the age at onset and age at death. Due to their repetitive nature, it has been difficult to accurately characterize the endogenous transcripts originating from SVA loci and identify SVA intrinsic promoters. Limitations inherent in short-read sequencing techniques for their transcriptional profiling include ambiguity in read mapping and inability of reads to fully span tandem repeats. Conversely, long-read sequencing technologies may overcome these issues by providing full-length or near full-length transcripts that result in fewer ambiguous alignments and successfully span low complexity regions. With the increasing number of public datasets, we analyzed genome-wide SVA expression and identified a novel putative antisense promoter intrinsic to the 5' tandem repeats. Moreover, we found a subset of SVAs that primarily contribute to the observed overall expression signal. Further investigation into the specific context of this subset of SVA sequences may provide insights into the dynamic behavior of SVAs, their influences on gene expression, and consequently how these elements may contribute to disease-associated phenotypes.

PB3323 Antibodies and Aptamers: A Comprehensive Evaluation of the Current State-of-the-Art Technologies in High-Throughput Proteomics**.**

Authors:

P. Schreiner[1,2], C. Yandava[3], D. Panyard[4], N. Duro[5,3], D. Dochtermann[3], C. Gauthier[1,3], P. Devineni[3], M. Francis[3,6], B. Gorman[6,3], P. Tsao[7,8], S. Pyarajan[9,3]; [1]Booz Allen Hamilton, Lexington, MA, [2]VA Boston Hlth.care System, Boston,, MA, [3]VA Boston Hlth.care System, Boston, MA, [4]Stanford Univ., Sunnyvale, CA, [5]Booz Allen Hamilton, Tampa Bay, FL, [6]Booz Allen Hamilton, Boston, MA, [7]VAPAHCS/Stanford Univ., Palo Alto, CA, [8]Stanford Univ. Sch. of Med., Stanford, CA, [9]Brigham Women's Hosp., Boston, MA

Proteins are the functional unit of diverse cellular functions whose detection and quantification can be used to inform diagnostic, prognostic, and therapeutic applications. Genetic, epigenetic, transcriptional, and translational abnormalities can all influence protein expression and function, which can directly or indirectly cause disease. Traditionally, these proteins have been measured using methods such as mass spectrometry, enzyme-linked immunosorbent assay (ELISA), or multiplex bead array assays, but new platforms are emerging to detect protein abundance with higher throughput. We profile aptamer- and antibody-based high-throughput proteomics platforms in the Million Veteran Program (MVP), alongside other high-throughput omics data, which presents a unique opportunity to assess platform performance and associate protein levels with disease in a diverse cohort.
In this MVP pilot study, we observe the performance of 8,761 total proteins (6,386 unique) in a common cohort of 829 MVP participants of European, African, and Hispanic ancestry using Olink Explore 1536 (OE1536) and Somascan v4 (SSv4). We discuss considerations and recommendations for best practices regarding data quality control and sample inclusion by platform. Metrics including platform-specific data properties, sample-level and batch variability metrics, technical reproducibility, and concordance of commonly profiled proteins are reported for each platform. We identify 865 statistically significant protein-disease associations with abdominal aortic aneurysm (AAA), 116 significant associations with lung cancer, and 2 significant associations with Alzheimer's disease. To assess the validity of identified protein-disease associations, the top significant protein-disease associations were subjected to review in accepted, peer-reviewed literature. We also perform a genome-wide protein quantitative trait loci (pQTL) analysis to identify 4,449 statistically significant genetic variant-protein associations from 147 unique loci. Finally, we assess the efficacy of proteomics data to predict known covariates - like age, gender, and ethnicity - using machine learning. Our results demonstrate a direct comparison of high-throughput proteomics platforms which provide unprecedented insights into the current state of proteogenomic applications.

PB3324 Assessing the stability of differential gene expression signatures across assemblies.

Authors:

A. Lund[1], L. Liharska[2], R. Thompson[2], Y-C. Wang[2], A. W. Charney[2], N. D. Beckmann[1]; [1]Icahn Sch. of Med., New York, NY, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Reproducibility is a pillar of modern science. Consequently, many studies of complex traits rely on prior work to establish that their results are consistent with what is already known. With constant improvement of genome assemblies, an underlying assumption is that, while massive differences in gene expression can be explained by assembly version, these differences do not significantly impact the gene expression traits that are identified as associated with disease. Here, we present what is to our knowledge, the first systematic attempt to test this underlying assumption. To test this assumption, we utilized a large transcriptomics dataset from Alzheimer's disease (AD) patients and controls (ROSMAP). We aligned the raw RNA-seq reads to 3 genome assemblies that capture the breadth of what has been used in the literature to study that complex trait: hg18, hg19, and hg38. We also aligned to 2 hg38 transcriptome assemblies (GRCh38.p12 (release 30) and GRCh38.p13 (release 43)). To establish a baseline of differences due to assembly version, differential expressed genes (DEGs) were identified between each pair of assembly. Additionally, AD DEGs were compared across assemblies. As expected, we found that for all pairs of assemblies, between 98.8% and 99.3% of expressed genes were identified as significantly differentially expressed (DE). Interestingly, HLA-DRA was found as one of the top DEGs between hg19 and GRCH38.p13. This gene has been notoriously challenging to map, thereby exemplifying gene expression changes due to technical effects that are identified across assemblies. An in depth characterization of the changes of gene expression between assembly could be important to interpret changes in DEG associations to specific traits of interest. AD DEGs (FDR < 0.05) were found to be highly similar across assembly. Unsurprisingly, the greatest difference was between the oldest and newest assemblies (i.e., hg18 and GRCh38.p13) Included in those genes were a set of genes that have been repeatedly shown to be important to AD. Our results show that, while almost all genes are identified as DEGs between assemblies, AD DEGs remain mostly stable across them. While these findings were not unexpected, they nonetheless provide the first proof that the underlying assumption that complex trait DEGs are reproducible across assemblies is valid. It is important to note that, for a subset of specific AD genes, this was not the case, underlying the importance of realigning previous datasets to newer assemblies to ensure the most accurate results and to identify new genes associated to disease that may have been previously missed due to the use of contemporary yet inaccurate assemblies.

Session Title: Omics Technologies Poster Session I

PB3325 Assessing viral variant detection algorithms to improve characterization of gene therapy products and biologics.

Authors:

H. Desai, Y. Zhou, B. Hasson, A. Overgard, A. Bridgeland, W. Dolan; milliporesigma, Rockville, MD

Identity testing is an evolving requirement of regulatory agencies to characterize biologics intended for human therapeutic products such as vaccines and gene therapy. The use of Next generation sequencing (NGS) is increasingly used in the biosafety testing sphere to characterize and confirm the identity of viral seed stocks and expression vectors used in vaccine or gene therapy products. The most common approaches for gene therapy involve using a viral vector to deliver genetic material to patient cells. It is important to characterize viral vectors to ensure they do not contain variants which can negatively impact patient outcomes. Downstream bioinformatics analysis must capture true positive variants and limit spurious results to establish sequence identity and purity of the expression vectors. Advancements in best practices and standards for viral variant detection is critical to ensure the safety of patients and meet the expectations of regulatory guidance.

For identity testing, a diverse range of computational approaches is utilized to analyze 12 open-source and commercial variant callers to examine viral variant calling. In this presentation we will discuss how evaluation of these 12 open-source variant callers including: bcfTools, mutect2, varscan2, freebayes, deepvariant, vardict, variant callers affect sensitivity and specificity of viral variant detection. Specificity, sensitivity, and reproducibility is especially important for patient care which starts with determining the safety of biologics. We use 189 in silico and synthetic viral datasets representing different variants including snps, indels, large insertions and large deletions to conduct studies to determine false positives, false negatives and recommend optimal methods for viral variant detection. By improving the sensitivity and specificity for detecting variants within biologics we can improve the confidence in the results of clinical trials which can benefit clinical outcomes for patients requiring novel approaches to treating genetic conditions or cancer.

Results demonstrate that NGS can detect 1% variant frequencies, integrating multiple variant calling applications is essential for detecting different types of variants, and marking duplicate reads arising from PCR amplification can improve analysis turnaround time while maintaining sensitivity and specificity. This presentation will also demonstrate how utilizing paired-end inward oriented reads for analysis can improve confidence in variant calling by depleting false positive variants.

Session Title: Omics Technologies Poster Session II

PB3326 Automated localization and quantification of RNA transcripts and protein clusters in single cells

Authors:

B. Hospelhorn, B. K. Kesler, G. Neuert; Vanderbilt Univ., Nashville, TN

The regulation of gene expression is a major factor in cells' ability to respond to environmental stimuli and differentiate during the development of multi-cellular organisms. However, a transcriptional program is not only defined by which genes are upregulated and downregulated. Understanding the finer kinetics of transcriptional tuning is important for fully understanding transcription as a process and how its regulation impacts cellular phenotype. Because variability increases with length of time and the number of cells measured in a population, high resolution spatiotemporal localization of individual RNA molecules in single cells is important for studying these dynamics at high precision. RNA fluorescent in situ hybridization (RNA-FISH) is a frequently used technique for visualizing RNA in fixed cells using fluorescent probes. Automated processing of the resulting images is essential for large datasets that may include many different transcripts and time points. Here we demonstrate that our MATLAB based RNA-FISH image processing pipeline is a useful tool for automatically detecting the 3D locations of cell boundaries and RNA transcripts at single molecule resolution in an RNA-FISH image stack. In particular, this tool is effective for facilitating quantitative analyses of FISH data such as determining the colocalization of multiple transcripts or the relative amount of RNA in various subcellular compartments. Our tool also performs well on images with immunofluorescent (IF) and GFP tagged protein targets. We have developed a tool capable of performing analysis for a variety of imaging-based approaches to studying biomolecular dynamics. We will use this tool to advance understanding of eukaryotic transcription regulation mechanisms by studying the quantities and behaviors of transcripts, regulatory RNA, and other targets at discrete time points.

Session Title: Omics Technologies Poster Session III

PB3327 Automating next-generation sequencing: Ultra-long library preparation using a digital microfluidic system.

Authors:

J. Hosea[1], W. Timp[1], C-C. Lee[2], F. Christodoulou[2]; [1]Johns Hopkins Univ., Baltimore, MD, [2]INTEGRA BioSci.s, San Francisco, CA

Introduction: Single molecule sequencing has reached an inflection point where the quality and cost of data generation is now scalable for human studies. However, significant roadblocks preclude wide adoption, specifically because of the difficulty of DNA extraction and library preparation on high-molecule weight DNA. More careful DNA handling through automation would provide greater consistency between libraries and even potentially reduce the cost of prep reagents through a reduction in volume. Here we have implemented nanopore sequencing library preparation on the Miro Canvas, a digital microfluidics platform that allows for automation of a variety of complex NGS sample-prep protocols. The smaller volumes and gentle liquid handling could prove ideal for HMW library preparation.
Methods: We extracted HG002 (GIAB lymphoblast) HMW DNA using NEB Monarch HMW DNA Extraction Kit for Cells & Blood, then size selected using PacBio's SRE XL Kit. We used the Miro Canvas to generate an ultra-long library of HMW HG002 DNA using ONT's LSK110 library prep reagents. The DNA library was then sequenced on the ONT GridION instrument using a R9.4.1 flow cell. Quantification of library yield, sequencing data, and hands-on time were analyzed to assess the Miro Canvas' performance.
Results: The ONT ultra-long protocol automated on the Miro Canvas yielded a final DNA library concentration of 3.68 ng/uL in a volume of ~20 uL from an input of 1,000 ng DNA in a 12 uL volume. On average, the Miro Canvas used 4x less reagents than manual library preparation. The ONT sequencing run done using a MinION flow cell had a yield of 3.09 Gb and generated 174.14 k reads. The estimated N50 for the sample was 43.38 kb. The hands-on time for setting up the reagents for loading on the Miro Canvas was ~30 minutes, while the actual protocol took ~3 hours and 15 minutes to run on the Miro Canvas.
Conclusions: Our preliminary results suggest that the Miro Canvas can produce a high quality ultra-long library for sequencing on the ONT GridION instrument. Raw sequencing data is similar to that we have previously gotten for HG002 cells with manual library preparation. Further experiments and data analysis will be done to generate more consistent high-quality libraries to show Miro Canvas is a satisfactory replacement for manual preparation. Minimal hands-on time and less reagents usage will provide a more time and cost-effective option for NGS.

MOUSSA[1]; [1]Systems and data engineering team, The Natl. school of applied Sci.s, Abdelmalek Essaadi Univ., Tangier, Morocco, [2]Univ. of Ibadan, Ibadan, Nigeria, [3]African Society for Bioinformatics and Computational Biology, South Africa, South Africa, [4]Pwani Univ., , Intl. Ctr. of Insect Physiology and Ecology, Nairobi, Kenya, [5]BioMed. and Publ. Hlth.Res. Unit, Council for Scientific and Industrial Res.-WRI, Accra, Ghana, [6]Dept. of Biochemistry, Cell and Molecular Biology, Sch. of Biological Sci., Univ. of Ghana, Legon, Ghana, [7]West African Ctr. for Cell Biology of Infectious Pathogens, Sch. of Biological Sci., Univ. of Ghana, Legon, Ghana, [8]South African Natl. Bioinformatics Inst., Univ. of the Western Cape, Cape Town, South Africa, [9]Dept. of Hlth.Sci., Univ. of Cape Town, Cape Town, South Africa, [10]Inst. for Biotechnology Res., Jomo Kenyatta Univ. of Agriculture and Technology, Nairobi, Kenya

Background: The microbiomes within the human body play a crucial role in establishing and maintaining immune homeostasis, which is essential for overall human well-being. COVID-19, a respiratory tract infection caused by severe acute respiratory syndrome, enters the body through the oropharynx as one of its main entry points. Metagenomics offers powerful tools for studying the genomes of diverse microbial communities that cannot be easily cultured, allowing for the identification of novel or unexpected pathogens in an unbiased manner. Machine learning (ML) can help overcome challenges in handling large metagenomics data by leveraging advancements in computing power. Methods: A metagenomics dataset from China containing 16S rRNA data was retrieved for the purpose of developing ML tools. Data quality was checked using the DADA2 quality control pipeline, followed by filtering and trimming. Single-end reads were replicated and chimeras were removed. Amplicon Sequence Variant (ASV) tables were generated, which were then used in developing three ML models: LightGBM, Random Forest, and XGBoost. These models were evaluated based on AUC and prediction accuracy for identifying COVID-19 microbial biomarkers using human gut metagenomics dataset. Consensus biomarkers were generated as potential differentially abundant microbes. Results: Our study provides insights into the gut microbiome composition in COVID-19 patients and suggests a possible link between respiratory and gastrointestinal health. The identification of Streptococcus, Bacteroides, Pseudomonas, and TM7x species by all three ML models may indicate an association with COVID-19 or other diseases with similar symptoms. The accuracy rates of the LightGBM, Random Forest, and XGBoost algorithms are 1, 0.935, and 0.978, respectively. These findings have important implications for the potential use of these models in future research related to COVID-19 and related diseases. Conclusion: We have successfully created three machine learning models that can quickly diagnose COVID-19 infection using metagenomics data from the human gut microbiome. This methodology has the potential to be applied to other diseases as well.

Session Title: Omics Technologies Poster Session II

PB3329 Benchmarking enzymatic library preparation workflows in a PCR-free whole genome sequencing context

Authors:

P. Benson, J. Haimes, Z. Jaafar, T. Harrison, S. Mishkin, A. Gaines, D. Wendel, K. Giorda, M. Ranik, B. Kudlow; Watchmaker Genomics, Boulder, CO

PCR-free libraries are considered the gold standard for whole genome sequencing (WGS) with minimal bias. These libraries should contain appropriate insert lengths to make efficient use of 2x150bp read structure; however, size selection must retain yields that will efficiently cluster on the sequencer. Clinical samples are often scarce, thus balancing yield with size selection is an important consideration when selecting a WGS workflow. This study describes the ideal parameters for PCR-free WGS library preparation using eight commercially available library prep solutions, and assesses the sequencing data quality of each one.

PCR-free libraries for WGS were prepared from NA12878 using seven enzymatic fragmentation chemistries and one sonication-based workflow. Libraries were created from 300ng of input, varying size selection parameters to make libraries of similar size. An additional Watchmaker library was prepared from 75ng of input, to demonstrate the workflow's scalability and to determine the minimum viable input. Libraries were generated using both single and double-sided size selection to assess the benefits of removing long library molecules. The libraries were sequenced by 2x150 reads on a NovaSeq 6000, targeting 30X coverage.

Out of all chemistries surveyed, Watchmaker had the highest post-size selection yield by a factor of almost 2. The 75ng input into Watchmaker produced yields comparable to 300ng inputs into commercially available enzymatic fragmentation products. The Watchmaker libraries minimized adapter sequences, indels, softclips, chimeras, improper pairs, and hairpin artifacts identified in the sequencing data. Indicators of variant calling accuracy were consistent with the highest performance workflows. Watchmaker libraries had the highest coverage at difficult-to-cover promoter regions (Ross et al., 2013).

The Watchmaker DNA library preparation workflow offers significantly improved PCR-free yields while minimizing sequencing biases and artifacts. This increases the number of clinically relevant samples that can achieve the desired coverage depth for WGS.

PB3330 Benchmarking genotype-based demultiplexing algorithms in multimodal single-cell data

Authors:

T. Li[1], M. Alvarez[2], C. Liu[1], K. Abuhanna[3], Y. Sun[1], J. Ernst[2], K. Plath[1], B. Balliu[2], C. Luo[1], N. Zaitlen[2]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]UCLA, Los Angeles, CA, [3]Dept. of Human Genetics, David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Multiplexed single-cell sequencing has become a popular experimental design choice to reduce technical variation and sequencing costs. Genotype-based demultiplexing algorithms are a class of methods developed to infer cell-level individual identity and remove doublets without further sequencing. These methods have been benchmarked in single-cell RNA-seq data based on their ability to discriminate doublets. However, these methods are not well understood in other single-cell sequencing assays, such as ATAC-seq and 10X Genomics' joint RNA/ATAC-seq, nor have they accounted for ambient molecules in their modeling. Furthermore, it remains unclear if leveraging variant information from both modalities leads to more accurate deconvolution. To address these challenges, we developed ambisim, a novel read simulator that generates data similar to a 10X Multiome experiment based on user-input proportions of singlets, doublets, and ambient molecules, which allows us to control contamination rates and establish a ground truth for cell assignments. In addition, we develop a novel metric, variant consistency, to estimate lower bounds of ambient molecule contamination in cells. We then evaluated the performance of five widely-used demultiplexing algorithms in both simulated and real 10X Multiome data from a fibroblast to iPSC reprogramming trajectory, multiplexed across four samples.In simulations, we find that all demultiplexing methods cannot accurately classify droplet status in RNA-seq (min AUC = 0.55, max AUC = 0.62) and ATAC-seq (min AUC = 0.56, max AUC = 0.65) based on realistic proportions of singlets, doublets, and ambient molecules. In real data, the agreement of individual assignments between demultiplexing methods within and across modalities is low (average 75%), with most discordant calls arising from singlet vs. doublet cell classification. Finally, our variant consistency metric shows that deeper sequenced variants from ATAC-seq have upwards of 5-fold less contamination than RNA-seq, highlighting ATAC-seq's utility for demultiplexing. Taken together, our results suggest that all existing algorithms perform poorly in multimodal single-cell data and that new ambient molecule-aware demultiplexing algorithms are necessary to recover higher quality cells.

PB3331 Best practices for perturbation MPRA-a comprehensive evaluation of sequence design strategies

Authors:

J. Liu[1], T. Ashuach[2], F. Inoue[3], N. Ahituv[2], N. Yosef[4], A. Kreimer[1]; [1]Rutgers Univ., Piscataway, NJ, [2]UCSF, San Francisco, CA, [3]Kyoto Univ., Kyoto, Japan, [4]UC Berkeley, Berkeley, CA

Perturbation-based massively parallel reporter assays have enabled the identification of functional elements within non-coding genome regions. However, the gold standard of perturbation sequence design methods remains scant. Here, we utilize a publicly available dataset we recently generated of both wild type (WT) and perturbed (PERT) sequences. The perturbed sequences were carefully designed to target transcription factor (TF) binding motifs in regulatory regions, using three different perturbation approaches. The first two perturbation approaches replace the motif with a constant non-motif sequence while the third approach randomly scrambles the motif's nucleotides. The MPRA readout of each perturbation sequence consists of a) functional regulatory sites (FRS) identification: a multiclass label indicating whether is a functional or non-functional site; b) regulatory effect (Log2FC): a numeric variable.

We first define metrics to assess and compare the effect of the perturbation in each method. We next extract sequence based features of WT and PERT sequences, and subtract the corresponding WT features from each of the PERT features. We use these feature differences as input for several prediction models with FRS identity labels and Log2FC as target values in classification and regression models, respectively.

We find that the third perturbation approach has higher specificity for targeting the motif and the lowest number of net motif change. Moreover, we find that the non-linear models exhibit high robustness for classification and regression in the three perturbation approaches, with the third perturbation outperforming the first two.

Overall, our results suggest that modeling perturbation-based MPRA output is robust and that the random nucleotide shuffling model can serve as a framework for such assessments, leading to improvements in MPRA experimental design.

Inst. and Dept. of Pathology and Lab. Med., Univ. of British Columbia, Vancouver, BC, Canada, [7]Royal Columbian Hosp., New Westminster, BC, Canada, [8]Canada's Michael Smith Genome Sci. Ctr., Vancouver, BC, Canada, [9]Ctr. for Psychiatric Genomics and Dept.s of Genetics, Psychiatry, and Epidemiology, Univ. of North Carolina, Chapel Hill, NC, [10]Dept. of Psychiatry and Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada, [11]Dept. of Psychiatry and Neurology (Med.) and Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada, [12]Dept. of Psychiatry, Michael Smith Lab., and Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada

The Metabolic & Genetic Explorations in Refractory Schizophrenia (MAGERS) study is a pilot clinical, -omics and genetic counseling research project conducted in 50 participants with severe, treatment-resistant schizophrenia or schizoaffective disorder. As individuals with severe psychosis are more likely to harbor rare variants of large effect, we set out to identify candidate genetic drivers with the potential precision medicine implications.
All participants underwent deep medical and psychiatric phenotyping, neurological and dysmorphological exams, extensive biochemical/metabolic screening, and a cytokine and inflammatory marker panel; and clinical chromosomal microarrays (CMA). In the first phase of the project, we performed 10x Genomics linked-read whole genome and Illumina short read whole blood transcriptome sequencing on the first 25 participants. Here, we report a comprehensive bioinformatics investigation of the available data.
We developed a variant annotation and prioritization pipeline, which incorporates data from multiple genomic databases and leverages existing tools, such as GATK, Ensembl VEP and Long Ranger. The initial variant prioritization was done using a comprehensive set of criteria, aligned with current industry standards. SNVs and indels were validated using RNAseq data and visually inspected in the IGV browser. Structural variants were compared with CMA calls and validated visually in the Loupe browser. STRs were called with ExpansionHunter. We used both WGS and RNAseq data to compute allele-specific expression, by generating personalized phased haplotypes to which RNAseq reads were aligned. Significant allelic imbalances were inferred using ANEVA-DOT and GTEx whole blood expression data as background.
Finally, we used RNAseq data to search for expression and splicing outliers within our cohort. We used a combination of simple statistical approaches and existing tools, such as FRASER, to identify the most likely candidates for further investigation.
While results prioritization was challenging due to the lack of parental data, and the fact that very few genes have solid genetic evidence for conferring risk, our comprehensive bioinformatics investigation, aided by tools including SCHEMA, Franklin, and Varsome and intensive genotype-phenotype correlation, led to the identification of multiple candidate genes potentially relevant to schizophrenia neurobiology
(including *SETD1A*, *FOXP1*, *AIFM1*, *MDGA1*, *TENM1*, *TENM2*, and *CNOT1*). Overall, 6/25 (24%) of participants harbored a pathogenic/likely pathogenic sequence variant, 2 more had pathogenic CNVs, and all cases harbored at least one intriguing VUS.

PB3333 Biometric, Information Management and Sharing Strategy to success a Clinical Trial

Authors:

A. Diarra, O. Guindo, M. COULIBALY, B. MARIKO; Univ. Clinical Res. Ctr., Bamako, Mali

Background: Persistent clinical trial data management problems are slowing trials, sparking U.S. Food and Drug Administration (FDA) audit findings and 483s, and putting patients at risk. Many of these problems can be mitigated from the beginning, when a patient attends a clinical research trial for the first time. Objective: Biometric enrollment and verification of patients along the trial, visits management and automatic mobile real time dashboard reporting to ensure the patient safety and trial success. Methods: Centralized Information Management Solution utilizing biometrics to link clinical test subjects to their data at each stage of study, scheduled visits management and real time dashboard reporting for a better adherence of participants on scheduled visits, resulting in improved data management and more complete data. Scheduled visit management is key factor of success but can be relatively challenging with growing numbers of participants, multiplication of sites and duration of the trial. The system provides an extremely straightforward, secure, and accurate way to manage visits, share across study team in compliance with regulations on computer, smart phone. The system provides a dynamic study dashboard, a real time powerful Business Intelligent tool which helps streamline trial operations and improve efficiency in research, it provides also a fantastic report summarizing the number of screened, eligible, non-eligible and participants waiting into the circuit and gives the real time visit completion report by providing for each scheduled visit name, the number of completed, pending, and missed visits.
Conclusion: Our system has also many more useful management tools components such as: Workload prediction in different units during the planning visits, within the scheduled visits, in the sample management. With more accurate, reliable, and completed data, this innovation will result in more efficient development of vaccines for infectious diseases, as well as increased confidence in clinical trial findings.

PB3334 † Building the spectrum of ground truth genetic variation in a four-generation 21-member CEPH family.

Authors:

Z. Kronenberg[1], K. Munson[2], D. Porubsky[2], C. Nolan[1], W. Rowell[1], B. Pedersen[3], C. Fanslow[1], C. Lambert[1], N. Koundinya[2], W. Harvey[2], K. Hoekzema[2], J. Knuth[2], G. Garcia[2], T. Mokveld[1], E. Dolzhenko[1], S. Watkins[3], D. Neklason[3], A. Quinlan[3], L. Jorde[3], E. Eichler[2], M. Eberle[1]; [1]PacBio, Menlo Park, CA, [2]Dept. of Genome Sci., Univ. of Washington Sch. of Med., Seattle, WA, [3]Univ. of Utah, Salt Lake City, UT

Highly accurate long-read sequencing characterizes the full spectrum of genetic variation across the genome, but variant calling software is still catching up to the sequencing technologies. To develop long-read methods for calling difficult variants and variants in the genomic dark regions, it is important to have a comprehensive ground truth dataset for benchmarking. Until now, most benchmarking datasets were primarily built using short-read technologies that are limited to the easily characterized parts of the genome. We are developing a comprehensive truth set by utilizing the power of genetic inheritance within a four-generation family (CEPH pedigree 1463 plus a newly collected fourth generation) characterized with multiple sequencing technologies (PacBio, ONT, Illumina and Strand-seq) from blood-derived DNA. Large kinship pedigrees provide greater power to establish inheritance patterns when compared to trios; allowing us to adjudicate variant calls across the entire genome and not just in well behaved regions.

As a first demonstration of these data, we identified the chromosomal transmission from the parents (NA12877 & NA12878) to eight consented children. Combining the variant calls made by short and long reads, we identified 6,133,436 small variants (5,121,742 SNVs and 1,011,656 indels) that segregated consistently with the chromosomal transmission. Compared to current GiAB or Platinum Genomes benchmarking data we added an additional 18% and 10% small variants in NA12878, respectively. Our NA12878 long-read specific variants (245,997) were annotated with a high percentage of complex regions including 18% in segmental duplications, 35% in centromeric regions, 40% in repeats, and 7% unannotated. Similarly, in the diverse MHC region we note 43% (13,123 vs. 9,152) more SNVs in our truth set compared to previous work.

We identified that the long-read variants that failed our inheritance validation test mostly fell in centromeric and telomeric regions, where recent work by the T2T consortium is improving our knowledge of the genome. To understand the impact of a more accurate reference for long-read variant calling, we are repeating this analysis using the T2T-CHM13 reference genome. We will present on this ever-evolving benchmarking database including more complex variants such as an analysis of over 1M tandem repeats and an assessment of *de novo* variation where false positive and false negative rates can be assessed using the fourth generation of this pedigree. The sequence data, variant calls, and software required to rapidly benchmark new computational variant discovery tools will be freely available to the community.

Session Title: Omics Technologies Poster Session II

PB3335 Cell-free DNA metagenomic sequencing for pathogen detection and organ dysfunction monitoring.

Authors:

O. Mzava[1], A. P. Cheng[1], A. Chang[1], S. Smalling[1], L-A. Kounatse Djomnang[1], J. S. Lenz[1], R. Longman[2], A. Steadman[3], L. G. Gómez-Escobar[2], M. Salvatore[2], M. J. Satlin[2], M. Suthanthiran[2], J. R. Lee[2], C. E. Mason[2], D. Dadhania[2], E. J. Schenck[2], I. De Vlaminck[1]; [1]Cornell Univ., Ithaca, NY, [2]Weill Cornell Med., New York City, NY, [3]Global Hlth.Labs, Bellevue, WA

There is a significant interest in the use of metagenomic DNA sequencing to screen for infection. Yet, DNA contamination poses a major obstacle, as even small amounts of contaminant DNA can complicate the interpretation of the sequencing results. We have developed Sample-intrinsic microbial DNA Found by Tagging and Sequencing (SIFT-seq), a metagenomic sequencing assay that is robust against contamination. SIFT-seq tags sample-intrinsic DNA directly in plasma and urine with a chemical label that can be recorded via DNA sequencing. Contaminating DNA that is introduced in the sample after this initial tagging step can then be identified and eliminated. For tagging, we implemented deamination of unmethylated cytosines via bisulfite salt treatment of DNA. We applied SIFT-seq to screen for infections from microorganisms with low burden in blood and urine, to identify COVID-19 co-infection, to characterize the urinary microbiome, and to identify microbial DNA signatures of sepsis and inflammatory bowel disease in blood. Moreover, considering SIFT-seq uses bisulfite salt that is routinely used in standard Whole Genome Bisulfite sequencing (WGBS) to perform methylome analysis, we have shown that by leveraging the tissue and cell-type specificity of methylation profiles, SIFT-seq can be used to deconvolve the tissues/cell-types of origin of DNA molecules, enabling the inference of relative contributions of each tissue/cell-type within a DNA mixture. We have tested the utility of this assay in identifying sepsis-causing pathogens and monitor organ dysfunction in a cohort of sepsis patients (n=110) where timely and accurate identification of the sepsis-causing pathogens and precise monitoring of organ failure are critical for improved patient outcomes. We found a strong agreement between microbes detected by SIFT-seq and blood culture. Additionally, our analysis revealed a contribution of DNA from a diverse range of tissues and cell types, with the majority originating from Granulocytes. Furthermore, we observed signatures indicating solid organ damage in sepsis patients. Altogether we have demonstrated an assay that addresses the issue of environmental DNA contamination while simultaneously enabling monitoring of organ damage in patients.

PB3336 Characterization of cell type RNA isoform composition and alternative splicing events in the adult human cortex.

Authors:

Y. Hadas[1], X. Lin[1], B. Valdebenito Maturana[2], H. van Bakel[2,3,4], D. Pinto[1,2,3]; [1]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Dept. of Genetics and Genomics Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Icahn Genomics Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Dept. of Microbiol., Icahn Sch. of Med. at Mount Sinai, New York, NY

Genetic changes in regulatory regions play an important role in the etiology of neuropsychiatric disorders, resulting in dysregulation of gene expression and splicing. We have demonstrated that isoform-specific expression alterations and isoform networks in postmortem cortical tissue exhibit great effect sizes in psychiatric disorders, capture the largest genetic enrichments, and demonstrate substantial disease and cell type specificity. We have used long-read RNA sequencing (ISO-seq) to construct the highest resolution reference of full-length isoforms in the human prefrontal cortex (PFC) to date (IsoHuB), revealing thousands of novel isoforms at the tissue level. We further expand on this work by mapping isoform expression in the same brain region at a single-nucleus resolution. **Methods:** Full-length RNA isoforms of nuclei isolated from 13 postmortem PFC of control donors were profiled using four complementary sequencing methods including single nuclei RNA-seq (snRNA-seq, 9 donors), single nuclei ISO-seq (snISO-seq, 5 donors), multiplexed arrays isoform sequencing (MAS-ISO-seq; 4 donors) and switching mechanism at 5′ end of RNA template sequencing (SMART-seq-Pro, 4 donors). We added to our analysis publicly available cortical datasets of 8 snISO-seq and 4 SMART-seq-v4 controls. All the resulting sequences were aligned to our IsoHuB reference supplemented with GENCODE 41. The snRNA-seq data were used to quantify gene expression for cell type assignment, while long-read snISO-seq and MAS-ISO-seq data were used for isoform characterization and quantification. SMART-seq data were used for both. **Results:** A total of 106K nuclei across 25 donors passed QC. All 27 cortical cell subtypes, as defined by the PsychENCODE Consortium, were identified using each of the sequencing approaches, including excitatory and inhibitory neurons, glia, and immune cells. More than 160K distinct full-length isoforms were characterized and quantified using snISO-seq and MAS-ISO-seq data, and more than 300K isoforms were quantified using SMART-seq data. We further identified widespread differences in isoform expression and usage between PFC cell types, including isoforms with combinations of distant splice sites that cannot be resolved by short-read RNA-seq data alone. **Discussion:** We identified thousands of cell type-specific isoforms, many of which include novel isoforms in neuropsychiatric risk genes. Our results show that combining short-read and long-read RNA-seq at a single nuclei resolution is an efficient approach for characterizing cell type-specific isoform usage in tissues relevant to neuropsychiatric conditions.

Session Title: Omics Technologies Poster Session I

PB3337 Characterization of optimal protein quantification strategies for sensitive pQTL analyses in human blood plasma samples

Authors:

G. Venkataraman[1], Y. Huang[1], B. Lacar[1], A. Stukalov[1], J. Yao[1], L. Cantrell[1], J. Wang[1], H. Guturu[1], K. Motamedchaboki[1], M. K. R. Donovan[1], M. B. De Geus[2], S. Das[2], P. Kivisäkk[2], S. E. Arnold[2], A. Siddiqui[1], S. Batzoglou[1]; [1]Seer, Inc., Redwood City, CA, [2]Massachusetts Gen. Hosp., Boston, MA

Genome-wide association studies (GWAS) have associated millions of genetic variants with thousands of complex traits that likely act by modifying protein regulation. Protein quantitative trait loci (pQTL) analyses explicitly linking genetic variants to protein expression levels may offer insights into the mechanistic impact of genetic variation on complex traits. However, the large dynamic concentration range present in sample types like plasma makes it challenging to achieve the simultaneous coverage, throughput, and statistical power required for these analyses. Recent advancements in mass spectrometry (MS) proteomics (e.g. the development of the nanoparticle-based Proteograph™ XT [Seer, Inc.]) have facilitated deep, broad proteome analyses. As the application of nanoparticle-based MS proteomics to pQTL analysis is a relatively new advancement, comprehensive assessment of the impact of protein quantification strategy on pQTL results is required. Here, we explore multiple strategies and their impact on pQTL sensitivity.

In this study, we utilized the Proteograph™ XT workflow to identify and characterize pQTLs using blood plasma from 150 subjects (80 Alzheimer's Disease patients, 70 healthy controls). We systematically assessed pQTL sensitivity by surveying results from 121 protein quantification strategies. pQTL analysis was performed using PLINK v2.00a with age, sex, batch, and the first ten genetic principal components as covariates. Protein quantification strategies spanned various methods, including different protein grouping algorithms, filters for proteotypic peptides, normalizations across the protein quantifications, and summarizations of protein abundance from multiple nanoparticle measurements.

Our results showed that some quantification strategies yielded significantly improved pQTL sensitivity over others. Specifically, we found more pQTLs when data for each nanoparticle suspension was considered separately as opposed to summarized. Additionally, we found that using the "Top-N" approach to quantify proteins resulted in improved sensitivity over the "MaxLFQ" approach. There was a range (1-60) in the number of pQTLs found throughout the quantifications, emphasizing the importance of quantification strategy for downstream pQTL analyses; however, 224 of the 279 unique pQTLs found were replicated across quantifications. These results suggest that with the optimal quantification strategy, the application of the new, large-scale Proteograph™ XT workflow enables sensitive pQTL analyses for studying the genetic basis of protein regulation and its implications in human health and disease.

Session Title: Omics Technologies Poster Session II

PB3338 CLCLSA: cross-omics linked embedding with contrastive learning and self Attention for multi-omics integration using incomplete multi-omics data

Authors:

C. Zhao[1], A. Liu[2], X. Zhang[2], X. Cao[3], Z. Ding[2], Q. Sha[4], H. Shen[2], H-W. Deng[2]; [1]Michigan Technological Univ., Houghton, MI, [2]Tulane Univ., New Orleans, LA, [3]Michigan Technological Univ - Houghton, MI, Houghton, MI, [4]Michgan Technological Univ., Houghton, MI

Integrating heterogeneous and high-dimensional multi-omics data is of increasing importance in understanding genetic information. However, a major challenge in multi-omics data integration is the presence of unpaired data, resulting from variations in instrument sensitivity and cost. In this study, we propose Cross-omics Linked unified embedding with Contrastive Learning and Self Attention (CLCLSA), a deep learning method to integrate incomplete multi-omics data for multi-omics data classification. By utilizing complete multi-omics data as supervision, our model employs cross-omics autoencoders to learn feature representations across different omics data. Prior to latent feature concatenation, we leverage multi-omics contrastive learning to maximize the mutual information between different omics types. Additionally, we incorporate feature-level self-attention and omics-level self-attention mechanisms to dynamically identify the most informative features for multi-omics data integration. We conducted extensive experiments on four public multi-omics datasets to evaluate the proposed CLCLSA approach, including, ROSMAP, LGG, BRCA and KIPAN datasets with mRNA expression data, miRNA expression data and DNA methylation data. The experimental results indicate that our proposed CLCLSA produces promising results in multi-omics data classification. Our findings highlight the effectiveness of CLCLSA in addressing the challenges posed by incomplete multi-omics datasets, paving the way for improved understanding of complex genetic mechanisms.

Session Title: Omics Technologies Poster Session III

PB3339 Clinical Validation of AION: A Regulatory-Compliant AI platform for Variant Interpretation in Rare Diseases

Authors:

K. Ibañez[1], A. Bertana[1], E. Verdura[1], M. Schelker[1], J. Rayner[1], I. Lehtinen[1], R. Genomics England[2], D. Salvado[1], D. Neville[1], R. Acuna-Hidalgo[1]; [1]Nostos Genomics GmbH, Berlin, Germany, [2]Genomics England Res. Consortium, London, United Kingdom

Introduction

Genetic variant interpretation is critical in diagnosing rare diseases and guiding personalized treatments. AION is an AI-based software medical device designed to classify and prioritize genetic variants for automated variant interpretation. Regulatory compliance ensures medical software meets quality, safety, and reliability standards, building trust and leading to improved healthcare outcomes. To this purpose, we developed a streamlined regulatory-compliant evaluation pipeline for AION, our variant interpretation platform. Furthermore, we have conducted an external clinical performance validation study of AION using a sample from the 100,000 Genomes Project (100kGP) cohort.

Methods

We established validAION, a regulatory-compliant method for continuous assessment of AION's clinical, analytical and technical performance. Furthermore, our external clinical validation study included 318 individuals (57 singletons, 261 trios) with monogenic diseases and validated causative variant(s), diagnosed by a NHS Genomic Medicine Centre in the United Kingdom, with research consent and WGS data in GRCh37. Individuals with other types of causative variants (CNV, SV, STR, etc) were excluded. AION's sensitivity (detection of causative variants) and variant ranking were assessed.

Results

validAION enabled continuous validation and compliant implementation of changes in AION through rigorous evaluation processes across 1283 cases, including technical and clinical cohort evaluation, end-to-end production cohort assessment, and external clinical validation. In the external clinical performance validation, causative variants were detected in 91.3% of cases (95% CI=88-94), rising to 93.1% for trios (95% CI=89.4-95.6). Higher sensitivity was observed in the pediatric cohort (94%, 95% CI=89.5-96.9) and within the intellectual disability category (96.8%, 95% CI=91.0-99.3). In most cases analyzed, the top-ranked variant by AION was the diagnostic variant reported by clinicians across GMCs.

Conclusions

AION, a web-based variant interpretation software, utilizes genetic and phenotypic information to provide ranked molecular and clinical diagnoses. Our study emphasizes the importance of continuous assessment of AION's clinical, analytical and technical performance through a compliant and streamlined quality assurance process. The successful validation of AION using the 100kGP cohort demonstrates its potential to revolutionize variant interpretation and enhance patient care in the genetics field.

PB3340 Closing the gap: Targeting complex medically relevant regions of the human genome

Authors:

M. Mahmoud[1,2], H. Corbitt[3], J. Harting[4], X. Chen[4], S. Jhangiani[1], H. Doddapaneni[1], Q. Meng[1], C. Lambert[4], S. Zhang[4], P. Baybayan[4], Z. Kronenberg[4], T. Han[3], C. Riegler[3], J. Farek[1], G. Metcalf[1], R. A. Gibbs[1], M. A. Eberle[4], S. Kingan[4], C. Morrison[3], G. Henno[4], D. Muzny[1], F. J. Sedlazeck[1,2,5]; [1]Baylor Coll. of Med., Human Genome Sequencing Ctr., Houston, TX, [2]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [3]Twist BioSci., South San Francisco, CA, [4]PacBio, Menlo Park, CA, [5]Dept. of Computer Sci., Rice Univ., Houston, TX

Next-generation sequencing (NGS) has revolutionized personalized medicine. However, NGS still faces challenges in resolving complex genomic regions characterized by low mappability, extensive repeats, and large duplications. To meet these challenges, we present a cost-effective and scalable approach that combines DNA capture with long-read sequencing. This approach ensures highly accurate genomic analysis. We have developed a comprehensive panel of complex medically relevant genes to be coupled with the Twist target enrichment system. Additionally, we have developed an analysis workflow that leverages the advantages of multiplexed capture, HiFi sequencing, advanced mapping, assembly, and variant calling methods. This workflow also incorporates new, specialized tools. By combining these advancements, we achieved a higher accuracy in single nucleotide variant (SNV) and structural variant (SV) calling. The curated panel comprises 389 complete genes, including *LPA, HLA,* and *SMN1/2*. These genes have been associated with various medical conditions such as cardiomyopathies, neuropathies, and cancer. This framework can potentially enhance clinical applications for personalized medicine, leading to improved patient outcomes, while reducing costs. The approach was first assessed using 12 DNA reference samples, including the well-known HG002, all sequenced with a single Revio SMRT cell. Remarkably, the approach achieved an average gene coverage that was 1.4 times higher than that of HiFi whole-genome sequencing (WGS). This provided an approximate coverage of 38.34x per gene, compared to 26.78x for HiFi WGS. Additionally, our approach provided 1.10 Gbp of HiFi data covering 94% of the target regions with at least 8-fold coverage (HG002). The workflow provided high-quality variant calling even in these highly complex medically relevant regions, achieving 97% accuracy for substitutions, compared to WGS HiFi (97.53%). Regarding indels, we achieved an accuracy of 88% for deletions and 80% for insertions. Additionally, our SV calling demonstrated a high precision of 96% and an F1-score of 94%. We achieved an average gene coverage of up to 67x for the remaining benchmarked samples, accompanied by accuracy rates of 99% for substitutions and 95% for indels. These results highlight the reliability of this approach to accurately detecting variation in medically important genes. We will present data from HiFi WGS, Illumina WGS, and our panel from additional samples obtained from two programs: the HeartCare cardiovascular disease risk program and the GREGoR Mendelian disease discovery program.

Session Title: Omics Technologies Poster Session II

PB3341 Colocalization of proteomics and blood pressure GWAS signals identifies potential novel drug targets for treatment of hypertension

Authors:

A. Pozarickij[1], I. Millwood[1], N. Wright[1], L. Li[2], R. Clarke[1], Z. Chen[1], R. Walters[1]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Peking Univ., Beijing, China

Proteomics in diverse ancestries provides new opportunities to discover proteins related to human biology and disease, including potential drug targets. We assessed the relationship of the cis-pQTLs with blood pressure (BP) traits in the context of the China Kadoorie Biobank (CKB). We conducted genetic association analyses of 7,301 SomaScan aptamers in 3,965 CKB participants, identifying pQTLs for 4,958 (68%) aptamers targeting 4,256 (66%) proteins. Of these pQTLs, 1,487 (30%) were cis-pQTLs closer than 0.5 Mbp to the corresponding structural gene. We also conducted GWAS in 100,000 CKB participants of four BP traits - systolic and diastolic BP (SBP, DBP), pulse pressure (PP), and mean arterial pressure (MAP) - both with and without adjustment for BMI. We identified 18 protein cis-pQTL loci which included variants associated with at least one BP trait at P<5x10-6. The ARL3 and EFNA1 loci were associated with all four BP traits; conversely, seven cis-pQTL loci were BP trait-specific. We performed finemapping and colocalization analyses for each of these protein-trait pair using SuSiE and Coloc respectively and identified 41 shared signals (posterior probability >0.8) indicating potential causal relationships between protein levels and BP. These shared signals were further evaluated using two-sample bidirectional Mendelian randomization, using either the lead cis-pQTL variants or a genetic score derived from separate published BP GWAS performed in Biobank Japan. In some cases (e.g. GBA), we concluded that elevated BP caused higher protein levels, but not vice versa. For some other proteins (e.g. EFNA1) there appeared to be bidirectional causal effects. Notably, we identified several proteins with evidence for a unidirectional causal effect on one or more BP traits, including some proteins (e.g. ENPEP) with previous evidence for an association with hypertension; these joint signals may indicate novel potential drug targets for control of hypertension.

PB3342 Combined whole-genome and Sanger sequencing analyses of *GBA* revealed a pitfall depending on the reference human genome sequence.

Authors:

K. Orimo[1], J. Mitsui[1], T. Matsukawa[1], M. Tanaka[2], J. Nomoto[2], H. Ishiura[1,3], Y. Omae[4], Y. Kawai[4], K. Tokunaga[4], T. Toda[1], S. Tsuji[1,2]; [1]The Univ. of Tokyo, Tokyo, Japan, [2]Intl. Univ. of Hlth.and Welfare, Chiba, Japan, [3]Okayama Univ. Graduate Sch. of Med., Dentistry and Pharmaceutical Sci., Okayama, Japan, [4]Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan

Introduction: *GBA*, encoding glucocerebrosidase, is the causative gene for Gaucher disease. Furthermore, *GBA* variants that are causative for Gaucher disease are also associated with an increased risk of Parkinson's disease and multiple system atrophy (MSA). *GBA* locates near the highly homologous pseudogene (*GBAP1*), and gene-pseudogene rearrangements are not infrequently observed in patients with Gaucher disease, hence, identification of *GBA* variants by short-read sequencing is challenging. **Methods:** Genomic DNAs obtained from 502 cases of MSA were included in this study. We searched for *GBA* variants in these cases employing two pipelines, including short-read whole genome sequence analysis (NovaSeq 6000, Illumina) and Sanger sequencing. For Sanger sequencing, genomic DNAs were amplified using three primer pairs designed to selectively amplify exons 1-5, exons 5-8, and exons 9-11 of *GBA* but not *GBAP1* followed by direct nucleotide sequence analysis. In 170 cases, the reads were aligned to the reference GRCh38/hg38 (hg38) using BWA-MEM, and variant calling was performed using GATK4. In 332 cases, the mapping to hg38 and variant calling were performed using Clara Parabricks, a GPU-accelerated program that provides equivalent functionality to the BWA-MEM and GATK. Long read sequencing analysis employing PacBio Sequel II with circular consensus sequencing reads were further conducted to discriminate variants located in *GBA* and *GBAP1*. **Results:** While eleven kinds of variants were called by either of the pipelines, there were inconsistencies with the four variants. c.115+1 G>A (NM_00157.4) was called only by short-read sequencing. Long read sequencing analysis identified a structural variant in *GBAP1*, where exons 2-11 of *GBA* is inserted in *GBAP1*, resulting in calling c.115+1 G>A in *GBAP1* erroneously as a variant in *GBA*. p.K505K and p.L483P were only detected by Sanger sequencing, whereas p.A495P/p.V499V, which are located on the same allele, were only detected by short-read sequencing. These inconsistencies were due to the rare variants registered in *GBAP1* of hg38, which are identical to those of *GBA*. When hg38 is used in the mapping pipeline, inconsistencies in calling the variants of *GBA* were observed. Correct alignment was accomplished when hg19 was used as the reference genome. After validating the results, 3/502 (0.00598) cases carried p.L483P, which is higher than the previously reported incidence in control subjects (2/1509, 0.0013). **Conclusions:** We demonstrated the accuracy of variant calling may depend on the reference genome used in particular for genes with highly homologous paralogs and on the structural variants involving these genes.

PB3343 Comparative analysis of computational algorithms for spatial transcriptomics using REVEAL

Authors:

C. Bragdon, K. Sharma, M. Colosimo, J. Zahiri, Z. Pitluk, S. Sarangi; Paradigm4, Waltham, MA

Single cell multiomics sequencing has made impressive advancements in the past decade with rise of multiple techniques to profile the genome, transcriptome, and proteome. However, certain challenges persist - inducing stress responses, death, and aggregation in cells during the extraction process and loss of the spatial relationships (inter-cellular, cell-matrix, and cell clusters) due to spatial information not being captured. To address these challenges, spatial transcriptomics (ST) has emerged as a groundbreaking solution.Depending on the methodology, ST captures the transcriptional profile of individual cells or small groups of cells along with their spatial positions in relation to the tissue slice being analyzed. The spatial context provides invaluable insights into unraveling cellular phenotypes/cell states, novel cell types, physiological connections between cells, and the differences in physiology between healthy and diseased states. We had previously demonstrated a bioinformatics platform called REVEAL for storing, querying, and analyzing spatial transcriptomics datasets. Here, we extend that work by demonstrating a workflow in REVEAL for evaluating various analytical methods using numerous publicly available ST datasets. We tested an optimized version of the function AddModuleScore from the popular Seurat package. This function can be used to check expression of gene signatures, for example, a set of genes that characterize a particular cell state. Next, we performed a comparative analysis between AddModuleScore and another gene signature scoring algorithm called UCell. Finally, we show results from evaluation of SpaGCN - an algorithm that integrates gene expression, spatial location and histology to identify spatial domains and spatially variange genes by graph convolutional network.Advancement in computational tools and methods play a pivotal role in extracting meaningful biological insights from complex datasets such as ST. However, one of the challenges is often the ease of use for executing these different algorithms at scale across multiple datasets. Through this work, we highlight the application of a user-friendly workflow in REVEAL for evaluating multiple analytical methods.

Session Title: Omics Technologies Poster Session II

PB3344 Comparative analysis of multiple single-cell RNASeq platforms

Authors:

C. Kao[1], H. Qu[1], C. Hou[1], M. Hufnell[1], D. Slater[1], F. Wang[1], K. Wang[1], H. Hakonarson[1,2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Single cell transcriptomics, or scRNASeq, has experienced transformative progress especially within the last ~5 years, in large part driven by the accessibility of droplet microfluidics technology to partition each cell robustly into uniquely barcoded, individual gel-beads and encapsulating the cell/bead pair in an emulsion containing the requisite cDNA-generating reagents. The impact of scRNASeq on basic and translational studies in genomics and cellular biology has been exponential. However, a microfluidics platform requires the use of separate, specialized instrumentation which can be a bottleneck from both cost and technical perspectives. Recently, alternative scRNASeq platforms have become commercially available based on either successive split-pool barcoding techniques or proprietary emulsion reagents that generate single-cell/hydrogel droplets via self-assembly by mixing/vortexing. We performed scRNASeq using the following assays/platforms: 1) Parse Biosciences split-pool barcoding assay, 2) Scale Biosciences split-pool barcoding assay, 3) Particle-templated instant partition sequencing (PIP-Seq) from Fluent BioSciences, 4) 10x Genomics (10xG) Chromium single-cell 3’ gene-expression assay, v3.1, and 5) 10xG Chromium single-cell flex assay (v1). About 2,500-5,000 cells from 4 peripheral blood mononuclear cell (PBMC) samples derived from pediatric subjects with hypoplastic left heart syndrome (HLHS) were processed on each platform. Fixed cells were used for all assays except the standard 10xG 3’ gene-expression assay. The cDNA libraries generated from each type of assay were processed further according to manufacturers' instructions to generate Illumina-compatible sequencing libraries, then subsequently sequenced on the NovaSeq. For 4 of the 5 platforms, full-length cDNA libraries were generated, with the exception of the 10xG flex assay (which uses a probe-based method instead of priming and extension from 3’ poly-A tails). Thus, an aliquot from each full-length cDNA library was also processed and sequenced on Oxford Nanopore to generate long-read transcriptome datasets. The quality of both the short- and long-read transcriptome datasets were analyzed and compared, using the 10xG 3’ gene-expression assay as the benchmark. Additionally, the advantages and disadvantages/limitations of each platform with regards to processing and capture efficiency/input cell numbers were also assessed.

PB3345 Comparing HG38 to T2T-CHM13 and the need for new methods of annotation: non-syntenic genes, additional gene matches, and WASHC1 gone wild? Genomics. #itscomplicated

Authors:

M. Page, M. Wadsworth, B. Aguzzoli Heberle, J. Miller, M. Ebbert; Univ. of Kentucky, Lexington, KY

Background: In 2022, the T2T consortium released the first truly complete human genome, CHM13, that is already impacting genomics research—including resolving errors in hg38. For most genomics work however, a reference is only as insightful as its annotation. As CHM13 grows in popularity, understanding both structure and annotation differences between CHM13 and hg38 is critical to truly understanding what we have lost, gained, and changed with CHM13. Here, we highlight important differences between the two (including mistakes and oversights) not to criticize the excellent work already accomplished, but to demonstrate the need for improved methods and importance of accurate annotations. Here's the truth: Genomics. #itscomplicated, and we aim to help improve the human reference genomes and their annotations.
Methods: We compared annotations between Ensembl hg38 v101 & CHM13 UCSC GENCODEv35 CAT/Liftoff v2, identifying genes that were not strictly syntenic and chose one category to interrogate: non-syntenic genes (NSG). We BLAT'ed NSG sequences from hg38 to both the full CHM13 reference and back to hg38. We also compared to the newer CHM13 JHU RefSeqv110 + Liftoff v4 annotation after manually adding Ensembl IDs. Finally, we compared with long-read RNASeq.
Results: We identified 1,193 genes that were not strictly syntenic between hg38 & CHM13, including 68 NSGs (i.e., changed chromosomes). Of the 68 NSGs we verified only 39 matched CHM13 v2 annotations (requiring >90% identity); using liftover, however, only 9 matched. We also identified 229 additional unannotated BLAT matches from 9 NSGs, representing potentially 229 additional copies of these gene bodies. 6 NSGs were annotated >10kb larger in hg38 than CHM13. Comparing v2 with v4 annotations, 23,093 gene Ensembl IDs were missing in v4—likely because of compatibility challenges. Of the 68 NSGs, only 18 were found in the v4 annotation with gene ids. Some NSGs remained as annotated in CHM13 v2, some reverted to their original hg38 locus, some changed chromosome again, while others reverted to their original chromosome but were also duplicated elsewhere. *WASHC1* is an interesting example, where based on long-read RNASeq, none of the annotations appear accurate.
Conclusions: As the first complete genome, CHM13 brings powerful insights, but also highlights we still have much to learn. Specifically, our results suggest that there remain many inaccurate annotations across both references and liftovers can be wildly inaccurate, highlighting the need for better annotations and methods. Genomics requires more than just a reference—accurate annotations are vital to interpretation. In short, Genomics: #itscomplicated

Session Title: Omics Technologies Poster Session I

PB3346 Comparison of 5' and 3' capture techniques for performing pooled CRISPR screens in differentiated neurons.

Authors:

A. Anderson, B. B. Rogers, K. Trausch-Lowther, J. N. Cochran, L. F. Rizzardi, R. M. Myers; HudsonAlpha Inst. for Biotechnology, Huntsville, AL

Pooled CRISPR screens with single-cell sequencing, such as Perturb-seq and CROP-seq, have improved our ability to profile genomic perturbations and assess their individual effects on gene expression on a tremendous scale. The method of capture and barcoding of transcripts are a fundamental component of such assays that can have a significant impact on the interpreted results. 10x Genomics offers two methods for performing single-cell CRISPR screens. The first is their more established 3’ CRISPR assay, and the second is the newer and currently recommended 5’ CRISPR assay. We set out to identify any technical differences and confounding factors between using the 5’ and 3’ reagent sets for our future studies. We compared the performance of both kits under identical experimental conditions applied to CRISPRi screens in excitatory neurons (KOLF2.1J NGN2) with a pool of 130 targeted gRNAs and four safe harbor gRNAs profiling 16,472 and 20,750 cells in the 5’ and 3’ kits, respectively. We identified over 500 genes that were differentially measured between the two approaches. Additionally, we compared target genes that were significantly knocked down when the gRNA was present and found that the DEGs were often significant in both approaches. We observed similar rates of gRNA detection between the two approaches; however, the 5' kit exhibited significantly higher numbers of gRNA UMIs per cell than did the 3’ kit, increasing confidence in gRNA calls. Our findings provide a comprehensive comparison of the two approaches under controlled conditions and identified significant technical differences. These differences can be taken into consideration when making direct comparisons between previously published 3’ studies and future 5’ work. We demonstrate that despite these differences, the identification of knocked down target genes remains unaffected, ensuring the reliability of data generated using both kits.

PB3347 Comparison of structural variant calls from Oxford Nanopore haplotype resolved and telomere-to-telomere genome assemblies

Authors:

S. Mckenzie[1], S. Nurk[2], A. Dawson[2], S. Juul[3], P. Rescheneder[2]; [1]Oxford Nanopore Technologies, Spokane, WA, [2]Oxford Nanopore Technologies, Oxford, United Kingdom, [3]Oxford Nanopore Technologies, New York, NY

Structural variants (SVs), including large insertions and deletions, duplications, inversions, and translocations, represent a major source of genetic variation in human populations. These variants have historically been difficult to detect with array and short-read based approaches, however, hindering efforts to understand their importance in human health and disease. Modern long-read sequencing technologies have drastically improved our ability to identify and characterize SVs, recently culminating in complete "telomere-to-telomere" (T2T) *de novo* genome assemblies which can represent the full range of human sequence variation. Generating T2T genomes remains challenging and costly and requires a combination of multiple sequencing data types. It is therefore important to compare T2T assembly variant calling to other available methods - including raw read alignment and other haplotype-resolved assembly-based methods - to determine if and when T2T assembly is necessary.
Here we compare SV calls from alignment based, haplotype-resolved *de novo* assembly, and T2T *de novo* assembly approaches using Oxford Nanopore simplex and duplex whole genome sequencing data. We validate our calls against both Genome in a Bottle (GIAB) HG002 SV benchmarks and calls derived from the Telomere-to-Telomere Consortium's multi-technology HG002 assembly. We demonstrate very high accuracy SV calls from all approaches. Variant discovery accuracy within Genome in a Bottle high-confidence regions was comparable across the different approaches. However, sequence-resolved accuracy was higher for *de novo* assembly-based methods than current raw read alignment methods. *De novo* assembly approaches also showed higher concordance with Telomere-to-Telomere Consortium validation variants in challenging genomic contexts outside the GIAB high-confidence regions. T2T *de novo* assembly outperformed other *de novo* assembly methods, though the gains were marginal for the majority of SVs in most genomic contexts, therefore haplotype-resolved *de novo* assembly may strike the best balance between cost and accuracy for the majority of SV detection applications

Session Title: Omics Technologies Poster Session III

PB3348 Comprehensive characterization of V(D)J recombination using long-read transcriptome data

Authors:

K. Hu[1,2], Z. Chong[1,2]; [1]Dept. of Genetics, Heersink Sch. of Med., Univ. of Alabama at Birmingham, Birmingham, AL, [2]Informatics Inst., Heersink Sch. of Med., Univ. of Alabama at Birmingham, Birmingham, AL

V(D)J recombination, a genetic process in developing B and T cells, is crucial for generating the diversity of the immune repertoire. Novel long-read transcriptome sequencing technologies, such as PacBio Iso-Seq and Nanopore Direct RNA-seq, deliver full-length transcript sequencing reads. Unlike short reads, long reads can capture the entire V(D)J sequence in a single read, thereby enhancing the potential accuracy of V(D)J detection. This study introduces VDJCrafter, a robust pipeline specifically developed for in-depth analysis of V(D)J recombination in long-read transcriptomes. The pipeline begins by aligning long-read Iso-Seq data to the latest human GRCh38 reference genome using Minimap2. Following this, a bed file comprising V(D)J chromosome locations is created using GENCODE annotation. Subsequently, candidate long reads overlapping the V(D)J regions are extracted using the bed file, and then are aligned to the IMGT V(D)J database via BLAST, yielding a V(D)J gene list complete with sequences and annotations. Finally, CDR1 and CDR2 are generated on germline V genes by IMGT CDR consensus sequences and CDR3 through V(D)J assembly, and then are translated into respective amino acid sequences. The results of VDJCrafter performance on 12 Iso-seq datasets from HGSVC are compared with TRUST4, a short-read V(D)J identification tool. VDJCrafter successfully identified full-length V(D)J gene sequences that exhibited up to 100% alignment with known V(D)J sequences in the IMGT database. V gene subclasses from long reads showed approximately 60.74% overlap with short reads, while D gene and J gene detection demonstrated overlaps of roughly 96.42% and 100%, respectively, between long and short reads from the same sample. When examining the top enrichments of light chain recombination of immunoglobulin, 8 out of the top 10 recombinations were of the same type, with closely aligned percentages in long and short reads. These observations are supported by validation against short reads and the application of the standard immune repertoire from IMGT database. We also found that V(D)J genes in cancer samples displayed distinct types of enrichment compared to healthy samples, indicating that disease samples are likely to exhibit unique V(D)J recombination patterns. In conclusion, our findings suggest that long reads outperform short reads in V(D)J recombination identification with higher accuracy. The results above indicate that long-read sequencing provides more robust information to elucidate V(D)J recombination, potentially discovering novel genes and recombinations, thus enhancing our understanding of the immune repertoire in diseases.

Session Title: Omics Technologies Poster Session I

PB3349 Comprehensive, integrated long-read genomic, epigenomic, and transcriptomic characterization for solving the molecular basis of Mendelian conditions.

Authors:

M. Vollger[1], J. Korlach[2], K. Eldred[1], E. Swanson[1], J. Underwood[3], J. Ranchalis[1], Y. Mao[1], E. Blue[1], U. Schwarze[4], C. Saunders[5], A. Wenger[6], I. McLaughlin[7], A. Souppe[6], C. Lambert[6], A. Allworth[1], S. Chanprasert[1], I. Glass[4], M. Horike-Pyne[1], K. Leppig[8], E. Rosenthal[1], S. Sheppeard[1], S. Strohbehn[1], P. Byers[1], M. Bamshad[1], F. Hisama[4], G. Jarvik[9], T. Reh[1], Y. Sancak[1], K. Dipple[10], A. Stergachis[1]; [1]Univ. of Washington, Seattle, WA, [2]PacBio, Camas, CA, [3]PacBio, Seattle, WA, [4]Univ of Washington, Seattle, WA, [5]PacBio, San Diego, CA, [6]PacBio, Menlo Park, CA, [7]Pacific BioSci.s of California, Inc., Menlo Park, CA, [8]Kaiser Permanente of Washington, Seattle, WA, [9]Univ Washington Med Ctr., Seattle, WA, [10]Seattle Children s Hosp. and Univ. of Wash, Seattle, WA

Highly accurate long-read sequencing has the potential to dramatically enhance our understanding of the genetic basis of Mendelian conditions through the improved detection of genetic variation (e.g., HiFi sequencing), as well as the elucidation of the functional impact of genetic variation on RNA splicing (e.g., Iso-Seq), and gene regulation (e.g., mCpG detection and Fiber-Seq). To test the utility of these long-read approaches for evaluating individuals with Mendelian conditions, we combined HiFi sequencing, bulk MAS-Seq, and Fiber-seq to enable the simultaneous long-read multi-omic profiling (i.e., genome, methylome, chromatin epigenome, and transcriptome) of patient samples using a single sequencing run.

First, we developed a machine learning approach for Fiber-seq data to accurately assemble single-molecule chromatin accessibility, nucleosome positioning, and transcription factor occupancy using the N6-methyladenine stenciled-patterns produced during the Fiber-seq reaction. Application of this approach to GM12878 and HG002 cells permits the genome-wide identification of haplotype-specific chromatin architectures. In addition, Fiber-seq data retains highly accurate variant calling (SNV F1 99.94%) and the diploid de novo genome assembly capabilities from a single PacBio Revio sequencing run (contig N50s 36.3/28.8 Mb).

We next applied long-read multi-omic profiling to fibroblasts from a participant within the Undiagnosed Diseases Network (UDN) with unexplained developmental delay, polymicrogyria, sensorineural hearing loss, and bilateral retinoblastomas, with a known chromosome X-13 balanced translocation of uncertain significance. Long-read genomic data identified that the translocation causes NBEA haploinsufficiency, explaining her developmental delay. Long-read transcriptomic data identified that the translocation also creates a PDK3-MAB21L1 fusion transcript that is presumed to result in PDK3 gain-of-function, which inhibits pyruvate dehydrogenase activity, explaining her features associated with mitochondrial and pyruvate dehydrogenase dysfunction. Finally, long-read epigenomic data identified that the translocated chromosome containing both XIST and RB1 is subjected to X chromosome inactivation (XCI) in ~5% of cells, resulting in the silencing of the RB1 locus that is located 13 Mb away from the translocation breakpoint, thus representing the “first hit” for predisposing her to retinoblastomas. Overall, we demonstrate the utility of long-read multi-omic profiling for resolving the mechanisms underlying unsolved rare conditions.

Session Title: Omics Technologies Poster Session II

PB3350 ContextSV: A novel computational method for calling structural variants and integrating information across sequencing platforms.

Authors:

J. Perdomo[1], K. Wang[2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]CHOP, Philadelphia, PA

Structural variants (SVs) are genomic alterations generally larger than 50 bp which form the largest source of human genome variation. SV identification and characterization are important for gaining insight into the genetic basis of diseases: Identifying SVs associated with specific clinical phenotypes empowers clinical diagnoses and enables researchers to identify potential molecular mechanisms for these genomic alterations. Emerging long read sequencing technologies such as the Oxford Nanopore (ONT) and Pacific Biosciences (PacBio) platforms provide the resolution required to resolve larger and more complex SVs. Nevertheless, variable error rates in these technologies possibly result in a high false positive rate and low robustness for SVs detected using only long read sequencing data. The rich repertoire of available technologies, such as Illumina short read sequencing and Bionano optical mapping, can be leveraged to resolve these limitations. Here we introduce ContextSV, a novel structural variant calling method which uses a hybrid approach to achieve high-accuracy, robust SV calling: Long read sequencing data is used to identify SV candidates, while short read sequencing provides high-accuracy sites for resolving breakpoints in complex SVs, and optical maps are used as long-range scaffolds for high-quality read assembly prior to running SV detection algorithms. To improve accuracy, we train a binary classification model which is used to score candidate SVs based on coverage and genomic context, which are key features for SV validation. We then filter likely false positives by thresholding SVs based on score. Finally, we plan to incorporate support for pangenome graph reference formats in ContextSV: Pangenome graph structures can better represent common haplotypes in the human population relative to a single linear reference genome, and thus they would form a more comprehensive reference for identifying SVs. Large efforts led by projects such as the Human Pangenome Reference Consortium (HPRC) aim to release a pangenome graph reference representing a large, diverse set of human genome sequences, and thus there is a growing importance for future SV callers to provide support for these formats. In summary, our ContextSV method enables capturing large, complex SVs with high accuracy and robustness by leveraging information across multiple genome analysis technologies and using a machine learning model to compute confidence scores, while providing support for future developments in pangenome graph reference formats.

Session Title: Omics Technologies Poster Session III

PB3351 Cost-effective, high-resolution whole transcriptome sequencing for gene fusion detection applications

Authors:

J. Pavlica[1], J. Haimes[1], P. Benson[1], K. Reed[1], T. Harrison[1], N. Iremadze[2], D. Wendel[1], T. Clark[2], A. Kathiria[2], A. Jaimovich[3], B. Kudlow[1]; [1]Watchmaker Genomics, Boulder, CO, [2]Ultima Genomics, Newark, CA, [3]Ultima Genomics, Menlo Park, CA

As per-base sequencing costs continue to decline, there is less of a need to restrict reads to pre-identified regions of interest through targeted sequencing. This is particularly relevant for RNA analysis, where cost-effective sequencing allows for a hypothesis-free whole transcriptome sequencing (WTS) approach - useful for identifying new features such as gene fusions. We optimized the Watchmaker RNA Library Prep Kit with Polaris Depletion for sequencing on the Ultima Genomics platform, an ultra-high capacity, single-end read sequencing system, and evaluated the workflow for gene fusion detection via WTS.

The Watchmaker RNA-seq solution generates high-complexity libraries in under 4.5 hours, including rRNA depletion, and maintains stranded information via uracil incorporation during the synthesis of the second strand. During library amplification, the polymerase stalls at uracils resulting in amplification of only the first cDNA strand. To create a workflow compatible with Ultima, however, an alternate method for second strand removal is necessary. We optimized a uracil DNA glycosylase incubation process that works in tandem with the adapter ligation reaction, effectively degrading the second strand without increasing workflow time. Several workflow variables such as RNA mass, template quality, library insert size, and sequencing depth were evaluated to determine their impact on data quality and interpretation.

The UG 100 system can handle longer (300 bp and greater) reads, which is advantageous for accurately mapping split reads important for fusion detection. We evaluated various library insert sizes with both intact and FFPE RNA to understand the performance impact of longer inserts versus including shorter molecules to increase library complexity. We also evaluated the effect of insert length on sequencing quality metrics from the Ultima system, which employs emulsion PCR for clonal templating. We performed an impact assessment of insert size on key Ultima sequencing metrics, as well as final library complexity and fusion detection sensitivity. Overall, we demonstrated robust performance across a wide input range from 1 to 1000 ng, as well as with FFPE control materials. Overall, results indicate excellent compatibility of the Watchmaker RNA Library Prep Kit with Polaris Depletion solution with the Ultima UG 100 system for whole transcriptome sequencing applications, including fusion detection.

Session Title: Omics Technologies Poster Session II

PB3353 CRAM compression: Practical across-technologies considerations for large-scale sequencing projects.

Authors:

A. Al Ali[1], P. Kandavel[1], H. Al Mabrazi[1], G. Carvalho[2], V. Kusuma[1], G. Katagi[1], S. Elavalli[1], A. Yousif[1], M. Akhter[1], J. Mafofo[1], T. Magalhaes[1], J. Quilez[1], F. Al Marzooqi[1], The Emirati Genome Program; [1]G42 Hlth.care, Abu Dhabi, United Arab Emirates, [2]UCLA, Los Angeles, CA

CRAM is an efficient format to store high-throughput sequencing data and it has been widely adopted. We thus plan to use CRAM for the Emirati Genome Program, which aims to sequence the genomes of ~1 million nationals in the United Arab Emirates using short- and long-read sequencing technologies (Illumina, MGI and Oxford Nanopore Sequencing). We conducted a pilot study on the three technologies before start using CRAM at scale. We found CRAM achieved 40-70% compression depending on the sequencing platform. As expected, CRAM compression was data lossless and did not alter variant calls. In our cloud, we observed compression speeds 0.7-1.4 GB per minute, varying on the sequencing platform too. This translates into ~1-2 hours using a single CPU to compress a ~30X human whole-genome sequencing sample. Despite its wide use, we found little publicly available information about CRAM compression rate, speed, losslessness and parallelization, especially across many sequencing platforms. This work will have direct application for Emirati Genome Program and provide practical considerations for other large-scale sequencing efforts.

Session Title: Omics Technologies Poster Session III

PB3354 CRISPR/Cas9 depletion of high expression genes in human fibroblast samples increases the diagnostic potential for rare diseases

Authors:

R. Corona[1], G. Carvalho[1], L-K. Wang[1], A. Y. Huang[1], D. Ramachandran[2], J. Diaz[2], M. F. Khalid[2], O. Abinader[2], S. Ranganathan[2], A. Siddique[2], K. Brown[2], J. R. Armstrong[2], S. F. Nelson[1]; [1]UCLA, Los Angeles, CA, [2]Jumpcode Genomics, San Diego, CA

Whole genome sequencing (WGS) improves identification of rare variants compared to whole exome sequencing (WES), but diagnostic rates for rare genetic disorders remain modest. To enhance diagnostic yield, whole transcriptome RNA sequencing (RNA-Seq) is combined with WGS to assess functional consequences of genetic variation. However, RNA-Seq data is most useful for observing splicing, mono-allelic expression, or outlier expression of more highly expressed genes. This limits the global utility of using any one tissue source for RNA-Seq to augment WGS data. To partially improve observation of more low expression genes using RNA-Seq, we present an approach to selectively remove highly expressed genes from RNA-Seq on large scale by CRISPR/Cas9 cleavage and size selection to enrich the observation of mRNAs of lower expression transcripts. As implemented here, this method targets 4450 expressed genes (TPM > 30) in RNA-Seq data from cultured fibroblasts using 353,628 different guides. Virtually all genes are reduced in abundance in the treated library relative to the untreated library, and on average there is a 5-fold increase reads that are not targeted (TPM < 30) in the sequenced library, and the depletion of library fragments from highly expressed genes increases the number of genes observed above a TPM of 30 by 4,477 at similar sequence depth. Thus, large scale library depletion can increase the proportion of an RNA-Seq library of less well observed genes and results in enhanced assessment of rare splicing aberrations and allelic expression alterations, increasing interpretability of WGS data. Because there is high gene expression correlation across technical replicates within both the targeted genes and non-targeted genes, the method, in effect, broadens the dynamic range of RNA-Seq, and can be designed for any tissue type. This advancement provides a valuable tool for understanding and diagnosing rare genetic disorders, unraveling disease mechanisms, and identifying potential biomarkers and therapeutic targets.

PB3355 Cross-platform Hi-C meta-analysis identifies functional insulators that actively block enhancer-promoter interactions

Authors:

W. Xu[1,2], J. Cui[1,2], S. Zhang[1,2], L. Lu[1,2], X. Liu[1], Y. Li[1], F. Jin[1,3,4]; [1]Dept. of Genetics and Genome Sci., Sch. of Med., Case Western Reserve Univ., Cleveland, OH, [2]The BioMed. Sci. Training Program (BSTP), Sch. of Med., Case Western Reserve Univ., Cleveland, OH, [3]Dept. of Computer and Data Sci., Case Western Reserve Univ., Cleveland, OH, [4]Dept. of Population and Quantitative Hlth.Sci., Case Comprehensive Cancer Ctr., Case Western Reserve Univ., Cleveland, OH

Insulator protein CTCF controls genome architecture through forming thousands of cohesin-dependent structural loops. However, genome-wide studies only found mild transcriptional consequences upon acute CTCF-depletion, raising confusions about how CTCF regulates enhancer-promoter (E-P) interactions and gene expression. Here we reanalyze independent Hi-C, in situ Hi-C, and micro-C data in mouse embryonic stem cells upon acute CTCF-, RAD21-, and WAPL-depletion; DeepLoop is used to enable robust comparison of orthogonal Hi-C data at kb-resolution regardless of sequencing depth. All datasets show that most loops are lost upon CTCF depletion, but E-P interactions are enriched among the retained loops, and interestingly a small number of newly gained loops repressed by CTCF.From multiplatform Hi-C data, we identified several hundred recurrent events in which new E-P interactions form after the insulating CTCF loops disappear. We therefore define FINs (functional insulators) as CTCF sites that actively insulate their flanking sequences. In CTCF-depleted cells these newly gained E-P interactions require cohesin activity. WAPL-depletion causes relaxation of FIN loops and abolish insulator functions. Importantly, CTCF-repressed genes are enriched near FINs, but CTCF-dependent genes are enriched near TAD-boundaries. We also validated the transcription regulatory functions of several FINs with CTCF-blocking assays. Taken together, DeepLoop meta-analysis unifies multiplatform Hi-C data and demonstrated that FINs, but not TAD-boundaries, are bona fide insulators.

PB3357 Deciphering cell functions with micrometer precision, leveraging ultra-high-resolution spatial transcriptomics datasets

Authors:

Y. Si[1], C. Lee[2], G. Jun[3], S. Zöllner[1], J. Lee[1], H. Kang[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Genetics Dept. HMS, Boston, MA, [3]Univ. of Texas Hlth.Sci. Ctr. at Houst, Houston, TX

Recent advances in single-cell and spatial multi-omics technologies are rapidly improving the resolution of spatial transcriptomics. Microscopic-resolution (<1μm, compared to typical cell size 8~100μm) spatial transcriptomics technologies, such as Seq-Scope or Stereo-seq, assay transcriptomes over hundreds of millions of spatial barcodes per tissue section. Each spatial barcode, however, captures only a small number of genes, producing a notably sparse digital expression matrix. As a result, typical procedure in analyzing high-resolution spatial transcriptomes relied on fixed coarsely patterned segments or (nuclear) staining-based segmentations, compromising their microscopic resolution or expression information. To overcome these limitations, we developed an efficient computational method for cell function decoding at the level of individual spatial barcode (pixel) without requiring external, image-based cell segmentation. Our method annotates millions of unique pixels to cell functions or tissue conditions using stochastic variational inference under a model that resembles latent Dirichlet allocation.
We applied our method to the injured mouse colon dataset generated by Seq-scope and the mouse embryo dataset generated by Stereo-seq, which contain tens to a couple hundred millions of spatial barcodes spaced at ~0.5μm resolution. In mouse colon data, our pixel-level decoding method revealed the fine-scale architecture of colon tissue, profiling cellular heterogeneity in epithelial, connective tissue and smooth muscle layers responding to physical injury with remarkable preservation of tissue texture, such as smooth muscle orientation and colonic crypt organization. Different immune cell populations infiltrating into different tissue layers were also profiled at microscopic level. In the developing mouse embryo dataset, our method effectively captures spatially organized gene expression modules that represent cellular functions as well as developmental processes. It detects cell-level boundaries between as well as within tissues, and utilizes transcripts that were typically thrown out in conventional nuclear segmentation methods. Our method enables large scale inference of spatial transcriptomics fully realizing the potential of the microscopic-resolution of the cutting-edge technologies.

PB3358 Deep coverage full-length isoform characterization and quantification using highly accurate long-read sequencing

Authors:

D. Wissel[1], M. Mehlferber[2], V. Pavelko[2], F. Reese[3], M. D. Robinson[1], G. Sheynkman[2]; [1]Univ. of Zurich, Zurich, Switzerland, [2]Univ. of Virginia, Charlottesville, VA, [3]Univ. of California, Irvine, Irvine, CA

Long-read RNA sequencing resolves transcript structures at high resolution. Recent studies (Glinos et al. 2022, Abood et al. 2023) have shown the utility of long-read RNA sequencing data in interpreting the molecular mechanisms of disease-associated splicing, for example, by connecting GWAS-colocalized sQTLs with the impacted protein isoforms. Despite these developments, the high sequencing cost and lower throughput on previous PacBio systems have hindered scalable isoform classification and quantification over large numbers of samples and broader use in functional genomics.

Recently, a methodological breakthrough of an amplicon concatenation approach—MAS-Seq (Al'Kafaji et al. 2023) - has enabled an order-of-magnitude higher throughput in sequencing coverage while maintaining high read accuracy (average Phred 35). PacBio has recently commercialized this approach for bulk isoform sequencing, and in collaboration, we obtained MAS-Seq bulk Iso-Seq data on the PacBio Revio system of the WTC-11 stem cell line, covering 6 different time points (Day 0 through 5) with replicates (11 samples). We included strategic spike-ins of multiple SIRV and ERCC mixes and generated over 600 million full-length reads ranging from 100-10,000 bp (average: 2.5 kb). The transcript length distributions were similar to traditional non-concatenation libraries, and had CAGE and PolyA signal support, indicating a level of comprehensiveness of sampling of full-length transcripts that has not been reported before.

With this dataset, we address open questions about required read depth for isoform discovery, quantification, and read saturation, including read-number equivalence to Illumina data on the same samples. We detected 22,201 annotated genes and a total of 119,891 isoform models that were common across all samples. We detected 30,614 (25.5%) novel transcripts not found in the GENCODE comprehensive annotation. Data were highly reproducible (gene-level Pearson's r ranged from 0.93 to 0.96 across replicates). Rarefaction curve analysis revealed complete saturation of gene and isoform identification at 10-20M reads per sample, indicating future opportunities for multiplexing.

These samples also were subjected to deep coverage MS, and we will describe novel ORF prediction pipelines for patient-specific proteomics, concurrently capturing amino acid variants (de Souza et al. 2022, unpublished) in addition to splicing, for complex disease and cancer immunotherapeutic applications. These studies and rigorous benchmarks lay the groundwork for the application of population-scale transcriptome analysis for functional genomics and disease splicing analysis.

PB3359 † Deep long-read RNAseq in human brain identifies *de novo* RNA isoforms, novel gene bodies, and complex isoform diversity for Alzheimer's disease genes

Authors:

B. Aguzzoli Heberle[1], J. Brandon[1], M. Page[2], K. Nations[1], M. Wadsworth[1], K. I. Dikobe[1], S. Goodwin[3], E. Ghiban[4], R. Wappel[4], S. Mavruk Eskipehlivan[4], P. Nelson[1], J. Miller[1], J. Fryer[5], M. Ebbert[1]; [1]Univ. of Kentucky, Lexington, KY, [2]Univ. of Kentucky, Lexington, KS, [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY, [4]Cold Spring Harbor Lab, Cold Spring Harbor, NY, [5]Mayo Clinic, Scottsdale, AZ

Intro: We often discuss genes as if they have a single function, yet human genes average 7 RNA isoforms, potentially resulting in 7 distinct proteins/functions. Due to limitations in short-read RNAseq, researchers are forced to collapse all isoforms into a single gene measurement—a major oversimplification. Long reads, however, span entire RNA molecules in a single read, allowing accurate quantification of all isoforms, including de novo isoforms. Accurately quantifying isoforms further enables differential isoform expression analysis and reveals isoform diversity within a single tissue/cell—a major advantage over short reads, enabling researchers to begin discerning specific functions for each isoform within a "single" gene (e.g., two BCL-X isoforms: XL = anti-apoptotic, XS = pro-apoptotic). Here, we perform deep long-read RNAseq in human brain to: (1) discover all isoforms across all genes (including de novo gene discovery); and (2) begin exploring functions for individual RNA isoforms in human health and disease. Methods: We sequenced 12 frontal cortex postmortem aged human brain samples (6 Alzheimer's (AD) cases & 6 controls, 50% female) using 1 Oxford Nanopore PromethION flow cell per sample (~40M mapped reads/sample). Analysis included pychopper, minimap2, bambu, and DESeq2. We only report high-confidence isoforms/genes. Results: We discovered 267 new high-confidence spliced gene bodies expressed with median Counts Per Million (CPM) > 1 and 437 new high-confidence RNA isoforms in annotated genes (9 new spliced mitochondrial isoforms w/ 4 PCR confirmed), where 53 are from medically relevant genes, including MAOB and POLB. We identified 7042 genes expressing multiple RNA isoforms in one tissue, including key AD genes: MAPT (4), TARDBP (4), APP (5), PSEN1 (5), and BIN1 (8), demonstrating the diversity of a "single" gene and the need to determine individual isoform function. As proof of concept, we identified 23 differentially expressed isoforms (FDR $p < 0.01$ & $|log2FC| > 1$) between AD cases and controls, where the gene (all isoforms collapsed as a single measurement) was not differentially expressed. Conclusions: We identified hundreds of new high-confidence RNA isoforms and gene bodies, demonstrating significant gaps remain in our understanding of RNA isoform diversity. More importantly, we began to explore RNA isoform function for every gene by quantifying individual isoform expression levels in human brain tissue. We demonstrate that performing differential gene-level expression is important, but insufficient, and suggest that deep long-read RNAseq is necessary to understand the full complexity of transcriptional changes during disease.

Session Title: Omics Technologies Poster Session III

PB3360 Deep-learning based bulk RNA-seq deconvolution method recovers cell-type specific signals.

Authors:

C. Tang[1], Q. Sun[2], J. Wen[3], Y. Li[4]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]UNC-Chapel Hill, Chapel Hill, NC, [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [4]Univ North Carolina, Chapel Hill, NC

Bulk RNA-seq deconvolution is distinctly useful in revealing cell type specific (CTS) gene expression profiles by combining the advantages of bulk and single-cell(sc) or single-nuclei (sn) RNA-seq data. The former, available in target samples at tissue level, tend to have larger sample size and high signal-noise-ratio, while the latter, available as reference, are at single cell level resolution. Distinct from traditional cell-type-deconvolution methods that infer only cell type proportions for each target sample, we aim to estimate their CTS expression for every gene, by integrating with sc/sn RNA-seq reference. Here we propose DL-unmix, a deep-learning based method that utilizes sc/sn RNA-seq reference for model training and applies the trained model on target samples' bulk RNA-seq data to infer a sample by gene by cell type expression matrix. DL-unmix first constructs pseudo bulks from sc/snRNA-seq reference, and then builds a Deep Neural Network to predict its CTS expression without using the truth. After model convergence, bulk RNA-seq data with cell type proportions estimated using traditional deconvolution method will be treated as model input to obtain inferred CTS expression. Since it is challenging to accurately estimate CTS expression for all genes in each cell type, DL-unmix includes a pre-training process that solely utilizes the reference data to select gene-cell type combinations that can be "well inferred" to guide pre- and post-training filtering. For simulation-based evaluation of DL-unmix, we split mouse primary motor cortex snRNA-seq data as reference and target set, created pseudo bulks for the test set, and applied DL-unmixed and alternative methods (TCA and bMIND). With pretraining-guided filtering, DL-unmix demonstrates best performance: correlation between estimated and true CTS expression improves by up to 50%, compared to TCA/bMIND. We then applied DL-unmix to deconvolute ROSMAP real bulk RNA-seq data with ROSMAP 48-donor snRNA-seq data reference. As the downstream analysis, we identified differentially expressed genes (DEG) between Alzheimer's disease (AD) cases and controls for each cell type. We ran functional enrichment analysis for these CTS DE genes via g:Profiler. Among others, we found enrichment of the UDP-glucosyltransferase activity GO pathway for DEGs identified in astrocytes. The finding is consistent with previous studies which identified strong links between expression levels of glycosyltransferases and neurodegenerative diseases including AD. We believe DL-unmix will be a novel, valuable method for revealing CTS insights.

Session Title: Omics Technologies Poster Session I

PB3361 Detection and confirmation of structural variants in a human trio using three Next-Generation Sequencing technologies.

Authors:

K. Hilkert[1], T. Oleksyk[2], K. Shchubelka[1], W. Wolfsberger[1], S. O. Castro-Marquez[1]; [1]Oakland Univ., Rochester, MI, [2]Oakland Univ. - Biology, Rochester, MI

A structural variant (SV) is defined as a DNA rearrangement of more than 50 nucleotides such as inversions, translocations, insertions, and deletions. SVs, which can be called by long and short read sequencing, are a root cause and risk factor of various human diseases including autism, schizophrenia, and HIV. As a result, accurate detection is crucial for future diagnosis and treatment. Assessment of SV callers' reliability, sensitivity, and precision has revealed that they may fail to detect SVs and report false positives. Understanding the precision and accuracy of SV callers is important as a trade-off exists between the two for identifying SVs, for this reason, we require a more robust protocol for validation of such genomic events. Currently, there is no gold standard for how to call SVs from sequencing data. We hypothesize that some SVs will be falsely called by proprietary callers and the utilization of various technologies will highlight this low accuracy.

Our study utilizes whole genome sequencing and PCR product-based verification to evaluate the accuracy of SV callers by various sequencing and computational methods. A family trio was sequenced using several different technologies including long read Oxford Nanopore Technologies, along with that of Illumina and BGI short read approaches. Our efforts included combining data analyzed to detect and classify various SVs found in the trio. Raw sequencing data were interrogated for the presence of SVs, and the resulting dataset was then filtered to obtain variants of 50 nucleotides or greater in size. Next, the data from the various platforms were compared to evaluate their concordance. The resulting dataset of discordant SVs was verified using PCR for the purposes of independent validation.

Although concordance exists, a discrepancy is seen, highlighting the fact that we cannot rely on one technology for valid proof of an SV's existence. The accuracy of a single SV caller has inherent limitations, we found this roadblock is remedied by comparing SV callers combined with a PCR method of validation. This protocol has proven to be useful for increasing confidence to enable this methodology to be taken seriously in a future clinical setting.

Session Title: Omics Technologies Poster Session II

PB3362 Detection of *de novo* mutations in incomplete trio with missing parent information.

Authors:

S. Lee, M-h. Choi, J-W. Nam; Hanyang Univ., Seoul, Korea, Republic of

Trio-based (parent and child) whole genome sequencing studies have enabled the detection of de novo mutations (DNMs) by identifying mutations present in the child's genome but not in the parent's genome. However, the genomic information of both parents is often not available for various reasons. Here, we present a caller to identify DNMs when one or both parental genomes are missing. The unit of DNM calling in this situation is also a trio, but with the genomes of siblings replacing those of the missing parents, which are referred to as incomplete trios - "linear trio" takes into account two siblings instead of the missing parents, and "reverse trio" takes into account one sibling instead of one missing parent. For these scenarios, our method can call putative DNMs in genomic regions where both of a proband's haplotypes are found in other incomplete trio members. Hidden Markov Models are used to infer sibling inheritance states, and callable regions are classified based on a combination of inheritance states with careful filtering methods. Theoretically, DNMs can be predicted in 56.25% of a proband's genome for linear trios and in 50% of a proband's genome for reverse trios. Our method was validated on artificial incomplete trios from CEPH families consisting of multiple complete trios, showing an average precision of 75.3% and a recall of 89.2% for linear trios, and an average precision of 68.5% and a recall of 91.7% for reverse trios. The DNMs also showed a significant paternal age effect for both types of trios. We also estimated the sample size required in a case-control study to investigate the effect of a given exposure on the number of DNMs, which revealed that 92 linear or 110 reverse trios are required to detect a 5% difference in DNMs under current false positive rates. We believe that our work provides a practical means to detect disease-related DNMs in older probands, especially with sporadic late-onset disorders and in the absence of parental genomic information.

Session Title: Omics Technologies Poster Session III

PB3363 Detection of germline copy number variation from whole genome sequencing on UG100: A cost-effective and robust approach.

Authors:

T. Biniashvili, S. Pollock, D. Bogumil, G. Hornung, P. Winer, I. Soifer, O. Barad; Ultima Genomics, Newark, CA

Copy Number Variations (CNVs) play a pivotal role in genetic diversity and have been widely acknowledged for their clinical significance, particularly in relation to numerous genetic diseases. With the advent of whole-genome sequencing, there has been a significant breakthrough in uncovering copy number variants on a genome-wide scale, both in population studies and clinical applications.

In this study, we present a comprehensive pipeline, leveraging an optimized version of cn.mops, to accurately detect germline copy number variations (CNVs) using whole-genome sequencing data generated on the novel UG100 sequencing platform. To ensure reliable CNV calling for variants longer than 10Kb, we employed a cohort-based approach that effectively normalizes sequencing biases. To validate the accuracy of our pipeline, we conducted a thorough comparison of our CNV calls with those obtained from the NYGC cohort, consisting of samples from the 1000 Genomes Project. Notably, we achieved a high average precision and recall concordance of 98.5% for calls across all samples. It is worth mentioning that this concordance assessment was performed in an "apples-to-apples" manner, where the CNV calling tool was independently applied to each dataset, and the resulting CNVs were compared within the high-confidence regions.

Furthermore, we demonstrated the efficacy of our pipeline by successfully identifying known pathogenic CNVs in 16 clinical samples. These samples exhibited lengths ranging from 100Kb to 35Mb, as well as instances where entire chromosomes were affected. The associated diseases for these samples encompass a diverse spectrum, including DiGeorge syndrome, Miller-Dieker syndrome, Albinism, Angelman syndrome, Williams-Beuren syndrome, Smith-Magenis syndrome and Wolf-Hirschhorn syndrome. This validation underscores the robustness of our methodology and its potential in clinical settings.

Additionally, we showcased the versatility and cost-effectiveness of our approach by conducting analyses across a wide range of sequencing coverages, spanning from 5X to 47X per sample.

In summary, we present an optimized version of cn.mops using UG100 whole genome sequencing providing a robust and cost-effective method that holds promise for both research and clinical applications.

Session Title: Omics Technologies Poster Session I

PB3364 Different but similar: Systematic investigation of proteogenomic variation in men and women and relevance for human diseases

Authors:

M. Koprulu[1], E. Wheeler[1], N. Kerrison[1], S. Denaxas[2], H. Hemingway[3], N. Wareham[1], M. Pietzner[4], C. Langenberg[5]; [1]MRC Epidemiology Unit, Univ. of Cambridge, Cambridge, United Kingdom, [2]Inst. of Hlth.Informatics, UCL, London, United Kingdom, [3]UCL Inst. of Hlth.Informatics, London, United Kingdom, [4]Univ. of Cambridge, Cambridge, Germany, [5]Precision Hlth.care Univ. Res. Inst., Cambridge, United Kingdom

Sex is an important factor involved in almost all biological processes and profoundly affects human health and disease. The mechanisms underlying these differences remain largely unknown and have not been systematically studied. Here, we conducted a large-scale investigation of sex differences in the genetic regulation of the human plasma proteome across 4,979 protein targets assessed in 4,403 women and 3,945 men and their relevance for human disease.

Plasma levels of almost two-thirds (60.5%, n=3,105) of measured proteins significantly differed by sex, but genetic effects on protein targets were remarkably similar between men and women with very few (0.3%, n=15 of 4979) protein quantitative loci (pQTLs) showing evidence of statistically significant differences (heterogeneity p-value <1.01x10-11). Of the 15 identified sex-differential pQTLs, only one cis pQTL associated with PATE4 (prostate and testis expressed 4) showed sex dimorphic effects, i.e. different effect directions in men versus women. Heterogeneity of the most of the remaining 14 loci were driven by small differences in directionally consistent, significant effects in men and women. Systematic evaluation of associations between the identified sex-differential pQTLs and 1,312 disease outcomes did not reveal any significant heterogeneity between men and women (heterogeneity p-value < 3.8x10-5). Our results emphasise a conserved genetic regulation of the plasma proteome between sexes and suggest that differences in levels are not explained by germline genetic effects. With few exceptions, our results suggest that pQTLs identified in sex-combined analyses that provide greater statistical power can be utilized for downstream applications such as genetically guided drug discovery, validation and causal inference across sexes.

Session Title: Omics Technologies Poster Session II

PB3365 Dissecting cis-regulatory interactions in the Major Histocompatibility Locus using single cell CRISPR/dCas9-based regulatory element screening.

Authors:

L. Bounds[1], A. Barrera[1], M. ter Weele[1], E. Wu[2], S. Liu[1], S. Li[1], P. Giusti-Rodriguez[3], T. Reddy[1], Y. Li[2], R. Gordan[1], M. Love[2], P. Sullivan[2], A. Allen[1], G. Crawford[1], C. Gersbach[1]; [1]Duke Univ., Durham, NC, [2]Univ North Carolina, Chapel Hill, Chapel Hill, NC, [3]Univ. of Florida Coll. of Med., Gainesville, FL

The Major Histocompatibility (MHC) locus is the most SNP-dense region in the human genome and is linked with >100 polygenic disorders. However, it remains unknown which variants affect gene expression. To dissect cis-regulation within the locus, we performed noncoding CRISPR/dCas9-based regulatory element screening with targeted single-cell RNA-sequencing in human induced pluripotent stem cells (iPSCs), iPSC-derived neural progenitor cells (NPCs), and K562 cells. We designed a gRNA library targeting a union set of 537 putative regulatory elements (pREs) based on accessible chromatin regions across all three cell types and 44 previously identified POU5F1 enhancers with TSS-targeting positive controls and nontargeting negative controls for a total of 12,723 gRNAs. We engineered iPSCs, NPCs, and K562 cells to express the repressor dCas9-KRAB, and iPSCs and NPCs to express the activator dCas9-p300 and transduced each cell line with the gRNA library at high multiplicity of infection. We profiled 1.2 million single cell transcriptomes at seven to nine days post-transduction. To assign pRE-gene links, we performed differential expression testing between all cells in which a given gRNA was observed versus all cells in which a different gRNA was observed.

Across all five screens, we identified a pRE for 72.4% of genes detected in the locus and connected genes to 36.1% of all perturbed regions, with 53.7%-75.3% of pRE-gene pairs spanning <100kb and 9.0%-17.0% spanning >1Mb. For all cell types, the overlap of active histone marks increases as the pRE-gene link becomes more significant. Concordantly, 94% of pREs in K562 cells are also in accessible chromatin in that cell type. In contrast, 20%-40% of pREs in iPSCs and NPCs are not in accessible regions in these cell types and in some cases also overlap the repressive mark, H3K27me3.

We next investigated cell-type specificity. 63.8% of pREs displayed function in only one cell type and the iPSCs had the greatest number of unique links. Given the association of the MHC locus with schizophrenia (SCZ), we analyzed the overlap of SCZ GWAS SNPs with the linked pREs. We observed significant enrichment of overlap in the NPCs, but not iPSCs or K562 cells, consistent with the etiology of this disorder. Finally, we delivered individual gRNAs to the iPSCs and confirmed the change in expression of the linked target gene for 11/11 tested links. Collectively, this study clarifies the cis-regulatory landscape within one of the most complex and disease relevant regions in the human genome, characterizes shared and cell-type specific regulatory mechanisms, and reveals cell-type specific relevance to disease-associated genetics.

Session Title: Omics Technologies Poster Session III

PB3366 Distinct and overlapping metabolomic profiles across cardiometabolic diseases reveal converging points of disease etiology.

Authors:

J. Dron[1,2], J. Lee[1], A. Schuermans[1], S. Koyama[3], W. Hornsby[1], G. Peloso[4], P. Natarajan[1,2,5]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [3]Broad Inst. of MIT and Harvard, Boston, MA, [4]Boston Univ., Boston, MA, [5]Cardiovascular Res. Ctr., Dept. of Med., Massachusetts Gen. Hosp., Boston, MA

Cardiometabolic diseases often co-occur and share common risk factors. To reveal converging and distinct points of disease etiology, we utilized Mendelian randomization (MR) to identify metabolites with distinct and overlapping genetic associations between coronary heart disease (CHD), type 2 diabetes (T2D), chronic kidney disease (CKD), non-alcoholic steatohepatitis (NASH), non-alcoholic fatty liver disease (NAFLD), and hypertension (HTN). Genetic instruments (IVs) for 168 metabolites were selected from GWAS summary statistics of Nightingale NMR metabolomics in ~115K European individuals from the UK Biobank. IVs were selected to be significantly associated with the metabolite of interest (P<5e-8) and clumped into independent loci <10Mb (R^2 <0.001; based on the 1KG European reference panel). GWAS summary statistics for the outcomes of interest were obtained from non-overlapping FinnGen v9 samples, which included ~430K Finnish individuals. Two-sample MR was used to test for causal relationships between each metabolite and outcome. The inverse-variance weighted method was used for the primary analysis, and metabolites with directionally consistent effects across alternative MR methods (MR Egger, weighted median, weighted mode) were retained. MR revealed relationships between 139 (82.7%) metabolites with at least 1 of the 6 outcomes. CHD had a distinct risk profile, with 74.0% (60/81) non-overlapping metabolites mainly defined by low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) metrics. T2D shared 54.5% (12/22) metabolites with CHD and was defined almost exclusively by high-density lipoprotein (HDL) metrics. CKD shared 66.7% (6/9) metabolites with CHD, including 4 intermediate-density lipoprotein (IDL) metrics with effects in opposite directions for the two outcomes. NASH also had a distinct risk profile with 76.9% (10/13) non-overlapping metabolites and was primarily defined by larger VLDL particles and triglyceride content. Neither NAFLD nor HTN had exclusive lipid or lipoprotein associations. Simultaneous assessment of multiple diseases and metabolomics data enables the identification of key components of lipoprotein metabolic pathways relevant across diseases.

Session Title: Omics Technologies Poster Session I

PB3367 Diversion in endometrium adhesion pathway in Indian female with recurrent implantation failure (RIF)

Authors:

V. Chettiar[1], A. Patel[2], S. Chettiar[2], D. Jhala[3]; [1]Dept. of Life Sci., Sch. of Sci., Gujarat Univ., Ahmedabad, India, [2]GeneXplore Diagnostics and Res. Ctr. Pvt. Ltd., Ahmedabad, India, [3]Dept. of Zoology, Sch. of Sci., Gujarat Univ., Ahmedabad, India

Understanding implantation of embryo to endometrium is one of the most finely regulated processes required for successful pregnancy. Implantation in the uterus occurs in a limited time frame called the "window of implantation" (WOI) . Knowledge of predicting an accurate WOI in recurrent implantation failure (RIF) patients is still at infancy. There are many methods to predict WOI, recent method of choice being molecular gene expression evaluation of endometrial biopsy. To understand the gene expression profile in Indian females with RIF endometrial samples (n=34) and positive control (n=33) endometrial samples of females with successful IVF implantation in first two attempts, were collected during mid-secretory phase of hormone replacement therapy cycle, P+5 from the females between the age group of 28 to 35 years. Case history of each patient were studied in detail, samples were subjected to RNA isolation and were taken forward for microarray based expression profiling. Results were evaluated using GeneSpring software (Agilent, USA) for adhesion pathway analysis followed by validation experiments. Total of 133 genes were analyzed, of adhesion pathway for their direct and indirect influence on endometrial positioning for implantation. Results revealed major number of differentially regulated genes belonging to different group of cadherin, claudins, Major histocompatibility complex, integrins and chemokine (C-C motif) in females with RIF. Genes involved showed significant role and evaluating their expression profile it can be useful as candidates for biomarker to predict WOI. This study can pave the way for identification of group of genes in Indian female using cost effective techniques like RT-PCR that will make the testing protocol affordable to larger fraction of population.

Session Title: Omics Technologies Poster Session II

PB3368 Efficient computational pipeline for processing and analysis of single-nucleus transcriptome sequencing data

Authors:

P. NM[1], J. Bendl[1], D. Lee[2], G. Hoffman[2], J. Fullard[2], P. Roussos[2]; [1]Icahn Sch. of Med. at Mount Sinai, New York City, NY, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Revolutionising our understanding of gene expression at the single-cell level, single-nucleus transcriptome sequencing (snRNA-seq) enables researchers to analyse gene expression profiles from individual nuclei, providing valuable insights into cellular heterogeneity and complex biological processes. As snRNA-seq continues to advance, standardised analysis pipelines are increasingly important to effectively process and interpret the expanding volume of data generated.To address the challenges associated with diverse experimental and computational setup of snRNA-seq experiments, including the requirement for processing multiplexed design and configuration of high-performance computing (HPC) resources, we have developed a comprehensive computational pipeline. Built on Snakemake framework, our pipeline offers an easy setup, scalability, reproducibility for processing snRNA-seq data of any size, from one-off experiments to large-scale sequencing projects. The main pipeline steps include read alignment, quality control and generation of gene expression matrix. The pipeline outputs can be seamlessly used for subsequent analyses such as differential expression, pseudotime trajectories, and various quantitative trait loci (QTLs). The pipeline code and documentation are maintained through version control systems Github and Read the Docs, respectively.

The pipeline output includes convenient quality control plots, summary statistics, and a variety of generally useful data formats to set the groundwork for subsequent project-specific data analysis. Applying our pipeline to over 2,000 samples linked to neuropsychiatric and neurodegenerative disorders, including Alzheimer's disease, Parkinson's disease, schizophrenia, and bipolar disorder, we successfully handled the challenges of large-scale datasets.

In conclusion, our comprehensive pipeline for snRNA-seq enables efficient processing and interpretation of data. The successful application of our pipeline to thousands of samples associated with various neuropsychiatric and neurodegenerative disorders highlights its effectiveness in unravelling the molecular underpinnings of complex diseases.

PB3369 Efficient quantification of pattern similarity between spatial genomics and cell morphology

Authors:

Y. Yang, J. Hu; Emory, Decatur, GA

Spatial transcriptomics (ST) is a powerful tool for studying gene expression patterns in spatial context, complemented with tissue histology image. Despite the availability of various methods to integrate the gene expression and tissue histology imaging in ST, the lack of a gold-standard metric to accurately quantify the similarity between features across different modalities has been a limitation for data integration. There is a strong demanding to measure the pattern similarity across features from different modalities, which provides insights into the association between molecular profile and cell morphology and enhances our understanding of tissue organization and function. To address this, we introduce VOGC, a spatial pattern similarity measurement using variance of orthogonal gradient curve that effectively captures the pattern similarity of features from different modality in the spatial context. Our method starts from identifying the common regions indicated by different modalities. Next, within each domain, it characterizes the pattern of each features using gradient curves in two orthogonal directions. Then, we calculate the variance of the different curves for each direction in every domain, summing them up to quantify the dissimilarity between two comparing features. The maximum variance observed across all regions serves as an indicator of the highest level of feature disparity. VOGC has been evaluated on multiple datasets, and compared with other popular spatial pattern measurement, i.e., SSIM, spatial correlation and Moran's I. The results demonstrate that our method can better identify image features that exhibit concordance with gene expression as well as those that show dissimilarity than all existing metrics. VOGC can be further used to filter out image features dissimilarity to all gene expression patterns, which captured artificial effect such as blurriness resulting from loss of camera focus. VOGC serves as a bridge between gene expression patterns and tissue histology imaging in ST, providing a robust metric to assess the similarity of features across diverse modalities.

PB3370 Empowering immunogenetic analysis with Biofilter 3.0 via enhanced annotation and filtering capabilities.

Authors:

V. Truong, X. Li, S. Dudek, J. Wherry, M. Ritchie; Univ. of Pennsylvania, Philadelphia, PA

Autoimmune diseases are a growing global health concern, affecting approximately 4.5% of people worldwide. In addition, 25% of affected individuals suffer from multiple autoimmune disorders. While hundreds of genetic variants have been identified for the most common autoimmune diseases, the small effect sizes and limited explanatory power underscore the need for an integrative knowledge-driven approach. The body of knowledge for genetic and immunological information is vast and oftentimes overwhelming. We discuss how incorporating immune-relevant information can empower the discovery and interpretation of combinations of genetic variations based on prior immunological knowledge. In this work, we present Biofilter 3.0 which contains enhanced annotation and filtering capabilities for empowering immunogenetic analyses. Previous versions of Biofilter provided a convenient single interface for accessing multiple publicly available human biological databases stored within the supporting knowledgebase of the Library of Knowledge Integration (LOKI). We integrated additional public databases of autoimmune and immune-mediated information into LOKI to bolster existing information on genomic locations of SNPs, genes, ontological categories, and interaction pairs. Furthermore, we expanded the functionality of Biofilter to make it possible to leverage this prior knowledge in analyses. This approach yields a collection of functions which enable researchers to efficiently annotate, subset, and filter thousands of SNPs, genes, proteins, and genomic locations based on immunological criteria, including relevant immune terms, pathways, and/or diseases.

PB3371 Enhanced promoter occupancy of SUMO1 bound proteins in AC16 cells during hypoxia

Authors:

D. Sharma, C. Rai, M. Kumari, A. Kumari, R. Varshney, R. C. Meena; Defence Inst. of Physiology and Allied Sci., Delhi, India

Hypoxia and its intricate regulation is the epicenter of cardiovascular diseases. It triggers reactivation of the fatal gene programme, induces cardiac hypertrophic response, changes the composition of extracellular matrix, affects mitochondrial biogenesis and has an impact on myocardial contractility. Cellular energy demand and supply under hypoxic conditions is also regulated by post-translational modification of various proteins, which complicates studies on individual pathways. SUMOylation is one such transient post-translational modification where small-ubiquitin like modifiers (SUMO) get covalently attached to their target-proteins by a multi-step enzymatic mechanism. In addition to regulating diverse cellular processes and deciding the fate of proteins, SUMOylation is also known to maintain cardiac function and can protect against a hypertrophic response to cardiac pressure overload. However, the detailed transcriptional regulation of cardiac cell responses by SUMOylation during hypoxia, has not yet been fully determined. Here, we uncover a genome-wide relationship between global SUMOylation and chromatin-associated SUMOylation in AC16 cells exposed to hypoxic stress (1% O_2) for 24 h. To address this, we performed immunoassays and chromatin immunoprecipitation sequencing (ChIP seq) with SUMO1 antibody. Chromatin immunoprecipitation and its sequencing was done by our previously optimized protocol. Further to analyse and visualise the immunoprecipitated regions, MACS2 software was used for peak calling, followed by Cis-regulatory element annotation system (CEAS) tool for promoter analysis of regulated genes and gene region annotation. Also, the narrow peak files were further visualised in Integrative Genome Viewer. With the analysis, we found that global SUMOylation of proteins by SUMO1 was significantly decreased while chromatin-associated SUMO1 signals increased at promoter-transcriptional start sites in response to hypoxic stress. The number of peaks detected by MACS2 analysis were 10 fold more in hypoxia exposed AC16 cells, as compared with unexposed control. These peaks are associated with active chromatin regions including promoter, introns, exons and UTR's. The promoter occupancy of SUMO1 associated peaks was higher in hypoxic condition, which represents the enhanced SUMO1 binding to transcription factors. These observations provide evidence that SUMO1 might play a pivotal role in controlling the transcription in AC16 cells during hypoxic stress. These findings can be further analysed and validated to precisely identify SUMO1 bound targets for modulating hypoxic response in cardiovascular diseases.

PB3372 Enhancing Scalability and Consistency in Translational Multiomics with an Optimized Fixed-Cell ATAC-seq Method.

Authors:

R. Graham, M. Johnson, C. Mao, E. Louie, A. O'Hara, J. Kim, B. Niu, B. Sereni, D. Corney, C. Mozdzierz, H. Latif, G. Zhou; Azenta Life Sci., Burlington, MA

ATAC-seq has an emerging role in decoding mechanisms of gene regulation, offering valuable insights into pathology and treatment response in disease models for cancers, autoimmune conditions, and neurocognitive disorders. However, clinical adoption of conventional ATAC-seq methods has been limited by logistical hurdles, including time-sensitive processing of fresh samples and compromised viability of cryopreserved cells. These constraints, compounded by changes in open chromatin regions (OCRs) following cryopreservation, introduce unintended bias and pose obstacles for the translational impact of ATAC-seq experiments. Here, we introduce an optimized fixed-cell ATAC-seq approach to overcome these limitations and unlock new sample types for ATAC-seq analyses. Our solution improves and simplifies the workflow from sample collection to clinical deliverable. This allows for the investigation of a more diverse range of sample types and facilitates complex experimental designs including time course studies, drug efficacy screens, and cell differentiation analyses. To demonstrate the effectiveness of this method, we compared our optimized fixed-cell method with fresh and cryopreserved samples of GM12878 cells prepared in parallel. Remarkably, we observed consistent patterns of OCR enrichment at key regulatory elements across the three sample preparation methods. We observed consistent OCR enrichment across the promoter region of known highly-expressed B-cell genes including *CD48* and *LCP1*, underscoring this assay's potential for detection of key gene activity in disease models. Our optimized method also enhances compatibility with RNA-Seq data collection and integration, enabling the simultaneous study of chromatin and transcriptional activity from a single sample. In this study, RNA-seq pathway analyses revealed that the top 6 significant pathways are related to B-cell function and known B-cell diseases, demonstrating the opportunity to generate multiomic analyses with this fixed-cell approach. This novel ATAC-seq approach offers enhanced scalability and consistency over conventional ATAC-seq, and presents new opportunities for seamless and efficient multiomic data collection in clinical and research settings.

Session Title: Omics Technologies Poster Session I

PB3373 Estimating heritability of gene expression from single cell measurements by modeling intra-subject variation with linear mixed models

Authors:

Z. Xu, T. Amariuta; Univ. of California, San Diego, San Diego, CA

Heritability estimation has been extensively applied to understanding the genetic component of gene expression in bulk RNA-sequencing data. However, the role that genetic variation plays in regulating gene expression depends heavily on the cell type. Single cell RNA-sequencing techniques enable studies of cell-type-specific genetic regulation of gene expression at unprecedented resolution. Recent heritability estimation using single cell RNA-sequencing relies on aggregating reads across cells of the same individual (pseudo-bulking), leaving the potential value of modeling variation between single cell measurements completely unexplored. In this work, we aim to improve the power and accuracy of gene expression heritability estimation by leveraging per-cell measurements. To this end, we implement a new linear mixed model to explicitly account for the shared environment of cells within an individual. Our model partitions the variance of gene expression into intersubject (genetic) variance, intrasubject (cell-cell) variance, and random noise. We also propose a new restricted maximum likelihood estimation (REML) algorithm using a Poisson distribution to address the common model misspecification issue of applying Gaussian distributions to single cell RNA-sequencing data. Our model is designed to be computationally robust and efficient in finding the best estimation of variance terms via a combination of expectation-maximization (EM) and average information (AI) algorithms. In simulations, we generate heritable gene expression phenotypes across 100 individuals and a variable number of cells per individual to mimic single cell RNA-sequencing data. Cell-cell relatedness is approximated by the 2D UMAP projection of the gene expression data. We found that our model produces unbiased estimates of heritability and that modeling multiple measurements per individual greatly reduced noise in estimating small heritability (i.e., <10%, which is realistic for the heritability of gene expression attributed to cis variants). We observed a 98.9% reduction in heritability standard error when simulating 100 cells per individual compared to conventional pseudo-bulk analysis using GCTA. In real data analysis, we assess the validity of our method applied to the 1K1K single cell RNA-sequencing cohort of 982 individuals and 1.27 million immune cells. We anticipate that our approach will more powerfully quantify the genetic component of gene expression than pseudo-bulk analysis. This work is important for understanding cell-type-specific genetic regulatory mechanisms and co-regulation across fine-grained cellular populations.

Session Title: Omics Technologies Poster Session II

PB3374 Evaluating performance and applications of sample-wise cell deconvolution methods on human brain transcriptomic data

Authors:

R. Dai[1], T. Chu[2], M. Zhang[2], X. Wang[2], A. Jourdon[3], F. Wu[3], J. Mariani[3], F. Vaccarino[3], D. Lee[4], J. Fullard[4], G. Hoffman[4], P. Roussos[4], Y. Wang[5], X. Wang[6], D. Pinto[4], S. Wang[7], C. Zhang[8], C. Chen[2], C. Liu[1]; [1]SUNY Upstate Med. Univ., Syracuse, NY, [2]Central South Univ., Changsha, China, [3]Yale Univ., New Haven, CT, [4]Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Virginia Polytechnic Inst. and State Univ., Blacksburg, VA, [6]UTHSC, Memphis, TN, [7]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [8]Upstate Med. Univ., Syracuse, NY

Sample-wise deconvolution methods have been developed to estimate cell-type proportions and gene expressions in bulk-tissue samples. However, the performance of these methods and their biological applications has not been evaluated, particularly on human brain transcriptomic data. Here, nine deconvolution methods were evaluated with sample-matched data from bulk-tissue RNAseq, single-cell/nuclei (sc/sn) RNAseq, and immunohistochemistry. A total of 1,130,767 nuclei/cells from 149 adult postmortem brains and 72 organoid samples were used. The results showed the best performance of dtangle for estimating cell proportions and bMIND for estimating sample-wise cell-type gene expression. For eight brain cell types, 25,273 cell-type eQTLs were identified with deconvoluted expressions (decon-eQTLs). The results showed that decon-eQTLs explained more schizophrenia GWAS heritability than bulk-tissue or single-cell eQTLs alone. Differential gene expression associated with multiple phenotypes were also examined using the deconvoluted data. Our findings, which were replicated in bulk-tissue RNAseq and sc/snRNAseq data, provided new insights into the biological applications of deconvoluted data.

PB3375 Evaluating the genome-wide off-target edits mediated by CRISPR/CAS9 in human iPSCs

Authors:

D. Liu[1], S. Marlow[1], G. Nagappan[1], C-F. Xu[2], A. Cortes[2]; [1]GSK, Cambridge, MA, [2]GSK, Stevenage, United Kingdom

Background: Since its inception, CRISPR-Cas systems have been the core toolkit for targeted genome editing in research. One potential concern of CRISPR-Cas-based therapy is that the guide RNA may induce double-strand cleavages at off-target sites and thus generate unintended genetic alterations. Evaluating the scope and functional impact of such unintended edits is hence crucial for understanding phenotypic changes. In this study, we aim to provide a thorough view of the off-target events in targeted CRISPR-Cas experiments as well as the suggested workstream using whole genome sequencing (WGS). **Methods and results:** The human biological samples were sourced ethically, and their research use was in accord with the terms of the informed consents under an IRB/EC approved protocol. Human induced pluripotent stem cells (iPSCs) were subjected to CRISPR-Cas9 editing using pooled small guide RNAs targeted to two exons, with the intent of creating knockout of two target genes of interest either individually (single KO) or together (double KO). We performed short-read whole genome sequencing (WGS) of the genomic DNA from our derived iPSC clones.We assessed the suitability of three genomic analysis tools and selected GATK Mutect2 somatic variant caller as the preferable analysis pipeline for genome-wide editing evaluation. Mutect2 compared the pre- and post-editing WGS data on 30 iPSC clones (including 5 unedited wild type, 16 single KOs, and 9 double KOs) in genomic regions with in-silico (Cas-OFFinder) prediction of the guide RNA (gRNA) binding. The number of SNPs and Indels identified per clone ranged from 1 to 96 and 0 to 14, respectively. The majority of off-target changes overlap non-coding regions while a small number were missense or frameshift variants. We also identified genes that were frequently affected at a rate on par with the genes that gRNAs were designed for. We are following up on this data by undertaking a series of enrichment analyses and will report on the genomic features and biological networks disproportionally represented among the unexpectedly disrupted regions. **Conclusion:** This study provided benchmarking data and novel insights into the scope and impact of off-target events in CRISPR-Cas systems, which will be highly valuable in understanding phenotypic changes upon editing. By demonstrating the utility of GATK Mutect2 in the context of detecting unwanted editing events, we also expanded the use case of this widely used somatic calling pipeline.

PB3376 Evaluating the mouse neural precursor line, SN4741, as a suitable proxy for midbrain dopaminergic neurons: A lesson in obtaining genomic rationale for the use of in vitro models of human biology and disease.

Authors:

R. Boyd, S. McClymont, N. Barrientos, P. Hook, W. Law, R. Rose, E. Waite, J. Rathinavelu, D. Avramopoulos, A. McCallion; Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Since the emergence of next generation sequencing, a surge in technological advances has enabled various innovative approaches by which to study human genetic disease and evaluate novel therapeutic strategies. As multiomics data become more commonplace in human genetics research, it seems increasingly imperative to apply these technologies to validate and annotate model systems of human disease that accurately represent the biological context in which disease associated variants mediate their effects. To overcome ethical and technical limitations of in vivo models, model organism-derived cell lines are often employed to investigate disease mechanisms and therapeutic avenues. However, despite their ubiquitous use, many in vitro models lack contemporary genomic analyses supporting their suitability as surrogates of human disease.

One such proxy is the mouse neural precursor cell line, SN4741, which has been used to study genetic variation, cell signaling, transcriptional regulation, neurotoxicity, and therapeutic intervention in Parkinson Disease/PD for >25 years. PD is a neurodegenerative disease characterized by the progressive onset of motor and cognitive impairments due to accumulation of α-synuclein aggregates and loss of midbrain dopaminergic/DA neurons. PD disrupts the quality of life of >8.5 million people worldwide; therefore, it is crucial to determine the extent to which biological surrogates of this disease reflect the processes they are assumed to model.

Using a combination of classic and contemporary genomic techniques - karyotyping, RT-qPCR, scRNA-seq, bulk RNA-seq, and ATAC-seq - we characterized the transcriptional landscape, chromatin landscape, and genomic architecture of the SN4741 cell line to evaluate its suitability as a proxy for midbrain DA neurons in PD research. We found that SN4741 cells are polyploid and exhibit low expression of DA neuron markers. Transcriptional signatures suggest that these cells remain undifferentiated at a permissive temperature (37°C) and differentiate into immature neurons at a non-permissive temperature (39°C) - not DA neuron precursors, as previously suggested. Furthermore, the chromatin landscapes of differentiated and undifferentiated SN4741 cells lack concordance with open chromatin profiles of ex vivo, mouse E15.5 midbrain-derived DA neurons. Our data suggests that SN4741 cells may reflect early aspects of neuronal differentiation but are a less suitable proxy for DA neurons than previously thought. The implications of this study extend broadly, exemplifying the need for robust biological and genomic rationale underpinning the use of in vitro models of human disease.

Session Title: Omics Technologies Poster Session II

PB3377 Exploring mass spec proteomics data using REVEAL: an easy-to-use bioinformatics platform for comprehensive analysis

Authors:

K. Sharma, A. G. van der Velde, J. Zahiri, Z. Pitluk, S. Sarangi; Paradigm4, Inc., Waltham, MA

The crux of precision medicine is to use molecular tools to define biomarkers for diagnosis and disease targets for intervention, sometimes on individual scales. The basic informatics approach is to look for differentially expressed proteins (DEP) between normal and diseased samples. Mass spec proteomics has evolved to the point where recent advances have gained more than 10-fold sensitivity over traditional methods by leveraging numerous techniques like TIMs to enrich less abundant proteins. The fundamental roadblock to further progress is managing and manipulating the large datasets. Key challenges include - cross sample comparisons that are essential for DEP analysis, intrasample queries that easily capture the many to many relationships of protein group to protein to peptide, and research reproducibility to ensure tracking of data processing steps. Considering these issues, this study aims to evaluate alternative statistical methods and tools for detecting DEPs, while analyzing the advantages and disadvantages of employing different algorithms. We utilized REVEAL, a bioinformatics platform that enables easy loading and efficient storage of large multiomics datasets including mass spec proteomics, while providing APIs (REST, R, Python) to perform cross-dataset queries such as searching for protein and precursor signatures or mapping features between ontologies, among others. The primary dataset that we evaluated was a publicly available pan-cancer cell line proteomic map (accession number: PXD030304), which quantified 8,498 proteins across 949 cell lines. In our workflow, the raw data format was converted using ProteoWizard followed by the generation of the intensity matrix using DIA-NN. Subsequently, the batch correction was performed using the Combat package. Finally, various statistical methods implemented in packages: limma, edgeR and deseq2 as well as Wilcoxon rank-sum test which were applied to the batch-corrected intensity. This study demonstrates how REVEAL serves as a solution for managing and analyzing large proteomics datasets, showcasing cross-dataset use cases and comparative algorithm analysis. With data exceeding 1TB, REVEAL effortlessly handles data loading and management in this case study. Additionally, we harnessed REVEAL: Features, utilizing its gene-protein mapping and accession number conversion capabilities for gene ontology (GO) and pathway enrichment analysis.

Session Title: Omics Technologies Poster Session III

PB3378 From Gene Regulation to Metabolites: A Multi-Omics Framework for Investigating Airway Hyperresponsiveness in Pediatric Asthma

Authors:

R. Sharma[1], S. Chu[1], R. Kelly[1], S. Begum[1], K. Mendez[1], J. Celedon[2], C. Clish[3], S. Weiss[1], J. Lasky-Su[1], M. McGeachie[1]; [1]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Children's Hosp of Pittsburgh of UPMC, Univ. of Pittsburgh, Pittsburgh, PA, [3]Broad Inst. of Massachusetts Inst. of Technology and Harvard, Cambridge, MA

Introduction Airway hyper-responsiveness (AHR) is a prominent feature of asthma, with complex molecular mechanisms involving multiple pathways. This study explores how changes in miRNAs and metabolites during childhood asthma may lead to changes in AHR. **Methods** In the Childhood Asthma Management Program (CAMP), we analyzed 564 children with asthma using longitudinal AHR (PC20) measures and plasma metabolomic profiling, among whom 491 children also provided serum for miRNA sequencing at baseline. Our aim was to uncover time-dependent interactions between metabolites or miRNAs and AHR. Linear Mixed models were used to assess the interactions between metabolite/miRNA and AHR adjusting for age, sex, race, treatment group and recruitment clinic, where interaction $p < 0.05$ was considered significant. Joint pathway enrichment analysis of miRNA and metabolites with significant interactions was performed with MetaboAnalyst V5. **Results** The mean ages at the three studied time-points across 16 years of follow-up in CAMP were 8.8, 12.8, and 17.4 years; the mean PC20 were 2.1 mg/ml, 7.7mg/ml and 11.6 mg/ml, respectively, indicating less AHR as children grew. Decreasing PC20 values was found to be associated with lower levels of lung function (prebronchodilator percent predicted FEV1, $p < 0.001$), asthma symptoms, and a subjective clinical staff assessment of asthma severity ($p < 0.001$). We found that 72 (14.4%) of the 501 identified metabolites and 72 (27%) of the 266 identified miRNAs exhibited a significant interaction with time on AHR. The joint pathway enrichment analysis of significantly interacting metabolites and miRNA target genes revealed the enrichment of several biochemical pathways that have been implicated in AHR development through impact on allergic airway inflammation, mucus hypersecretion, smooth muscle contraction, and oxidative stress. **Conclusion** Our findings provide evidence to support broad changes in metabolites and miRNA regulation of genes accompanied general clinical trends of asthma improvement and decreasing AHR in children with mild to moderate severe asthma. These omic indicators were enriched in pathways associated with key molecular mechanisms involved in AHR. Longitudinal multiomic analysis is likely to be informative in additional populations and conditions.

Session Title: Omics Technologies Poster Session I

PB3379 GenCompass: A cloud-enabled, accelerated, end-to-end workflow for analysis of large whole-genome sequencing (WGS) cohorts.

Authors:

L. E. Egolf[1,2], B. T. Jordan[1,2], B. D. Hicks[1,2], K. Jain[1,2]; [1]Div. of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD, [2]Cancer Genomics Res. Lab., Frederick Natl. Lab. for Cancer Res., Frederick, MD

Ultra-high throughput next generation sequencing (NGS) platforms have dramatically lowered the time and cost of genome sequencing, surpassing Moore's law. This has made population genetics studies feasible, driving a better understanding of the contributions of germline genetics across multiple disease areas. However, computational tools have not advanced as rapidly, and there is a need for accelerated pipelines to analyze data from large cohort studies. Bioinformaticians and data analysts frequently employ many small pipelines to analyze data, encountering difficulties in installation, lack of reproducibility, long runtimes, and unoptimized resource requirements. To address this challenge, we have developed GenCompass (Germline ENsemble Calling Of Mutations with Parabricks Accelerated Software Suite): a modular, resource-optimized, end-to-end comprehensive workflow consisting of NGS data preprocessing, Nvidia Parabricks GPU-accelerated mapping and ensemble variant calling using three popular germline callers, comprehensive quality control and reporting at each step, and variant annotation. This optimization yields a runtime of 3-4 hours and processing cost of $9 per 40x sample on cloud platforms using spot instances. Our workflow is system agnostic and uses standardized Docker images, GitHub, Workflow Development Language, and Cromwell for reproducibility. Here we present results from rigorous benchmarking conducted using guidelines from Genome in a Bottle (GIAB) and National Institute of Standards and Technology (NIST). We tested a total of 9 WGS samples from GIAB and synthetic diploid standard benchmarking datasets, downsampled to 40x coverage to represent a typical cohort study. GenCompass achieved a median F1 score of 98.4% for SNPs (precision 99.6%; recall 97.2%) and a median F1 score of 97.7% for INDELs <50 bases (precision 98.8%; recall 96.5%) genome-wide. Performance remained strong in difficult-to-call regions defined by GIAB for both SNPs (median F1 94.8%; precision 98.0%; recall 91.8%) and INDELs (median F1 97.1%; precision 98.5%; recall 95.8%). In contrast to other commercial and open-source pipelines that are either limited in scope, rely on a single variant caller, or lack thorough benchmarking for population studies, GenCompass offers complete functionality, performs ensemble calling, and is benchmarked with multiple whole genomes using latest community standards. Our open-source pipeline does not depend on any commercial license for software or proprietary hardware. Finally, GenCompass has been tested on WGS datasets up to 80X and can be extended to primary and secondary analysis of non-germline NGS datasets.

Session Title: Omics Technologies Poster Session II

PB3380 Genetic influences of gene co-expression using individual-specific networks without single-cell omics

Authors:

F. Melograna[1], B. Yousefi[1,2,3], Z. Li[1], E. Gervasoni[4], B. Schwikowski[2], I. Konigsberg[5], K. Kechris[6], P. Castaldi[7], M. Cho[8], K. Van Steen[1,4]; [1]KU Leuven, Leuven, Belgium, [2]Inst. Pasteur, Le Perreux-sur-marne, France, [3]Sorbonne Université, Paris, France, [4]Univ. de Liege, Liege, Belgium, [5]Univ. of Colorado, Denver, CO, [6]Colorado Sch. of Publ. Hlth., Aurora, CO, [7]Brigham and Women s Hosp., Cambridge, MA, [8]Brigham and Women s Hosp., Duxbury, MA

Reverse-engineered *individual-specific networks* (ISNs) (Kuijjer et al. 2019) from an aggregate network offer the opportunity to investigate the impact of individual-level network wirings, paths or connectivity on decision-making in the individual's interest. This work investigates the potential of Kuijjer's ISNs to identify *co-expression QTL epistasis* (co2-eqtls). To this end, we identified those zones in a collection of ISNs that exhibited the most significant heterogeneity in network wiring. Our approach uses principles of individual similarity assessment (Euclidian distances between spectral vectors), computation of a measure of ISN wiring heterogeneity (Fiedler values of symmetrically normalized Laplacians), and significance assessment of the subsystems (stepdown *maxT* algorithm). For each significant zone (a "HotZone") in this sense, we analyzed the weighted edges for their relationship to disease phenotypes. We subsequently prioritized the most promising disease-associated edges for co2-eqtl analysis with *MB-MDR* (Van Lishout et al. 2015), a data mining tool for large-scale epistasis detection. To construct individual-specific gene co-expression networks, we used *RNA-seq* data and 4,524 genes with a coefficient of variation of at least 1, adjusted for age, sex and clinical center, available for 2,655 Non-Hispanic White (NHW) and 1,024 African American (AA) smokers, part of COPDgene (www.copdgene.org). We observed 15 (16) significant HotZones in AA (NHW) of size 3-37 (3-33). In AA (NHW) 75% (64%) of Zones that significantly linked to FEV1 via their eigengene representations were Hot, indicating non-negligible stratification of individuals according to their ISNs. Standard and ISN edge analyses were found to be complementary. For NHW HotZones, 3% of edges were significantly associated to *FEV1* and covered 4 Zones. These Zones were enriched for *Reactome* pathways related to the immune system and transport of small molecules. The top FEV1 associated HotZone edges in AA and NHW involved the gene pairs (*OLIG2*-Novel transcript-antisense to *AJAP1*) and (*ABCG2* - *TSPO2*). We detected 40 (AA) and 201 (NHW) co2-eqtls in autosomal chromosomes (adjusted for main effects). Gene interaction networks exhibited varying network properties including hubs *PTPRF* (AA) and *GMDS-DT*, *PRKN*, *CNKSR3*, *LINC02432*, *RBM47* (NHW). Several examples highlighted varying relationships between gene co-expression and polygenic risk score by multilocus genotype profile. In summary, our results showcase that ISNs, even without single-cell omics, can increase our understanding of (genetic modifiers of) co-eQTLs as direct or indirect regulators of gene co-expression.

Session Title: Omics Technologies Poster Session III

PB3381 Genetic prediction performance of molecular traits is driven by their genetic architecture.

Authors:

F. Nyasimi, L. Yanyu, H. Im; Univ. of Chicago, Chicago, IL

Genetic predictors of molecular traits are powerful instruments to probe the biology of complex diseases. Gene expression traits represented as mRNA levels, splicing, and protein levels have been successfully predicted and linked to disease etiology using Transcriptome-wide Association Study (TWAS)-like approaches. However, these only represent a small fraction of the molecular scaffold connecting genotype to phenotype. Expanding genetic prediction downstream is essential to advance our understanding of the mechanisms that drive complex disease etiology.

For gene expression traits, given their sparse genetic architecture in cis, elastic net predictors have been shown to perform well. However, optimal prediction approaches for metabolite levels and other downstream traits remain less understood.

Here we propose a user-friendly software, Arch-Predict, to investigate the genetic architecture of these mediating traits and select the optimal prediction approaches. We use the performance of the elastic net family of prediction models that span the spectrum of sparse to polygenic (infinitesimal model) architecture to identify models that are more likely to perform well. Given a validation set, we provide a snakemake pipeline that will compare a suite of prediction approaches including a range of polygenicity levels in the elastic net family as well as several summary statistics-based approaches, including PRS-CS, lassosum, PRSice, DBSLMM, and LDpred.Application to metabolite levels and brain MRI-derived features showcased the utility of our pipeline. We found that for metabolites, sparse models outperform polygenic ones whereas for brain features, fully polygenic models provide better performance. Our pipeline will be of great value for researchers looking to develop their own prediction models.

Session Title: Omics Technologies Poster Session I

PB3382 Genome In A Bottle Mosaic Benchmark for HG002: Initiating MDIC's Somatic Reference Sample Program.

Authors:

C. Daniels[1], A. Abdulkadir[1], M. Cleveland[2], N. D. Olson[2], M. de Mars[1], J. Zook[2]; [1]Med. Device Innovation Consortium (MDIC), Arlington, VA, [2]Natl. Inst. of Standards and Technology (NIST), Gaithersburg, MD

A landscape analysis conducted by The Medical Device Innovation Consortium (MDIC) identified a lack of well characterized somatic variant reference samples and benchmarks for use in development of cancer biomarker diagnostics. The Somatic Reference Samples (SRS) Initiative was launched by MDIC to address this need by engineering clinically relevant somatic variants into the extensively characterized Genome in a Bottle (GIAB) sample HG002. To establish a baseline for the engineered cell lines, we first identified low frequency mosaic variants in HG002 by leveraging a novel trio-based approach with unedited GIAB genomes (HG002, HG003, and HG004) and the somatic variant caller, Strelka2. To determine that the Strelka2 variant caller was fit for purpose, we used *in-silico* mixtures of real data from HG002 and HG003 to establish the allele frequency limit of detection. Then, high coverage (300X) Illumina data from the Ashkenazi Jewish trio was used for low frequency variant detection in the son. Data from HG002 (son) was passed to Strelka2 as the tumor data and the combined parents' data (HG003-father and HG004-mother) was passed as normal. These HG002 variants identified with Strelka2 were subsequently compared against the Genome In A Bottle v.4.2.1 reference set, and complex variants causing artifacts were removed to create a draft mosaic benchmark. Candidate variants were evaluated by manual curation using the high-coverage (300X Illumina) trio along with four orthogonal datasets: PacBio HiFi, Element, BGI, as well as Illumina duplex sequencing data. We will next conduct an external validation by subject matter experts in mosaic and somatic variant calling using high quality mosaic variant callsets to confirm the draft mosaic benchmark reliably identifies false positives and false negatives. We expect this new benchmark to be particularly useful as a negative control for mosaic and somatic variants. This benchmark will also inform the sequencing and informatic methods we will use to characterize off-target edits and mosaic variants in the forthcoming somatic reference samples from the SRS Initiative.

PB3383 Genome Integrity assessment by optical genome mapping for cell manufacturing/bioprocessing applications

Authors:

A. Pang[1], A. Hastie[2], A. Chaubey[3]; [1]Bionano, San Diego, CA, [2]Bionano Genomics, San Diego, CA, [3]Bionano Genomics Inc., San Diego, CA

Cells and cell lines are used for multiple applications such as bioprocessing, therapy, and research. To ensure quality of cells and downstream applications, appropriate quality control (QC) methods are critical. Historically, karyotyping has been employed, but it is limited by its very low resolution and tedious laboratory workflow. Other methods such as PCR and targeted sequencing can characterize only small genomic variants at specific loci. Whole genome sequencing can detect small variants genome-wide but has limited sensitivity in detecting structural variants (SVs). Optical genome mapping (OGM) is a novel genome analysis technique that can fill many of the gaps in current capabilities for assessing genome integrity. To find clonal variants, 400 Gbp of data is collected from the parental/control and test samples. For both samples, a de novo assembly is constructed, and homozygous or heterozygous SVs are assessed. Subsequently, the dual variant annotation pipeline identifies unique SVs in the test sample compared to the parental sample. To discover subclonal SVs down to 5% variant allele fraction (VAF), the workflow leverages the generation of 1.5 Tbp of data, requiring a simple adjustment to longer data collection time. Comparison of test sample to parental sample enables easy determination of acquired variants. Finally, generation of ~5 Tbp of data, requiring 2-3 flow cells to be run, enables the detection of SVs at ultra-low VAF down to ~1%. In this study, several dilutions and simulations were performed to examine OGM's limit of detection. Targeting a coverage of 5 Tbp and analysis using the somatic SV-analysis workflow revealed that OGM has the sensitivity to detect deletions >50kbp, insertions >20kbp, duplications >100 kbp, and translocations at ~1% VAF. We have applied the clonal and somatic workflows to verify genomes' integrity after cell immortalization, induced pluripotency, transgene-integration, and gene-editing. The data using the robust and sensitive workflows demonstrate that the OGM platform is a cost-effective solution for cell manufacturing/bioprocessing QC applications.

PB3384 Genome wide CRISPR screen identifies ceramide-1-phosphate transporter as a regulator of the CLEAR gene network

Authors:

T. Han[1], A. Hirt[2], A. Kim[3], L. Allende[4], M. Kono[4], R. Proia[4], C. Tifft[1]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]NIH, Bethesda, VA, [3]NHGRI, Bethesda, MD, [4]Natl. Inst. of Diabetes and Digestive and Kidney Diseases, Bethesda, MD

The Coordinated Lysosomal Expression and Regulation (CLEAR) gene network contributes to cellular homeostasis by responding to changes in nutritional state, primarily through the activity of transcription factors TFEB and TFE3. Increased TFEB and TFE3 activity are associated with some cancer types, while overexpression of these transcription factors has been shown to alleviate the lysosomal storage phenotype associated with multiple neurodegenerative disease models. Thus, better understanding the regulatory mechanisms underlying the CLEAR gene network will lead to a better understanding of the pathophysiology of these diseases and identify potential therapeutic strategies. We performed a genome wide CRISPR knockout screen to identify genes and pathways that regulate the CLEAR network. Among the top hits from the screen was the ceramide-1-phosphate (C1P) transporter *CPTP*. This gene is of interest because several lysosomal storage disorders are caused by disruption of sphingolipid and ceramide metabolism. We generated a *CPTP* knockdown cell line that demonstrated altered lipid profiles, including elevated C1P and decreased ceramides, hexosyl-ceramides, and sphingomyelin. RNA-seq of our knockdown cells identified 24 differentially expressed CLEAR genes, one of which was *HIF1A*. Similarly, pathway analysis identified enrichment for several gene sets related to HIF1a activity, including hypoxia response, angiogenesis, and hypertrophic cardiomyopathy. Notably, pathway analysis did not identify enrichment of lysosomal or autophagy gene sets, suggesting that the CLEAR activation in this system occurs independent of those canonical mechanisms. Our study indicates that subsets of transcriptional programs exist within the CLEAR network that enable tailored responses to specific environmental stimuli. This further suggests that it may be possible to modulate individual CLEAR gene transcriptional programs based on the therapeutic strategy of interest, e.g. increasing lysosomal biogenesis and autophagy in neurodegenerative diseases or decreasing hypoxia response in solid tumors.

PB3385 Genome-wide analysis of radiation-induced somatic mutations in mouse long-term hematopoietic stem cells

Authors:

Y. Matsuda[1,2], A. Uchimura[1], Y. Satoh[1], N. Kato[1], M. Toshishige[1], K. Kume[2], J. Kajimura[1], K. Hamasaki[1], K. Yoshida[1], T. Hayashi[1], A. Noda[1], O. Tanabe[1]; [1]Radiation Effects Res. Fndn., Hiroshima, Japan, [2]Hiroshima Univ., Hiroshima, Japan

Molecular mechanisms for late adverse radiation effects such as increased neoplasm incidence after accidental exposure and secondary malignancies after radiotherapy remain unresolved even now. The major cause of the neoplasm development is thought to be somatic mutations resulting from DNA damages by radiation exposure. However, it has not been clarified at the genome-wide level what somatic mutational scars are carried in seemingly normal cells after radiation exposure, and how those scars contribute to neoplasm development. Recently, we focused on long-term hematopoietic stem cells (LT-HSCs), which have a potential to maintain hematopoiesis throughout life, and comprehensively analyzed somatic mutations introduced by whole-body X-irradiation by whole-genome sequencing (Matsuda et al. PNAS 2023). By whole-genome sequencing of clonal cell populations propagated in vitro from single isolated LT-HSCs, we comprehensively identified and characterized somatic mutations in LT-HSCs. In non-irradiated mice, the numbers of spontaneous SNVs and small indels were around 30-60 per genome, and those mutations were increased up to 2 to 3-fold in a dose-dependent manner by 3.8-7.7-Gy X-irradiation. We identified characteristic base substitutions and various mutational signatures specific to radiation exposure, which include small non-repeat deletions occurring outside tandem repeats, multisite mutations (multiple small mutations occurring within short regions), and structural variants. Further analysis of somatic mutations in multiple LT-HSCs from mice exposed to higher doses indicated that large fractions of LT-HSCs originated from single HSCs that survived the irradiation and expanded in vivo to confer marked clonality to the entire hematopoietic system. Further, we report here a detailed analysis of genomic features related to susceptibility to spontaneous and radiation-induced somatic mutations. We believe that these findings in a mouse model will provide clues for elucidating molecular mechanisms of late adverse radiation effects.

PB3386 † Genomics at scale with the NHGRI AnVIL

Authors:

M. Schatz[1], A. Philippakis[2], AnVIL Team; [1]Johns Hopkins Univ., Baltimore, MD, [2]Broad Inst. of MIT and Harvard, Cambridge, MD

Modern genomics often require very large numbers of samples to detect any subtle patterns that may be present. The scale of these projects opens new opportunities for discovery; however, this scale also introduces major new technical challenges that require overhauling how genomics and genomics data science are performed. Addressing this, the NHGRI Genomic Data Science Analysis, Visualization, and Informatics Lab-Space, or AnVIL (https://anvilproject.org/), provides a secure cloud environment for the storage and analysis of large genomic and related datasets. By providing a unified environment for data management and compute, AnVIL eliminates the need for data movement, allows for active threat detection, and provides elastic, shared computing resources on demand. AnVIL currently provides harmonized access to >600,000 genomes, with many more on the horizon. We also provide access to thousands of software tools, plus several options for interactive and batch analysis.
In this presentation, we describe how AnVIL has been used in several major studies of human genomics. First, we discuss how AnVIL supports the Telomere-to-Telomere (T2T) consortium through a large-scale reanalysis of the 1000 Genomes cohort orchestrated through the Workflow Description Language (WDL) on Terra. This enabled us to identify over one million variants in the newly resolved regions of the human genome, including within the recently completed chromosome Y sequence. Next, we present new results detecting single- and multi-tissue SV-eQTLs by genotyping SVs discovered with long-reads within the GTEx short-read sequencing data. This work was quickly and securely executed through WDLs, Jupyter notebooks, and R/Bioconductor, and lead to the discovery of 5,580 SV-eQTLs where the SV has the highest CAVIAR score (a metric of causality) over other nearby SNVs. Finally, we discuss how to analyze pangenomes and haplotype diversity using Galaxy within Terra. This is critically important to diversity and disease studies, especially to capture and analyze variation not found in any single reference genome.

Session Title: Omics Technologies Poster Session III

PB3387 GenoPhenoCorr: Simplifying the Characterization of Genotype-Phenotype Correlations

Authors:

L. Rekerle, D. Danis, P. Robinson; The Jackson Lab. for Genomic Med., Farmington, CT

Understanding the intricate relationship between genotypes and phenotypes is a fundamental pursuit in genetics. Although many other areas of genetics research have been optimized through new computational technologies, genotype-phenotype correlations have remained tedious and time consuming for researchers. We present GenoPhenoCorr, a Python package that is designed to expedite the identification of genotype-phenotype correlations. GenoPhenoCorr takes Global Alliance for Genomics and Health (GA4GH) phenopacket data as input. A typical use case investigates a cohort of individuals with pathogenic variants in a given gene and compares different classes of variants (e.g., missense vs. nonsense), different locations (e.g., variants in distinct protein domains) or different variants (e.g., if there are variants that occur in multiple individuals). Each phenopacket represents a single patient with a list of recorded phenotypes and at least one variant. The software organizes the data into a table, showcasing all the recorded phenotypes, variants, affected transcripts, and the corresponding proteins along with the frequency of each within the cohort of patients. Users can choose from available comparisons to run based on the information in the table. Genotype phenotype correlations are then calculated by analyzing the counts of individuals with vs. without annotations to HPO terms. Results are presented in an interactive table. We evaluated GenoPhenoCorr on ten cohorts of individuals with diseases including KBG Syndrome and Isolated Sulfite Oxidase Deficiency. We could replicate results of some published genotype phenotype correlation studies and will present new results on other cohorts. GenoPhenoCorr is designed to be run in a Jupyter notebook environment, and requires only that users format existing data as GA4GH phenopackets. It enables interactive exploration of results, provides a library of functions for investigating correlations, and can be easily extended. By integrating novel algorithms, comprehensive data management, and interactive visualization, GenoPhenoCorr simplifies the identification of genotype phenotype correlations.

PB3388 Genotyping coding-VNTR in the *MUC1* gene using k-mer frequency based alignment-free method allows genetic diagnosis of *MUC1*-related autosomal dominant tubulointerstitial kidney disease

Authors:

H. Saei[1], V. Morinière[2], L. heidet[1], O. Gribouval[1], s. Lebbah[2], F. Tores[1], M. Mautret[1], B. Knebelmann[2], S. Burtey[3], V. Vuiblet[4], C. Antignac[5], P. Nitschke[1], G. Dorval[1]; [1]Imagine Inst. of Genetic Diseases, Paris, France, [2]Univ. Hosp. Necker for Sick Children, Paris, France, [3]Marseille Publ. Univ. Hosp. System, Marseille, France, [4]Univ. Hosp. Ctr. Reims, Reims, France, [5]Imagine Inst.-Inserm UMR1163, Paris, France

The Human genome includes tandem repeats with variable length (VNTR) and a subset of these repeats have been associated with rare human diseases. Specific frameshift variants in the coding-VNTR of the *MUC1* gene cause autosomal dominant tubulointerstitial kidney disease - *MUC1* (ADTKD-*MUC1*). Calling variants from VNTR using short-read sequencing (SRS) is challenging due to poor read mappability, motif complexity, variable repetition, and enormous motif sequence similarity. To address this issue, we developed an efficient computational pipeline named VNtyper, for reliable detection of *MUC1* VNTR pathogenic variants and demonstrated its clinical relevance using two comprehensive patient cohorts. The pipeline utilizes mapping-free genotyping using k-mer frequencies (Kestrel algorithm) to detect small indels within MUC1-VNTR using SRS. To identify and analyze deleterious variants, we employed a combination of our self-developed *MUC1*-VNTR motif dictionary and a mapping-free genotyping algorithm. This approach allowed us to accurately detect and process these variants. The pipeline was applied to SRS data from two distinct cohorts. The first cohort, known as the historical cohort, consisted of 108 families (237 individuals) where at least three family members exhibited ADTKD including 32 families with known *MUC1* related ADTKD. The second cohort, referred to as the replication naive cohort, comprised 2910 patients who had previously undergone testing for monogenic renal diseases using a gene panel including 228 genes. In the historical cohort, our pipeline successfully re-identified all cases previously confirmed to carry pathogenic *MUC1* variants using the fastidious probe-extension assay. Additionally, we identified a previously unknown 25bp frameshift insertion in another family that had been overlooked. Within the replication cohort, we identified and validated 30 new cases with pathogenic variants that were overlooked. By establishing a minimal confidence depth-score, we achieved a sensitivity of 100% and a specificity of 94.40% in VNtyper testing. These findings demonstrate the effectiveness of our well-optimized pipeline in accurately screening the *MUC1*-VNTR region for the detection of deleterious variants. This pipeline could be simply integrated to SRS gene panel testing, and consistently call small indels in the *MUC1* VNTR, hence improving ADTKD-*MUC1* diagnosis, especially as innovative therapies begin to emerge.

PB3389 Germline short variants detection from UG100 Sequencing Data

Authors:

D. Shem-Tov[1], I. Soifer[1], A. Jaimovich[2], Y. Etzioni[1], D. Lipson[2], O. Barad[1]; [1]Ultima Genomics, Tel-Aviv, Israel, [2]Ultima Genomics, Menlo Park, CA

Accurate detection of short variants is crucial for understanding the genetic basis of complex diseases and guiding precision medicine approaches. Variant calling (VC) algorithms discern true biological mutations from errors, by inspecting multiple reads at each genomic position. Here we present advances in the UG100 sequencing chemistry and analysis methods that result in improved germline VC performance.

HG001-HG005 cell lines were sequenced on the UG100 at 40X coverage. New sequencing chemistry and base-calling algorithm were used to obtain better coverage over AT rich regions and improved coverage uniformity. DeepVariant (DV) algorithm was further optimized. The filtering accuracy of the DV model was improved by enriching the training-set, and by adding an extra channel encoding the size of insertions. Furthermore, the sensitivity of the candidate generator was elevated by separating and calibrating allele-frequency thresholds of homopolymer and non-homopolymer indels. Additionally non-homopolymer insertion sensitivity was improved by considering imperfect-matches between reads to haplotype as potential support. Finally, the robustness of DV to coverage variations was improved by two complimentary methods. Using adaptive down-sampling, the observed mean coverage is automatically adjusted to match the coverage the model was trained on. This mode is suitable for over-sequenced WGS samples, where we want to preserve the natural WGS coverage variance. In coverage-capping mode, we truncate the number of reads shown to the model at a maximal value, which is suitable for cases where the coverage is more variable such as WES. Using coverage-capping enables us to call WES samples with general WGS models, without retraining on WES data.

The modifications lead to a measured average improvement in coverage uniformity F95 from 1.8 to 1.5, and an improvement in base-quality Q30 from 85% to 89%. To evaluate the variant calling performance, we used GIAB v4.2.1 as ground truth, with corresponding High Confidence Regions (HCR) excluding homopolymer regions of length greater than 11 (0.3% of HCR), and low complexity regions (1.5% of HCR). The SNP F1 results improved from 99.6% to 99.8% and indel F1 from 96.4% to 98.6%.

In conclusion, our study demonstrates a set of improvements to the UG sequencer and DV for VC on UG germline data, which offers a robust, accurate, and efficient VC solution, enabling researchers and clinicians to unravel the genetic underpinnings of diseases and advance personalized medicine.

Session Title: Omics Technologies Poster Session III

PB3390 Global metabolomics is a powerful tool for diagnosing rare diseases devoid of clear genetic causalities

Authors:

A. Kennedy[1], K. DeBalsi[1], A. Crawford[2], L. Sommerville[1], A. Evans[1]; [1]Metabolon, Durham, NC, [2]Illumina Inc, San Diego, CA

Inborn errors of metabolism (IEMs) are rare inherited disorders that disrupt metabolic function to result in health complications or death. The symptomologies of many IEMs are non-specific, and a genetic cause is not always clear. In these cases the lack of specific tests can appreciably delay diagnosis, leading to poor outcomes. Addressing this gap in care relies on gaining deeper insight into a patient's phenotype from diagnostic testing. Here, we evaluated untargeted metabolomics as a tool for diagnosing IEMs. Using Metabolon's Global Discovery Platform, we obtained metabolomic profiles of plasma and urine from 29 persons suspected of having an IEM but with no clear underlying genetic susceptibility. Raw peak metabolite intensities were normalized, log-transformed, and Z-scored. Patient metabolite concentrations that were higher than the 95th percentile or lower than the 2.5th percentile of the normal range were flagged as potential diagnostic markers. We found evidence of numerous IEMs in the cohort including dysregulation of glycolysis, fatty acid oxidation, biosynthetic pathways, and mitochondrial function. In nearly every case, global metabolomic profiling identified a pathway disruption that either suggested an IEM or was key to clinical decision making. One patient presented with muscular hypotonia, seizures, and ataxia. Metabolic profiling showed a significant increase in acylcarnitines, hydroxy-acylcarnitines, and beta-hydroxy fatty acids that are elevated in certain mitochondrial disorders. Follow-up targeted molecular testing revealed a diagnosis of mitochondrial aminoacyl-tRNA synthetase deficiency. Another patient presented with non-specific growth delay and intellectual disability. His metabolic profile revealed significantly elevated amino acid metabolites and bilirubin, and significantly reduced carnitine; all suggestive of liver dysfunction. Indeed, this patient was eventually found to have a mutation in *KMT2D*, revealing a diagnosis of Kabuki syndrome. Another patient had significantly decreased metabolites upstream of DHODH, an enzyme involved in pyrimidine synthesis. Follow-up genetic testing showed a pathogenic variant in *DHODH*, the gene that encodes the enzyme. Yet, a pathogenic variant would be expected to decrease DHODH enzymatic activity to thereby elevate upstream metabolites. Finding that this patient showed the opposite effect impacted their treatment plan considerably. Altogether, this study provides compelling support for including global metabolomics in IEM diagnostic testing as a complement to genetic profiling to ultimately reduce the time-to-diagnosis and improve patient outcomes.

Session Title: Omics Technologies Poster Session I

PB3391 † Health and economic outcome analysis of patient journeys in a large seizure cohort: a case for rapid whole genome sequencing.

Authors:

R. Subaran[1], D. Corrigan[1], Z. Liu[1], K. Parsons[2], M. Higashi[1]; [1]GeneDx, Stamford, CT, [2]Gene Dx, Stamford, CT

Seizures are the most frequent neurological emergencies in children, including neonates. Since the risk of adverse neurodevelopmental outcomes increases with the time elapsed between seizure onset and remediation, rapid precision intervention is paramount. However, seizure phenotypes are highly heterogenous, and depending on the underlying molecular and neurophysiological etiology, many seizures can be refractory to, and even contraindications for, common first- and second-line therapies. Rapid whole-genome sequencing (rWGS) has been transformative in seizure intervention, with consensus mounting that differential targeting of epilepsy pathways based on individualized genomic results can significantly improve clinical outcomes. Unfortunately, despite this evidence, the prospect of adopting or expanding rWGS in many clinics, particularly in historically underserved populations, is met by competing economic considerations. Thus, there is an impetus to synthesize and articulate epilepsy patient odyssey data that can allow providers to also make the economic case for rWGS. Here, we explore the treatment odyssey of 20,712 consented and deidentified seizure patients recruited at The Mount Sinai Hospital (New York, NY) with longitudinal electronic health record data covering diagnoses between 2004 and 2020. We stratified epilepsy groups into neonatal-, infant-, early childhood-, late childhood-, and adolescent-onset, then performed patient journey mapping focusing on seizure 1) phenotype and severity, 2) nosocomial procedures, and 3) changes in medication. Using data from third-party payers across five states (MA, CA, MA, OH, PA, TX), we were able to estimate the median cost of imaging-based diagnostic procedures across each journey. We found that failure to resolve seizures in the first visit was associated with an estimated average imaging-based diagnostic cost of $3,929.61 USD (range by state = $2,532.05 - $6,454.50) in the total cohort and most pronounced in adolescent-onset population of the subgroups examined (estimated average = $4,073.52). Patients in this group who required imaging also had the had the highest incidence of status epilepticus (average per journey = 1.25) - a severe seizure phenotype characterized by prolonged and/or rapidly recurring paroxysmal episodes and which is associated with increased risk of brain damage and death - suggesting special urgency for rapid seizure resolution in this group. Therefore, our patient journey mapping analysis in this cohort adds to the clinical case for diagnosis via rWGS and poses an economic case for its adoption.

Session Title: Omics Technologies Poster Session II

PB3392 Heritability, pQTLs, and environmental influence of proteins involved in age and cardiovascular disease using highly multiplex proteomics

Authors:

B. Epstein, T. Lai, **T. Johnson**, M. A. Hinterberg, D. P. Astling; SomaLogic, Inc, Boulder, CO

Background: Highly multiplex proteomic assays have enabled a growth in protein quantitative trait locus ("pQTL") studies. By linking genomic variation to the proteome, pQTLs can reveal the mechanisms underlying the genetic risk of disease and suggest potential therapeutic targets. Here we explore the relationship between genetic effects on variation in protein abundance, as captured by pQTL studies, and associations between phenotypic or physiological variation and protein abundance.
Methods: We compiled a list of pQTLs and protein abundance heritability estimates from 15 pQTL studies based on the SomaScan™ assay. We calculated the association between protein analytes and age and cardiovascular disease risk (CVD), dividing the analytes into those strongly associated (FDR < 10%) and not strongly associated (FDR > 10%) with the endpoints. For analytes in each endpoint association category, we calculated the proportion that were tagged by a cis-pQTL and examined the distribution of heritability.
Results: Across the ~ 5,000 analytes, about half (50.6%) were cis-pQTL-associated, while 30% had significant heritability. By contrast, 70% of analytes strongly associated with age or CVD were also pQTL-associated, and 48-50% (depending on ancestry) had significant heritability. Overall, mean heritability across analytes was 13-14% regardless of endpoint association status.
Conclusions: Proteins associated with aging or CVD are more likely to have evidence of genetic influence than proteins not associated with aging or CVD, supporting the use of proteomic data in Mendelian randomization and proteome-wide association studies. However, there are still many proteins that have a strong association with an endpoint, but no cis-pQTL association or low heritability. These proteins are likely strongly influenced by environmental, rather than genetic, factors. The ability of proteomics to capture the effects of environmental variation complements the genetic effects captured by genomics.

Session Title: Omics Technologies Poster Session III

PB3393 High throughput human sample prep and sequencing on PacBio Revio system

Authors:

D. Moine[1], G. Young[1], J. Burke[1], J. Rocha[2], P. Baybayan[3], I. McLaughlin[4], K. J. Liu[1]; [1]PacBio, Menlo Park, CA, [2]Pacific BioSci.s, Bel Air, MD, [3]Pacific BioSci.s, Menlo Park, CA, [4]Pacific BioSci.s of California, Inc., Menlo Park, CA

Improved throughput and cost of long-read sequencing, driven by recent technological advances of the PacBio Revio system, enables investigation of whole human genomes across larger populations. To support the growing capabilities of long-read sequencing, high throughput (HT) sample and library preparation solutions are necessary. We present a fully automated HT DNA extraction, shearing, and library preparation workflow for different human sample types for PacBio HiFi sequencing. High molecular weight (HMW) DNA extraction is performed utilising Nanobind magnetic disk technology on automated Hamilton NIMBUS Presto or ThermoFisher KingFisher systems. Nanobind disks feature micro-and-nanostructured silica wrinkles to shield bound DNA from damage during extraction. We obtained ~6 µg of DNA per 200 µL blood sample (96 well plate) and ~30 µg of DNA per 1 mL blood sample (24 well plate) in 2.5 hours. HMW DNA is then sheared to 15-20 kb using robotic pipette shearing. Automated PacBio library and loading preparation is then performed on the fully automated Hamilton NGS STAR. The methods presented utilize standard configurations of Hamilton instruments and can easily be incorporated into existing workflows. Data is presented using different sample types for a workflow which can prepare 96 samples from DNA extraction to library ready for loading in ~10 hours. A Revio SMRT Cell typically generates ~30X coverage of high-quality sequence data sufficient for analysis including phasing, 5mC, and variant calling.

Session Title: Omics Technologies Poster Session I

PB3394 High-density and scalable protein arrays are generated for comprehensive single-molecule proteomic studies.

Authors:

J. Kuhar, M. R. Newman, J. K. Robinson, B. Nortman, S. Paul, A. Sohi, M. De Garate, C. Guerrero, K. Cosert, C. Inman, P. Indermühle, P. Hao, T. Aksel, H. Qian, S. Yan, T. Gillies, S. Tan, S. Sankar, S. K. Wilcox, P. Mallick; Nautilus Biotechnology, San Carlos, CA

Introduction: Massively parallel Next-generation DNA sequencing dramatically improved access to genomic data by increasing the scale by which DNA could be read, however to-date proteomic analyses have been severely limited in scale. To solve this challenge, we created a novel, highly-scalable system that allows for single-molecule protein interrogation across a wide dynamic range from minimal sample input. This system comprises a mono-disperse DNA scaffold with a single protein attachment site and a nanoscale-patterned surface with billions of landing pads. Our solution creates massively parallel super-Poisson single-molecule protein arrays where captured proteins are bound and can be interrogated repeatedly by multi-affinity probes or traditional affinity reagents.
Methods: Lysate is processed through a denaturing workflow that chemically disrupts cysteine-mediated complexes and covalently adds a methyltetrazine click group to amines to generate functionalized single polypeptides. The methyltetrazine is subsequently used to conjugate proteins to a DNA scaffold displaying a single trans-cyclooctene (TCO) moiety. In this manner, we efficiently create a protein library consisting of a population of protein-conjugated scaffolds, each displaying only a single individual protein captured from the sample lysate. The scaffold ensures spatial isolation of individual proteins when deposited onto a hyper-dense nanostructured array containing DNA binding sites surrounded by HMDS modified interstitial chemistry. To demonstrate single-molecule occupancy of the array, the scaffolds are dye labeled and loaded for imaging.
Results: When low micrograms of human cell lysate are used with the workflow we observe DNA scaffolds conjugated to a diverse set of proteins. The workflow disrupts model protein complexes and does not impair detection by multi-affinity probes. Minimal co-localization of two or more polypeptides is observed. A nanoarray loaded with protein-scaffold conjugates shows approximately 98% single molecule occupancy.
Conclusions: We demonstrate a workflow for the straightforward preparation of conjugated protein libraries that can be deposited as single molecules on a densely patterned array. When interrogated with multi-affinity probes, these libraries can provide proteomic information at scale.

Session Title: Omics Technologies Poster Session II

PB3395 † High-throughput Allele-Specific Expression Analysis Can Detect Allelic Imbalance in Clinical Patient Samples as a Proxy for Quantitative Measures of Gene Expression

Authors:

H. Mirsafian[1], H. Zimmermann[1], L. Hudish[1], S. Belhadj[1], D. Cheng[2], E. Chao[1], R. Karam[1], M. Schultz[2]; [1]Ambry Genetics, Aliso Viejo, CA, [2]REALM IDx, Aliso Viejo, CA

RNA analysis has recently emerged as a powerful tool for variant classification. However, most RNA analysis performed on clinical RNAseq data involves the detection of qualitatively different transcripts produced as a result of aberrant splicing. Identifying quantitative differences in the amount of transcript produced from an allele at the gene-level is a more difficult task and has historically relied upon quantitative real-time PCR (qRT-PCR) experiments. In this study we used the phASER tool on high-throughput clinical paired DNAseq and RNAseq samples to detect allelic differences in gene expression caused by *cis*-acting variants. phASER employs RNASeq reads to phase heterozygous variants (called from DNASeq data) relative to one another within a given gene. Allele-specific expression (ASE) analysis is then applied to evaluate the relative expression of the two alleles present at heterozygous loci to produce a single expression measurement for each haplotype. To validate this method in our clinical samples, we performed ASE analysis on samples from two patients heterozygous for a known pathogenic variant in the 5`UTR of the *MLH1* gene (*MLH1* c.-27C>A) that has been shown to result in reduced promoter activity. As predicted, this ASE analysis was able to detect significant ASE of *c.-27C>A* and a downstream benign polymorphism (*c.655A>G*) in both probands and not in controls. We then performed this analysis on two novel variants impacting the canonical donor splice sites of the noncoding first exons of *BRCA2* (*BRCA2* c.-40+2T>C) and *TP53* (*TP53 c.-29+1G>C*). We suspected these variants may cause ASE based on literature reports demonstrating ASE for other variants impacting the same canonical donor sites. We identified two patients heterozygous for the *BRCA2* variant and one for the *TP53* variant and were indeed able to show significant ASE for benign downstream heterozygous polymorphisms in the 5`UTR (*c.-52A>G*, *c.-26G>A)*, exon 10 (*c.1114A>G*), exon 11 (*c.3396A>G*), and exon 14 (*c.7242A>G*) of *BRCA2*, and in exon 3 of *TP53* (*c.215C>G*). ASE was not detected in controls. Although preliminary, these data indicate that ASE analysis using phASER is capable of detecting RNA allelic imbalance associated with variants identified through clinical DNA samples. These results raise the tantalizing possibility that high-throughput ASE analysis could be used to identify patients with allele-specific expression of unknown origin. Future directions of this study include validating the method for additional variants and variant types and assessing potential candidate variants in a variety of genes using our in-house database of >300000 paired DNAseq and RNAseq samples.

Session Title: Omics Technologies Poster Session III

PB3396 High-throughput full-length isoform sequencing with long, accurate reads

Authors:

E. Tseng[1], H. Ferrao[1], J. Bruand[1], A. Toepfer[1], M. Mehlferber[2], V. Pavelko[2], G. Sheynkman[2]; [1]Pacific BioSci.s, Menlo Park, CA, [2]Univ. of Virginia, Charlottesville, VA

Long-read RNA sequencing has been demonstrated to eliminate the need for short-read transcript assembly and applied to discovering novel isoforms in disease research. Long-read transcript sequencing using PacBio (the Iso-Seq method) can characterize full-length isoforms and has been used in bulk RNA studies to identify alternative splicing, fusion genes, and allele-specific isoform expressions. However, the high sequencing cost and lower throughput on previous PacBio systems have prohibited the ability to perform scalable isoform classification & quantification over large number of samples.

PacBio is commercializing the MAS-Seq method (Al'Khafaji et al., 2021) - an amplicon concatenation method for throughput increase - for bulk isoform sequencing. Using an 8-fold concatenation approach, the MAS-Seq for bulk Iso-Seq kit achieves an 8-fold throughput increase on PacBio Sequel II/IIe and Revio systems. We demonstrate that we can achieve 40-60 million full-length reads per sample on the Revio system, where the average transcript is ~2.5kb spanning from 100 bp to over 10,000 bp. Further, we show that the concatenation approach maintains the relative abundance of cDNA molecules without concatenation, an important need for facilitating isoform-level quantification and differential analysis.

The companion SMRT Link software release contains a new Iso-Seq workflow that robustly analyzes full-length reads, from isoform-level clustering to transcript characterization and quantification. The workflow integrates with popular tertiary analysis tools such as tappAS and Cerebus for differential expression analysis and joint sample transcript annotation.

Concurrent with the kit and software, we release a high-accuracy Iso-Seq reads HG002 dataset demonstrating saturation of known genes and isoforms that can be used for variant calling and detection of allele-specific isoform expressions. A second dataset consists of 11 WTC-11 samples totaling over 600 million reads - the largest bulk Iso-Seq dataset for a single cell line to date. In contrast to previous PacBio sequencers and Iso-Seq methods, this scope would have required >200 SMRT Cells 8M and over 200 sequencing days to generate the equivalent amount of data. Here, the WTC-11 dataset required 11 Revio SMRT Cells which were sequenced in 3 days. This dramatic throughput increase and reduction in sequencing time will enable high-throughput, population-scale full-length RNA sequencing that has the potential to reveal novel insights into human disease.

PB3397 HiPhase: Jointly phasing small and structural variants from HiFi sequencing.

Authors:

J. Holt, C. Saunders, W. Rowell, Z. Kronenberg, A. Wenger, M. Eberle; PacBio, Menlo Park, CA

In diploid organisms, phasing is the problem of assigning heterozygous variants to one of two haplotypes. For human genetics, phasing variants within a gene is required for clinical applications including donor matching (HLA typing) and determining drug interactions (pharmacogenomics). Additionally, knowing whether variants occur in cis or trans is an important factor in identifying the causes of autosomal recessive conditions both for known conditions (e.g., Tay Sachs) or when trying to identify the causes of novel rare diseases. While inherited variants can be phased with parental information, read-backed phasing allows all variants, including de novo variants, to be phased using read level evidence. These reads can also be assigned to a haplotype, enabling epigenetic analyses linking genetic and epigenetic changes on the same haplotype to detect allele specific methylation and imprinting disorders (e.g., Prader-Willi syndrome). Reads from PacBio HiFi sequencing provide long, accurate observations that can be used as the basis for identifying and phasing both inherited and de novo variants of all types. However, current phasing tools typically only phase smaller SNV and indel variants, leaving larger structural variants unphased.

We developed HiPhase, a tool that jointly phases small (SNV/indel) to large (structural) variants in a single, easy-to-use program. Compared to the current state-of-the-art approach, HiPhase increased phase block NG50 by 21% (493 kb), decreased errors by 42% (933 switchflips), increased the number of fully phased genes by 3.6% (90.6% of genes), and enabled allele-specific methylation analysis for 2.2% more CpG islands (73.6% of CpG islands). To our knowledge, HiPhase is the first tool to jointly phase small variants (SNV/indel) with structural variants.

Additionally, HiPhase includes novel algorithmic contributions, innate multi-threading, statistics gathering, and concurrent phased alignment output generation. The improvements from HiPhase in fully phased genes and CpG islands can provide more explanations in rare disease research.

HiPhase is freely available on Bioconda with documentation on GitHub:
https://github.com/PacificBiosciences/HiPhase.

Session Title: Omics Technologies Poster Session II

PB3398 † Human Pangenome Reference Consortium Coordinating Center.

Authors:

T. Lindsay[1], L. Antonacci-Fulton[2], S. Cody[1], H. Lawson[1], T. Wang[3]; [1]Washington Univ., Saint Louis, MO, [2]Washington Univ., St. Louis, MO, [3]Washington Univ. in St. Louis, St. Louis, MO

The goal of the Human Pangenome Reference Consortium (HPRC) is to increase the diversity of the human reference by moving from a linear reference to one comprised of many genomes. Including more diversity in the human reference will lead to a better understanding of human variation, which patients and clinicians need for better outcomes in the clinic.
Plans include data generation from 350 genomes over the five-year grant, with many of the genomes selected from the 1,000 Genomes Project. Development efforts focus on inventing the pangenome tools the research and clinical communities need.
An international outreach effort, Human Pangenome Project, is also underway to expand the number of partners leading to additional genomes being made available for the resource. These efforts will include the coordination of events, and discussions in pangenomic resource development with the aim of fostering necessary interaction and debate in the area of genomics and ethical oversight, Identifying projections of diversity in the pangenome, developing strategies to evaluate and measure gaps in diversity, forming international partnerships to establish an accessible resource to improve clinical genomics and biomedical research globally, openly share protocols and methods, and community engagement.
The HPRC is a multi-component consortium, and efficient and effective logistical and scientific coordination is critical to maximizing the value of the project. The HPRC components include the Coordinating Center and Sequencing Center. The HPRC organizational framework comprises a steering committee and working groups with specific work streams. Unique to the HPRC is a funded ELSI component consisting of leaders in this field. Their primary function is to help guide the HPRC as it negotiates sample selection, data use, and other situations.
Within the past year, the HPRC has released our first Human Pangenome assembly graph, comprised of 47 diploid individuals built together into one Pangenome. The complete resource contains each genome's raw sequence data and haploid assemblies. The sequencing data types include Pacific Biosciences HiFi data, Oxford Nanopore Technologies (ONT) long-read sequencing, Bionano optical maps, and Hi-C Illumina short-read sequencing for all HPRC samples. Researchers and clinicians can access the resources provided by the HPRC through GitHub, AnVIL, and NCBI.
We will fully detail the workings of the consortium and available resources that researchers and clinicians can access.

Session Title: Omics Technologies Poster Session III

PB3399 Human plasma metabolite outliers identified in Estonia Biobank knockouts

Authors:

L. Bomba[1], K. Yu[2,1], T. Esko[3], K. Estrada[1], A. Wuster[1]; [1]BioMarin Pharmaceutical Inc., Novato, CA, [2]Univ. of Michigan, Ann Arbor, MI, [3]Estonian Genome Ctr., Inst. of Genomics, Univ. of Tartu, Tartu, Estonia

Metabolomics, in combination with genetic data, is a powerful technology to assess the biochemical consequences of genetic variation. We studied the impact of human gene knockouts (KOs) on the metabolite levels of the Estonia Biobank (EstBB) participants and integrate these findings with electronic health record (EHR) data. We leveraged 723 knockouts selected from 153 loss of function (LoF) variants and 258 controls from the EstBB with 1,505 metabolites profiled using ultra-high-performance liquid chromatography-tandem mass spectrometry. We define a human knockout as an individual carrying at least two predicted homozygous LoF variants in a gene. The LoF variants were validated using Sanger sequencing. We identified 48 associations implicating rare LoF variants in 22 genes and 43 metabolites using Wilcoxon rank sum test. Approximately two-thirds of the associations were found in genes that cause inborn errors of metabolism (IEM). The top associations identified in our analysis included genes and metabolites involved in the degradation pathway of the pyrimidine bases uracil and thymine (*DPYD* and *UPB1*). We found *DPYD* gene knockouts associated with elevated levels of Uracil, confirming that DPD-deficiency is a leading cause of severe 5-Fluorouracil toxicity. Overall, 54% of reported associations are gene targets of approved drugs or bioactive drug-like compounds. Our findings contribute to assessing the impact of human knockouts on metabolite levels offering insights into gene functions, disease mechanism and drug target validation.

Session Title: Omics Technologies Poster Session I

PB3400 Identify cell-type-specific and shared eQTLs in single-cell eQTL analysis by leveraging cell type similarities.

Authors:

C. Lin[1], W. Li[1], C. Su[1], Y. Lin[2], H. Zhao[1]; [1]Yale Univ., New Haven, CT, [2]The Univ. of Sydney, Sydney, Australia

Expression quantitative trait locus (eQTL) studies aim to identify the genetic variants and their effects on gene expression levels, providing insights into the genetic regulations of complex traits. While previous eQTL studies on bulk tissues provide an average effect across cell types and states, recent research has highlighted the significance of cell-type-specific eQTLs. The emergence of population-scale single-cell RNA sequencing (scRNA-seq) datasets with annotated cell types has greatly improved our understanding of cell-type-specific eQTLs. However, existing strategies often neglect the shared genetic effects among similar cell types, leading to potential loss of statistical power. In this study, we propose a statistical framework that leverages cell type similarities with a Bayesian model to identify cell-type-specific and shared eQTLs. Our framework begins by separately analyzing each cell type using MatrixEQTL with a pseudo-bulk aggregation of single-cell data. The estimated eQTL effect sizes are then used to capture the similarities between cell types incorporating the cell type ontology. By fitting priors for cell-type-specific eQTL effect sizes using these similarity matrices, we then apply Bayes' theorem to obtain posterior estimates of eQTL effect sizes that incorporate the information from multiple cell types to derive the false discovery rates. We demonstrate the performance of our framework in cell-type specific eGene identification using the OneK1K scRNA-seq data with peripheral blood samples from 981 donors. We identified a total of 7544 eGenes (genes associated with at least one significant eQTL) across 29 cell types. Notably, 4156 eGenes exhibited cell-type-specific genetic effects, whereas the other 3388 eGenes demonstrated shared genetic effects among similar cell types. Comparing our framework with conducting MatrixEQTL separately in each cell type, we observed an 18% increase in the number of shared eGenes, suggesting increased statistical power to identify shared genetic effects across similar cell types. By leveraging information across cell types, our framework also yielded greater power in identifying eQTLs for rare cell types (cell type proportion < 0.01% in the data), as evidenced by a four-fold increase in eGenes identified in CD4-positive, alpha-beta T cells, and a two-fold increase in eGenes identified in plasmacytoid dendritic cells. These findings underscore the importance of considering cell-type-specific and shared genetic effects when studying the regulatory mechanisms underlying complex traits.

Session Title: Omics Technologies Poster Session II

PB3401 Identifying genetic variation in cancer using targeted long-read sequencing.

Authors:

S. Iyer[1,2], M. Kramer[1], A. N. Habowski[1], D. A. Tuveson[1], S. Goodwin[1], W. McCombie[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY, [2]Stony Brook Univ., Stony Brook, NY

Structural variations (SV) tend to be recurrent and contribute to cancer. Next-generation sequencing (NGS) technologies are mostly blind to many SVs, with false positive and false negative rates of >50% in SV detection. Long-read sequencing generates read lengths of tens of thousands of bases, helping identify thousands of genomic features previously missed by NGS. However, whole genome, long-read sequencing at the coverage needed to detect variants in heterogeneous samples is impractical due to its high cost. Targeted sequencing on the other hand, improves accuracy and coverage by providing the depth necessary to detect rare alleles in a heterogenous population of cells.

We developed ACME, an Affinity-based Cas9-Mediated Enrichment method, which is an improvement on the widely used nanopore Cas9-targeted sequencing (nCATS). Like nCATS, ACME is an amplification-free approach that can simultaneously assess genomic variations and DNA methylation from the same sequencing run. Importantly, ACME helps reduce background non-target reads, increasing coverage and size of the target regions that are captured. Using ACME to target 10 cancer genes in MCF 10A and SK-BR-3 breast cell lines, we showed a 2- to 25-fold increase in target coverage and 3- to 7-fold increase in number of reads that span the whole target from start to end compared to nCATS. Using ACME, we obtained >60-fold target enrichment, 35-65x coverage, and 3-20 end-to-end reads spanning *BRCA2*, a 95 kb target on our panel. The main advantage ACME offers over other amplification-free long-read targeting approaches is the ability to capture contiguous reads, up to 100 kb in size. This reduces mapping errors and aids in SV detection. As proof of concept, we showed that ACME successfully detected all SVs within our targets previously inferred by whole genome long-read sequencing.

Expanding on this work, we used ACME on four pancreatic ductal adenocarcinoma (PDAC) patient-derived organoids (PDOs). Organoid models represent the full spectrum of disease, making them invaluable to assess personalized treatment options. Using ACME we observed comprehensive SV detection within our 10 targets, of note, a homozygous exon deletion covering an ~500 bp region in the *STK11* gene in one of the organoids, which correlated with decrease in gene expression. We also identified known driver SNPs in the *KRAS* gene in all four organoids.

We are currently working on a multiplexed approach using native barcoding that would not only make ACME even more cost-effective but also take it a step further in helping answer longstanding biological questions.

Session Title: Omics Technologies Poster Session III

PB3402 IL1R+ antimicrobial molecule program and heterogeneity study.

Authors:

C. Hu, P. R. Andrade, M. Pellegrini, R. Modlin; UCLA, Los Angeles, CA

The study of the relationship between Th17 and Treg cells has emerged as a crucial area of research in immunology. T-helper 17 (Th17) cells have been described as “pathogenic” vs. “non-pathogenic” based on their contribution to tissue injury and their secreted cytokine pattern. Our previous study defines “antimicrobial Th17 cells” based on the expression of interleukin 1 receptor type I (IL-1RI), production of IL-26 and the ability to mediate a rapid antimicrobial response against extracellular bacteria. Our transcriptome analysis revealed that the IL-1RI+ Th17 cells express T regulatory (Treg) markers *FOXP3*, *LRRC32*, *CTLA4* and *CD25* (Weiss et al., 2019), leading to the hypothesis that some of these cells represent intermediates in Th17 development from Treg precursors (Valmori et al. 2010).Terminally differentiated cells fulfill opposite functions: Th17 cells cause autoimmunity and inflammation, whereas Treg cells inhibit these phenomena and maintain immune homeostasis. Thus, unraveling the mechanisms that affect the Th17/Treg cell balance is critical if we are to better understand autoimmunity and tolerance (Lee et al., 2018).Here we address this relationship by investigating the effect of TCR activation and IL-1β stimulation on the antimicrobial gene program and heterogeneity of memory Th17 cells populations that express IL1RI, as well as the differentiation trajectory of Th17 and Treg populations in acne and rosacea. We performed scRNA seq data on IL-1RI+ and IL-1RI- memory Th17 cells (*CD4+CD45RO+CCR6+CD161+CCR4+CXCR3-*) from five healthy donors stimulated or not with IL1β or anti-CD3/CD28 for 9 hours. After integration of the scRNA-seq data from the five donors using the R package Seurat, we identified 14 clusters across the IL-1RI+ and IL-1RI- Th17 populations and their conditions (media, IL1β and CD3/CD28). Our analysis identified a continuum between cluster Th17 cells and cluster Treg cells on the UMAP visualization, suggesting the existence of a progression between cellular states within the CD3-activated IL1RI+ Th17 population. In vivo, we performed scRNA seq analysis with the same process on acne and rosacea data. Using the same computational tools as in our in vitro data, we found a similar pseudotime trend going from the Th17 clusters to the Treg clusters, suggesting that the Th17 to Treg phenotypic differentiation route is also present in vivo. Our findings indicate that a portion of the Th17 IL1RI+ population consists of intermediate phenotypes that are differentiating towards T regulatory phenotype, which could be involved in control mechanisms of the inflammation elicited by antimicrobial responses.

Session Title: Omics Technologies Poster Session I

PB3403 Implementation of ONT long-read WGS in routine clinical genetic testing.

Authors:

A. Kaplun, L. Kaplun, G. Krautz-Peterson, N. Neerman, C. Stanley, S. Hussey, M. Folwick, A. McGarry, S. Weiss; Variantyx, Framingham, MA

Whole Genome Sequencing (WGS) has allowed exploration of areas of the genome that might not have been targeted by other approaches, such as intergenic regions. A single technique detecting all genetic variants at once is intended to expedite the diagnostic process while making it more comprehensive and efficient, making WGS a preferable approach as a first line diagnostic test. Nevertheless, there are still several shortcomings that cannot be effectively addressed by short read sequencing, such as determination of the precise size of short tandem repeat (STR) expansions, phasing of potentially compound recessive variants, resolution of some structural variants and exact determination of their boundaries, etc. Fortunately, those weak spots of short read sequencing can be compensated by long read sequencing technology that have comparable or better detection of some types of variants while lacking the mentioned above limitations of short read sequencing. We have developed an integrated clinical genetic testing approach, augmenting short read WGS-based variant detection with Oxford Nanopore Technologies (ONT) long read sequencing, providing improved detection and simultaneous orthogonal confirmation of all types of variants with the additional benefit of improved identification of exact size and position of the detected aberrations. The validation study of this augmented test has demonstrated that ONT sequencing can efficiently verify multiple types of reportable variants, thus ensuring highly reliable detection and a quick turnaround time for WGS-based clinical genetic testing.

PB3404 Improving methods for high throughput epigenomics studies.

Authors:

B. Marosy[1], H. Ling[1], P. Zhang[1], J. Gearhart[1], J. Paschall[1], C. Oncago[1], M. Mawhinney[1], L. Aker[1], A. Robinson[1], B. Craig[1], Z. Xu[2], K. Doheny[1]; [1]Ctr. for Inherited Disease Res., DGM, Johns Hopkins Univ., Baltimore, MD, [2]Biostatistics and Computational Biology Branch, Natl. Inst. of Environmental Hlth.Sci., NIH, Research Triangle Park, NC

The Center for Inherited Disease Research (CIDR) provides high-throughput genomic services and statistical genetics consultation to investigators working to discover genes that contribute to diseases. In response to the growing requests for epigenetic studies, we recently evaluated an alternative chemistry for methylation detection - an enzymatic library conversion of methylated sites (NEB EMseq) paired with a targeted methylome panel (Twist BioSciences). The performance of this method (Methyl-Seq) was compared with our existing methylation array (EPIC), which uses bisulfite conversion. The Methyl-Seq and Illumina EPIC assays are designed to capture 3.98M and 935K CpG sites, respectively. On average, the Methyl-Seq data (with a mean coverage of 25-55x) detected 6.5M CpG sites per sample, approximately 7 times as many as the EPIC array. The peaks of raw beta value distribution in the sequencing data are tighter than the EPIC array for both methylation controls and experimental samples. The Pearson correlation coefficient, derived from HapMap duplicate pairs (9 for EPIC and 3 for Methyl-Seq), exhibits comparable values for both sequencing and array data, exceeding 0.99. For both, the correlation of beta values between non-duplicate pairs (n=12 for Methyl-Seq and n=27 EPIC) falls within the range of 0.88 to 0.91, roughly 10% lower than the duplicate pairs. The between-technology correlation is 0.96 to 0.97 (18 cross-platform duplicate pairs). Our current EPIC array studies typically involve hundreds to a few thousand samples. However, the size of recently funded studies is expanding to the tens of thousands, necessitating the implementation of automated bisulfite conversion methods. We have successfully validated the Zymo EZ-96 DNA Methylation Lightning assay on our in-house automation, in preparation for population-scale studies. 32 samples were run with a mean of 932,871 (99.6%) %CpG detected at p=.01. Lastly, we have automated EPIC array sample level QC to date using *ewastools* and *minfi* packages. We are exploring the *ENmix* package to allow for a more in-depth QC including normalization on both sample and probe level, with the aim of providing our investigators with a dataset closer to “analysis ready.” From our initial analyses, Methyl-Seq is a promising new platform for epigenomic studies.

Session Title: Omics Technologies Poster Session III

PB3405 Inducible CRISPR interference in iPSC-derived neurons

Authors:

M. Nelson, D. Ramos, M. E. Ward; NIH, Bethesda, MD

CRISPR interference (CRISPRi) is a method for targeted gene knockdown. A single guide RNA (sgRNA) targets a catalytically dead Cas9 enzyme (dCas9) to a specific transcriptional start site, whereupon a transcriptional repression domain fused to dCas9 silences the targeted gene. CRISPRi facilitates multiplexed genetic screens in induced pluripotent stem cell (iPSC)-derived neurons: a library of sgRNAs can repress a catalogue of genes in a population of neurons, whose phenotypes can then be studied. Lentivirus is typically used to deliver sgRNA libraries, and common lentivirus backbones have poor tropism for iPSC-derived neurons. Thus, sgRNA libraries are commonly delivered to cells as iPSCs, which are then differentiated into neurons. In this paradigm, the effects of gene knockdown in iPSCs, differentiating cells, and post-mitotic neuron-like cells are conflated, making it difficult to study neuron-specific effects of gene knockdown. Here, we developed a method for inducible CRISPR interference using a Cre recombinase system in which dCas9 is expressed upon Cre delivery to post-mitotic iPSC-derived neurons. This limits screens solely to neuronal phenotypes. Our versatile platform for inducible CRISPRi is compatible with numerous sgRNA libraries, robustly induces dCas9 without detectable baseline expression, and results in gene knockdown in iPSC-derived neurons.

Session Title: Omics Technologies Poster Session I

PB3406 Inferring super-resolution tissue architecture by integrating spatial transcriptomics with histology.

Authors:

D. Zhang[1], A. Schroeder[1], H. Yan[1], H. Yang[1], J. Hu[2], M. Y. Lee[1], K. S. Cho[3], K. Susztak[1], G. X. Xu[1], M. D. Feldman[4], E. B. Lee[1], E. E. Furth[1], L. Wang[3], M. Li[5]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Emory Univ., Atlanta, GA, [3]MD Anderson Cancer Ctr., Houston, TX, [4]Indiana Univ., Indianapolis, IN, [5]Univ. of Pennsylvania, Philadelphia, PA

Spatial transcriptomics (ST) has demonstrated enormous potential for generating intricate molecular maps of cells within tissues. Here we present iStar, an end-to-end workflow that integrates ST data and high-resolution histology images to predict spatial gene expression and characterize tissue architecture with super-resolution. Our method not only enhances gene expression resolution to near-single-cell levels in ST, but also enables gene expression prediction in tissue sections where only histology images are available.

Session Title: Omics Technologies Poster Session II

PB3407 Integrated ambient modeling and genetic demultiplexing of single cell RNA+ATAC multiome experiments with Ambimux

Hosp., Kuopio, Finland, [9]Inst. of Precision Hlth., Univ. of California Los Angeles, Los Angeles, CA, [10]Dept. of Med., Endocrinology and Clinical Nutrition, Kuopio Univ. Hosp., Kuopio, Finland, [11]Ctr. for Neurobehavioral Genetics, Semel Inst. for NeuroSci. and Human Behavior, David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [12]Dept. of Neurology, Univ. of California, Los Angeles, Los Angeles, CA

Single cell technologies have advanced at a rapid pace, providing assays for various molecular phenotypes. Droplet-based single cell technologies, particularly those based on nuclei isolation, such as simultaneous RNA+ATAC single cell multiome, are susceptible to exogenous ambient molecule contamination, which can increase noise in cell type-level associations. We reasoned that genotype-based sample multiplexing can provide an opportunity to infer this ambient contamination by leveraging DNA variation in sequenced reads. Thus, we developed Ambimux, a likelihood-based method to estimate ambient fractions and demultiplex single cell multiome experiments using genotype-level data. Ambimux models the ambient or nuclear probability at the read level, and thus can classify empty droplets and estimate droplet-specific ambient molecule fractions in each modality. We first evaluated our method using simulated data sets across a range of parameters. As an example, we simulated an 8-sample multiome data set across a uniform range (0-100%) of ambient contamination. We found that Ambimux closely estimated the ground truth droplet contamination fractions in the RNA (MSE=0.0088) and ATAC (MSE=0.0055) modalities. As a result, Ambimux maintained high specificity (>95%) and was able to correctly assign singlets at considerably high ambient fractions (up to 80%) for both RNA and ATAC modalities. In comparison with models that do consider ambient contamination, e.g. Demuxlet, these only maintained similar sensitivity levels at considerably lower ambient fractions (up to 26%). We then generated a real data set of seven visceral adipose tissue biopsies run on a single 10X Multiome channel. We ran Ambimux and detected 4,595 singlets, capturing 96% of those identified by Demuxlet in either modality and taking ~9 hours less than Demuxlet. Then, we sought to evaluate the fidelity of the ambient fraction estimates from Ambimux. We split the 4,595 singlets into size-matched ambient-enriched (>=25% contamination in either modality) or nuclear-enriched (<25% in both) droplets and performed gene-peak linkage analysis in 310 adipocyte marker genes. While the clean set of droplets resulted in 522 significant gene-peak links across 217 marker genes, the ambient-enriched droplets exhibited less links (n=107) across fewer marker genes (n=79), suggesting that the ambient droplets identified by Ambimux hamper the identification of biologically meaningful signals. In summary, we developed a joint single cell multiome demultiplexing method, Ambimux, that accurately models and estimates ambient molecule contamination in each modality.

Session Title: Omics Technologies Poster Session III

PB3408 Integrated multimodal analysis of simultaneous single-cell profiling opens a new frontier for characterizing cell states.

Authors:

H. Lee[1,2]; [1]Brigham Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Univ. of Massachusetts Amherst, Newton, MA

Recent advances in single-cell sequencing methods uncover cellular heterogeneity and dynamics of individual cells that conventional bulk-population level measurements cannot reveal. Additionally, simultaneous multimodal single-cell profiling promises a new frontier for single-cell genomics, demanding rigorous computational methods to define cell states based on multimodal data. In this study, we present our experimental and analytic framework based on peripheral blood mononuclear cells collected at the baseline visit of four participants in the autoimmunity-blocking antibody for tolerance (AbATE) clinical trial and four participants in the high-dose immunosuppression and autologous transplantation for multiple sclerosis (HALT-MS) clinical trial at Immune Tolerance Networks (ITN). Equal number of sorted T cells (CD3+CD19-CD14-CD56-) and B cells (CD3-CD19+CD14-CD56-) from each subject are pooled together for droplet-based single-cell assay and downstream analyses. We simultaneously sequenced the multiplexed samples through two sequencing platforms, single-cell multiome ATAC+Gene Expression and CITE-seq (RNA and 163 antibody proteins) and TCR/BRC repertoire. We performed demultiplexing and quality-control on the pooled samples based on dense genotyping information of the subjects and obtained 7102 nuclei for the multiome platform and 21850 cells for the latter platform for analysis. The T cells and B cells are identified and characterized by simultaneous profiling of gene expression, surface protein, BCR/TCR repertoire and chromatic accessibility through the two sequencing platforms in parallel. For downstream analyses, we first merge the RNA data from both platforms and link the merged RNA data with surface protein data by using canonical correlation analysis. we adopt machine learning techniques such as dimension reduction and clustering algorithms and annotate each cluster of cells based on marker genes and reference mapping. We examine clonal expansion using BCR/TCR data and identify open chromatin regions in our peak-calling analysis using ATAC data in the annotated clusters. This experimental and analytic framework highlights the potential application of simultaneous multimodal single-cell profiling in tracking changes of profile over time during immune-modulating therapies.

Session Title: Omics Technologies Poster Session I

PB3409 Integrative approach to reveal adverse impacts of butylparaben in homologous human genes from *Daphnia magna* via BLAST and network analysis.

Authors:

J. Lee[1], Y. Jang[1], S. Dong Yeop[1], H. Jun Pyo[1], S-W. Lee[2], D. Choi[3], E-M. Cho[4], J. Lee[5], **Y. Seo**[1]; [1]Dongguk Univ., Goyang, Korea, Republic of, [2]Korea Conformity Lab., Incheon, Korea, Republic of, [3]Korea Conformity Lab., Incheon, Korea, Republic of, [4]Seokyeong Univ., Seoul, Korea, Republic of, [5]Gachon Univ., Seongnam, Korea, Republic of

Butylparaben, an estrogen-like compound, is a common pollutant in aquatic ecosystems and a major threat to aquatic life and other organisms, including humans. Some previous reports have indicated that this pollutant has been toxic to human despite this pollutant having been conventionally regarded as 'safe' and widely used commercially such as an antimicrobial preservative in cosmetics. However, most research on butylparaben toxicity in humans is limited to acute toxicity, while only a few studies have elucidated the underlying molecular mechanisms of butylparaben exposure in humans. Considering its property and usage, we conducted a chronic reproductive test with *Daphnia magna* (*D. magna*), which has a unique parthenogenic and short reproductive cycle. As a result, we discovered that butylparaben at a dose of 0.32 mg/L for 21 days significantly reduced *D. magna* fecundity. Furthermore, we identified 843 differentially expressed genes (DEGs) through RNA sequencing, using the groups that demonstrated a decrease in fecundity. To predict the adverse effects of chronic butylparaben exposure to humans, we performed BLAST analysis on the daphnia DEGs and we identified 87 homologous human genes. Through network analysis, it was predicted that various diseases such as neurogenetic, male urogenital, and endocrine disorders and *SRS* and *POU*, would be selected to as potential biomarkers for human exposure to butylparaben. Our integrative approach allowed for the identification of adverse effects of following long-term exposure to butylparaben in humans and provided a perspective of identifying genes that should be considered as potential biomarkers for environmental disease following long-term exposure to a chemical.

PB3410 Integrative network analysis identifies miRNA signatures for neuropathology and cognition in Alzheimer's disease

Authors:

Y. Park[1], S-W. Han[2], J-M. Pyun[3], K. Nho[4]; [1]Seoul Natl. Univ. Bundang Hosp., Seongnam-si, Korea, Republic of, [2]Chuncheon Sacred Heart Hosp., Chuncheon-si, Korea, Republic of, [3]Soonchunhyang Univ. Seoul Hosp., Seoul-si, Korea, Republic of, [4]Indiana Univ Sch. of Med., Indianapolis, IN

Background The exact mechanisms underlying the pathogenesis of Alzheimer’s disease (AD) remain unclear due to the involvement of complex neurochemical and genetic factors. MicroRNA (miRNA) dysregulation is a potential mechanism contributing to gene expression changes in AD. Integrative network analysis based on the correlation of miRNA profiles can provide insights into the pathogenesis of AD.Methods We performed miRNA co-expression network analysis to identify network modules associated with AD, neuropathology markers, and cognition and their hub miRNAs using brain tissue miRNA profiles from a large longitudinal study of aging cohort (N=702) as a discovery dataset. We also performed association analysis of the hub miRNAs with AD, neuropathology markers, and cognition. After selecting target genes of the hub miRNAs, we performed association analysis of the hub miRNAs with their target genes and then performed pathway-based enrichment analysis. Furthermore, we performed differential expression analysis of target genes using brain tissue RNA-Seq data. For replication analysis, we performed a consensus miRNA co-expression network analysis using the ROSMAP dataset and an independent miRNA profile dataset (N=16) from the Gene Expression Omnibus (GEO). Finally, we performed a machine learning approach using penalized logistic regression to assess the performance of hub miRNAs for the classification of AD.ResultsNetwork analysis identified a module (M3) as significantly associated with AD, amyloidopathy, and cognition. Five hub miRNAs (miR-129-5p, miR-433, miR-1260, miR-200a, and miR-221) of M3 exhibited significant associations with AD, neuropathology markers, and/or cognition. Gene-set enrichment analysis of target genes associated with their corresponding hub miRNAs identified significantly enriched biological pathways including ErbB, AMPK, MAPK, and mTOR signaling pathways. Consensus network analysis identified two consensus network modules as significantly associated with AD in ROS/MAP and marginally associated with AD in GEO. Notably, consensus network analysis also identified miR-129-5p and miR-221 as hub miRNAs. Machine learning analysis showed that the AD classification performance (area under the curve (AUC)=0.847) of age, sex, and *APOE* ε4 carrier status was improved by 4.2% with inclusion of five AD-associated hub miRNAs.Conclusion An integrative network approach identified miRNA signatures as associated with AD, neuropathology markers, and cognition, enhancing our understanding of AD pathogenesis and leading to better performance of AD classification as potential diagnostic biomarkers.

PB3411 Interpretable Multi-View Integrative Approaches Imputing Serum Short-Chain Fatty Acids from Gut Microbiome

Authors:

A. Liu[1], B. Tian[2], K-J. Su[1], L. Jiang[1], C. Zhao[3], M. Song[4], Y. Liu[5], G. Qu[1], Z. Zhou[1], X. Zhang[1], Y. Gong[1], C. Qiu[1], Z. Luo[1], Q. Tian[1], H. Shen[1], Z. Ding[1], H-W. Deng[1]; [1]Tulane Univ., New Orleans, LA, [2]Central South Univ., Changsha, China, [3]Michigan Technological Univ., Houghton, MI, [4]Univ. of Southern Mississippi, Hattiesburg, MS, [5]Sch. of Basic Med. Sci., Central South Univ., Changsha, China

Short-chain fatty acids (SCFAs) are the main metabolites produced by bacterial fermentation of dietary fiber within the gastrointestinal tract. The SCFAs produced by the gut microbiota (GM) are absorbed by the host, reach the bloodstream, and are distributed to different organs, thus influencing host physiology. Recent deep learning approaches have paved the way for innovative predictive models being capable of analyzing complex gut microbiome data to provide insights into disease risk, metabolic functionality, and other microbiome-associated outcomes, offering new opportunities for personalized medicine. However, there are insufficient explorations on predictive models that can accurately link the GM composition and the actual production of serum SCFAs in the host. Most existing predictive models (e.g., disease prediction model) do not fully account for the complex interplay among host characteristics (race, age, exercise, etc.), dietary habits, and GM composition. Here, we developed an innovative multi-task multi-view integrative approach (M^2AE, Multi-task Multi-View Attentive Encoders) to predict the abundances of serum SCFAs by capturing the intricate interplay among three views, i.e., gut microbiomes, dietary habits, and host characteristics. This method jointly explores view-specific representation and cross-view correlation for effective prediction. We demonstrated that this method outperforms traditional regression-based approaches (Isobutyric acid: Spearman correlation coefficient (SCC) = 0.327, p value < 0.05; Hexanoic acid: SCC = 0.308, p value< 0.05). The host characteristics, dietary habits, GM composition, and serum SCFAs data are from 964 males in our own Trans-omics Integration of Multi-omics Studies for Male Osteoporosis Study. Furthermore, this method identified that the bacterial species Bacteroides (stercoris, oleiciplenus), Prevotella (copri), and Flavonifractor (plautii) showed a more significant contribution of gut microbiome in predicting serum SCFA profiles. To further detect the complex associations between GM composition and SCFAs, we also further constructed the GM interplay networks for high SCFAs and low SCFAs groups, respectively. To summarize, the microbial association network analysis revealed the complex interplay of GMs for high SCFAs and low SCFAs groups. Our method and findings can enhance our comprehension of the complex biological processes involved in SCFA production, offering fresh perspectives on how dietary habits and GM composition contribute to this process.

PB3412 Investigating deep learning nuclei segmentation of H&E images for bulk RNA sequencing expression deconvolution.

Authors:

J. Balan, S. K. McDonnell, Z. Fogarty, N. B. Larson; Mayo Clinic, Rochester, MN

Recent developments in single-cell RNA sequencing (scRNA-seq) technologies facilitate characterization of transcriptomic patterns for individual cell types. However, scRNA-seq remains costly, requires high-quality tissue samples, and presents numerous analytical challenges. With large bulk RNA-seq datasets available for various tissues and conditions, new algorithmic approaches have emerged for expression deconvolution of bulk RNA-seq using well-defined scRNA-seq reference panels. However, these panels may not be available on relevant cell types and/or fully capture expression profile variability. With the common availability of pathological H&E-stained slides for tissue-based bulk RNA-seq and the ease of slide digitization, an alternative approach is to characterize and quantify cell types using deep learning (DL). In this study, we explored the integration of bulk RNA-seq expression data with DL-based cell proportion estimates from digitized pathological H&E slides in 120 normal prostate tissue samples.

Bulk RNA-seq gene expression was quantified using an HTSeq and normalized via CQN (24,075 total genes). Corresponding H&E slides were manually annotated by pathologist to provide crude estimates of percent epithelium (deciles; range = 40-80%) and presence of infiltrating lymphocytes. The slides were then digitized using the Aperio Leica GT-450 digital pathology scanner platform. The digitized slides in SVS format were analyzed using a DL model (Hovernet) to perform nuclei segmentation and quantify epithelial, neoplastic, inflammatory, connective, dead, non-neoplastic epithelial, lymphocyte, macrophage, and neutrophils. We then performed gene expression variance decomposition using linear mixed models to quantify explained variation by estimated cell-type proportions. Hovernet segmentation demonstrated overall agreement with manual epithelium estimates (Spearman corr. = 0.392, P<1e-05) while additionally providing single-cell resolution estimates. Expression variance decomposition analyses yielded comparable findings between the two cell-type proportion methods, with the manual and DL-based methods explaining >10% of total variation in 4079 (8.4%) and 5051 (10.5%) of total genes, respectively. Furthermore, DL-based methods tended to explain more expression variability on a per gene basis. The subset of 163 genes with high explained variation by epithelial proportion (>30%) were significantly enriched for relevant biological pathways. These results further highlight the potential of augmenting bulk RNA-Seq with H&E slide digital pathology for innovative multi-omics analyses.

Session Title: Omics Technologies Poster Session II

PB3413 Isolate and neaten VNTRs (InVNTR): A command-line tool for VNTR analysis and visualization.

Authors:

E. Kaufman, P. N. Valdmanis; Univ of Washington, Seattle, WA

Variable number tandem repeat (VNTR) length and internal repeat structure are associated with several disorders, including neurodegenerative disease. As a greater number of long-read genomes with accurate resolution of VNTRs become available, a suite of tools to investigate VNTR variation and structure at a high throughput are needed. We developed Isolate and neaten VNTRs or InVNTR as a command-line tool for rapidly parsing and analyzing VNTRs in whole genomes. It can be used to identify repeat expansions or contractions, as well as variation in repeat structure. InVNTR simplifies the process of creating data visualizations like Seattle plots, allowing for simple repeat visualization, either delimiting by sub-motif or by length of repeat motif. It requires unique sequence directly before and/or after the VNTR, and repeat length or a sub-motif by which to split it by. InVNTR has shown its utility for analysis of VNTR repeat allele length, accurately identifying individuals and populations with repeat expansions in both exons and introns in publicly available repositories of long read genomes, such as from the Human Pangenome Reference Consortium and the Human Genome Structural Variation Consortium.

As proof of principle, we utilized InVNTR to identify repeat sequence and structure in a series of the largest coding VNTRs in the human genome. We identified 12 VNTRs with variability in allele length in mucin genes, of which the pattern of repeat expansion could be identified in 11. A 34bp VNTR in *MUC2* has a 50-fold dynamic range in repeat length, while a VNTR in *MUC12* with a repeat unit of 84bp is more than 77 times larger in some individuals than others, corresponding to a nearly 35kb expansion event within an exon. We leveraged short read WGS data from the 1000 Genomes Project and found high concordance between short and long-read repeat length estimates. From this analysis we found a significant ~1.5-fold increase in average repeat length for *MUC2* specifically in samples of East Asian ancestry relative to the four other superpopulations ($p<0.0001$ by one-way ANOVA followed by Tukey's multiple comparison test), perhaps reflecting selection for increased repeat length. Collectively InVNTR is a powerful tool to identify and visualize human variation in VNTRs.

Ctr., Brookline, MA, [19]Univ. of California, Davis, CA, [20]Emory Univ., Atlanta, GA, [21]Harvard Med. Sch., Boston, MA, [22]Univ. of Bristol, Bristol, United Kingdom, [23]King's Coll., London, United Kingdom, [24]Sahlgrenska Univ. Hosp., Gothenburg, Sweden

Hip fractures are associated with significant disability, high cost, and mortality. However, the exact biological mechanisms underlying hip fractures remain incompletely understood. In an exploratory search of the underlying biology as reflected through the proteome, we performed a comprehensive Circulating Proteome Association Study (CPAS) meta-analysis on incident hip fractures.

Analyses included 6,430 subjects from two prospective cohort studies (Cardiovascular Health Study [CHS] and HUNT Study) with available circulating proteomics data (aptamer-based 5K SomaScan version 4.0 assay; 4,979 aptamers). Associations between circulating protein levels and incident hip fractures were calculated for each cohort using age and sex-adjusted Cox regression models.

Participants experienced 643 incident hip fractures. Inverse-variance weighted meta-analyses yielded more significant associations than either individual study and identified 23 aptamers that were significantly associated with incident hip fractures (conservative Bonferroni correction 0.05/4,979, $P<1.0\text{x}10^{-5}$). The most strongly associated aptamers with hip fracture risk corresponded to two proteins of the growth hormone/insulin growth factor system (GHR and IGFBP2) as well as GDF15 and EGFR. High levels of several inflammation-related proteins (CD14, CXCL12, MMP12, ITIH3) were significantly associated with increased hip fracture risk.

These analyses identified several circulating proteins and pathways consistently associated with incident hip fractures. These findings underscore the usefulness of the meta-analytic approach for comprehensive CPAS in a similar manner as has previously been observed for large scale human genetic studies.

Based on the CPAS results in CHS only, we developed a protein-based risk score for hip fracture prediction including 18 proteins. The performance in predicting incident hip fractures was determined in the independent HUNT validation cohort, as well as in a separate HUNT cohort with 1,988 subjects with proteomics data from the 7K SomaScan assay. The performance was better than existing genetic risk scores for bone mineral density and fractures, and it improved fracture discrimination and reclassification significantly in the independent validation data sets. Thus, proteomics may add clinically useful information for hip fracture prediction.

PB3415 Learning transcriptional signatures from high-dimensional data: Creating a set of spatially-resolved patterns of gene coexpression in the mouse cortex.

Authors:

K. Woyshner, Y. Wang, K. Hansen, G. Stein-O'Brien, L. Goff; Johns Hopkins Univ., Baltimore, MD

With the development of spatial transcriptomic technologies, researchers are able to profile gene expression across tissues of interest, retaining information about the location of individual genes, cell types, and features. This opens up the potential for more comprehensive profiling of complex and intricate structures such as the mammalian brain. However, meaningful interpretation of these high-dimensional data remains difficult. Non-negative matrix factorization is a machine learning algorithm that can reduce high-dimensional data into a meaningful set of latent space factors. When applied to transcriptomic data, these factors capture shared and distinct biological and cellular processes. We have adopted non-negative matrix factorization to learn a set of spatially-resolved patterns of gene coexpression in the mouse brain to better understand the diversity of transcriptional signatures across different brain regions and to establish a baseline representation of biological features and cellular processes engaged across the mammalian brain. Applying this technique to the Allen Brain Atlas in situ hybridization dataset of adult mouse brain, we have identified spatially resolved patterns that delineate distinct features of the mouse cortex. Many factors correlate strongly with known anatomical regions, while others capture shared spatial features that do not correlate with a single structure.

By projecting external gene expression datasets into this learned latent space catalog, we have the ability to predict the spatial extent of additional features such as disease-relevant signatures, and areas of shared developmental- and degeneration-associated regulatory networks to elucidate the spatial effect based on transcriptional changes. Defining a catalog of spatially informed transcriptional signatures in a healthy adult mouse brain would provide a more comprehensive understanding of the composition and organization of the mammalian brain and serve as a foundational resource for exploring the spatial extent of transcriptional changes involved in disease.

Session Title: Omics Technologies Poster Session II

PB3416 Leveraging Clinical Intuition to Improve Accuracy of Phenotype-Driven Prioritization

Authors:

M. Beckwith[1], D. Danis[2], J. Jacobsen[3], D. Smedley[3], C. Boerkoel[4], P. Robinson[5]; [1]The Jackson Lab. for Genomic Med., Famington, CT, [2]The Jackson Lab. for Genomic Med., Farmington, CT, [3]Queen Mary Univ. of London, Cambridge, United Kingdom, [4]Univ. of British Columbia, Vancouver, BC, Canada, [5]The Jackson Lab., Farmington, CT

Next-generation sequencing technologies (NGS), including exome sequencing and genome sequencing, have had dramatic effects on the cost, accuracy, and utility of genetic testing. A major focus of translational genomics research is to improve the performance of NGS-based diagnostics in rare disease. Efforts have focused on improving the performance of phenotype-driven prioritization, which leverages a comparison of the phenotypic abnormalities of the individual being investigated with those previously associated with human diseases or genetically modified model organisms to rank candidate variants. To our knowledge, no available algorithm explicitly models clinical intuition. However, the clinical assessment often involves the identification of the general group of diseases, such as non-syndromic intellectual disability and epileptic encephalopathy. We recently introduced LIRICAL, a likelihood-ratio based approach for phenotype-driven prioritization, in which the pretest probability of diseases was modeled uniformly. Here, we introduce L4CI, which extends the LIRICAL algorithm to model clinical intuition, exploiting the ontological representation of diseases of the Mondo ontology. For example, increasing the pretest probability adjustment value for metaphyseal chondrodysplasia-retinitis pigmentosa syndrome from 0, which corresponds to the uniform model used in LIRICAL, to 20 increases the disease rank from 52 to 1. Therefore, adjusting the pretest probability of a group of diseases that reflect clinical intuition can improve the ranking of candidates with the LIRICAL algorithm. Additionally, L4CI can be used with a group of genes associated with diseases that are commonly seen in specialty clinics for disease groups such as skeletal dysplasia. We provide a desktop application with graphical user interface that can be used to run the L4CI algorithm and produce an HTML output file.

PB3417 Leveraging Existing DNA Sequence-to-Expression Models for Enhanced Single-Cell Gene Expression Prediction

Authors:

Y. Zhou[1], T. Adeluwa[1], S. Gona[1], L. Zhu[2], M. Chen[1], H. Im[3]; [1]The Univ. of Chicago, Chicago, IL, [2]The Univ. of Chicago, chicag, IL, [3]Univ. of Chicago, Chicago, IL

Advancements in single-cell RNA sequencing (scRNA-seq) technologies have enabled the characterization of cellular heterogeneity and the identification of cell-type specific gene expression patterns. However, accurately predicting gene expression at the cell-type level remains a challenge. To address this problem, we developed Single-cell PrediXcan, a multitask model specifically designed for multi-cell-type gene expression prediction. Our model adopts a transfer learning approach, making use of the cutting-edge 'enformer' DNA-to-epigenetics deep learning model (Avsec, Ž., et al. 2021) and incorporating epigenetic features inferred from DNA sequences to improve prediction accuracy. Most existing gene expression prediction methods operate at the tissue level, lacking the resolution to capture cell-type specific variations. Existing methods designed for cell-type level prediction do not utilize epigenetic features during training and consequently demonstrate suboptimal performance. In contrast, Single-cell PrediXcan focuses on training a neural network model on scRNA-seq datasets with predicted epigenetic features, enabling accurate gene expression prediction in different cell types.

Here we show that our Single-cell PrediXcan model trained on Enformer predicted epigenetic features with single-cell RNAseq data from the OneK1K dataset (Yazar, S., et al. 2022. Science) achieves a correlation of 0.85 across all the cell types in the dataset between measured and predicted expressions. These results highlight the potential to generate single-cell prediction models for diverse contexts, advancing the development of our proposed method, single-cell prediXcan.

Moreover, Single-cell PrediXcan paves a way for transcriptome-wide association studies (TWAS) at the cell-type or cell-state level, which could provide new insights into the molecular mechanisms underlying complex traits and diseases.

Session Title: Omics Technologies Poster Session I

PB3418 Leveraging multiomics data to improve diagnostic yield: A prospective study of 29 familial cases.

Authors:

A. Crawford[1], J. Albay[1], D. Hernandez[1], R. Wang[1], Q. Zhang[1], E. Chekalin[1], Y. Zhuang[1], C. Glidewell-Kenney[1], J. Taylor[1], A. Clause[1], A. Malhotra[1], A. Coffey[1], A. Chandrasekhar[1], K. Bluske[1], K. Robinson[1], R. Bombardi[1], I. Khrebtukova[1], E. Puffenberger[2], K. Brigatti[2], D. Basel[3], J. McCarrier[3], B. Sadikovic[4], J. Kerkhof[4], A. Kennedy[5], K. DeBalsi[5], R. Taft[1]; [1]Illumina Inc., San Diego, CA, [2]Clinic for Special Children, Strasburg, PA, [3]Med. Coll. of Wisconsin, Milwaukee, WI, [4]Verspeeten Clinical Genome Ctr., London Hlth.Sci., London, ON, Canada, [5]Metabolon, Durham, NC

Background

Undiagnosed rare diseases affect at least 200 million individuals worldwide. Although whole exome sequencing (WES) and whole genome sequencing (WGS) have improved the ability to rapidly diagnose many of these patients, approximately 50% of cases remain without a definitive molecular diagnosis. This study aimed to investigate the potential of multiomic assays to narrow the diagnostic gap across a broad spectrum of clinical presentations suggestive of a genetic disease.

Methods

We conducted a prospective, observational study encompassing 29 consenting families including probands, biological parents, and available unaffected siblings. Study participants were recruited based on a suspected genetic origin of their clinical presentation and participation of at least two unaffected family members. Five families had previously received a molecular diagnosis and served as positive controls, whilst the remaining 24 families had not received a molecular diagnosis from previous whole genome sequencing. Probands presented with a diverse range of phenotypes across multiple systems and spanned in age from 2 to 43 years. We performed a set of multiomic assays on blood samples including both long and short read whole genome sequencing, deep whole genome sequencing, methylation profiling, plasma proteome analysis, bulk T cell and B cell immune repertoire sequencing, whole transcriptome sequencing, and metabolomic profiling. Due to the limited sample size and lack of publicly available datasets, most of the analyses were conducted in a one-versus-all approach, comparing the proband results to the cohort.

Results

Systematic analysis resolved 9 of 24 previously undiagnosed cases. This included the identification of three novel gene-disease relationships, three cases solved using short read WGS data, two cases with whole transcriptome analysis, and two cases through detection of disease-associated whole epigenome signatures using EpiSign™. The genetic findings in at least two cases did not explain the entirety of the participant's phenotypes and were thus considered only partially resolved. Supporting evidence for the molecular findings was observed in multiple multiomic assays, including plasma proteomics and metabolomics, providing additional confirmation of the reported results in both positive controls and the newly solved cases.

Conclusion

The integration of multiomic analyses demonstrates great potential to increase the diagnostic rate for patients with undiagnosed disease. Sequence data from these pilot cases will be made available for further research in partnership with the NHGRI GREGoR Consortium.

Session Title: Omics Technologies Poster Session II

PB3419 Localized spatial dimensionality reduction on spatial transcriptomics

Authors:

J. Chen, Y. Li, D. Li; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Dimension reduction has become a crucial technique in the analysis of omics data, particularly due to its high dimensionality, such as gene expression measurement, which often involves more than 10,000 genes. However, the selection of genes for analysis remains an open question, and no or minimal selection can be computationally prohibitive. Therefore, incorporating dimension reduction is essential in such analyses. In the field of transcriptional studies, spatial transcriptomics has gained popularity due to its ability to capture gene expression while preserving spatial coordinates. It has been observed that spots or cells in close spatial proximity tend to exhibit similar gene expression patterns. Consequently, when performing dimension reduction, considering the spatial location may enhance reduction efficiency. In this study, we propose a novel method, Localized Spatial Dimensionality Reduction (LSDR), for dimension reduction while incorporating spatial coordinates. For each spot or cell, we leverage neighboring spots or cells to perform PCA analysis. Additionally, we introduce a penalty term to ensure that the dimension reduction matrix reflects the spatial distance between spots or cells. Through simulation studies and real data analysis, we demonstrate the advantages of our LSDR approach. By obtaining a dimension reduction matrix corresponding to each spatial coordinate, we can leverage transfer learning to apply this matrix to other slides in a common coordinate space without the need for retraining the model. Furthermore, utilizing the local dimension reduction matrix demonstrates better performance on the application of clustering methods to detect biologically meaningful spatial domains.

Session Title: Omics Technologies Poster Session III

PB3420 Long read RNA-sequencing demarcates cis and trans-directed alternative RNA splicing.

Authors:

G. Quinones-Valdez[1], K. Amoah[1], X. Xiao[2]; [1]UCLA, Los Angeles, CA, [2]Univ. of California, Los Angeles, Los Angeles, CA

RNA splicing is largely determined by the contribution of both *cis*-acting genomic elements and *trans*-acting splicing factors. Genetic variants may disrupt *cis*-regulatory motifs and alter splicing, constituting an important link between genotypes and phenotypes. Determining splicing events that are directed primarily by the *cis*- or *trans*-acting mechanisms will greatly inform our understanding of the genetic basis of disease. Here, we leverage long-read RNA-seq to demarcate splicing events that are primarily *cis*- or *trans*-directed, using a new method, isoLASER, that performs *de novo* variant calling, gene-level phasing and allele-specific splicing analysis for long reads. Using ENCODE data from human and mouse samples, we identified 2,807 and 5,322 unique exonic parts, respectively, exhibiting *cis*-directed splicing. Our findings demonstrate that the inclusion of most alternatively spliced exons is predominantly regulated by tissue-specific factors, while the splicing of *cis*-regulated exonic parts remains largely consistent across tissues with a shared genetic background. Additionally, we observed that genes under *cis*-directed splicing are frequently associated with immune function, and the novel exons resulting from *cis*-regulation significantly overlap with SINEs, LINEs, and simple repeat elements known to shape immune response. Leveraging isoLASER's joint analysis function, we analyzed pooled samples from the same tissue type but with different genetic backgrounds to identify likely functional variants. Remarkably, the putative functional variants exhibit significant alterations in RNA-binding protein (RBP) binding and represent a subset of splicing quantitative trait loci (sQTLs) enriched with highly significant p-values, validating the functionality of these candidate variants. Furthermore, we analyzed *cis*- and *trans*-directed splicing of brain samples from patients with Alzheimer's disease (AD) and healthy controls. Our analysis uncovered many cis-directed events, some of which reside in genes of close AD relevance. We highlight a notable difference in the genetic modulation of *HLA-A* gene splicing between AD and controls, which was further confirmed through sQTL analysis using short-read data from the Mount Sinai Brain Bank Consortium. In summary, this study establishes a clear demarcation between genetically and non-genetically driven splicing. We also provide a framework for identifying such events and splicing-associated variants in cohorts with a limited sample size.

Session Title: Omics Technologies Poster Session I

PB3421 Long read single cell whole genome sequencing from human brains

Authors:

C. Proukakis[1], E. Kalef-Ezra[1], D. Horner[1], M. izydorczyk[2], M. Toffoli[1], N. Holmes[3], S. Scholz[4], F. Sedlazeck[2]; [1]Univ. Coll. London, London, United Kingdom, [2]Baylor Coll. of Med., Houston, TX, [3]Univ. of Nottingham, Nottingham, United Kingdom, [4]NIH, Bethesda, MD

Somatic mutations occur in human brains, and may have a role in neurodegenerative disorders. Their study is challenging because of the low allelic fraction, which may necessitate sequencing of single cell DNA. This is preceded by whole genome amplification, which is possible by a number of methods. Multiple displacement amplification (MDA), performed isothermally by the phi-29 enzyme, yields long amplicons (>10 kb), making the detailed study of all classes of somatic structural variants (SV) by long reads theoretically possible. It results, however, in incomplete and uneven amplification, which could be improved by dividing the genome into droplets on the X-Drop (Samplix), as well as complex chimeras.Multiple system atrophy (MSA) is a rare synucleinopathy, a sporadic neurodegenerative disorder similar to Parkinson's disease. We previously demonstrated somatic CNVs (gains) of the disease-relevant alpha-synuclein gene using FISH, and large CNVs in almost a third of cells from two brains using low coverage Illumina single cell whole genome sequencing (scWGS). We have selected these two MSA brains for further study by long read scWGS. We prepared nuclear preparations from the cingulate cortex, and one control brain cortex, and isolated single nuclei using the CellRaft device (Cell Microsystems), followed by droplet MDA. We performed Nanopore sequencing of 6 cells from each brain, using two library prep protocols: one digesting MDA side-chains with T7 endonuclease, and a PCR-based one. Up to 6 cells were multiplexed per flow cell, with maximum yields of 25 Gb for MinION R9.4 (PCR protocol, N50 ~2.8 kb) and 115 Gb for Promethion R10.4 (T7 protocol, N50 ~3 kb). Sniffles2 analysis allows detection of Alu insertions and other SV in areas adequately covered, after filtering chimeras which manifest as inversions. As a comparison, we studied 5 cells from one MSA brain amplified with Primary Template Amplification (BioSkryB), which also uses phi-29, but the addition of "stop" nucleotides leads to shorter amplicons and more complete and even genome coverage. MinION sequencing (3.3 Gb yield) led to much lower N50 as expected (0.77 kb), but no inversions. Further filtering of single cell dMDA SV calls and comparison to bulk Nanopore (55x) and Illumina (85x) data is underway.

Session Title: Omics Technologies Poster Session II

PB3422 Long-read RNA sequencing identified the different gene isoforms in different brain regions and their relationship with DNA methylation.

Authors:

M. Shimada[1], Y. Omae[1], A. Kakita[2], R. Gabdulkhaev[2], T. Miyagawa[3], M. Honda[3], A. Fujimoto[4], K. Tokunaga[1]; [1]Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, [2]Brain Res. Inst., Niigata Univ., Niigata, Japan, [3]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan, [4]Univ. of Tokyo, Tokyo, Japan

Background: In neuropsychiatric disorders, site-specificity in the brain has been suggested and differences in gene expression could potentially explain this mechanism. However, long-read transcriptome analysis of the human brain is very limited, and none has focused on brain region-specific gene expression. In this study, we performed long-read RNA sequencing on 12 samples that were derived from three different brain regions of the same individuals: the cerebellum, hypothalamus, and temporal cortex. We then compared the differences in expression profiles between regions. **Results:** We identified numerous novel isoforms; approximately 40% of the detected isoforms were novel, some of which were confirmed by publicly available LC-MS/MS data of the brain cortex. We found that, compared to other regions, many genes with higher expression levels in the cerebellum and temporal cortex were associated with neuronal pathways, whereas those with higher expression levels in the hypothalamus were primarily linked to immune pathways. In the analysis of genes expressed in high numbers of isoforms in each brain region, immune-related genes were detected only in the hypothalamus as well, although the correlation between the number of isoforms and expression levels per gene was not strong. In addition, we investigated genes with different major isoforms in each brain region, even with similar overall expression levels among regions. As a result, *GAS7* was found to show the most significant difference in the major expressed isoforms among the three brain regions and the region-specific *GAS7* isoforms were confirmed by western blotting. Many of the genes with different major isoforms among regions were found to be involved in "actin filament-based process" and "cell projection organization" pathways, suggesting that region-dependent isoforms may have distinct roles in dendritic spine and neuronal formation in each region. Furthermore, we investigated the involvement of DNA methylation in these isoforms differentially expressed in each region. We found that there are significantly more CpG sites differentially methylated around genes that express different major isoforms among regions, especially in the region within 1 kb downstream from the transcription start sites between isoforms that have different TSSs between regions. **Conclusions:** Our results provide potentially valuable findings for future research on brain disorders and shed light on the mechanisms underlying isoform diversity in the human brain.

PB3423 Long-read RNA sequencing identifies consistency amongst tissues and laboratories for RNA-isoforms of known genes and *de novo* gene bodies.

Authors:

L. Gordon[1], M. Page[2], B. Aguzzoli Heberle[1], J. Brandon[1], K. Nations[1], M. Wadsworth[3], S. Goodwin[4], E. Ghiban[5], R. Wappel[5], S. Mavruk Eskipehlivan[5], P. Nelson[1], J. Miller[1], M. Ebbert[1], J. Fryer[6]; [1]Univ. of Kentucky, Lexington, KY, [2]Univeristy of Kentucky, Lexington, KY, [3]Univ. of Kentucky, lexington, KY, [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY, [5]Cold Spring Harbor Lab, Cold Spring Harbor, NY, [6]Mayo Clinic, Jacksonville, FL

Intro: Traditionally, short-read sequencing is used for RNASeq studies that, due to technical limitations, forces researchers to collapse all RNA isoforms for a given gene into a single value—ultimately hiding the diversity and variation of individual RNA isoforms. Long-read sequencing, however, can sequence an entire RNA molecule in a single read, enabling researchers to identify and quantify all RNA isoforms from known genes and new gene bodies. Since long-read sequencing is relatively new, there have been few studies characterizing and quantifying individual RNA isoforms across body tissues. Here, we compare our deep long-read human brain RNASeq to the recently released GTEx data by Glinos et al. and demonstrate the reliability of quantifying isoform expression, and the expression patterns for newly discovered genes and isoforms across tissue types. **Methods:** We sequenced 12 frontal cortex post-mortem aged samples (Brodmann area 9/46; 50% female) using 1 Oxford Nanopore PromethION flow cell/sample. We quantified expression of new isoforms in 9 tissue types from GTEx data. GTEx data were sequenced using the same protocol, except using 1 MinION flow cell/sample. Analysis included pychopper, mimimap2, Bambu, and Ensembl annotations for GRCh38 v107 (July 2022). **Results:** In our deep brain sequencing, we identified 1534 new isoforms from 1255 known genes and 1861 isoforms from 1677 new gene bodies (relative to GRCh38 v107), where 431 (28%) and 269 (14%) of these isoforms are high-confidence and expressed at median CPM (counts per million) > 1, respectively. Limiting to only medically relevant genes, we identified 54 (45%) new isoforms expressed at median CPM > 1. In the 9 GTEx tissues, 10% to 32% of new isoforms from known genes were present with median CPM > 1, notably 32% in the same brain area as our data. The percentage of new isoforms from new gene bodies with a CPM > 1 fell between 0.9% and 6% (6% in same brain region). New isoforms from medically relevant genes increased to between 20% and 43% (42% in same brain region). Additional statistics will be included during presentation. **Conclusions:** Properly characterizing and quantifying individual RNA isoforms across all genes is essential to truly understanding human health and disease. Here, we identified hundreds of new high-confidence RNA isoforms since GRCh38 v107 (July 2022), and quantify their expression across human tissues—allowing us to begin discerning individual RNA isoform function. We also demonstrate that long-read sequencing gives consistent results for the same tissue across different samples and laboratories.

Session Title: Omics Technologies Poster Session I

PB3424 Long-read sequencing reveals transcriptome variations in a right ventricle pressure overload Porcine model administered autologous umbilical cord blood-derived mononuclear stem cell therapy.

Authors:

N. Odogwu, C. Hagen, S. Cantero, B. Rasmussen, S. Oommen, T. Nelson, Wanek Pre-clinical Pipeline; Mayo Clinic, Rochester, MN

Background The genetic complexity, variable phenotypic manifestations, familial inheritance patterns, and a wide variety of genes that characterize congenital heart disorders (CHDs) including hypoplastic left heart syndrome make them difficult to understand. Stem cell therapy and their paracrine activity has been implicated in cardiac repair and restoration of heart function however, their mechanism is still under intense investigation. **Objective**To provide a mechanistic and functional understanding of how umbilical cord blood (UCB) derived mononuclear stem cells potentiate cardiac regeneration and improve cardiac function. We evaluated the effects of administering UCB-derived mononuclear stem cell therapy on failing heart transcriptome by synergistically combining filtering, and multiple multi-omics sequencing approaches to pinpoint candidate genes and gene variants that may affect cardiogenic pathways. **Method** A right ventricle pressure overload porcine model of heart failure was created by pulmonary arterial binding (PAB). Piglets were administered single and multidose umbilical cord mononuclear cells (UCB-MNCs) (3 million/kg) therapy on the right ventricle heart chamber and followed for 12 weeks. Chamber-specific transcriptome expression was assessed using Illumina RNA sequencing, and long-read RNA sequencing. Differentially expressed genes were validated by quantitative real-time PCR. **Results and Conclusion** Next-generation RNA sequencing, refined by pathway analysis, pinpointed distinct transcript genes across the right and left ventricles that are recognized for their role in cardiac pathophysiologies and clinical benefits. Importantly, *WT1, ACTN2*, were significantly upregulated in the left ventricle in pig-administered single-dose UCB-MNCs (3 million/kg) **(P_{WT1}, P_{ACTN2} < *0.05; Kruskal-Wallis*)**. *TBX 20* gene was highly upregulated in the multidose group (P_{TBX20} < 0.05; ***Kruskal-Wallis,*** multidose vs single dose). Long-read RNA-seq unmasked allelic changes and *cis* effects of genetic variants on transcripts. Given the role of genetic variants affecting transcript structure in disease risk, we resolve that a high-resolution characterization of the transcriptome with long-read data is crucial for the discovery of regulatory mechanisms of disease-associated genetic variants.

Session Title: Omics Technologies Poster Session II

PB3425 Low-pass whole genome sequencing with imputation provides an accurate and cost-effective alternative to array genotyping for GWAS and PRS approaches.

Authors:

A. Mulford[1], A. R. Sanders[1,2]; [1]NorthShore Univeristy Hlth.System, Evanston, IL, [2]Univ. of Chicago, Chicago, IL

Introduction. Reduced sequencing costs have prompted interest in low-coverage whole genome sequencing (lcWGS), with imputation, as an alternative to other genome-wide genotyping approaches. Previously reported comparisons have been done with simulation or downsampling approaches generally in European ancestry (EA) samples, or for direct empirical comparisons in much smaller N datasets.
Methods. DNAs from the Genomic Health Initiative (GHI), an institutional biobank, underwent lcWGS at an average 0.5× coverage. Generated paired-end FASTQ files underwent quality control (QC), and passing samples were imputed using the 1,000 Genomes Phase 3 haplotype reference panel. Variants from imputation of lcWGS data with a posterior probability of ≥0.90 were compared to previously generated array genotypes (UK Biobank Axiom Array, following manufacturer's recommended QC filters) for 5,783 individuals across an average of 640,000 variants using SnpSift and BCFtools.
Results. The average concordance for common (>5%), uncommon (1-5%), and rare (<1%) minor allele frequency (MAF) bins was high overall (0.989, 0.993, 0.995) with consistent concordance rates across autosomes and chromosome X, with very similar results for subsets self-identifying as non-Hispanic EA (N=4,305) or African ancestry (AA; N=326). Restricting comparisons to exclude homozygous reference matches showed decreased average concordance overall (0.976, 0.902, 0.934), again with similar results in EA and AA subsets. Genotype grids showed heterozygote mismatches as the most common type of discordance, as expected.
Conclusions. We found high genotype concordance rates overall and in various subsets (MAF bins, self-reported ancestry, non-reference genotypes) for two methods: lcWGS with imputation vs. array genotypes. Here, we demonstrate the applicability (i.e., high genotype concordance) in an institutional biobank setting with a much larger and more diverse sample population that previous reports. We will further present evidence of the utility of this genotyping method by describing replication of known genome-wide association study (GWAS) associations and polygenic risk score (PRS) findings for exemplar disorders and variants.

Session Title: Omics Technologies Poster Session III

PB3426 Machine learning and misalignment: Towards a comprehensive approach.

Authors:

D. D'Onofrio, J. Fu, B. N. Pusey, D. R. Adams; NIH, Bethesda, MD

INTRO: The NIH Undiagnosed Diseases Program (UDP) enrolls participants with significant illnesses that remain undiagnosed despite extensive standard of care clinical evaluation. Increasingly, individuals present with a history of a negative clinical exome or genome study. For this reason, the UDP utilizes genomic analysis pipelines optimized for detecting variants that may be missed by other analyses. This high-sensitivity approach generates many false-positive results. Methodologies for prioritizing results include the identification of short read misalignments. We hypothesize that currently available mapping and genotype scores do not capture all the available information for quantifying alignment quality for individual variants. To address this question, we are developing a machine learning-based tool to assist with ranking variants based on the quality of the alignment associated with short read variants. **METHODS:** We are generating a list of alignment characteristics (i.e., mapping quality, coverage, % of soft clipping, density of apparent variants, # of haplotypes), building on those incorporated into existing tools such as the GATK pipelines. These characteristics are being built into a random forest classifier from the python library scikit-learn. This model will be trained and tested with a combination of highly characterized genomes (Genome in a Bottle and Platinum Genomes), synthetic genomes, and a set of 7748 hand-curated variants from prior UDP evaluations. **RESULTS:** Initial assessment of potential model classifiers has demonstrated marked operator bias in hand-curated datasets. Evaluation of a heuristic alignment filtration system from a prior project suggests that some specific alignment patterns, such as >2 haplotypes covering the called variant, provide information that is not captured by traditional mapping or genotype score filters. **CONCLUSIONS:** We present preliminary data for in-progress work on a machine learning classifier designed to assist with the prioritization of results in noisy short read variant datasets. Our hope is that the work will prompt discussion and feedback that will be useful as tool development proceeds.

Session Title: Omics Technologies Poster Session I

PB3427 MAJIQ-CLIN: A novel tool for the identification of Mendelian disease-causing variants from RNA-seq data

Authors:

D. Issakova[1], J. K. Aicher[1], S. Jewell[1], G. R. Grant[1], N. F. Lahens[1], E. Bhoj[2], Y. Barash[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Children`s Hosp. of Philadelphia, Philadelphia, PA

Exome sequencing (ES) is the current standard of care for patients with suspected Mendelian genetic disorders; however, the diagnostic rate is only 31%. Traditional ES analysis methods have difficulty incorporating differences in RNA splicing. Alternative RNA splicing is a highly regulated process in which different segments of pre-mRNA are joined, or spliced, together resulting in different mature mRNA transcripts. Alternative splicing occurs in over 90% of human genes, and changes in gene splicing can drastically alter the mRNA transcript and severely affect function of the mature protein. It is estimated that 15-50% of human pathogenic variants alter splicing, with several synonymous splice-altering variants being causal for known Mendelian disorders. It is therefore extremely crucial to develop reliable diagnostic tools to detect aberrations in RNA splicing from patient RNA-seq.
Previous studies have approached this problem, contrasting RNA-seq splicing variations found in patient samples to those found in healthy controls. However, tools developed for this task, such as FRASER and LeafCutterMD, have several limitations. Specifically, LeafCutterMD does not quantify intron retention, nor correct for the effect of confounding factors. In addition, LeafcutterMD and FRASER also require re-running many or all modeling steps from scratch upon the introduction of new data, which results in long run times that are impractical for clinical use.
We present MAJIQ-CLIN, a clinical pipeline developed using an updated version of our previously published MAJIQ pipeline for quantifying alternative splicing. Unlike FRASER and LeafCutterMD, MAJIQ-CLIN detects both unusually enriched outlier variants and entirely novel splice sites in patients. Like FRASER, MAJIQ-CLIN quantifies intron retention and corrects for the effect of known and unknown confounding factors. However, MAJIQ-CLIN can reuse quantifications of controls and learned models of unobserved confounders, requiring only fast updates of intermediate files when comparing a new sample against the controls. We assess MAJIQ-CLIN's accuracy using both synthetic data with spiked-in splice variations as well as several datasets of solved test cases, demonstrating it compares favorably to both LeafCutterMD and FRASER, and demonstrate its use in clinical cases.
In summary, we introduce a new method to accurately and effectively detect disease-causing splicing outliers in patients with suspected Mendelian disorders, with many advantages over currently available tools. By employing MAJIQ-CLIN we hope clinical geneticists will be able to improve molecular diagnosis rates and clinical care.

Session Title: Omics Technologies Poster Session II

PB3428 Massively parallel reporter assays and 3D chromatin structure in innate immune cells identify novel putative Alzheimer's Disease risk genes.

Authors:

M. Bond, I. Y. Quiroga, S. D'Costa, J. L. Bell, I. R. Sahasrabudhe, J. C. McAfee, K. S. Reed, S. Lee, M. Patrucco, H. Won, D. H. Phanstiel; Univ. of North Carolina, Chapel Hill, NC

Alzheimer's Disease (AD) is a progressive neurodegenerative disease that is the leading cause of dementia world-wide, affecting over 55 million people. Genome-wide association studies have identified 75 genomic loci associated with AD; however, interpreting these loci is difficult for multiple reasons. Multiple variants fall within linkage disequilibrium (LD) and are inherited together, making causal variants difficult to identify. Further, a majority of variants are located within the noncoding genome and it is unclear which genes they are affecting. Massively Parallel Reporter Assays (MPRA) allow us to identify putative active enhancers, yet it is also critical to perform MPRAs in relevant cell types and biological contexts. Therefore, we performed MPRAs to quantify the transcriptional activity of AD-associated variants in resting and activated human macrophages revealing hundreds of expression modifying variants. To understand these epigenetic changes and connect them to the genes that they regulate, we mapped H3K27ac (CUT&RUN), chromatin accessibility (ATAC-seq), gene expression (RNA-seq), and chromatin loops (Hi-C) in resting and activated iPSC-derived microglia. In total, we identified 20,992 chromatin loops across resting and activated iPSC-derived microglia. Among these, 9,544 loops linked 14,576 enhancers to 11,487 genes. 58 of these loops connected 414 AD-risk variants that were queried in our MPRA assays to 85 genes. 212 loops, 19,256 enhancers, and 2,790 genes changed in response to immune activation, highlighting the need to study these regulatory events in the correct biological context of disease. Continued analyses and data integration will reveal further mechanistic insight and identify novel AD risk genes that can be potentially targeted for therapeutic development. This intersection of MPRA results and dynamic regulatory networks with AD GWAS in a cell-type and context specific fashion has added to our understanding of the etiology underlying AD.

Session Title: Omics Technologies Poster Session III

PB3429 Metabolomic profile in Pre-eclampsia: a case control study in third trimester.

Authors:

C. Colmenares[1], P. Bautista-Niño[2], D. Quintero-Lesmes[2], C. Riaño[2], N. Serrano Díaz[2]; [1]Univ. del Valle. Fundación Cardiovascular de Colombia, Floridablanca, Colombia, [2]Fundación Cardiovascular de Colombia, Floridablanca, Colombia

Aim: Establish metabolomic profile associated with Pre-eclampsia and its severity (HELLP and early Pre-eclampsia) through metabolome wide association analysis and weighted correlation network analysis. **Methodology**: Case-control study derived from Colombian GenPE biobank that recruited pregnant women at the moment of delivery. Metabolomic analysis was performed on serum samples by Proton Nuclear Magnetic Resonance (Nightingale Health Ltd). 250 were assessed (169 direct measures and 81 ratios from direct measures): Fatty acids, lipoproteins, inflammation, fluid balance, apolipoproteins, glycerides and phospholipids, glycolysis related metabolites, lipoprotein particle concentration and size, amino acids, ketone bodies, cholesterol. Metabolomic quality control was good (Success rate for quantification was above 95% for 246 metabolites) and only 4 serum samples did not report values for any metabolite. Imputation (half minimal) and standardization (inverse normal transformation) was carried out prior to the analysis. For metabolome wide association analysis logistic (Pre-eclampsia) and multinomial (HELLP syndrome and early Pre-eclampsia) regression was conducted adjusting for potential confounders and p value was corrected through FDR (Liu method). A weighted metabolite co-expression network analysis (WGCNA) was constructed using a soft thresholding power of 20, R2 of 0.7, minModuleSize of 5, mergeCutHeight of 0.25 and then, correlation between modules and clinical outcomes were assessed to identify significant modules. **Results:** 596 women were included (controls n=357 and cases n=239). Age was 18.6 years (DE 2.8) for controls and 20.7 years (DE 5.2) in cases; metabolites associated with less risk for Pre-eclampsia were those related to HDL (XL-HDL-FC, XL-HDL-C, XL-HDL-PL, XL-HDL-L, XL-HDL-CE and HDL size), XL-HDL-FC was also associated with less risk of HELLP syndrome and early Pre-eclampsia. WCGNA identify seven modules, and one was inversely associated with all outcomes (corr -0.21 pval: 2,7 x10-7 for Pre-eclampsia, -0.12 pval: 0.004 for HELLP, -0.2 pval: 1.2 x 10-6 for early Pre-eclmapsia). Metabolites in that module were XL-HDL-P, XL-HDL-L, XL-HDL-PL, XL-HDL-C, XL-HDL-CE and XL-HDL-FC. **Discussion:** As in cardiovascular diseases, HDL-related metabolites of different sizes had a protective effect for Preeclampsia and its severity. A recent mendelian randomization analysis reported a causal and protective effect for HDL in this disease. These findings provide evidence of molecules of interest for establishing risk or developing potential therapeutic targets.

Session Title: Omics Technologies Poster Session I

PB3430 † Microbiome Preterm Birth DREAM Challenge: Crowdsourcing Machine Learning Approaches to Advance Preterm Birth Research

London, London, United Kingdom, [14]Inst. de Investigacion Sanitaria La Fe (IIS La Fe), IVI Fndn., Valencia, Spain, [15]Columbia Univ., New York, NY, [16]NIH, US Dept. of Hlth.and Human Services, Detroit, MI, [17]Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Introduction: Every year 11% of infants are born preterm with significant health consequences. The vaginal microbiome has been extensively correlated in single center studies with the risk for preterm birth (PTB), opening the promise of using microbiome data to build rigorous, generalizable, and robust predictive models to identify at-risk pregnancies. However, combining data from different microbiome studies into a single dataset is needed for greater statistical power but a non-trivial feat. We aggregated multiple vaginal microbiome studies and leveraged this data for a crowdsourced challenge to predict the risk of PTB. **Methods:** Using a novel technique (MaLiAmPi) we aggregated public raw data from 9 vaginal microbiome studies (total: 3578 samples from 1268 pregnant individuals) and two not-public datasets for validation (total: 331 samples from 148 pregnant individuals). We organized a challenge that took place July-September 2022 to predict: (a) preterm (PTB; <37 weeks) or (b) early preterm birth (ePTB; <32 weeks). Challenge teams worldwide received the training data, then built and submitted their models through our online platform. Model performance metrics on the validation data were returned to the teams. Teams were limited to 5 total submissions with the top performing model selected for ranking. We carried out several techniques to ensure robustness of the resulting rankings including test set label inversion, bootstrapping, over- and under-sampling. **Results:** Top performing models (among 148 and 121 submissions from 318 teams) achieved AUROC scores of 0.69 and 0.87 predicting PTB and ePTB respectively, exceeding organizers' baseline models performance. Most top performing models used ensemble approaches including tree-based methods, e.g., random forest and relatives. A few used regression approaches with feature pruning and clustering, or neural networks. Alpha diversity, VALENCIA community state types (CSTs), and taxonomy-independent composition were important features in top performing models. Through feature permutation combined with independently-developed highly predictive models, we identified multiple organisms that associate with PTB risk. Specifically, there seems to be physiologically-relevant species- and strain-level variability within the Lactobacillus and Gardnerella genera across trimesters that indicates a potential role for intraniche competition in vaginal microbiome during pregnancy and the risk for early PTB. **Discussion:** This work is a model for implementing a crowdsourcing strategy to power the translation of microbiome data into clinically relevant predictive models and better understand PTB.

Session Title: Omics Technologies Poster Session II

PB3431 † Mind the reference gap

Authors:

J. Eisfeldt[1], K. Bilgrav Saether[1], E. Ten Berk De Boer[1], I. Bunikis[2], C. Carvalho[3], A. Ameur[4], A. Lindstrand[5]; [1]Karolinska Inst, Stockholm, Stockholm, Sweden, [2]Uppsala Univ., Uppsala, Sweden, [3]Pacific Northwest Res. Inst., Seattle, WA, [4]Uppsala Univ, Uppsala, Sweden, [5]Karolinska Inst.t, Stockholm, Sweden

Since its release in the early 2000s, the human reference genome has been an invaluable resource in the field of human genomics. Yet, despite significant improvements, considerable sections of GRCh38 remain absent or computer simulated. The recently published Telomere to Telomere (T2T) reference genome offers a continuous sequence, promising heightened structural variant detection and improved mapping. We initiated this study when an inv6(p12.3q16.1) was undetected in the GRCh37 genome, but clearly visible in T2T, GRCh38, and the genomes of both chimpanzees and bonobos. The inversion was first detected by karyotyping in a male patient with hearing impairment, intellectual disability, strabismus, diplopia, anosmia, autistic features and hypogonadism. We next aligned short read genome data from 100 healthy individuals to various reference genomes, including T2T, GRCh37, GRCh38, and those of chimpanzee and bonobo. This allowed us to detect regions present in primate genomes but missing in at least one human reference, Differential Reference Regions (DRRs), thereby uncovering an intriguing similarity between GRCh37 and the chimpanzee genome. Our analysis reveals that most analyzed DRRs demonstrate low coverage, and it underscores the impact of such regions on structural variant detection and variability. Despite the promising prospects of the T2T reference, we found GRCh38 to be the most dependable for optimal structural variant detection and mapping. Our results highlights the need for high-quality diploid assemblies or graph genomes to enhance the efficiency of structural variant workflows. Specifically, a pangenome or de novo assembly may be necessary for comprehensive population representation, particularly in the diagnosis of rare diseases. Our findings collectively call attention to the criticality of ancestral sequences missing from current human reference genomes.

Session Title: Omics Technologies Poster Session III

PB3432 Miqa: A no-code, automated bioinformatic QA platform to continuously improve the accuracy and reliability of computational tools used in clinical genomics.

Authors:

V. Lau, G. Berry, K. McKeag; Magna Labs, Falls Church, VA

Software quality impacts research output and decision making in clinical genomics. While next-generation sequencing (NGS) data continues to scale in size and complexity, quality assurance (QA) processes of bioinformatic pipelines struggle to keep up with the speed of their development. Reliable bioinformatic tools for genetic variant detection are crucial to providing accurate disease diagnosis and patient treatment. Continuous and systematic evaluation in clinical bioinformatics is often hindered by inadequate resources (time and funding) or software engineering expertise. Researchers often rely on periodic benchmarking studies for performance data that may not be suitable to their particular genomic use case or datasets. Alternatively, bioinformatic engineers reportedly spend up to 40-60% of software development and maintenance time on manual troubleshooting. The “shift left” model of regularly detecting software defects early in the development process has proven to drastically improve software quality and delivery. This common practice in conventional software engineering is not well implemented in computational biology. To address the technological and knowledge gap in bioinformatic software testing, we have developed a no-code, automated QA platform, Miqa, to foster continuous quality surveillance and benchmarking of clinical NGS analysis pipelines. Miqa can fully automate the end-to-end QA process from test data preparation, NGS pipeline test execution to real-time QA result reporting. Its user-friendly graphical interface designed for scientific users regardless of programming skill level. To demonstrate Miqa’s real-time software bug detection, we performed a case study on the GitHub issue #1446 of the open-source variant caller, bcftools, which was generating inconsistent variant calls. Using Miqa, we benchmarked bcftools version 1.4 to 1.12 using an admixed small variant truthset from the Platinum Genome reference samples NA12877 and NA12878, using common quality metrics such as concordance, specificity and sensitivity. Miqa identified over 10% drop in variant call concordance in v1.4.1 which was released in 2017, but this bug was not reported until after the release of v1.12 in 2021. Miqa’s interactive visualization tools quickly pinpointed the cause of such discordance to an inconsistent read depth in indel regions in a specific version update. This case study highlighted the utility of QA automation tools like Miqa to proactively detect errors at each software release or code change. Ensuring software quality and reliability can further drive the safe adoption of clinical genomic tests to improve patient care.

Session Title: Omics Technologies Poster Session I

PB3433 MntJULiP and Jutils: Tools for differential splicing detection and visualization from complex RNA-seq data sets

Authors:

W. Lui[1], G. Yang[1], Z. He[1], S. Sabunciyan[2], L. Florea[3]; [1]Dept. of Computer Sci., Johns Hopkins Univ., Baltimore, MD, [2]Dept. of Pediatrics, Johns Hopkins Sch. of Med., Baltimore, MD, [3]Dept. of Genetic Med., Johns Hopkins Sch. of Med., Baltimore, MD

Differences in alternative splicing (AS) patterns can reveal important markers of phenotypic differentiation. Increasingly large and complex data sets that include multiple confounders such as sex, age, ethnicity and clinical attributes, are emerging from disease study cohorts and population-level projects, demanding highly specialized data analysis tools. We developed two tools, MntJULiP and Jutils, for differential splicing detection and visualization that can efficiently handle large-scale and complex RNA-seq data collections.

The first tool, MntJULiP, detects intron-level AS differences from RNA-seq data using a Bayesian mixture model. It identifies changes in intron splicing abundance and intron splicing ratio, and can capture AS variation more comprehensively than other tools (PMID:36104797). Notably, it allows for multi-way comparisons, which are better suited for complex and time-series experiments. To account for external relationships in the data, we recently introduced covariates as linear components in the model. The second tool, Jutils, visualizes AS variation with heatmaps, PCA and sashimi plots, and Venn diagrams. Our tools are scalable and can process thousands of samples within hours.

To illustrate, we applied our methods to 1,398 GTEx RNA-seq samples from 13 brain regions. The first comparison, among tissues, revealed distinct groupings between the cerebellar, cortex, and basal ganglia regions, which did not change when accounting for covariates including ‘sex’ and ‘age’ at death. Secondly, we compared 120 frontal cortex RNA-seq samples by age groups (‘20s’, ..., ‘70s’). Changes in the frontal cortex in aging are thought to contribute to sex-specific differences in the prevalence of neurological disorders (PMID:37284017). More differences were observed with more distant age groups. When ‘sex’ was used as a covariate, a significant increase in the number of differences was observed between the ‘20s’ and ‘40s’ groups, indicating a possible mark of sex-specific differentiation. Lastly, we compared the 83 male (M) and 37 female (F) frontal cortex samples to identify sex-specific differences in splicing. Jutils heatmaps revealed a subgroup of 22 samples (12F and 10M) with a distinct AS pattern, which became evident when regressing for ‘age’. This subgroup was higher aged (50-79), pointing to a distinct splicing program in a subset of individuals with aging.

MntJULiP and Jutils are highly effective and efficient analysis tools for large-scale complex RNA-seq datasets with confounding factors, and can reveal new insights into disease and population substructure. Funding: R01-GM129085.

PB3434 Molecular and cellular characterization of the Parkinson's disease olfactory bulb.

Authors:

A. Garton, K. Lehnert, M. Curtis, J. Jacobsen; Ctr. for Brain Res., Univ. of Auckland, Auckland, New Zealand

Parkinson's disease (PD) is a neurodegenerative disorder associated with motor symptoms (bradykinesia, rigidity, and resting tremor) and non-motor symptoms (such as sensory disturbances). Pathologically, PD is characterized by the presence of neuronal inclusions primarily composed of alpha-synuclein in the midbrain, and by a progressive degeneration of dopaminergic neurons in the substantia nigra pars compacta. It is a heterogenous and complex disorder, with more than 20 genes causative of or associated with PD; however, for the vast majority of cases the underlying cause remains unknown. Interestingly, up to 95% of PD cases have olfactory dysfunction prior to motor symptom onset, and alpha-synuclein pathology has been identified in the early stages of PD in the olfactory bulb (OB). However, the human OB remains largely uncharacterized, particularly in the context of disease processes. The aim of this project is to characterize the cellular structure of the human OB, and subsequently compare PD and non-PD OB tissue to identify vulnerable cell populations and transcriptional cascades in the OB that may lead to PD. This will be achieved by integrating transcriptomic (bulk, single-nuclei, and spatial RNA sequencing) and RNAscope in situ hybridization evidence from PD and control OBs from the New Zealand Neurological Foundation of New Zealand Human Brain Bank.To characterize and compare cell types in the PD OB, a pilot experiment (one PD OB and one non-PD OB) is being conducted, integrating spatial and single-nuclei RNA sequencing (RNA-seq) to assess transcriptional profiles of cells. For spatial RNA-seq, one medial and one lateral OB section was mounted on 10X spatial gene expression slides. Sections were stained with NeuN, UEA1-lectin, alpha-synuclein, and DAPI prior to library generation. Initial results show distinct spatial gene expression profiles that mirror known patterns of OB tissue architecture and organization (based on previous IHC work). For example, sections with anterior olfactory nucleus staining show significant differential expression of known marker *UCHL1* (PGP9.5). The remaining OB tissue was sectioned for single-nuclei RNA-seq (to obtain cell-type specific gene expression profiles), bulk RNA-seq, and will be used for RNAscope for the confirmation of pathological leads. Utilizing spatial transcriptomics in conjunction with single-nuclei RNA-seq will allow us to generate a spatially resolved map of the OB at single cell resolution for the first time in humans. This could lead to the identification of vulnerable cell types early in the disease cascade for PD, and ultimately identify novel intervention strategies prior to symptom onset.

PB3435 Morphology profiling driven by deep learning characterizes functional changes in CRISPR knockout cell lines

Authors:

V. Lu[1], A. Jovic[1], T. Vollbrecht[1], J. Mei[1], T. Pham[1], C. Corona[1], R. Carelli[1], K. Saini[1], J. Kim[1], Z. Lian[1], N. Banovich[1], D. Schraivogel[2], L. Steinmetz[2], K. B. Jacobs[1], S. C. Boutet[1], M. Masaeli[3]; [1]Deepcell, Inc, Menlo Park, CA, [2]EMBL Heidelberg, Heidelberg, Germany, [3]Deepcell, Menlo Park, CA

CRISPR/Cas9-based screens have revolutionized functional genomics by enabling the knockout (KO) or expression modulation of hundreds or thousands of genes in parallel. The link between perturbations and corresponding cellular phenotypes can be performed using phenotypic assays, sequencing of gRNA repertoires, or single cell RNA sequencing. However, these assays can be very expensive and inherently include many perturbations with weak or no effects on overall phenotype.

Accordingly, there is a need for orthogonal and high-resolution methods for characterizing phenotypes and isolating cells which receive meaningful and phenotypically relevant perturbations. To this end, we performed high-dimensional morphology profiling on multiple CRISPR KO cell lines to determine phenotypic differences arising from single gene perturbations. We used the REM-I platform, which combines deep learning, microfluidics, and high resolution imaging to characterize and isolate cells of interest.

We trained a self-supervised model using 115 deep learning and morphometric features extracted from images of single cells. To evaluate the application of this model in genetic screens, a library of 11 single gene KOs were generated in three cell lines: HEK 293 (Human Embryonic Kidney cells), Jurkat (T Lymphocyte), and K562 (Myelogenous Leukemia), and compared to a Cas9 only negative control cell line. Individual genes were selected based on previously reported effects on cell morphology, such as vesicle formation, cell size, and nuclear size. We found single gene KOs resulted in significant morphological changes relative to control cells. Morphology profiling results using the REM-I platform captured high-dimensional functional resolution of single gene KOs, including distinct responses from cell line to cell line, indicating the same gene perturbation translates to different phenotypic effects in accordance to cell context. We also found consistent phenotypic patterns in KOs from similar gene expression pathways within the same cell lines, suggesting that morphology as a functional readout is robust and orthogonal. Lastly, we observed several rare morphological phenotypes (~1% of the population), which give further insight into the relative importance of a single gene in each cell context. Future directions include sorting cells from a pooled CRISPR screen and expanding the scope of these results to large scale genetic perturbation screens. In conclusion, we show that deep learning-driven morphology analysis is a promising approach for capturing a wide range of phenotypes induced by genetic perturbations, such as CRISPR KO.

PB3436 Moving beyond sequence: leveraging DNA structure in genomic deep learning models

Authors:

R. Keivanfar[1], F. Yang[1], K. S. Pollard[2], N. M. Ioannidis[1]; [1]UC Berkeley, Berkeley, CA, [2]UCSF, San Francisco, CA

Genomic deep learning models that learn complex motifs and regulatory grammars from DNA sequence input have had success in predicting molecular phenotypes directly from sequence, such as transcription factor binding, histone modifications, chromatin accessibility, and gene expression. Once trained, these models have the potential to be powerful tools for interpreting personal genomes by predicting the molecular effects of individual genetic variants and haplotypes. There is great need for variant prioritization methods for non-coding variants, which contribute substantially to trait heritability. However, recent studies suggest that current models perform poorly at understanding variation in personal genomes and predicting the direction of effect of many genetic variants, despite being accurate from locus to locus using the reference genome in which they were trained. We hypothesized that these models, in their current form, do not adequately capture the role of DNA's structural attributes, known as “shape features”, in dictating molecular functions such as protein-DNA interactions. Here we investigate the extent to which current genomic deep learning models implicitly account for DNA shape information when processing sequence data alone. Initial findings suggest a potential gap in these models' ability to capture the structural features of DNA and to explain the binding of transcription factors that rely on DNA shape. We explore the impact of integrating explicit DNA shape features into sequence-based deep learning models to enrich their understanding of DNA-protein interactions, paving the way for the use of DNA shape features in predicting a wider array of molecular phenotypes.

PB3437 Multi Origins Cell type Alignment (MOCA): Deep Learning-Based Integration of Fibroblast Populations across Human Organs Reveals Universal Developmental Trajectories in Fibrotic Tissues

Authors:

Y. Lyu, B. Fang, E. Ayaub, K. Ask, J. Loureiro; Novartis Inst.s for BioMed. Res., Boston, MA

Fibroblasts are critical to maintain organ integrity, supporting other cell types, and driving fibrosis development. The presence and persistence of activated fibroblasts contribute to progressive fibrotic scarring observed in various organs including the lung, liver, heart, and skin. To identify and characterize fibroblast states in healthy and diseased organs, previous studies have integrated fibroblast populations from different tissues at a single-cell resolution. However, such directly comparing transcriptional profiles from different origins lacks the power to reveal universal gene regulatory dynamics and disease fibroblast developmental trajectories, as it fails to differentiate common fibroblast transcriptional programs from origin-specific ones.To address this limitation, we present "Multi Origins Cell type Alignment" (MOCA), a deep learning-based framework designed to align scRNAseq data across multiple origins, including distinct biological and technical sources. MOCA consists of two key components: a stacked autoencoder that captures distinct transcriptional states within cell populations, and an origin discriminator that removes origin-specific biological and technical artifacts. Such framework allows effectively capturing universal cell population dynamics from control to disease conditions, and uncover conserved transcriptional features shared by same cell type across different origins.Applying MOCA to single-cell transcriptional profiles of 28,228 fibroblasts/myofibroblasts from 173 human fibrosis/control tissues across 6 independent (public) studies, we construct a map illustrating universal fibroblast dynamics from control to fibrotic conditions. Our analysis uncovers a common disease-specific fibroblast shared by fibrotic liver and lung, along with its conserved transcriptional features. Moreover, we projected fibroblast population from in vitro mouse model onto the human fibroblast trajectory to evaluate its translation potential.Furthermore, MOCA's versatility extends beyond fibroblasts, as it can be easily adapted to analyze other cell types such as macrophages. We also demonstrate the robustness and scalability of MOCA as a batch removal method.In conclusion, our study introduces MOCA as a deep learning-based framework for aligning scRNAseq data across multiple origins. By enabling the construction of a map depicting universal fibroblast dynamics from control to fibrotic disease conditions, MOCA uncovers key fibroblast activation states present in multiple fibrotic tissues, offering novel insights into therapeutic strategies and targetable cell populations.

PB3438 Multi-cohort cerebrospinal fluid proteomics identifies robust molecular signatures for asymptomatic and symptomatic Alzheimer's disease

Authors:

M. Ali[1], J. Timsina[1], L. Wang[1], A. Do[1], D. Western[1], Knight Alzheimer Disease Research Center (Knight ADRC), Alzheimer disease neuroimaging initiative (ADNI), Dominantly Inherited Alzheimer Network (DIAN), Fundació ACE Alzheimer Center Barcelona (FACE), Barcelona-1 (Pau), Y. Sung[2], C. Cruchaga[1]; [1]Washington Univ. in St. Louis, St. Louis, MO, [2]Washington Univ. in St. Louis, St Louis, MO

Alzheimer's disease (AD), the most common form of dementia, is a complex polygenic disease characterized by the accumulation of Amyloid-β and hyperphosphorylated Tau proteins in the brain. An increased level of these proteins, among others, in the brain and cerebrospinal fluid (CSF) can be detected years before the symptoms of AD appear. Therefore, studying AD proteome in CSF can reflect its diverse underlying pathophysiology and pave the way for reliable diagnostic and therapeutic advancements.

Here, we present one of the largest AD proteomic profiles, based on 7,029 protein analytes measured in CSF of a total 3,065 individuals in a three-stage study. Firstly, discovery was performed in 1,170 samples from the Knight ADRC and FACE discovery cohorts using the ATN framework (AT- = 680 and AT+ = 490). Secondly, the proteins that passed multiple test corrections in these datasets were further tested in 593 individuals (AT- = 235 and AT+ = 358) from the ADNI and Barcelona-1 replication cohorts. Lastly, the proteins that passed multiple Bonferroni corrections on the meta-analysis were further utilized for creating AD prediction models and conducting pathway and network enrichment analyses to gain mechanistic insights into AD pathophysiology.

The differential abundance analysis in discovery identified 3,565 proteins significantly (FDR < 0.05) associated with AT(n) status. Of these, 2,543 also passed FDR in the replication with the same direction of effect, of which 2,173 passed the stringent Bonferroni correction and were used for downstream analyses. Some of the highly significant proteins included YWHAG ($P = 4\times10^{-219}$), SMOC1 ($P = 6\times10^{-208}$), and NRGN ($P = 3\times10^{-119}$). Using lasso regression, we identified a distinctive signature of 25 proteins with robust and high predictive capability for AD in three independent cohorts. They were unique to AD and showed no predictive power for other dementia such as FTD, DLB, or PD. Disease and pathway enrichment analyses highlighted several neurological disorders (e.g. AD, tauopathy, and synucleinopathy) and neuronal functions (neuron projection morphogenesis, synapse assembly, and axonogenesis) to be significantly enriched (FDR < 0.05) in the altered AD CSF proteome.

Our findings show the promising potential of AD CSF proteomics in the development of a robust AD prediction model. The employed systematic analysis revealed differentially abundant proteins and various biological pathways that are compromised in AD, thereby, increasing our understanding of AD biology. Our findings may accelerate the development of effective intervention therapies that target the earliest molecular triggers of AD.

PB3439 Multiomic single cell analysis of primary pancreatic ductal adenocarcinoma enhanced by fixation.

Authors:

J. Dahl[1], K. A. Kennedy[1], J. Remington[1], N. Lester[2,3], J. Su[2,3], C. Shiau[2,3], J. A. A. West[1], W. L. Hwang[2,3], **D. H. Gong**[3]; [1]BioSkryb Genomics, Durham, NC, [2]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [3]Broad Inst. of MIT and Harvard, Cambridge, MA

Introduction: Single-cell analysis of certain tumor types has been challenging based on the high levels of DNAses and RNAses found within the tumor cells. While traditional formalin fixation can inactivate these enzymes, it can also limit downstream single-cell analysis. The purpose of our study was to develop a non-formaldehyde fixation protocol that preserves single cells for whole genome and transcriptome amplification and evaluate its performance in clinical samples.
Methods: We fixed NA12878/HG001 cells with different formaldehyde-free fixatives and used live (unfixed) cells as a control. We then compared the performance characteristics of single-cell genomes and transcriptomes amplified using ResolveOME (BioSkryb Genomics) in both fixed and unfixed cells. Based on these data, we selected a fixative whose performance in fixed cells was undistinguishable from live cells. We next applied this workflow to human pancreatic ductal adenocarcinoma (PDAC) primary cells, which are notorious for high levels of DNAse and RNAse activity. Manually dissociated PDAC cells were sorted for viability and into pan-cytokeratin positive (CK+) tumor cells and tumor microenvironment (CK-) cells. Half of each cell population was fixed, while the other half was left unfixed. Whole genomes and transcriptomes were amplified using ResolveOME. Resulting libraries were sequenced by low pass whole genome sequencing. Bioinformatics analysis was performed using BaseJumper bioinformatics platform (BioSkryb Genomics).
Results: Fixation enhanced the probability of amplification from both CK+ and CK- PDAC single cells. Transcriptional profiling of these two populations by principal component analysis segregated single tumor cells from non-tumor cells across both components of the analysis. As expected, the CK- cells, identified as tumor infiltrating immune cells by transcriptional analysis, exhibited normal ploidy across the genome. Analysis of individual CK+ cells revealed known copy number alterations and transcription profiles consistent with known PDAC tumor biology. Key upregulated genes included *ERBB3* and *MET* in the MAPK pathway, and *CIB1* and *TENT4A* in the double strand break repair (DSBR) pathway. Mitochondrial pathways were also up-regulated in CK+ relative to CK- cells, likely reflecting a tumor-specific response to increased energy needs within the cells.
Conclusions: We have developed a method for improved retrieval of multiomic details from challenging cell types. This approach leverages a new fixation approach coupled with whole genome and transcriptome amplification, enabling single-cell analysis in human PDAC samples.

PB3440 Multi-omics Integration Analysis for Osteoporosis Biomarker Discovery

Authors:

C. Qiu, K. Su, X. Zhang, A. Liu, Y. Gong, L. Jiang, W. Lin, Z. Luo, Q. Tian, H. Shen, H-W. Deng; Tulane Univ. Sch. of Med., New Orleans, LA

Osteoporosis is an increasingly serious public health problem, which is characterized by low bone mineral density (BMD). To date, the functional roles of the most reported biomarker that are associated with BMD remain unclear. To increase the understanding of the biological mechanisms of BMD variation, it is necessary to leverage multiple-dimensional datasets to capture the complexity of biological networks. The recent advent of high throughput technologies has created an opportunity for integrating multi-omics data to build a novel model of the molecular changes in osteoporosis. In this study, we performed a most comprehensive trans-omics study with various omics data, such as transcriptomics, methylomics, metabolomics, and lipidomics, from 546 subjects, to identify interactions/networks and particularly causal regulatory relationships within and especially those between omic molecules with the purpose to discover molecular genetic mechanisms underlying osteoporosis etiology in vivo in humans. By focusing on potential interesting biomarkers (e.g., differentially expressed genes, differentially methylated CpG sites, differential metabolites, and differential lipids) generated from single-layer analysis, we applied a data integration analysis for biomarker discovery using latent components (DIABLO) to identify the key omics biomarkers for BMD variation. We identified 19 mRNA biomarkers, 46 methylation biomarkers, 12 metabolomics biomarkers, and 8 lipid biomarkers, respectively. Pathway analysis showed that most of the identified biomarkers are enriched in bone-related signaling pathways, such as MAPK/TGF-β pathway. In addition, our preliminary results of network analysis also showed an extensive correlation among the identified biomarkers. Further causality analysis will be performed to test their causal regulatory effects within and between omic molecules. In conclusion, the integration of trans-omics and comprehensive bioinformatics analyses provided us a holistic understanding of the underlying functional mechanisms, molecular regulatory information flow, and the interactive molecular systems among different omic molecules for osteoporosis risk.

Session Title: Omics Technologies Poster Session III

PB3441 Multiomics reveals oral microbiome mediated biological mechanisms underlying obesity in Emiratis.

Authors:

T. Denekew, A. A. Shibl, A. Ahmad, C. E. Leonor, L. Utenova, E. Zhang, M. Abd AlBaqi, T. ., R. Ali, Y. Idaghdour, A. R. Jha; New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

The gut microbiome has been causally linked to human diseases but the contributions of the oral microbiome - the second largest microbial ecosystem in the human body - in human health and diseases is markedly underexplored. Here, we characterized the oral microbiome structure using 16S rDNA sequencing in 629 Emiratis enrolled in the UAE Healthy Future Study (UAEHFS). Our results revealed robust associations between the oral microbiome composition and diversity with BMI in this cohort. We further validated our results after matching for potential confounders and demonstrated that obese individuals (BMI≥ 30) had significantly less diverse microbiota and were compositionally different from those of healthy weight ($18.5 \leq BMI \leq 24.9$). To elucidate the oral microbiome driven biological mechanisms underlying obesity, we performed a multi-omics analysis integrating whole-metagenomics shotgun sequencing, untargeted metabolomics, blood markers, and health data. Strain-level microbial community structure obtained from metagenomic sequencing corroborated results from 16S analysis. Notably, we identified several bacterial species differentially abundant between the obese and non-obese groups. Functional profiling revealed a large repertoire of differentially enriched metabolic pathways in obesity-associated microbiomes. Of particular interest were pathways involved in biosynthesis of essential vitamins, which exhibited notable depletion in obese individuals. These pathways were further validated using clinical biomarkers obtained from blood and urine samples. By incorporating untargeted metabolomics analysis into our study, we aim to uncover metabolic signatures and further elucidate metabolic alterations associated with obesity and the oral microbiome. Overall, our study illuminates the unexplored connection between the composition and function of the oral microbiome and obesity. These findings lay the foundation for utilizing oral microbiome markers as diagnostic tools for cardiometabolic conditions, presenting a promising avenue for personalized healthcare and disease prevention.

Session Title: Omics Technologies Poster Session I

PB3442 Multi-transcriptomic analyses reveal altered expression profiles of immune response genes in Pick's disease

Authors:

N. Tamvaka, A. I. Soto-Beasley, Y. Ren, M. G. Heckman, Z. S. Quicksall, S. F. Roemer, E. Udine, M. van Blitterswijk, D. Dickson, O. A. Ross; Mayo Clinic, Jacksonville, FL

Background: Pick's Disease (PiD) is a rare neurodegenerative disorder characterized by dementia, with frontotemporal degeneration and pathognomonic tau cytoplasmic inclusions known as Pick bodies observed at autopsy. PiD is a type of primary tauopathy along with Progressive Supranuclear Palsy (PSP) and Corticobasal Degeneration (CBD). Tauopathies can be classified as 3-Repeat (3R; PiD), 4-Repeat (4R; PSP, CBD), and 3R+4R (Alzheimer's disease, AD) based on the predominance of the tau isoform present in the cytoplasmic inclusions characterizing each disease. PiD is the only known 3R tauopathy, however due to disease rarity it remains significantly understudied and the causes that are driving this preferential 3R tau accumulation in PiD remain unclear. Furthermore, no study has characterized the transcriptomic profile of PiD, which is imperative for gaining insight into disease specific mechanisms and pathways contributing to disease pathogenesis. Methods: We have performed the first multi-transcriptomics experiments on PiD cases (n=28) using short-read (bulk), long-read (PacBio, IsoSeq), and single-nuclei (snRNA) RNA sequencing approaches. We used the significant differentially expressed genes (DEGs) to inform into differential transcript expression, cell type specific expression, network analysis, and gene expression association studies with neuropathology measures and we compared our findings to control samples (n=15) and PSP cases (n=25). Results: Differential gene expression analysis of the bulk data identified 14 significant DEGs between PiD cases and controls and IsoSeq data was used to quantify specific transcript expression of those genes. Network analysis revealed their enrichment in immune system associated modules significantly upregulated in PiD cases. A subset of those (*CCL2* and *SERPINA3*) were also significantly overexpressed when comparing PiD and PSP cases. Interestingly, *CCL2* was significantly positively associated with increased Pick body burden in PiD. *CCL2* and *SERPINA3* are two known modulators of the immune system and our snRNA Seq data confirmed their expression in cell populations involved in immune processes. Conclusions: Our data highlights the use of multi-transcriptomics to capture the unique transcriptional signature of 3R tau pathology in PiD and suggests the involvement of inflammatory and immune processes in the pathophysiology of the disease. We are further investigating the relationship between the DEGs and integrating this data with spatial transcriptomics and whole genome sequencing to better define 3R tau-specific disease relevant pathways and nominate molecular therapeutic targets.

Session Title: Omics Technologies Poster Session II

PB3443 Nanopore Adaptive Sampling combines both targeted and low-pass whole genome sequencing in a single assay.

Authors:

E. Harrington[1], S. Aganezov[2], C. Tyer[3], H. Greenfield[4], S. Hickey[3], P. James[4], **S. Juul**[5]; [1]Oxford Nanopore, New York, NY, [2]Oxford Nanopore Technologies, Inc., Reading, MA, [3]Oxford Nanopore Technologies, Alameda, CA, [4]Oxford Nanopore, Oxford, United Kingdom, [5]Oxford Nanopore Technologies, New York, NY

In the 15 years since the first large-scale genome-wide association study (GWAS), there has been an explosion in the number of diseases and traits with significant associations. These discoveries not only shed light on the biology underlying complex traits but also enable the use of polygenic scores (PGS) to predict phenotypes. Genotyping arrays have played a crucial role in this by providing a cost-effective method to assay common SNVs in large cohorts. More recently low-pass whole-genome sequencing (lpWGS) in combination with genotype imputation has emerged as an alternative method for GWAS and PGS calculation. However unlike higher-coverage WGS and targeted sequencing, these technologies are not well-suited to the detection of rare or novel variation, limiting their ability to explore the effects of rare variants and make phenotype predictions based on the full allele-frequency spectrum. Previous work has shown that genotypes can be accurately imputed using Oxford Nanopore lpWGS data. We expand on this work to explore the effect of DNA fragment length on imputation accuracy. We show that read count is a more important metric than coverage and that <1kb reads can be used for accurate imputation. We also show that PGS for common diseases can be accurately calculated at depths as low as 0.5X. We think that nanopore lpWGS will be particularly useful for populations and applications not well served by current arrays. The absence of a design-cycle combined with the low up-front cost of nanopore sequencing removes a barrier to entry for large genotyping projects. Adaptive Sampling (AS) is a method of targeted sequencing unique to the Oxford Nanopore platform. It works by sequencing part of a strand of DNA, and, based on the initial sequence of the strand, a decision is made to either eject it from the pore or continue sequencing the entire strand. Most often this decision is based on whether the initial sequence maps to a target region in the genome. The result is that these regions are covered to a higher depth with long reads, which can be used to call and phase SVs, SNVs, repeat expansions, CNVs, and epigenetic modifications. The rest is covered to a lower depth with short reads, essentially lpWGS data. We show that AS data can be used for accurate imputation, providing a method to simultaneously assay common genetic variation genome-wide as well as genotype and discover variants in target regions. Several other features of AS make it particularly useful: i) it can target regions refractory to other methods (e.g. HLA); ii) the informatic nature of the targeting method means that there are no up-front costs in designing a panel, enabling bespoke panels to answer specific hypotheses.

Session Title: Omics Technologies Poster Session III

PB3444 Novel Optical Genome Mapping Algorithm for Detection of Structural Variants in Hematological Cancers

Authors:

M. Muggli[1], T. Anantharaman[1], M. Molnar[1], S. Al-Saffar[1], N. Miller[2]; [1]Bionano, San Diego, CA, [2]Bionano Genomics, San Diego, CA

Optical genome mapping (OGM) enables detection of genomic structural and copy number variants that cannot be detected reliably by next-generation sequencing (NGS) technologies and are often missed by conventional cytogenetic techniques. Bionano has developed bioinformatics analysis pipelines for calling structural variants in constitutional and cancer samples. The Bionano Solve de novo assembly pipeline performs a whole genome de novo assembly using a consensus overlap graph method and is intended for constitutional analyses. The Rare Variant Analysis (RVA) pipeline, aimed at low allele-fraction cancer applications, uses an approach where candidate structural variant sites are identified through a molecule-to-reference alignment, followed by localized assembly around the candidate sites.

Bionano has developed a new analysis pipeline that aims to combine the low-allele fraction detection capability of the RVA pipeline with the whole genome coverage and ability to detect smaller structural variants enabled by the de novo assembly pipeline. The Guided Assembly pipeline uses the reference genome as an initial seed followed by extension, refinement and structural variant calling steps. This new analysis method has been evaluated through comparison to previous results from both existing pipelines as well as standard benchmarking datasets used to estimate structural variant calling performance.

Guided assembly was performed for 10 acute myeloid leukemia (AML) samples and 10 myelodysplastic syndrome (MDS) samples which had previously been analyzed with the RVA pipeline. Structural variant calls from guided assemblies were compared to previous results and evaluated for concordance. Simulated samples representing structural variants at 5%, 10%, 20%, 30% and 50% variant allele fraction were created and detection sensitivity and precision for different structural variant types and size ranges were calculated.

Concordance between the Guided Assembly results and previous RVA pipeline results was established. Increased sensitivity for detecting insertion variants smaller than 5 kb and larger than 200 kb was observed, while finding equivalent performance for other variant types with the updated methods.

Session Title: Omics Technologies Poster Session I

PB3445 Optimization of long-read platforms for clinical utility.

Authors:

D. Muzny[1], Q. Meng[1], Y. Han[1], H. Shen[1], G. Weissenberger[1], V. Vee[1], J. Hwang[1], S. Dugan[1], G. Metcalf[1], S. N. Jhangiani[1], J. Hu[1], H. Doddapaneni[1], Y. Zhou[1], Z. Khan[1], M. Mahmoud[1], F. J. Sedlazeck[1,2,3], R. A. Gibbs[1], All of Us Research Program; [1]Human Genome Sequencing Ctr., Baylor Coll. Med., Houston, TX, [2]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [3]Dept. of Computer Sci., Rice Univ., Houston, TX

Long-read sequencing platforms, including Pacific Biosciences (PacBio) and Oxford Nanopore (ONT), have the potential to revolutionize personalized medicine through the ability to accurately assess all clinically relevant structural variants (SVs), repeats and rearrangements, often undetectable with short read technologies. While much progress has been achieved in the application of long read technologies for research, true production-scale processing for clinical reporting requires consistent high-quality data, low DNA sample input requirements (1-3ug), platform and software stability, data standards as well as competitive cost models. The Baylor College of Medicine - Human Genome Sequencing Center (BCM-HGSC) has assessed long-read data from both the PacBio Sequel IIe/Revio and the ONT PromethION long-read platforms by the generation of >25x whole genome sequence data. Samples were selected from a Hispanic population that was part of the NIH All of Us Research Program (AoURP) Freeze one (98K) short read data and to date, we have completed 403 ONT genomes averaging 30x coverage/PromethION flow cell and 173 PacBio genomes averaging 38x coverage/three PacBio Sequel IIe SMRT cells each of at ~20kbp N50 read length. Optimized protocols for library, sequencing, and analysis pipelines were established, along with performance metrics that will provide assessment of each platform's readiness for clinical applications. Specifically, library and sequencing kits (PB Express 3.0/Sequel V3 kits and ONT LSK114/ R10.4.1 kits) were optimized to consistently deliver >24Gb/Sequel IIe SMRT cell and >80Gb/PromethION flow cell with an insert size >15Kb. Laboratory optimizations included precision size cuts using Pippin HT, controlled shearing parameters, optimization of all library steps for maximum yield and titration of instrument loading amounts to maximize yield. Key production metrics were established for both platforms, including mean coverage, % genome coverage at 10x, HIFI yields, mean read length, contamination, and Q30 or Q10 mapped bases. Initial accuracy for SNVs was assessed using the standard NIST control (HG002) at 99.8% for PacBio and 97.1% for ONT. For SVs we observe similar high accuracies of 97.0% and 92.6%. These platforms are now ready for integration into the clinical laboratory for application in routine clinical testing. This work was part of the operational development of platforms and data for the All of Us Research program.

Session Title: Omics Technologies Poster Session II

PB3446 Optimizing generation of human isogenic iPSC lines via CRISPR prime editing

Authors:

E. Mansell[1], A. Swift[1], A. Lee[1], E. Winnicki[1], E. Li[1], T. Huynh[1], N. Narisu[1], C. Krilow[1], C. Robertson[2,1], M. Erdos[1], F. Collins[1], L. Bonnycastle[1]; [1]NIH - Natl. Human Genome Res. Inst., Bethesda, MD, [2]Univ. of Michigan, Ann Arbor, MI

CRISPR prime editing (PE) is a transformative gene editing tool that enables precise and versatile genomic modification without inducing double-stranded breaks. PE requires multiple components, including a prime editor enzyme complex, pegRNA (finds the target and provides the new sequence), and sgRNA (directs prime editor complex to nick non-edited strand). Recent studies have identified additional PE components that can improve editing, including PEmax (optimized prime editor complex), epegRNA (structural addition to stabilize pegRNA), and MLH1dn (dominant negative version of mismatch repair protein). Effective design/combinations of these elements are essential for optimal editing efficiency. Here, we use PE to introduce type 2 diabetes (T2D) candidate risk variants (*ABCC8* rs137852671
, *MTNR1B* rs10830963, *ADCY5* rs11708067, *TCF7L2* rs7903146, *HNF4A* rs1800961, *CAMK1D* rs11257655, *CAM K2B* rs878521) into human induced pluripotent stem cells (iPSCs), a cell type which can be differentiated into numerous disease-relevant cell types. We optimized PE systems (components and guide RNA design) across seven T2D risk loci and developed a highly efficient and effective pipeline that generated isogenic lines carrying heterozygous or homozygous risk or non-risk alleles for six of the seven T2D loci. We found that PE can support editing in iPSCs, but optimization of all components is critical to achieve high efficiency. PE systems utilizing PEmax, epegRNA modifications, and MLH1dn provide significant benefit, with maximal editing efficiency ranging from 36-73% depending on the target. We screened for edited cells at two different stages, a primary next-generation sequencing screen of pooled cells to identify transfections with the highest number of edited alleles, and a secondary screen to sequence individual clones. This approach reduced downstream single clone isolation efforts by up to 90%. Editing success and degree of optimization required for each variant differs considerably depending on the sequence at the target site. pegRNA design also plays a critical role, as slight variations in sequence guide parameters can have significant effects. In general, previously established guidelines for pegRNA design should be followed during the initial optimization for each target. After that, making small changes to pegRNA lengths and/or shifting the position of the pegRNA may be required to enhance editing rate to a level that is feasible to screen for edited clones. Although considerable effort is required to optimize PE, it is a promising approach to generate isogenic iPSC lines, enabling the study of specific genetic changes in a common genetic background.

PB3447 Optimizing Multimodal Single Cell Sequencing to Fine-Map an Alloimmunization Susceptibility Locus in Sickle Cell Disease

Authors:

A. Motter, A. Haldipur, Y. Han, E. Banfield, N. Hanchard; Natl. Human Genome Res. Inst., NIH, Bethesda, MD

Regular transfusion of red blood cells (RBCs) is a mainstay of treatment in sickle cell disease (SCD). Despite this, persistent transfusions increase the risk of developing alloantibodies against donor RBCs, a phenomenon disproportionately exhibited by individuals with SCD. The reason some individuals develop many alloantibodies while most do not is unclear, although host genetic factors are thought to play a prominent role. We have previously identified a novel genetic association between the development of alloantibodies and a genetic variant of African ancestry at chromosome 5q33, further localized to an ENCODE project enhancer annotated to the proximal immunoregulatory genes *ADRB1* and *IL12B*. We proposed to fine-map the risk locus by co-assessing transcription and epigenetic regulation of the candidate genes in risk variant carriers and non-carriers. To facilitate this, we undertook an optimization study to establish an experimental and computational pipeline for single cell RNA and ATAC-sequencing that maximizes cell viability, sequencing depth, and cell type integrity. Peripheral blood mononuclear cells (PBMCs) were isolated from freshly drawn whole blood and subjected to different sample processing- (cell viability enrichment using magnetic levitation vs. no processing) and storage- conditions (freshly isolated vs. cryopreserved), followed by the 10x Genomics Single Cell Multiome ATAC + Gene Expression. We found that cryopreserved, viability-enriched PBMCs provided 97% cell viability post-thaw (3.7 million live cells/ml, 99k dead cells/ml) and retained the highest integrity of cell types compared to the non-frozen control (7% B, 44% CD4+ T, 13% CD8+ T, 1.3% DC, 17% monocytes, 6% NK, 8% other). These results validate pre-sequencing cell viability sorting as an optimal step in real-world single cell application that will allow for efficient processing and analysis of patient samples, whilst providing biologically representative results that can reliably inform multimodal single cell studies.

PB3448 Overcoming Limitations of RNA-Seq Library Construction from FFPE Samples Using a Novel Workflow

Authors:

C. Jiang, A. Olcott, L. Lingelbach, E. Jordan Dreskin; Bio-Rad Lab., Hercules, CA

Formalin-fixed, paraffin-embedded (FFPE) tumor tissue is a common biospecimen for oncology research and often proposed as a key resource for RNA sequencing (RNA-Seq) to evaluate tumor gene expression signatures. However, RNA purified from FFPE samples typically yields highly degraded material whose poor quality is suboptimal for RNA-Seq library construction. The RNA-Seq workflow can further impair data quality, as traditional library preparation workflows may result in the loss of valuable information due to small fragments being washed away during ribodepletion. Moreover, small, degraded fragments are a challenging template for ligases, and the resulting adapter addition may be inadequate. Here we evaluated a novel workflow that utilizes a proprietary enzyme that bypasses the bias and limitations of reverse transcriptases (RT) and ligases, coupled with a post-library ribodepletion strategy that retains more of the transcriptome. This study also evaluated FFPE RNA extraction methods from breast cancer samples using 2 commercially available kits (RecoverAll and PureLink) to evaluate quality metrics such as RNA integrity number (RIN), DV200, and the recovery of small RNAs during NGS library construction as well as transcriptome coverage. A matching fresh frozen RNA sample was extracted using a phenol-based extraction reagent. Results show that our novel workflow generates a richer data set that represents more of the transcriptome, including both small and long RNAs from FFPE samples. By performing ribodepletion after library preparation, smaller RNAs were detected than when pre-library ribodepletion was used. The excellent analytical performance of this novel library preparation workflow supports its use in RNA-Seq for common archival FFPE specimens in oncology research.

PB3449 Partitioning the plasma proteome into genetically mediated causal signals and environmental sensors of complex disease risk

Authors:

K. Tsuo[1,2], D. Gadd[3,4], M. Kurki[5,2,6], Z. Zheng[5,2,6], Z. Kuncheva[3,7], D. Baird[8], A. Lehisto[6], R. Marioni[3,4], C. Foley[3,7], H. Runz[8], H. Huang[1,2], B. Sun[8,9], C-Y. Chen[8], M. Daly[1,2,6], A. Martin[1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]Optima Partners, Edinburgh, United Kingdom, [4]Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, United Kingdom, [5]Broad Inst. of MIT and Harvard, Boston, MA, [6]Inst. for Molecular Med. Finland, Univ. of Helsinki, Helsinki, Finland, [7]Bayes Ctr., The Univ. of Edinburgh, Edinburgh, United Kingdom, [8]Biogen, Cambridge, MA, [9]Dept. of Publ. Hlth.and Primary Care, Univ. of Cambridge, Cambridge, United Kingdom

The plasma proteome uniquely bridges the gap between inherited and modifiable risk factors for disease. Previous disease-specific studies have identified handfuls of proteins that play potential causal roles in mediating genetic effects on disease onset. However, few studies have systematically categorized disease-associated proteins into causal mediators of genetic risk vs. sensors of environmental risk. Here, we used one of the largest proteomic studies to date analyzing ~3K plasma proteins, measured in 54,306 participants in the UK Biobank (UKB), that have been tested for association with time-to-onset for several diseases in previous work. Here, to characterize the proteins significantly associated with incident disease (N=956), we first employed Mendelian randomization (MR) using pQTL instruments from UKB for these proteins and the largest publicly available GWAS of 19 disease outcomes from other studies to assess potential causal roles of these proteins in disease onset. As an example, we observed MR evidence for levels of EFEMP1, a proposed therapeutic target for malignant pleural mesothelioma, on chronic obstructive pulmonary disease (COPD) (β = -0.17, P = $4.3x10^{-5}$). We validated our findings by conducting MR using pQTL instruments from FinnGen for the same proteins and the largest available disease GWAS from UKB and other biobanks. We next evaluated the utility of the proteins without MR signals as predictive biomarkers of disease by applying a decomposition approach not previously applied proteome-wide (termed de-Mendelization), which adjusts for the genetically-mediated variance of the protein levels to improve the observational protein-disease associations. Identifying proteins that could be useful predictors of disease through this approach, we hypothesized that these proteins may serve as quantitative sensors of commonly-measured environmental risk factors and could be more precise predictors of disease than the factors themselves. For example, we found that more than half of the proteins associated with incident disease (576/956) were significantly associated with self-reported smoking status in UKB, and for COPD, after adjusting for smoking, the remaining disease-associated proteins were still significantly associated with smoking. We are comparing prediction models with survey variables of smoking and these proteins to investigate their utility as sensors of cumulative smoking risk. Our study presents a novel strategy that integrates large-scale MR and genetic adjustment to partition protein-disease associations, illustrating another avenue for translating GWAS findings into drug target and biomarker discovery.

Session Title: Omics Technologies Poster Session III

PB3450 Performance of an artificial intelligence-enabled genome sequencing system for universal newborn screening, diagnosis, and precision medicine for 410 severe childhood genetic diseases in over 460,000 individuals.

Authors:

J. Schleit[1,2], M. Wright[1,2], W. Mowrey[3], L. D. Smith[1], C. Kunard[4], M. Bainbridge[1,2], S. Batalov[1,2], E. Blincow[1,2], S. Caylor[1,2], C. Chambers[5], G. del Angel[3], K. Ellsworth[1,2], A. Feigenbaum[1,2,5], E. Frise[6], L. Guidugli[1,2], K. Hall[4], C. Hansen[1,2], C. Hobbs[1,2], M. Kiel[7], L. Van Der Kraan[1,2], C. Krilow[8], Y. H. Kwon[1,2], L. Madhavrao[1,2], J. Tokita[1,2], S. S. Mehtalia[4], S. Papadopoulos[8], E. Sanford[1], S. Schwartz[7], D. Tran[4], M. Reese[6], K. Wigby[5,1,2], M. J. Willis[1], A. Wolen[8], M. Yandell[9], T. Defay[3], S. Kingsmore[1,2,10], M. J. Owen[1,2]; [1]Rady Children's Inst. for Genomic Med., San Diego, CA, [2]Rady Children's Hosp., San Diego, CA, [3]Alexion, Astra Zeneca Rare Disease, Boston, MA, [4]Illumina, Inc., San Diego, CA, [5]Dept. of Pediatrics, Univ. of California San Diego, San Diego, CA, [6]Fabric Genomics, Inc., Oakland, CA, [7]Genomenon Inc., Ann Arbor, MI, [8]TileDB Inc., Cambridge, MA, [9]Univ. of Utah, Salt Lake City, UT, [10]Keck Graduate Inst., Claremont, CA

Newborn screening (NBS) dramatically improves outcomes in selected, severe, childhood disorders by identification and treatment initiation at/before symptom onset. Expansion of the NBS Recommended Uniform Screening Panel (RUSP) has lagged identification and approval of effective therapeutic interventions leading to unnecessarily delayed diagnosis and suboptimal outcomes in hundreds of severe, early childhood onset single locus (mendelian) genetic diseases. BeginNGS supplements RUSP-NBS for these diseases by combining NBS-by genome sequencing (GS) with automated interpretation and virtual guidance regarding confirmatory testing, specialist referral, and urgent management. While clinical development is incomplete, here we report results of the second retrospective study of BeginNGS. Of 518 gene-disorder dyads evaluated for BeginNGS using modified Wilson and Jungner principles and Delphi methods, 410 disorders associated with 341 genes and 1,654 effective therapeutic interventions were retained, with a total incidence in newborns of ~5%. The analytic performance of BeginNGS is trained with genome sequences of large retrospective true positive (TP) and true negative (TN) cohorts. Previously we reported training of 29,865 pathogenic (P) or likely P (LP) variants associated with 388 disorders in 459,083 TP and FN individuals. Following training, BeginNGS had 3 FP/1,000 subjects and TP rate (sensitivity) of 88.8% (119 of 134 diagnoses). Here we will report results of BeginNGS version 2 with 410 disorders, ~50,000 variants from both ClinVar and Genomenon's Mastermind, as well as new artificial intelligence software for detection of novel loss of function variants (Transformer) in a larger cohort including 7,575 critically ill children with suspected genetic disorders and their parents. We will also report results of an actual/counterfactual comparison of the clinical utility, average cost per diagnosis, and incremental cost cost effectiveness ratio of rapid diagnostic GS ($7,000 cost per newborn with return of results during an intensive care unit admission) with BeginNGS ($500 with results on day of life (DOL) 10) and RUSP-NBS ($211 with results on DOL 10).

PB3451 Pipeline for improved genotype imputation using blended genome-exome sequencing and a diverse reference panel for large-scale population studies

Authors:

M. Gatzen, C. Kachulis, C. Patterson, M. Coole, E. Malolepsza, M. Shand, J. C. Meldrim, M. DeFelice, N. J. Lennon; Broad Inst. of MIT and Harvard, Cambridge, MA

Recent advancements in sequencing technologies have provided the research community unprecedented opportunities for conducting large-scale population studies to understand the genetic underpinnings of disease. Whole genome sequencing (WGS) remains the gold standard for genetic studies, but even though it has become more affordable the relatively high cost remains a barrier to the feasibility of many population studies. Whole exome sequencing (WES) is a more affordable option, however, the shortcomings of being blind to significant portions of the genome may be prohibitive for certain research questions. Imputation from genotyping arrays provides a bridge between affordability and information about large regions of the genome, however, the limitation of only being able to capture predefined alleles results in reduced applicability to diverse populations and disease characteristics. We recently launched blended genome-exome (BGE) sequencing which provides full-depth coverage over the exome and low-pass coverage over the entire genome. The genome portion is a basis for imputation that is superior to arrays while the exome portion provides valuable high-confidence exome calls. We evaluate the imputation accuracy by comparing genotypes imputed from BGE data sequenced on the Illumina NovaSeqX to matched WGS data for a cohort of diverse ancestries. We find that using BGE as an input to imputation results in superior accuracy to existing genotyping arrays while allowing for leveraging arbitrary reference panels due to BGE sequencing not being limited to certain genotyping sites. Furthermore, we updated the reference panel to use the 1000 Genomes Project + Human Genome Diversity Project panel provided by gnomAD, which adds additional 828 samples from 54 populations to the 1000G cohort. After removing singleton sites this panel increases the number of covered sites by 91% as compared to the commonly used 1000 Genomes Project panel. As a result, the coverage of sites used for polygenic risk scores of 10 chronic medical conditions implemented by the NHGRI eMERGE network in a recent clinical study increases from 99.3% to 99.8%. Leveraging the GLIMPSE imputation tool we created a cloud-native imputation pipeline that is optimized for cost-effective processing of large-scale cohorts. The combination of BGE data as an input for imputation with an improved, more diverse reference panel significantly improves the accuracy of results as compared with current approaches. Combined with the high-confidence exome calling this method provides a cost-effective and accurate solution for population genetics studies without the need for multiple analysis modalities.

PB3452 Poverty shapes the transcriptome of immune cells.

Authors:

N. Arnold[1,2], J. Resztak[2], A. Alazizi[2], D. Witonsky[2], N. Noren Hooten[3], M. Evans[3], V. Odera-Marah[1], D. Dluzen[4], R. Pique-Regi[2], F. Luca[2]; [1]Morgan State Univ., Baltimore, MD, [2]Wayne State Univ., Detroit, MI, [3]Natl. Inst. on Aging, NIH, Baltimore, MD, [4]Johns Hopkins Univ., Baltimore, MD

Psychosocial factors exert a powerful influence on health and contribute to disparities among marginalized populations. For example, overall life expectancy at birth throughout the United States tracks with poverty level, educational attainment, economic security and other upstream social determinants of health. Socioeconomic status (SES) and psychosocial factors may affect gene expression in peripheral blood mononuclear cells, suggesting a molecular mechanism for some health disparities. Here we investigated the effects of poverty among participants in the Healthy Aging in Neighborhoods of Diversity across the Life Span (HANDLS) study. We examined 204 participants whose reported household income was either above or below poverty. The population sample was balanced by self-reported race and sex. We performed RNA sequencing in peripheral blood mononuclear cells to assess differential gene expression patterns associated with poverty. We found 138 genes differentially expressed between individuals living in poverty compared to those living above poverty. We found 104 differentially expressed genes in women, however, we did not observe any genes differential expressed in men living in poverty. Differentially expressed genes in individuals living in poverty are enriched in processes related to wound healing and coagulation. Of the genes differentially expressed in individuals living in poverty, *VIL1* and *EEF1DP7* are also associated with hypertension in transcriptome-wide association studies. Our results suggest that the impact of poverty on gene expression varies between men and women. We show that poverty may affect wound healing and coagulation processes by causing changes in gene expression in immune cells.

PB3453 Predicting chromatin interactions and gene expression by artificial intelligence methods

Authors:

M. Chilinski[1,2], J. Lipiński[3], A. Agarwal[2], Y. Ruan[4,5], D. Plewczynski[1,2]; [1]Warsaw Univ. of Technology, Warsaw, Poland, [2]Univ. of Warsaw, Warsaw, Poland, [3]Cellular Genomics, Warsaw, Poland, [4]The Jackson Lab. for Genomic Med., Farmington, CT, [5]Life Sci. Inst., Zhejiang Univ., Hangzhou, China

In our work, we have developed 3DNBERT - a Artificial Intelligence (AI) model for the prediction of the HiChIP interactions. We have used deep learning model, that is composed of the BERT architecture as well as transformer encoder for the ChIP-Seq and ATAC-Seq signals. Our pipeline first trains ChIP-BERT for detection of the ChIP-Seq and ATAC-Seq signals, then 3DN-BERT in two cases - one for prediction of the anchors, and one for predicting which anchors will be connected together.
The final model is trained on all chromosomes and experimental epigenetic profiles, except for the chromosome 9 that is used for validation purposes. Our learning architecture firstly predicts the epigenomic signal in the testing chromosome, then predicting the potential anchors, and finally identifying which anchors will form chromatin loops with each other. We are predicting from DNA sequence all the downstream genomic information - as we are using SNPs, indels and structural variants (SVs) for creating of the personalised and phased genomes, that are used as input to the network.
We have conducted additional research, which the extend the spatial structure in silico identification with the gene expression prediction. This time we used convolutional neural network as in ExPecto - improved by including the spatial information. This allowed us to increase the expression prediction accurancy using various ChIA-PET experimental datasets. We have obtained an improvement of the spearman correlation score of up to 0.042 (in case of RNAPOL2 ChIA-PET GM12878).
Concluding, our results show that the modern Artificial Intelligence algorithms are capable of predicting the chromatin spatial interactions from the DNA sequence, and those interactions can be further used to improve the gene expression prediction. Our research is one of first steps in connecting DNA sequence, spatial organisation of the chromatin, and the gene expression in quantitative form.

Session Title: Omics Technologies Poster Session I

PB3454 Profiling of stranded RNA biotypes during early mouse gonad development

Authors:

F. Ou[1], H. SUN[2], Z. Wang[1], K. Miu[1], P. Shi[2], W-Y. Chan[1]; [1]The Chinese Univ. of Hong Kong, Hong Kong, China, [2]The City Univ. of Hong Kong, Hong Kong, China

Gonad development involves complex spatial and temporal genetic and epigenetic regulations. While several scRNA-Seq and scATAC-Seq investigations have provided refined gonadal transcriptome and chromatin accessibility profiles of different species, the functional networks of non-coding RNAs in gonad development remain largely unknown. This study performed the first complete stranded RNA-Seq to profile all the stranded RNA biotypes from mouse male and female gonads at four different time points. 2419 differentially expressed genes (DEGs) were identified from E12.5-vs-E11.5 with cut-offs as $|LogFC| \geq 1$ and $FDR \leq 0.05$, and 333 and 770 DEGs were identified from E13.5-vs-E12.5 and E14.5-vs-E13.5, respectively. microRNA, lincRNA, and antisense were the major differentially expressed RNA biotypes in addition to protein-coding mRNA from the datasets. RT-qPCR and RNA spatial assay further validated the spatial and temporal expression of selected DE miRNAs. miR202 showed dramatic expression fold change with a low expression level, which is consistent with the previous report by Wainwright EN et al. in 2013. miR6236 was the most highly expressed miRNA and showed significant downregulation from E11.5 to E12.5 and then significant upregulation from E13.5 to E14.5, suggesting that mmu-miR-6236 plays important roles in early sex determination and germ cell development initiation with different pathways. Target identification suggests that miR6236 interacts with lincRNA Miat and promotes Foxd3 expression, which may further contribute to cell-type specific transcription factors chromatin reconstruction.

Session Title: Omics Technologies Poster Session II

PB3455 Protein Detection Correlations: Examining the Correlation of Protein Detection in High-throughput Proteomics Platforms in Million Veterans Program Proteomics Study.

Authors:

C. Yandava[1], P. Schreiner[2,1], D. Panyard[3,4], P. Devineni[1], B. Gorman[2,1], P. Tsao[5,6], S. Pyarajan[1,7]; [1]VA Boston Hlth.care System, Boston, MA, [2]Booz Allen Hamilton, Lexington, MA, [3]Stanford Univ., Sunnyvale, CA, [4]VA Palo Alto Hlth.Care System, Palo Alto, CA, [5]VAPAHCS/Stanford Univ., Palo Alto, CA, [6]Stanford Univ. Sch. of Med., Stanford, CA, [7]Brigham Women's Hosp., Boston, MA

Proteins carry out the major functions of an organism and are involved in structural, enzymatic, inter and intracellular communications, immunity and many other functions. Protein levels are indicators of the health of an organism and used for diagnostic, prognostic, and therapeutic purpose. The Million Veteran Program (MVP) at VA is a national research program to understand the genetic basis for the illnesses of veterans and is a great resource for clinical data in diverse and minority ethnic groups. We measured the plasma protein levels of about 900 individuals, using Olink Explore 1536 and Somascan v4, comprising both a control group and those with diseases, using both Somascan and Olink platforms. The Olink Explore 1536 platform profiles 1472 proteins of which 1463 are unique and correlations among proteins of this platform are studied. Three proteins of these proteins - *IL6*, *CXCL8* and *TNF* - are replicated in 4 distinct detection panels. These replicate proteins can be used to perform QC based on their correlations of log2 transformed Normalized Protein eXpression (NPX). There are very high correlations of the same protein profiled across all the panels. *CXCL8* has the highest correlation coefficients (between 0.94 and 0.99) between panels, followed by *IL6* (0.9 to 0.95) and *TNF* had the lowest correlation between 0.8 and 0.87. Apart from the replicates, there are 3337 pairs (381 proteins) with r values over 0.8. We evaluated the relationship of these proteins that could possibly explain coordinated expression for functional roles or indicate technical issues such as cross reactivity due to sequence similarity. One pair of proteins, *AMY2a* and *AMY2b* perform the enzymatic reaction of hydrolyze 1,4-alpha-glucoside bonds in oligosaccharides and polysaccharides. They are 98.83% identical and 99.02% similar in their sequence. Their detection is very highly correlated (0.988). Another pair of proteins with high correlation (0.95) is with proteins *PILRA* (Paired immunoglobulin-like type 2 receptor alpha) and *PILRB* (Paired immunoglobulin-like type 2 receptor beta). These proteins are not very identical (61.76%) or similar (66.01%) in their sequence. *PILRA* is an inhibitory receptor and *PILRB* is an activating receptor and cell signaling is balanced by the activity of these proteins. It is reasonable to suggest that these 2 proteins necessarily have similar protein levels to perform their function. It is possible that the reagents (antibodies) may cross-react or that the genes are locally co-expressed. These 2 pairs of proteins are not correlated with any other protein. The implications of protein correlations and disease state are investigated.

Session Title: Omics Technologies Poster Session III

PB3456 Proteomics of Urinary Exosomes Reveals Impaired Protein Trafficking in HPS-1 Renal Epithelial Cells.

Authors:

D. Maynard[1], B. R. Gochuico[1], H. Pri Chen[1], C. K. E. Bleck[2], P. Zerfas[3], W. A. Gahl[1], M. C. V. Malicdan[1]; [1]NHGRI (NIH), Bethesda, MD, [2]NHLBI (NIH), Bethesda, MD, [3]OD (NIH), Bethesda, MD

Background: Hermansky-Pudlak syndrome type 1 (HPS-1) is a rare, autosomal recessive disorder caused by defects in BLOC-3 (biogenesis of lysosome-related organelles complex), leading to oculocutaneous albinism, a bleeding diathesis, granulomatous colitis, and pulmonary fibrosis (PF). Renal involvement in HPS-1 patients remains poorly understood. Exosomes, small endocytic vesicles (40-100 nm), play a crucial role in various cellular functions; urinary exosomes (UrEx) contain proteins from renal tubule epithelial cells and provide a non-invasive method for studying changes in protein expression. In this study, we investigated the protein composition of UrEx obtained from HPS-1 patients compared to controls to understand the mechanisms underlying renal manifestations in HPS-1. Methods: Twenty-four-hour urine samples were collected from five HPS-1 patients and five unaffected controls. Exosomes were pelleted by ultracentrifugation and treated to remove Tamm-Horsfall protein (THP), a major contaminant. 1D-gel electrophoresis and LC-MS/MS were used to analyze UrEx protein composition. ELISA was utilized to measure serum ApoA1 levels in a subset of HPS-1 patients enrolled in a natural history protocol. We generated a murine *Hps1* knockout using genomic engineering to investigate the impact of HPS1 deficiency on kidney function. Results: THP-depleted UrEx exhibited intact morphology and expected size. Proteomic analysis identified 1029 proteins, including those involved in kidney disease and fibrosis. Ingenuity Pathway Analysis revealed disruptions in mitochondrial proteins and the LXR/RXR pathway. Our *Hps1* knockout mice exhibited characteristic deposits and vacuolation in the proximal tubule epithelial cells, along with distinct morphological differences in ultrastructure. Compared to controls and HPS-3/HPS-5 patients, HPS-1 patients had decreased serum ApoA1 concentrations. Moreover, serum ApoA1 levels positively correlated with estimated glomerular filtration rate (eGFR), an indicator of kidney function. Conclusions: We optimized the preparations of THP-depleted UrEx and identified protein abundance differences in UrEx from HPS-1 patients compared to control, implicating mitochondrial dysfunction, alterations in lipid/lipofuscin metabolism, and kidney fibrosis. These findings contribute to our understanding of the pathophysiology of HPS-1.

Session Title: Omics Technologies Poster Session I

PB3457 Quality assessment of DNA and RNA for NGS libraries using Agilent Automated Electrophoresis Systems.

Authors:

M. Meister[1], **S. Siembieda**[2]; [1]Agilent Technologies, Waldbronn, Germany, [2]Agilent Technologies, Inc., Ankeny, IA

DNA and RNA sequencing enables the study of the genomic and transcriptomic background of cells or tissues and has become an established part of scientists' toolkit for cancer research. Critical for robust results of next-generation sequencing (NGS) applications is the accurate qualification and quantification of the samples used. To compare the performance of automated electrophoresis systems such as the Agilent 2100 Bioanalyzer, TapeStation and Fragment Analyzer systems, equivalent assays for the respective systems were used for quantitative and qualitative analysis of DNA libraries and RNA samples. For NGS, it is important to ensure that the starting material has been fragmented into DNA molecules of a size suitable for the sequencer and that the library contains enough material for sequencing. The final libraries were prepared and subsequently analyzed on the Bioanalyzer, TapeStation, and Fragment Analyzer systems. Each system reported comparable smear size and concentration. For RNA sequencing, the input quality of the RNA material is critical for obtaining reliable results. Total RNA samples were analyzed with the Bioanalyzer and TapeStation systems and showed similar concentrations and quality metrics on both systems. Finally, the analysis of total RNA with the Bioanalyzer and the Fragment Analyzer systems provided comparative RIN and RQN results as well as similar concentration values for the two systems. The RNA quality scores, as well as the quantification and electropherogram results obtained on the Bioanalyzer system were comparable to the results obtained with the TapeStation or Fragment Analyzer systems, illustrating the equivalent performance of the Agilent automated electrophoresis systems.

Session Title: Omics Technologies Poster Session II

PB3458 Quantification of the escape from X chromosome inactivation with the million cell-scale human blood single-cell RNA-seq datasets reveals heterogeneity of escape across immune cells

Authors:

Y. Tomofuji[1], R. Edahiro[1], Y. Shirai[1], K. Sonehara[2], Q. Wang[3], Asian Immune Diversity Network, A. Kumanogoh[1], Y. Okada[4]; [1]Osaka Univ. Graduate Sch. of Med., Suita, Japan, [2]Graduate Sch. of Med., the Univ. of Tokyo, Bunkyo-ku, Japan, [3]Osaka Univ., Osaka, Japan, [4]Osaka Univ. / The Univ. Tokyo / RIKEN, Osaka, Japan

One of the two X chromosomes of females is silenced through X chromosome inactivation (XCI) to compensate for the difference in the dosage between sexes. There exist several genes which escape from XCI, which could contribute to the differential gene expression between sexes. The differences in the escape across cell types are still poorly characterized, especially across immune cell types, even though a large number of immune-related genes are on the X chromosome. Escape in disease conditions and non-European people have also been poorly investigated. scRNA-seq analysis is useful for investigating the escape. However, most current methods require plate-based scRNA-seq data. To investigate escape with a wide variety of datasets, we need a new method to evaluate the escape with widely used droplet-based scRNA-seq technology. Here, we investigated the escape across immune cell types utilizing the largest scale scRNA-seq datasets (1) ~1,000,000 peripheral blood mononuclear cells (PBMCs) from 489 East Asian participants, (2) ~1,000,000 PBMCs from 147 Japanese (72 COVID19 patients and 75 healthy participants) (3) ~1,000,000 PBMCs from 162 systematic lupus erythematosus patients and 99 healthy participants including East Asian and European. Differential expression gene (DEG) analysis revealed that female-biased expression of escapee genes was stronger in lymphoid cells than in myeloid cells (median log2 fold change was 0.35 in CD4+ T cells and 0.15 in monocytes, P = 0.018). To investigate whether these differences originated from the differences in the escape, we developed a method, **s**ingle-**c**ell **L**evel **ina**ctivated **X** chromosome mapping (**scLinaX**), which directly quantify relative gene expression from the inactivated X chromosome (Xi) with droplet-based scRNA-seq data. The scLinaX successfully detected the escape for the previously reported escapees (median ratios of expression from Xi were 0.24 and 0.013, respectively for escapees and genes subjected to XCI; $P = 3.1 \times 10^{-14}$). The scLinaX revealed the stronger degree of escape in lymphocytes than in myeloid cells suggesting that difference in escape makes the heterogeneity of sex-associated differential gene expression across cell types. We also found several genes which had female-biased expression while showing little evidence of the escape in scLinaX analysis, emphasizing the limitation of DEG analysis and the importance of complementary analysis, such as the scLinaX. Finally, we systematically evaluated the association between diseases and escape. The scLinaX is applicable to a wide variety of scRNA-seq datasets. This study would contribute to understanding of the XCI and escape.

Session Title: Omics Technologies Poster Session III

PB3459 Quantitative profiling of hepatitis B virus transcripts in human liver transcriptome data

Authors:

Q. Cao[1], W. Cui[2]; [1]The first affiliated Hosp., Zhejiang Univ. school of medicine, Hangzhou, China, [2]Zhejiang Univ., Hangzhou, China

The existence of viral sequence in human High-Throughput Sequencing (HTS) data, potentially indicating viral infection in human cells, has been recognized for some time. Some studies have utilized the detection of these viral sequences to infer the viral infection status of the original sample. However, a quantitative analysis of such viral sequences in transcriptome data, based on which the host-virus interaction could be explored, is still lacking. Hepatitis B Virus (HBV) is a hepatotropic DNA virus, and in certain East Asian countries, chronic HBV infection remains the primary etiology of hepatocellular carcinoma. We performed de novo analysis of RNA-seq data from over 200 liver tissue samples, including those obtained from public domain database as well as in-house collected samples. By linearizing the circular genome of HBV based on transcriptional start/stop sites, incorporating it to the reference sequence set, and employing alignment-free transcript quantification algorithms, viral transcripts were quantified and distinguished in a manner similar to human transcripts. We observed the presence of highly abundant viral transcripts specific to HBV infected samples. The abundance of these viral transcripts correlated with the clinical infection phenotypes, as well as the expression of cell cycle and proliferation related human genes. Individuals with high abundance of viral transcripts also showed elevated levels of viral-human gene fusions and mutation rates. Furthermore, in nearly 70% of infected samples, the complete HBV genome could be assembled solely from viral fragments obtained from the human transcriptome. These results demonstrate that quantitative analysis of HBV sequences in liver transcriptome data provides a unique perspective for studying the pathogenic interactions between HBV and the human host. They also highlight the significance of exploring viral information within host transcriptome data as a research avenue.

PB3460 Rapid single -omic interpretation and analysis is a precondition for synthesis of large scale multiomics conclusions

Authors:

A. O'Hara, P. Vishwanath, E. Louie, D. Schneweis, L. Turner, H. Latif, C. Mozdzierz, G. Zhou; Azenta Life Sci., Burlington, MA

The -omics era expands the repertoire of approaches available for researchers and clinicians to unravel human health's complexity. Next Generation Sequencing (NGS) approaches characterize genomes, epigenomes, transcriptomes, and proteomes from a single sample source. Peripheral blood mononuclear cells (PBMCs) offer a window into the immune system that, when combined with omics tools, can provide a near holistic view of immune processes across patient cohorts. This proof-of-principle workflow utilizes a single blood draw to rapidly produce a diverse set of datatypes interrogating the genome, epigenome, transcriptome, and proteome. In 10 Hispanic men aged 50-60, five with diagnosed cardiovascular disease (CVD) and five unaffected healthy individuals, a single blood draw using a heparin tube was collected and PBMCs were isolated within 24 hours of collection to ensure high viability and yield of PBMCs, along with simultaneous plasma separation and collection. These samples were then aliquoted and simultaneously processed for whole exome sequencing, single cell RNA sequencing (scRNA-Seq), epigenetic characterization, and Olink proteomic assays.
Here we present the scRNA-Seq results using the rapid first look analysis tool known as the ROSALIND platform. ROSALIND is an interactive sequencing analysis platform, offering a powerful analysis rich downstream method connecting experimental design, quality control and pathway exploration. scRNA cluster analysis was utilized for grouping of cell types both within and between samples to identify trends and differences between the affected and control individuals. Comparative analysis between the CVD affected and healthy control individuals indicate several statistically significant differentially expressed RNA transcripts and pathways. Conclusions from this standalone analysis are then aggregated into downstream multiomics analyses, including Olink proteomics, showing that integrative downstream analyses can drive greater insights and innovation in human health applications.

PB3461 RDAP: a web-based pipeline to analyze RNA-seq data

Authors:

B. Lee; Korean Bioinformation Ctr., Daejeon, Korea, Republic of

The complexity of transcriptomes and their regulative pathways make RNA-Seq one of the most complex NGS applications, addressing several aspects of the expression process. RDAP (RNA-seq Data Analysis Pipeline) is an integrated transcriptome analysis service allowing users to analyze their own RNA-seq data. RDAP consists of analytical pipelines covering the entire spectrum of RNA-seq analysis, quality assessment, aligning reads, differential gene expression analysis, and visualization. RDAP is a fully automated and user-friendly cloud-based platform that does not require application installation or testing steps. Instead, the user simply uploads RNA-seq data and chooses an appropriate analysis pipeline and parameters. RDAP aims at a broad group of users, from beginners with little command-line experience to advanced users with the ability to customize the parameters used by their chosen tools.

PB3462 Refining Telomere-to-Telomere Human Genome References: Insights from a novel high accuracy sequencing-by-binding platform

Authors:

M. Fleharty, L. Fleming, M. Coole, S. Low; Broad Inst., Cambridge, MA

Advancements in genome sequencing technologies have enabled more accurate and comprehensive representations of the human genome. We used a high-fidelity sequencing platform which leverages a novel sequencing-by-binding chemistry (Onso, Pacific Biosciences, CA) to further refine two Telomere-to-Telomere (T2T) human genome references, CHM13-T2T and HG002-T2T, with a focus on reducing homopolymer errors.

For CHM13, the sequencing-by-binding data showcased superior homopolymer accuracy relative to other technologies, thus enabling the identification and potential amendment of approximately 12,000 homopolymer sites in the CHM13-T2T reference. This represents a significant step towards further improving the already high-quality CHM13 reference.

In parallel, we sequenced the Ashkenazi trio (NIST samples HG002, HG003, and HG004) using the same sequencing platform. Here, we employed a unique approach that leveraged pedigree information alongside Mendelian inheritance assumptions to spotlight regions of the HG002-T2T reference that could benefit from further refinement. Our results are highly concordant with orthogonal techniques to identify homopolymer errors using assembly-based phasing. Our results have been submitted to the T2T-Consortium as proposed polishing sites for inclusion in the HG002-T2T v0.8 reference.

Our work collectively exhibits how novel sequencing chemistries combined with novel analytical strategies can significantly contribute to improving the fidelity of human genome references. These enhancements will invariably facilitate more accurate genetic research, contributing to the development of personalized treatments, better understanding of genetic diseases, and the exploration of human genetic diversity.

PB3463 RNA-seq data analysis identifies blood-based biomarkers for diagnosis and disease progression of Alzheimer's disease.

Authors:

A. Yamakawa[1], R. Mitsumori[1], M. Suganuma[1], S. Akiyama[1], S. Niida[2], K. Ozaki[1,3], D. Shigemizu[1,3]; [1]Med. Genome Ctr., Res. Inst., Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [2]Core Facility Admin., Res. Inst., Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [3]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Kanagawa, Japan

Mild cognitive impairment (MCI) patients have an increased risk of developing Alzheimer's disease (AD). Biomarkers for early detection of individuals at high risk for MCI-to-AD conversion are required. Here, we performed RNA-sequencing data analysis of 1227 Japanese blood samples, representing 424 AD patients, 543 MCI subjects, and 260 cognitively normal (CN) adults, to identify blood-based biomarkers associated with MCI-to-AD conversion. Differentially expressed genes (DEGs) between CNs and MCIs and between MCIs and ADs were detected, and subsequent gene set enrichment analysis using the DEGs revealed biomarker candidates for the disease diagnosis. The DEGs were enriched in 4 pathways (coronavirus disease, ribosome, salmonella infection, and ubiquitin mediated proteolysis) for CNs and MCIs, where 54 unique genes were used: 6 pathways (phagosome, salmonella infection, yersinia infection, necroptosis, coronavirus disease, and pathogenic *Escherichia coli* infection) for MCIs and ADs, where 73 unique genes were used. Retrospective prediction models were constructed with logistic regression by using the combination of these unique genes. The best model in CNs and MCIs (CN-MCI) achieved an AUC of 0.866 (95% confidence interval [CI]: 0.861 to 0.871) when using 12 candidates: MCIs and ADs (MCI-AD), AUC = 0.763 (95% CI: 0.757 to 0.767) with 8 candidates. Common two genes (*CDC42: Cell division cycle 42* and *SKP1: S-phase kinase associated protein 1*) were used in both retrospective prediction models of CN-MCI and MCI-AD. *CDC42* protein levels are increased in the frontal cortex of AD patients, whereas *SKP1* levels are decreased in patients with sporadic Parkinson's disease. Based on these two candidates, we further constructed a prospective prediction model with a Cox proportional hazards model by using 318 MCI cohort data followed over one year (175 MCI patients converted to AD and the remaining 143 patients remained stable with MCI). The Kaplan-Meier curves showed a statistically significance in the log rank trend test (P<0.001) for AD conversion-free survival. These results suggest that *CDC42* and *SKP1* can be potential biomarkers for early diagnosis of AD. Further understanding of these potential biomarkers will contribute to the elucidation of the AD pathogenesis mechanism, and integrated analysis including clinical and genomic information may facilitate clinical application of early diagnosis of AD.

Session Title: Omics Technologies Poster Session II

PB3464 RNAseq driven diagnosis of *NBAS* deficiency expands the phenotypic spectrum of disease.

Authors:

S. Silverstein[1,2], T. Cassini[3], J. Fu[1], B. Pusey[1], E. Macnamara[1], C. Tifft[1], M. Malicdan[1], Undiagnosed Diseases Network, D. Adams[1]; [1]NHGRI, Bethesda, MD, [2]NINDS, Bethesda, MD, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN

Rare diseases affect 1 in 10 individuals, and for those evaluated with exome and genome sequencing, typical diagnostic rates average 30%. RNA sequencing can be used to augment genome analysis and improve diagnosis. Open-source computational tools such as OUTRIDER provide a standard framework for RNAseq analysis and may uncover diagnoses missed by genome driven approaches.

We present a young woman with global developmental delay, poor growth, characteristic facial features, osteopenia, premature ovarian insufficiency, and ocular abnormalities who had non-diagnostic genome sequencing. RNAseq performed on patient derived skin fibroblasts was included in a cohort of 72 undiagnosed patients and run through OUTRIDER. *NBAS* gene expression was reported as significantly reduced for this patient compared with controls. Manual inspection of the BAM files revealed compound heterozygous variants: a rare deep intronic variant NM_015909.4 c.2423+403G > C which creates a hypomorphic pseudoexon not seen in control samples (gnomad AF 0.000006572) and a rare premature termination codon (PTC) c.4753C > T; p.Arg1585Ter (gnomad AF 0.000006572). Both variants are predicted to cause nonsense mediated decay of transcripts, as the pseudoexon contains a PTC.

Biallelic variants in *NBAS* are associated with two phenotypes: infantile liver failure syndrome 2 (MIM # 616483) and short stature, optic nerve atrophy, and Pelger-Huet anomaly (MIM # 614800). More recent literature has detailed a wide clinical spectrum of disease. Re-evaluation of the patient's clinical presentation revealed that it is consistent with the *NBAS* phenotypic spectrum, in a more severe form than previously reported. Published cases of *NBAS* related disease are caused by either biallelic missense variants or a missense and a PTC. To our knowledge this would be the first report of a patient with biallelic PTC variants in *NBAS*. We hypothesize based on reported genotype-phenotype data that biallelic missense variants likely cause infantile liver failure while PTC variants likely cause developmental defects, explaining our patient's unusually severe form of the disease.

We provide an example demonstrating the utility of incorporating early use of RNAseq to generate diagnostic candidates. RNAseq has the potential to further expand genotype-first molecular diagnostics, helping to extend the phenotypic spectrum of identified diseases. We recommend consideration of this approach as part of diagnostic pipelines, especially for exome or genome negative patients.

Session Title: Omics Technologies Poster Session III

PB3465 Saliva as a sample type for the evaluation of miRNA biomarkers using small RNA sequencing

Authors:

C. Dillane, M. Tayeb; DNA Genotek, Ottawa, ON, Canada

Sequencing of salivary microRNA (miRNA) is rapidly becoming a means to explore disease biomarkers. In this study we demonstrate that stabilized saliva samples provide RNA of sufficient quality for detection of miRNA biomarkers including miRNAs with reported links to cancer, head injury and mental health disorders.
Saliva was collected from 14 participants using the ORAcollect™·RNA device (DNA Genotek). RNA was extracted using the miRNeasy Serum and Plasma kit (QIAGEN) and sequencing libraries were generated with the QIAseq miRNA Library Kit with UDIs (QIAGEN) without normalization of the input RNA. XpressRef Universal Human RNA Reference (QIAGEN) was used as a positive control. Libraries were sequenced on the NextSeq 550 (Illumina) targeting a mean of 20 million reads per sample. FastQ files were uploaded to QIAGEN GeneGlobe Design & Analysis Hub and annotated using miRbase and piRNAdb databases.
The mean number of reads per sample was 20.7 million and Q scores of Unique Molecular Index (UMI) reads were above 30 demonstrating a high sequencing performance in all libraries.
On average 47% of the reads per sample did not contain a UMI; observed across both the saliva and control samples. Of the reads containing UMIs, a range of 10-51% of the reads in each sample were annotated with miRBase or piRNAdb, while the XpressRef Control contained 69% of annotated UMI reads. The range of annotated reads in saliva samples is expected given the variable miRNA input that is inherent of saliva samples.
Notably, saliva samples covered 35-50% of the total number of Annotation Records in miRbase despite the variable input of miRNA into library prep. Comparatively the XpressRef RNA Control prepared from 20 different human adult and fetal major organs, contained 58% of the total Annotation Records.
Recently a retrospective cross-sectional miRNA sequencing study utilizing 1225 saliva samples was published and gives greater insight into the expected expression of salivary miRNA's from multiple cohorts (Sullivan R. et al., 2022). We used a cohort of expression profiles from the Sullivan et al. study and compared them to our data to discern concordance between the two. After accounting for sequencing depth we found a 3.5-fold increase in annotated reads in our samples, demonstrating that the QIAseq miRNA Library Kit with UDIs performs well with saliva samples collected using the ORAcollect™·RNA device. The most highly-expressed miRNAs in each study were distinctive, though there was a 50% concordance between the top 20 most-expressed miRNAs in the two studies.
These results demonstrate that saliva is a suitable sample type for miRNA biomarker detection using small RNA sequencing.

PB3466 Scalable Nanopore long-read sequencing to resolve complex regions in Parkinson's disease

Authors:

A. Miano-Burkhardt, P. Alvarez Jerez, K. Daida, L. Malik, M. Abdelhalim, B. Baker, C. Blauwendraat, A. Singleton, K. Billingsley; NIH, Bethesda, MD

Parkinson’s disease (PD) is the second most common neurodegenerative disorder worldwide, and genetics is one of the major underlying causes of this disease. The majority of PD genetic studies to date have focused on single nucleotide variants. However, current risk loci only explain 16-30% of the heritability of PD, leaving a large portion of the genes driving PD unknown. Structural variants contribute substantially to genetic variation in the human genome, yet little is known about the role they play in PD. Long-read sequencing is required to accurately identify these complex regions of the human genome, but until recently, it was expensive, error-prone, and low throughput. Here, we take advantage of recent advancements in long-read technology and develop a scalable wet lab protocol for Oxford Nanopore Technologies (ONT) long-read sequencing of whole human blood samples at the population level (dx.doi.org/10.17504/protocols.io.ewov1n93ygr2/v1). This protocol yields high-quality ONT data with average N50s of approximately 30kb and 30X coverage. As part of the Global Parkinson's Genetics Program (GP2), we applied this framework to hundreds of PD samples. This new genetic resource will allow us to not only resolve existing complex PD risk haplotypes but also unlock the impact of novel genetic variants that have been previously inaccessible using short-read and array-based datasets.

Phillippy[17], M. Chaisson[12], F. Sedlazeck[18], C. Blauwendraat[1], B. Paten[14]; [1]NIH, Bethesda, MD, [2]Univ. of California, Santa Cruz, Santa Cruz, CA, [3]UC Santa Cruz, Santa Cruz, CA, [4]NIH, Bethesda, MD, [5]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [6]Georgetown Univ., Washington, DC, [7]Baylor Coll. of Med., Houston, TX, [8]Google LLC, Mountain View, CA, [910]DNAnexus, Santa Cruz, CA, [11]Chan Zuckerberg Initiative, San Jose, CA, [12]Univ. of Southern California, Los Angeles, CA, [13]Natl. Inst Aging, Bethesda, MD, [14]UCSC, Santa Cruz, CA, [15]Univ. of California Santa Cruz, Santa Cruz, CA, [16]Johns Hopkins Univ., Baltimore, MD, [17]NIH/NHGRI, Bethesda, MD, [18]Baylor Coll. Med., Houston, TX

Long-read sequencing technologies substantially overcome the limitations of short-reads but to date have not been considered as feasible replacement at scale due to a combination of being too expensive, not scalable enough, or too error-prone. In this work, we designed an ONT sequencing protocol that produces over 100Gb of ONT reads using a single PromethION flow cell. We developed new workflows and adapted and updated existing tools, combined into an end-to-end open-source pipeline implemented in WDL. Using the sequencing data from 3 human cell lines and 14 post-mortem brain tissue samples, we showed that our pipeline produces state-of-the-art SNP, structural variant and methylation calls. The protocol is currently being used to sequence thousands of brain genomes as a part of the NIH CARD initiative.

Our new Hapdup method generates de novo diploid assemblies from ONT sequencing only. Outside of centromeres and segmental duplications, our assemblies are structurally highly concordant with the current best human de novo assemblies produced from the more expensive combination of Pacbio HiFi and trio sequencing (structural variant F1-scores 0.95-0.97). The assembly representation allowed us to construct pangenomes of the MHC and IGH regions that are highly polymorphic and are otherwise difficult to analyze with linear references.

Our SNP calls produced with PEPPER-Margin-DeepVariant were similar or better than calls produced by the state-of-the-art Illumina-based methods (SNP F1-scores 0.997 and 0.996 respectively). The most noticeable improvement was associated with the regions of low short-read mappability. Small indels inside homopolymers and low-complexity repeats remain the major source of the residual errors (indel F1-score 0.87). However, our evaluation of the R10 sequencing protocol showed substantial improvements, in particular inside protein-coding regions (indel F1-score 0.997) and exons (indel F1-score 0.985).

We also added a new functionality to phase small and structural variant calls into megabase-scale haplotypes and reduce phasing switch error. Methylation calls produced from ONT data were highly concordant with the standard bisulfite sequencing, but in addition had haplotype-specific resolution, highlighted by our analysis of differentially methylated promoters in brain genomes.

Session Title: Omics Technologies Poster Session III

PB3468 scEmbed: Single-cell ATAC-seq clustering via representation learning of genomic regulatory regions.

Authors:

N. LeRoy, J. P. Smith, G. Zheng, E. Gharavi, J. Rymuza, A. Zhang, N. Sheffield; Univ. of Virginia, Charlottesville, VA

BACKGROUND: Thanks to the efforts of large consortia and thousands of individual labs, there is an explosion in the amount of scATAC-seq data available. However, critical challenges have emerged: handling the 1) inherent sparsity; and 2) high dimensionality of this data. Typically, this is addressed through dimensionality reduction techniques such as PCA, SnapATAC, or SCALE. These approaches cast cells into a low-dimensional representation, or embedding, for downstream tasks such as clustering or cell-type annotation. Existing methods typically use a one-step approach that embeds individual cells directly from a binary accessibility matrix. This requires significant compute power and resources. Here, we propose a two-step approach called scEmbed that first embeds genomic regions, and then uses these to build cell embeddings.
METHODS: For the first step, we use Word2Vec, an unsupervised machine learning framework, to learn low embeddings of genomic regulatory regions. For the second step, we use the learned region embeddings to compute embeddings of individual cells for downstream clustering tasks. We trained scEmbed on publicly available scATAC-seq data and then assessed it with two tasks: First, we compared scEmbed's cell clustering performance to existing analysis methods. Second, we tested the ability to apply scEmbed models pre-trained on reference data to unseen datasets.
RESULTS: First, we found that scEmbed performs as well as alternatives at cell clustering tasks. Our method consistently achieves high scores (>=0.4) for AMI, ARI, and homogeneity clustering metrics across three different clustering techniques (K-means, HC, and Louvain). Second, a major advantage of scEmbed over existing approaches is that pre-trained scEmbed models can embed unseen scATAC-seq data. Indeed, a pre-trained scEmbed model from a reference hematopoetic progenitor cell dataset could effectively cluster entirely independent hematopoetic and PBMC scATAC-seq data it had never seen. The clustering results from pre-trained models remain highly competitive against current methods (ARI > 0.4). Moreover, by using pre-trained models, we were able to generate the embeddings of >10,000 cells with >100,000 features in only a few minutes on standard desktop hardware.
SUMMARY: scEmbed will greatly improve the accessibility and throughput of scATAC-seq data analysis. scEmbed reduced the computation time of traditional scATAC-seq workflows from hours to minutes, while achieving comparable performance. This work sets the stage for large, general-purpose pre-trained models capable of generating embeddings of any scATAC-seq samples.

Session Title: Omics Technologies Poster Session I

PB3469 † ScISOr-ATAC reveals convergent and divergent splicing and chromatin specificities between cell types across cortical regions and disease states.

Authors:

C. Foord[1], W. Hu[1], J. Hsu[1], L. Fan[1], M. Corley[1], T. N. Bhatia[2], S. Xu[3], N. Belchikov[1], F. He[1], A. Pang[1], S. N. Lanjewar[2], J. J. Jarroux[1], A. Joglekar[1], T. A. Milner[1], L. Ndhlovu[1], J. Zhang[3], S. A. Sloan[2], L. Gan[1], H. U. Tilgner[1]; [1]Weill Cornell Med., New York, NY, [2]Emory Univ., Atlanta, GA, [3]Univ. of California Irvine, Irvine, CA

Multimodal measurements have become widespread in genomics, however measuring chromatin accessibility and splicing simultaneously in frozen brain tissues remains unconquered. To this effect, we have devised Single-Cell-ISOform-RNA sequencing coupled with the Assay-for-Transposase-Accessible-Chromatin (ScISOr-ATAC). First, we applied ScISOr-ATAC to Rhesus macaque (Macaca mulatta) prefrontal (PFC) and visual cortex to compare splicing and chromatin accessibility across brain regions and investigate how they may correlate. We found a higher number of excitatory neurons (ExN) compared to our human samples and identified 3 distinct subtypes characterized by layer-specific markers; RORB marks L3-L5; CUX2 marks L2/3 and L6; both CUX2 and RORB mark L2-L4. We profiled splicing and chromatin accessibility patterns in each ExN subtype between regions and showed that splicing is highly brain-region specific for RORB ExN, moderately specific in CUX2.RORB ExN and unspecific in CUX2 ExN. At the chromatin level, however, CUX2.RORB ExN show the highest brain-region specificity compared to other subtypes. These results indicate that some excitatory subtypes exhibit variable transcriptomic and chromatin accessibility patterns across tissues, while others do not. This suggests that splicing and chromatin can identify differences in excitatory subtypes within and across multiple regions, likely due to differences in morphology and signaling patterns. To compare chromatin accessibility and splicing patterns in disease, we also performed ScISOr-ATAC on Human Alzheimer's Disease (AD) and control PFC samples. We found a lower number of excitatory neurons in AD compared to controls, likely caused by disease-associated cell death. Due to this discrepancy in cell numbers, we developed a downsampling approach which samples from an equal number of reads across RNA and ATAC data. With this method, we found that oligodendrocytes are most affected by splicing and chromatin accessibility changes, suggesting that myelination may play an important role in AD. We additionally found an enrichment in spliced genes related to neurotransmitter receptors and synaptic transmission indicating that these changes play a role in neuronal signaling and function. Altogether, these results indicate that chromatin and splicing can show convergent or divergent dynamics depending on specific cases and justify the need for multimodal measurement to investigate complex systems and disease states. Here, ScISOr-ATAC allows for the characterization of single-cell patterns splicing and chromatin accessibility and the comparison of sample groups in frozen brain samples.

Session Title: Omics Technologies Poster Session II

PB3470 Screening Copy Number Variation with an Autoencoder

Authors:

K. Im, P. Ng, P. Shah, A. Kumar; MyOme, Inc, Menlo Park, CA

Background: Copy number variants are known causes of Mendelian diseases such as 22q11.2 microdeletion syndrome, spinal muscular atrophy, or hereditary breast and ovarian cancer syndrome and have also been shown to be associated with more complex phenotypes such as autism. Typically, CNVs are detected using chromosomal microarrays, array comparative genomic hybridization (aCGH), SNP arrays or, more recently, next-generation sequencing. We use whole genome sequencing to identify copy number variation (CNV) using a suite of algorithms such as Smoove, CNVnator, and Manta. The candidate CNVs are visually inspected to assess breakpoints and abnormal read depth, which is time-consuming, prone to error, and not scalable.
Methods: We implemented an autoencoder to efficiently remove technical artifacts and identify putative clinically relevant CNVs. An autoencoder is a deep learning model that learns to reconstruct input data, enabling anomaly detection by measuring the reconstruction error between the input and output. For each candidate CNV, we trained an autoencoder on reference samples without known disease-causing CNVs. We then tested whether the autoencoder's reconstruction error from a clinical sample was similar to reference samples (no CNV) or significantly different (CNV present). We evaluated the autoencoder on clinical samples with known pathogenic CNVs and rare (&lt0.01) CNVs from Genome in a Bottle's HG002.
Results: We observed improved sensitivity with the autoencoder compared to using z-scores based on average read depth. The autoencoder showed sensitivity of 100% (22/22) and 99.85% (667/668) on clinical samples and HG002, respectively. Using z-scores based on the average read depth in the candidate CNV region compared to a reference population, sensitivity was 100% (22/22) and 99.4% (664/668) on clinical samples and HG002, respectively. There was a small trade-off between sensitivity and specificity as the autoencoder had lower specificity. Specificity for the autoencoder and average read depth is 87.5% (385/440) and 88.2% (388/440), respectively.
Conclusions: The autoencoder is platform-specific and classifies polymorphisms and difficult-to-sequence regions as normal with an increase in sensitivity compared to a z-score based method. Implementing such a solution saves the need for manual sequence review of these regions while still preventing wasted time on clinical interpretation of sequence artifacts

Session Title: Omics Technologies Poster Session III

PB3471 Sequence-based deep learning for predicting gene expression from personal genomes

Authors:

A. Spiro, S. Mostafavi; Univ. of Washington, Seattle, WA

Sequence-to-function deep learning models trained on genomic DNA sequence can predict a variety of functional properties, including gene expression, with state-of-the-art accuracy. Currently, common models are trained on regions from the Reference Genome and are evaluated on their ability to predict population average features. Our recent work has shown that although these models are good predictors of population mean gene expression, they fall short when predicting gene expression from personal genomes. To address this gap in prediction performance, we propose a new approach to model training where we incorporate personal genomes into the training process. Our algorithm consists of two steps: training models on population average features (e.g., mean gene expression), followed by a fine-tuning step that utilizes personal-genomes paired with gene expression values. The effectiveness of the second step depends on the ability of the model to decompose gene expression per gene and per individual into its deviation from its mean value. We develop a composite loss function that enforces models to explicitly consider this decomposition. To assess our approach, we use paired Whole Genome Sequencing and gene expression data from n=190 individuals in the ROSMAP cohort where data is available for 18,776 protein-coding genes. We create personal genomic sequences for each individual and each gene, thus multiplying the size of our data by the number of individuals in the cohort (x190 fold for this experiment). We evaluate our model on individuals and genes that were not seen by the model during training. We assess model performance based on three correlation metrics between observed and predicted expression value: correlation across all data points, mean correlation per individual, and mean correlation per gene. As a baseline, we consider a model that has been trained only on the Reference Genome and population mean gene expression. We observe an increase in correlation across all data points from 0.530 to 0.606 and an increase in mean per individual correlation from 0.531 +- 0.011 to 0.608 +- 0.007 (+- indicates standard deviation). We do not observe an increase in mean per gene correlation. From these results, we conclude that training on personal genomes has the potential to increase the accuracy of sequence-based prediction of gene expression, however the differences between genes rather than between individuals dominate model learning when the prediction tasks are combined. We are currently exploring other fine-tuning strategies to better focus models on learning per gene expression differences across individuals.

PB3472 SEQUIN: interactive web app for rapid, reproducible bulk and single cell RNA-Seq analysis

Authors:

C. Weber[1,2], M. B. Hirst[3], B. Ernest[3], N. J. Schaub[2], K. M. Wilson[2], K. Wang[2], H. M. Baskir[2], P-H. Chu[2], C. Tristan[2], I. Singec[2]; [1]Natl. Eye Inst., Rockville, MD, [2]Natl. Ctr. for Advancing Translational Sci., Rockville, MD, [3]Rancho BioSci.s, San Diego, CA

SEQUIN is a web-based R/Shiny application that allows fast and intuitive analysis of RNA-sequencing data derived for model organisms, tissues, and single cells. Integrated app functions enable uploading datasets, quality control, differential gene expression analysis (DGE), gene set enrichment (GSE), and data visualization. We developed the iPSC Profiler, a practical gene module scoring tool that helps to measure and compare pluripotent and differentiated cell types. Freely available to the public, SEQUIN empowers scientists using interdisciplinary methods to investigate and present transcriptome data firsthand with state-of-the-art statistical methods. SEQUIN help democratize and increase the throughput of analysis using next-generation sequencing data with single-cell resolution. Here, we analyzed a new pair of unpublished datasets from human iPSCs of cell lines cultured with differing media, in order to determine optimal conditions for growth and self-renewal: E8, E8+Albumin, and mTeSR. Cell lines were: LiPSC GR1-1, GM25256, NCRM5, and WA09. Bulk RNA-Seq had 27 samples in triple technical replicates, while the scRNA had a total of 24,186 cells. We performed pairwise DGE and PCA-based clustering, followed by GSE. In both datasets we found samples were most tightly clustered by growing media first, then by cell line. In PCA plots, E8 and mTeSR media were more similar by overall expression than E8 and Albumin. After performing DGE with media as contrast (E8 vs. E8-Albumin) and evaluating iPSC Profiler gene module scores, pluripotency was equally high across media types and cell lines. By the intersection of significant DE genes in bulk and scRNA-Seq, for the same media comparison, there were 90 genes (adj. p-value < 0.001, abs. value log2 fold change >= 0.5). We performed GSE with this gene set in SEQUIN and found enriched Gene Ontology terms relating to prostaglandin biosynthesis and cell membrane raft organization. These terms included ANXA (annexin) gene family which relates to phospholipid binding. Since the media differ by lipid concentration, this could explain the upregulation of ANXA. These experiments exemplify the use of SEQUIN for rapid and reproducible analysis leading to actionable insights.

Session Title: Omics Technologies Poster Session II

PB3473 Serum sphingolipid levels are modified by *HLA-DRB1*15:01* and *HLA-A*02:01* in multiple sclerosis.

Authors:

E. Misicka[1], W. Tobin[2], M. Fereidan-Esfahani[2], J. Sagen[2], S. Liu[1], J. Oksenberg[3], S. Gregory[4], D. Crawford[1], F. Briggs[1]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Mayo Clinic, Rochester, MN, [3]Univ California San Francisco, San Francisco, CA, [4]Duke Molecular Physiology Inst., Durham, NC

Multiple sclerosis (MS) is a demyelinating autoimmune disease, and *HLA-DRB1*15:01* and *-A*02:01* are the most prominent risk and protective alleles that encode MHC class II and class I molecules, respectively, involved in antigen presentation. Examining metabolites in the context of genetic predisposition may highlight dysregulated processes relevant for the pathology of MS. Here, we sought to identify serum metabolites whose levels varied by *HLA-DRB1*15:01* and *-A*02:01* allele status in relationship with MS (gene-metabolite interactions). Metabolon's untargeted metabolomic profiling was completed for serum from 105 healthy controls (HCs) and 73 relapsing remitting (RR) MS cases who were DMT naïve/free, ≤5yrs from onset and ≤2yrs from diagnosis. All subjects were non-Latinx White. After QC, there were 1119 metabolites. *HLA-DRB1*15:01* and *-A*02:01* carriers were defined by tagging SNPs. Logistic regression models included an interaction term between each metabolite and allele carrier status in separate models, adjusting for age, sex, BMI, smoking status, and population substructure. Stratified models then characterized the direction of effects. 53% and 44% of MS cases and 35% and 37% of HCs were *HLA-DRB1*15:01* and *-A*02:01* carriers, respectively. In *HLA-DRB1*15:01* models, 75 metabolites had significant interactions, revealing an enrichment of sphingomyelins (fold change [FC]=9.3, $p=2x10^{-16}$) and ceramides (FC=5.6, p=0.01). In carriers, there were several notable associations with MS status, e.g., 3-hydroxybutyroylglycine (β=2.6, p=0.003), N2-acetyl,N6-methyllysine (β= -1.4, p=0.003), and kynurenine (β= -2.4, p=0.02). In non-carriers, sphingomyelins and ceramides were exclusively elevated in MS vs HCs, e.g. sphingomyelin (d18:1/17:0) (β=3.1, p=0.001). In *-A*02:01* models, there were 27 significant interactions, with an enrichment of tryptophan metabolites (FC=6.9, p=0.002), sphingomyelins (FC=4.3, p=0.03), and nucleotides (FC=3.6, p=0.05). Amongst carriers, several metabolites were associated with MS, e.g. tryptophan betaine (β= -1.1, p=0.008) and methyl indole-3-acetate (β=1.6, p=0.01). In non-carriers, there were also many associations, e.g. dopamine 3-O-sulfate (β= -1.9, p=0.003) and cholate (β= -1.2, p=0.008) both involved in processes previously associated with MS. In conclusion, there are differential serum levels of multiple metabolites in MS cases vs HCs, whose levels appear to be modified by the lead risk and protective alleles. Further investigation of the influence of these variants on the serum levels of serum lipids and amino acids may reveal novel biological mechanisms for the development of MS.

Session Title: Omics Technologies Poster Session III

PB3474 Single cell dissection of smoking and drinking addiction associated loci in multi-ancestry genetic studies.

Authors:

S. Gao, L. Wang, X. Wang, GWAS & Sequencing Consortium of Alcohol and Nicotine use; Penn State Coll. of Med., Hershey, PA

Genome-wide association studies (GWAS) are successful in detecting associations between genetic variants and tobacco and alcohol use. However, most of the associated variants lie within the non-coding regions with unknown functions for tobacco and alcohol use. To explore non-coding genetic signals, a common approach is to associate them with gene expression levels through expression quantitative trait loci. The majority of eQTL studies utilize bulk RNA-seq samples, which average the effect across cell types and hence remain underpowered to dissect cell type-specific effects. Thanks to improved single cell sequencing and multiplexing technology, scRNASeq datasets with 100s individuals start to emerge, which allow us to identify cell type specific eQTLs (sc-eQTLs) in the brain. To further identify risk genes in brain cell types, we propose a new method to integrate bulk and single-cell RNASeq data, improving cell type-specific eQTL detection and integrating it with multi-ancestry genetic studies. The method capitalizes the insights that bk-eQTLs are weighted averages of sc-eQTLs. By jointly analyzing bk- and sc-eQTLs, we can leverage large sample sizes of bk-eQTLs and enhance the cell type specific effect estimation. In this method, we jointly analyze the bk-eQTL from Cortex region in the MetaBrain data with the single cell RNASeq data from Bryois et al. (n = 192) to improve the sc-eQTL detection. To validate the improved cell-type-specific effect estimates of brain eQTLs, we seek replicate the microglia-specific signals in an independent microglia eQTL dataset. We replicate 1609 deconvoluted cell-type-specific eQTLs ($p < 1e-6$), which is 14% more than cell-type-specific eQTLs identified by single cell data alone. We then conduct co-localization analysis with *coloc* to exaimne whether European-specific local ancestry genetic variants related to smoking and drinking traits potentially act through brain cell type cis-eQTLs. Among 620 Smoking initiation associated loci, the deconvoluted cell-type-specific eQTL results identified 57 co-localized loci in Astrocytes, 130 in Excitatory neurons, 34 in Microglia, 30 in OPCs...COPs, 21 in Endothelial cells, 50 in Inhibitory neurons, 86 in Oligodendrocytes, and 17 in Pericytes using a H4-posterior probability cutoff of 0.9. Overall, the co-localization analysis identifies genes in brain cell types at 28-39% of the GWAS loci with deconvoluted results and only 3-10% using single cell data alone. Our ongoing research in deconvoluting brain cell-type-specific eQTL effect will narrow down the risk genes and enhance our understanding of the genetic basis underlying addiction traits in distinct brain cell types.

Session Title: Omics Technologies Poster Session I

PB3475 Single cell long read mRNA isoform regulation is pervasive across mammalian brain regions, cell types, and development.

Authors:

H. Tilgner[1], A. Joglekar[1], W. Hu[1], B. Zhang[2], O. Narykov[3], M. Diekhans[4], J. Balacco[5], L. C. Ndhlovu[1], T. A. Milner[1], O. Fedrigo[5], E. Jarvis, D[5], G. Sheynkman[6], D. Korkin[7], M. Ross[1]; [1]Weill Cornell Med., New York, NY, [2]spatialgenomics, inc, Pasadena, CA, [3]Worcester Polytechnic Inst., New York, NY, [4]UCSC, Santa Cruz, CA, [5]Rockefeller Univ., New York, NY, [6]Univ. of Virginia, Charlottesville, VA, [7]Worcester Polytechnic Inst., Worcester, MA

RNA isoforms influence cell identity and function. Until recently, technological limitations prevented a genomewide appraisal of isoform influence on cell identity in various parts of the brain. Our prior work developed single cell isoform sequencing for fresh and frozen tissues, spatial isoform sequencing and accurate long read interpretations[1-4]. Here, we present results under review[5] mapping isoforms accross multiple mouse brain regions, cell subtypes, and developmental timepoints from postnatal day 14 (P14) to adult (P56). For 75 percent of genes, full length isoform expression varies along one or more axis (brain region, cell subtype or age), underscoring the pervasiveness of isoform regulation across multiple scales. As expected, splicing varies strongly between cell types. However, certain gene classes including neurotransmitter release and reuptake as well as synapse turnover, harbor significant variability in the same cell type across anatomical regions, suggesting differences in network activity may influence cell type identity. Glial brain region specificity in isoform expression includes strong poly(A) site regulation, whereas neurons have stronger TSS regulation. Furthermore, developmental patterns of cell type specific splicing are especially pronounced in the P21 to P28 transition. The same cell type traced across development shows more isoform variability than across adult anatomical regions, indicating a coordinated modulation of functional programs dictating neural development. As most cell type specific exons in P56 mouse hippocampus behave similarly in newly generated data from human hippocampi, these principles may be extrapolated to human brain. However, human brains have evolved additional cell type specificity in splicing, suggesting gain of function isoforms. Taken together, we present a detailed single cell atlas of full length brain isoform regulation across development and anatomical regions, providing a previously unappreciated degree of isoform variability across multiple scales of the brain. Gupta*,Collier* et al, Nature Biotechnology, 2018 [2] Hardwick*,Hu*,Joglekar* et al, Nature Biotechnology, 2022 [3] Joglekar et al, Nature Communications, 2021 [4] Prjibelski*,Mikheenko* et al, Nature Biotechnology, 2023 [5] Joglekar et al, biorxiv, 2023

Session Title: Omics Technologies Poster Session II

PB3476 Single cell RNA sequencing reveals heterogeneity across the intestines in treatment naïve individuals diagnosed with Crohn's Disease.

Authors:

S. Washburn[1], V. Kolachala[2], A. Dodd[2], S. Maddipatla[2], S. Murthy[2], Y. Hwang[2], J. Matthews[2], G. Gibson[1], P. Qiu[1], S. Kugathasan[2]; [1]Georgia Tech, Atlanta, GA, [2]Emory Univ Sch. of Med., Atlanta, GA

Crohn's Disease (CD) is distinguished by chronic, relapsing transmural inflammation throughout both the small and large intestine. Multiple components can influence risk for developing CD such as environmental factors, genetic susceptibility, and microbial interactions within the intestines. Currently, the exact cause of CD remains unknown, and the specific cellular contribution to disease pathogenesis and therapeutic response remains to be elucidated. The aim of this study is to investigate the heterogeneity of underlying disease mechanisms and identify personalized disease signatures that are cell type or tissue specific. Treatment naïve subjects (n = 20) diagnosed with CD were recruited for this study, and droplet based single-cell RNA sequencing on 10X Genomics Chromium platform was performed on ileal (n = 19), colon (n = 21), and rectal (n = 17) mucosal tissue from each subject. After quality control, 142,245 cells were included in downstream analysis, analyzed using the R package, Seurat. Single cell transcriptomic profiles across tissue compartments were contrasted to validate the hypothesis that there are underlying cellular function differences across tissue. Within each tissue, immune, epithelial, and stromal cells were identified. The cellular proportion profiles for individuals were heterogeneous both within and across tissue compartments. Differentially expressed gene analysis was performed using MAST to investigate genetic differences of cell types across tissue. Pathway analysis, using ToppGene, revealed that oxidative phosphorylation pathways, which might affect cellular redox imbalance, and immune cell activation pathways are upregulated in the colon goblet cells relative to ileum goblet cells, supporting our hypothesis. Enrichment analysis was performed by overlaying Inflammatory Bowel Disease (IBD) Genome Wide Association Study (GWAS) genes with differentially expressed genes to inform upon potential pathogenic cell types within the mucosa. IBD GWAS genes were enriched in both immune and epithelial cells in the colon, highlighting the importance of investigating cellular interactions within tissue. Overall, our findings of marked differences in cellularity during disease presentation explains in part the differential treatment responses/non-responses observed in initial therapy in these individuals. This emphasizes the need for personalized medicine, perhaps based on initial mucosal single cell profiles in CD. Further, enrichment analysis can be leveraged to identify potentially pathogenic cell types for disease across tissue and inform upon therapeutic targets.

Session Title: Omics Technologies Poster Session III

PB3477 Single-cell analysis of the human infant airway epithelium reveals heterogenous cell subpopulations during RSV infection

Authors:

B. Bera[1], S. Bhattacharya[1], E. Chorvinsky[1], K. Salka[1], A. Welham[1], M. Rujana[1], D. Thompson[1], H. Morizono[1], M. Gutierrez[2], J. Jaiswal[1], G. Nino[1]; [1]Childrens Natl. Hosp., Washington, DC, [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Rationale: Respiratory Syncytial Virus (RSV) is the most common cause of severe viral respiratory infection in infants. The infant airway epithelium is a pseudostratified cell barrier that serves as the RSV point of entry and site of initial host defense. Dissecting the heterogeneity of virus-host interactions at the single cell level in the infant airway epithelium is essential to identify novel molecular pathways involved in viral infection and ultimately pave the way for targeted therapy. The goal of this study was to use to use Single Cell RNA seq (scRNA seq) to characterize the transcriptomic program of human infant airway epithelium during RSV infection. **Methods:** We performed scRNA seq of approximately 8037 nasal AECs from a single human infant donor cultured in the presence and absence of an eGFP tagged RSV-A2 virus (MOI 1). CellRanger was used to convert raw reads to gene expression, Seurat v3 and DoubletFinder were used for quality check, UMI counts were normalized using scTransform, Seurat package was used for downstream analysis. Differential expression (DE) was done by wilcox test (log FC > |0.25| & adj. pval < 0.05) in Seurat. Gene set enrichment analysis (GSEA) was used for functional annotation. **Result:** Based on Single cell eGFP expression, we identified subpopulations of AECs with high levels RSV infection above 75th percentile (RSV High) and those having expression below 75th percentile RSV Low). We found 491 differentially expressed (DE) genes between RSV high and RSV Low out of which 183 are upregulated genes in RSV High and 308 upregulated genes in RSV Low. Our data reveals subpopulations that have susceptibility and resistance genes during RSV infection which highlights functional roles that AECs have during infection. Integrated functional analyses identified that the Low RSV group (resilient AECs) demonstrate upregulation of interferon-inducible antiviral effectors (e.g., MX1) and High RSV group have RSV-induced upregulation of metalloproteinases (e.g., MMP10) and pro-inflammatory chemokines (e.g., CXCL8). **Conclusion:** Using our single-cell analysis of the human infant airway epithelium we have identified two subpopulations with susceptibility and resistance genes during RSV infection. By providing mechanistic insight surrounding the overall modulation of the inflammatory response, these results will be important in offering new target concepts for helping the pediatric population during RSV infection.

Session Title: Omics Technologies Poster Session I

PB3478 Single-cell long-read sequencing in human cerebral organoids uncovers autism-associated exons

Authors:

Y. Yang, R. Yang, B. Kang, S. Qian, X. He, X. Zhang; The Univ. of Chicago, Chicago, IL

Alternative splicing significantly increases transcript diversity and dysregulation of alternative splicing has been repeatedly associated with neurodevelopmental disorders. Single-cell analysis revealed unprecedented cellular diversity in the central nervous system but the extent of cell-type-specific splicing remains largely uncharted. Here we performed single-cell long-read sequencing in the human cerebral organoids and identified over 32,000 uncatalogued isoforms and 3,622 cell-type-specific splicing events. Long reads uncovered coordinated splicing and cell-type-specific intron retention events which were challenging to study with short reads. Retained introns were enriched in RNA splicing and translation and showed weaker 5′ splice sites. We used this rich dataset to explore the biological processes underlying neurodevelopmental disorders, focusing on autism. We found that the exons enriched in autism cases versus controls tend to have higher inclusions in progenitor cells than neurons, suggesting that the splicing program in autism is closer to the progenitor state than differentiated neurons. Furthermore, cell-type specific exons harbor significantly more *de novo* mutations in probands than siblings, highlighting the importance of these exons to autism genetics. We identified 118 autism genes displaying cell-type-specific isoforms, including an alternative exon in *UBE3A* that introduced an alternative translation start site in excitatory neurons. Overall, our results indicate pervasive splicing changes across neural cell types and highlight the importance of cell-type-specific splicing in autism.

Session Title: Omics Technologies Poster Session II

PB3479 Single-cell multi-omics analysis of mucosal immune cell profiles in ulcerative colitis

Authors:

S. Feng[1,2], E. Heidrich-O'Hare[1], Z. Xu[1,2], H. Hu[1], W. Chen[1], R. Duerr[1]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Tsinghua Univ., Beijing, China

INTRODUCTION: Ulcerative colitis (UC) and Crohn's disease (CD) are the two forms of inflammatory bowel disease (IBD). When UC involves only part of the colon, a sharp demarcation usually separates inflamed distal mucosa and uninflamed proximal mucosa. GWAS have successfully identified genetic risk loci associated with UC; however, the functional interpretation of these loci and their implications in disease pathogenesis remain incompletely understood. **RATIONALE:** Cells and molecules enriched in inflamed mucosa are candidate targets for UC therapy. Therefore, we compared single-cell assays for gene expression (GEX) and antibody-derived cell surface protein tags (ADTs) (CITE-seq), or GEX, ADTs and transposase accessible chromatin (ATAC) (DOGMA-seq) in immune cells from macroscopically inflamed and non-inflamed mucosa in UC patients. **METHODS:** Biopsies of inflamed and non-inflamed mucosa in UC patients were cryopreserved, thawed in batches, dissociated, and flow-sorted to enrich live immune cells. ~45,000 cells from 13 UC patients were profiled with CITE-seq, and ~4,000 cells from 6 UC patients were profiled with DOGMA-seq. Downstream analyses include trajectory inference by RNA velocity, identification of differentially expressed genes (DEG) or activated peaks (DA peaks), analysis of chromatin activity at GWAS loci, and genome-wide peak-to-gene linkages. **RESULTS:** We delineated 19 CD4+ T cell subtypes with CITE-seq. DOGMA-seq identified similar major clusters and precisely defined helper T cell subtypes based on transcription factor (TF) activities inferred from ATAC peaks. We also identified the POU family as marker TFs for the recently defined CXCR5- Tfh-like cells. Analysis of cell proportions and trajectory corroborated that CD127+ CD4+ T cell development dominates in non-inflamed mucosa, while that of CD279+ CD4+ T cells and Treg dominates in inflamed mucosa. Enrichment of UC GWAS lead SNPs in ATAC peaks was observed in CD127+ CD4+ T cells in non-inflamed mucosa, CD279+ CD4+ T cells in inflamed mucosa, and CD8+ T cells in non-inflamed mucosa. DA peaks between inflamed and non-inflamed mucosal immune cells that overlap UC or IBD (UC+CD) GWAS SNPs were linked to DEGs, suggesting regulatory roles of these UC/IBD GWAS SNPs. To further elucidate regulatory mechanisms in CD4+ T cells, we constructed a TF-gene regulatory network and identified immune cell ligand-receptor interactions that impact downstream signaling targets. **CONCLUSION:** We provide valuable insights into the phenotypic and regulatory landscape and intercellular communication networks of mucosal immune cells in UC, with a particular focus on the role of CD4+ T cells.

Session Title: Omics Technologies Poster Session III

PB3480 Single-cell spatial multiomics uncovers new mechanisms of myelin deforming diseases

Authors:

Y. Wang, A. Wang; Univ. of California Davis, Sacramento, CA

Demyelinating diseases, including conditions like multiple sclerosis, acute disseminated encephalomyelitis, and Balo's disease, afflict over a million people. Yet, the exact processes that cause myelin damage in these diseases remain largely elusive. In this study, we examine the brain sections of a demyelinating mouse model using cutting-edge single-cell spatial transcriptomics technologies like Stereo-seq, CosMx, Xenium, Visium, GeoMx, along with advanced epigenetic and metabolomics tools such as sc-spatial ATAC and imaging mass spectrometry and unveil the roles of several signaling pathways in the disease development like such as cell cycle arrest at G2 phase, dysregulated lipid metabolism and vesicle transport. Integration of the data from different sc-spatial omics offers a panoramic view to deepen our understanding of these diseases.

Session Title: Omics Technologies Poster Session I

PB3481 Single-nucleus RNA-seq reveals key contributors in Duchenne muscular dystrophy

Authors:

E. Jeon[1], J-H. Chae[2], M. Choi[1]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Duchenne muscular dystrophy (DMD) is a devastating X-linked disorder caused by mutations in the dystrophin gene. Slowly deteriorating muscle forces patients to lose ambulation in their early teens and to die in their 20s, mostly due to respiratory or cardiac complications. Deflazacort, a glucocorticoid derivative, has been used to control inflammation and delay muscle weakness. Despite recent progress in understanding of the genetics and pathogenesis of the disease and attempts to treat it, DMD still remains a major pediatric muscle dystrophy without cure due to an incomplete characterization of the molecular and cellular interactions responsible for muscle maintenance and functions. Here, we present single-nucleus RNA-sequencing (snRNA-seq) results of muscles from DMD, milder-form Becker muscular dystrophy (BMD), and healthy controls, followed by spatial transcriptomics analysis of DMD and healthy muscles. In addition, to examine the effect of deflazacort, we administered the drug to *D2-mdx* mice and subjected their muscles to snRNA-seq. Integrated analysis of human and mouse muscles revealed pathogenic features in the patients and palliative effects of deflazacort. Meanwhile, it also highlighted the perturbation of proliferating satellite cells, leading to an increased signal transduction pathway involving EZH2, NR3C1, and cell cycle progressor proteins in the patient cells, which was confirmed by EZH2 ChIP-seq in satellite cells. We also demonstrate a therapeutic effect by perturbation of these pathways in *D2-mdx* mice through improved muscle phenotype. Our analysis of DMD patient muscles reveals pathogenic mechanisms that can be readily targeted by pre-existing therapeutic options.

Session Title: Omics Technologies Poster Session III

PB3483 Spatially-resolved, single-cell transcriptomics detects cell types and novel cell states in kidney diseases

Authors:

J. Reeves[1], E. Metzger[1], R. Ivy[2], H. Ira[2], N. Brousaides[2], S. Kim[1], S. Murphy[1], R. Smith[2], R. Colvin[3]; [1]NanoString Technologies, Seattle, WA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Massachusetts Gen. Hosp., boston, MA

Spatially-resolved, single-cell tissue atlases can provide mechanistic insights not appreciable by bulk RNAseq or spatially-agnostic scRNAseq. We have begun to harness the power of space in understanding mechanisms in kidney diseases, beginning with pathogenetically relevant transplant glomerulopathy in chronic antibody mediated rejection (CAMR), the major cause of late kidney graft loss.

A necessary first step is to generate the spatial atlases themselves. To do this, gene expression was measured in FFPE biopsy sections from 7 CAMR cases, 4 TCMR cases, and 3 cases with no evidence of rejection (NER) with 1000 gene probes using the CosMxTM Spatial Molecular Imager. Cells were detected by IF staining of B2M/CD298 and DAPI with the machinery in the AtoMxTM Spatial Informatics Platform. The analyzed dataset consisted of 295,937 cells and a total of 51,142,869 transcripts. Cell typing was accomplished by semi-supervised clustering with the Kidney Cell Atlas database.

With the disease-inclusive spatial atlas, we report on 3 tests related to kidney rejection and cell states. First, we examined expressional differences of glomerular endothelial cells (GECs) within glomeruli between CAMR and controls. In the CAMR, GECs showed upregulation of genes related to repair and angiogenesis (e.g., COTL1: log2FC=1.1, FDR=2.9e-5); protective genes (e.g., CD59: log2FC=0.96, FDR=9.2e-7), and a downregulation of genes involved in VEGFR2 signaling including (e.g.,EFNB2: log2FC=1.25, FDR=1.8e-31). Second, we further interrogated the in-glomerulus CAMR GECs. We found two distinct classes of GECs with one class containing genes related to inflammation and angiogenesis and the other class previously identified in normal kidneys with genes related to cell adhesion and growth arrest. Third, we sought to understand the role of NK cells in CAMR. We found that NK cells tended to co-localize with GECs in CAMR (p=0.08). Moreover, differential expression showed evidence that CAMR-residing NK cells were activated relative to NER NK cells.

We found profound transcript changes in GEC affecting the VEGFA pathway, known to be required for normal GEC differentiation. NK cells were in proximity to glomerular endothelium and expressed increased activation transcripts in CAMR. Our data show that pathological phenotypes of cells may not be represented in normal cell atlases and these atlases can be improved with spatially-resolved, single cell approaches.

Snyder Dept. of NeuroSci., Johns Hopkins Sch. of Med., Baltimore, MD, [4]Biochemistry, Cellular, and Molecular Biology Graduate Program, Johns Hopkins Sch. of Med., Baltimore, MD, [5]Dept. of Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [6]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Sch. of Med., Baltimore, MD, [7]Dept. of Neurology, Johns Hopkins Sch. of Med., Baltimore, MD, [8]The Kavli NeuroSci. Discovery Inst., Johns Hopkins Univ., Baltimore, MD

Background: The hippocampus (HPC) is a 3-layered archicortex that plays key roles in plasticity, learning, and memory. It is composed of heterogeneous cell types localized across the major subregions like dentate gyrus (DG), CA1-4, and subiculum. Many important HPC functions are reflected in its spatial organization, and hence molecular profiling approaches that retain spatial information of gene expression are highly useful. The 10x Genomics Visium platform combines transcriptome-wide gene expression with high-resolution imaging, but not at the single-cell level. Methods like SPOTlight, Tangram, and cell2location have been developed to perform cell-type deconvolution of individual Visium spots, and the Visium Spatial Proteogenomics (SPG) platform provides orthogonal data by allowing for protein detection on immunofluorescence images. Methods: We used Visium-SPG to label 4 broad cell types in tissue sections at the level of the anterior hippocampus from 2 neurotypical donors. Tissue was immunostained for DAPI, GFAP, NeuN, OLIG2, and TMEM119 to identify nuclei, astrocytes, neurons, oligodendrocytes, and microglia, respectively. Multispectral imaging was performed followed by on-slide cDNA synthesis and Illumina sequencing. Data from Visium-SPG was paired with existing HPC Visium and snRNA-seq (150,917 spots and 81,123 nuclei from 10 donors) from spatially-adjacent tissue sections. Individual nuclei in the DAPI channel were segmented using Cellpose, and ~1,000 cells were manually classified. A decision-tree classifier was then trained to classify the remaining cells from all samples. Results: We investigated the performance of Tangram, cell2location, and SPOTlight, for cell type deconvolution. These tools mapped individual cell type annotation onto individual spots measured in the Visium-SPG expression data and all the results were compared to the orthogonal SPG-derived cell proportions. The best-performing method was used to perform spot deconvolution on the remaining Visium samples. Conclusion: Given the sparsity of gene expression data in the Visium platform, spot deconvolution is challenging in complex regions like HPC. While current methods can generate results that are satisfactory for downstream analyses, improved methods are needed for specialized neuroanatomical structures with unique cellular compositions. The data generated here provides a valuable resource for benchmarking future spot deconvolution methods by providing an archival dataset for the cellular composition in the anterior HPC.

Session Title: Omics Technologies Poster Session II

PB3485 Statistical inference and downstream analysis of cell-type-specific co-expressions from single cell RNA-sequencing data

Authors:

C. Su[1], X. Shan[2], Z. Xu[3], B. Cai[2], H. Zhao[2], J. Zhang[1]; [1]Emory Univ., Atlanta, GA, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT, [3]Univ. of Washington, Seattle, WA

The advancement of single cell RNA-sequencing (scRNA-seq) technology has enabled the direct inference of co-expressions in specific cell types, facilitating our understanding of cell-type-specific biological functions. For this task, the high sequencing depth variations and measurement errors in scRNA-seq data present two significant challenges, and they have not been adequately addressed by existing methods. We propose a statistical approach, CS-CORE, for estimating and testing cell-type-specific co-expressions, that explicitly models sequencing depth variations and measurement errors in scRNA-seq data. Systematic evaluations show that most existing methods suffered from inflated false positives as well as biased co-expression estimates and clustering analysis, whereas CS-CORE gave accurate estimates in these experiments. When applied to scRNA-seq data from postmortem brain samples from Alzheimer's disease patients/controls and blood samples from COVID-19 patients/controls, CS-CORE identified cell-type-specific co-expressions and differential co-expressions that were more reproducible and/or more enriched for relevant biological pathways than those inferred from existing methods. Based on CS-CORE, we further developed two pipelines for downstream analyses that utilize cell-type-specific co-expressions for biological discoveries: co-expression QTL analysis and module-trait association analysis. Using population-scale scRNA-seq data, the co-expression QTL analysis identifies genetic variations which correlate with co-expressions in specific cell types, revealing dysregulation in functional pathways that may be caused by genetic variations. Based on scRNA-seq data with rich phenotypes, the module-trait association analysis estimates the correlation between groups of genes and phenotypes, uncovering the involvement of biological pathways and molecular mechanisms in disease pathogenesis in cell types of interests.

Session Title: Omics Technologies Poster Session III

PB3486 † STDCC: Supervised Tensor Decomposition tool for studying Cell-cell Communication using single-cell RNA-seq data

Authors:

Q. Dai[1], M. Epstein[2], J. Yang[1]; [1]Emory Univ., Atlanta, GA, [2]EMORY Univ., Atlanta, GA

Motivation: Knowledge of communication patterns among different types of cells is crucial for studying biological processes and diseases. Multiple computational tools have been developed to infer such cell communication patterns using multi-subject single-cell RNA-seq (scRNA-seq) data. However, existing tools in this space are unsupervised and infer communication patterns without considering confounding factors and phenotypes of interest.
Methods: To fill this significant gap, we propose a Supervised Tensor Decomposition tool for studying Cell-cell Communication (STDCC) using scRNA-seq data, which simultaneously infers cell communication patterns, estimates phenotypic effects, and adjusts for confounding covariates. STDCC first constructs a 4-dimensional communication score tensor representing subjects, sender/receiver cell types, and ligand-receptor pairs per dimension, then employs a supervised tensor decomposition technique to obtain low-dimensional factors representing distinct communication patterns. Specifically, STDCC decomposes the communication score tensor within the defined feature space of confounding covariates and the phenotype of interest, and thus can identify phenotype-associated cell-cell communication patterns while adjusting for confounding covariates.
Results: Simulation studies based on communication patterns obtained from real data demonstrated that STDCC outperformed unsupervised methods with improved decomposition accuracy and reduced bias of phenotypic effects. Applying STDCC to scRNA-seq data profiled for 13 Autism Spectrum Disorder (ASD) subjects and 10 controls, we found that dysregulations of interactions between neurexin-neuroligin, neural cell adhesion molecules, and extracellular matrix-receptor in AST-FB, AST-PP, endothelial, L2/3, L4, L5/6, and L5/6-CC cells were most strongly associated with ASD. We also found that non-biological confounding covariates like batch effects were strongly associated with the decomposed communication patterns in ASD data, emphasizing the importance of accounting for confounding covariates to obtain robust and interpretable cell-cell communication patterns. We also applied STDCC to real scRNA-seq data profiled for studying COVID-19 severity (n = 60) and SLE (n = 221) and observed interesting cell-cell communication patterns as well.
Conclusion: We provide a useful tool STDCC for studying cell-cell communication using scRNA-seq data, which can account for confounding factors and accurately estimate phenotypic effects. A Python package for implementing the proposed STDCC tool will be publicly available through GitHub.

PB3487 Streamlined RNA-Seq workflow reveals extracellular vesicle transcriptome insights.

Authors:

T. Kainth, M. Isa, S. Perike, E. Dreskin, S. Okino, C. Jiang, L. Lingelbach, N. Kumar; Bio-Rad Lab., Hercules, CA

Extracellular vesicles (EVs), produced naturally within cells, are membrane-bound particles that contain DNA, RNA, protein, and other bioactive molecules. EVs released from parent cells deliver cargo to recipient cells, triggering vital biological responses such as cell proliferation, differentiation, and apoptosis. EVs thus play a critical role in cell-to-cell communication, an essential process that helps maintain the health of complex organisms. Current EV RNA research focuses primarily on miRNAs which, as a class, have regulatory effects on biological pathways and can be involved in cell-to-cell communication. Many of these studies used miRNA-specific reagents for RNA isolation and RNA-Seq library preparation; this approach likely limited the findings of non-miRNA transcripts. Here we present a novel workflow that overcomes these limitations, enabling comprehensive assessment of the entire EV transcriptome. This streamlined approach allows for the isolation of EV RNA from only 1.4 mL of conditioned cell culture media using a standard microcentrifuge and two separate, one-hour sessions over two days. Our 10-minute RNA extraction method efficiently removes protein and DNA from the lysate while preserving RNAs of all sizes. We employ a polyadenylation/template switch strategy for RNA-Seq library construction, which captures RNAs of all sizes. Our findings confirm that miRNAs are present in the EV transcriptome and correlate with the miRNAs found in cellular RNA. Additionally, we identify many small non-coding RNAs in the EV transcriptome, known components of ribonucleoprotein (RNP) complexes that have enzymatic activity and are implicated in cellular processes such as RNA modification, DNA replication, and RNA quality control. We evaluate EVs from a variety of cell lines to confirm the reproducibility and effectiveness of our workflow. Moreover, this novel approach includes a non-traditional data analysis technique that provides new insights into the EV transcriptome and EV biology.

PB3488 Structural similarity search in a comprehensive database of the human proteome.

Authors:

P. Russell, B. Hannigan; Generate Biomedicines, Somerville, MA

The ability to search entire proteomes for structural elements can eliminate bottlenecks in the prediction of molecular behavior inside cells. For example, in the context of drug development, substantial time and resources can be saved through computational identification of candidate molecules with potential off-target binders in the human proteome.

Structural similarity search across complete target proteomes has recently become possible due to advances in computational structure prediction. With the launch of the AlphaFold Protein Structure Database (AlphaFold DB) in 2021, high confidence structure predictions for several entire proteomes are newly available. These predicted structures supplement the structures solved through low-throughput structural analysis techniques such as cryo-EM, NMR and X-ray crystallography, accessible primarily through the Protein Data Bank (PDB). Despite the availability of structural search functionality in the PDB and several third-party tools supporting structure-based search of AlphaFold DB, there is no resource that enables researchers to easily search for structural motifs across a curated database of solved human protein structures supplemented with predicted structures.

We present the Human Motif Search ProteinStore (HMS: ProteinStore), a user-friendly application that takes in a protein structure and region of interest and identifies similar structural elements across a comprehensive structural database of the human proteome. The structural database is composed of a curated set of solved protein structures found in the Protein Data Bank and supplemented with predicted structures from AlphaFold DB to cover the complete UniProt human proteome. HMS: ProteinStore consists of a backend that executes the structural search against the database, as well as a frontend that takes queries in the form of a protein structure and region of interest. Results are returned as top structural matches with alignment scores.

Session Title: Omics Technologies Poster Session III

PB3489 Study of multi-omic variation across diverse peoples of rural Cameroon

Authors:

A. Harris[1], M. A. Rubel[2], M. E. Hansen[1], W. Beggs[1], M. Kachman[3], C. Fokunang[4], A. K. Njamnshi[4], S. A. Tishkoff[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]The Janssen Pharmaceutical Companies of Johnson & Johnson, San Diego, CA, [3]Univ. of Michigan, Ann Arbor, MI, [4]Université de Yaoundé I, Yaoundé, Cameroon

Many studies highlight the importance of the gut microbiome (GM) in shaping health. The GM is proposed to impact host metabolism, providing an axis of interaction between the digestive system and other organ systems. Associations with specific gut microflora have been identified in a spectrum of conditions, including diabetes, autism, colorectal cancer, and liver disease. However, knowledge about the human GM is disproportionately based on studies of urban cohorts from the Global North. These results might not transfer to the more than 40% of people worldwide living rurally—including over half of sub-Saharan Africans, per World Bank estimates. To better understand the composition of GMs from ethnically diverse rural populations, we generated shotgun metagenomic profiles for 178 study participants living across rural Cameroon, practicing hunter-gatherer (Baka and Bagyeli), pastoralist (Fulani), and agriculturalist (Bantu-speakers) lifestyles. We integrated GM profiles with targeted plasma lipidomic and host genomic data over the same individuals. GMs were highly variable across the cohort: permutation testing of non-omic features via PERMANOVA revealed that geography, lifestyle, sex, and gut parasite infection (all $p \leq 1.7 \times 10^{-3}$; $R^2 \geq 0.012$) were significantly correlated with GM β-diversity. In order to measure the contribution of host genetic and lipidomic variation to the GM abundance (genus) variation, we used Principal Components (PC) analysis. Upon regressing each GM PC on the host genetic PCs, host lipidomic PCs, and non-omics covariates, we find that the host genetics, lipidomics, and non-omics covariates explained 2.7%, 3.1%, and 4.1% of the GM variation, respectively. To find which components of the GM and lipidome interact, we used MiRKAT to detect lipids significantly associated with variation in GM β-diversity, and LASSO to select bacterial genera most associated with those lipids. We find that 30 of 1070 measured lipids (2.8%), primarily triacylglycerols, and 180 of 1385 genera (13%), 110 of which lack a standardized genus name, underlie the microbiome-lipidome correlations. Our work thus provides a more complete understanding of healthy GM diversity, and the factors that shape it, in rural sub-Saharan Africa. This work was supported by NIH grant 1R35GM134957-01 and American Diabetes Association grant ADA 1-19-VSN-02 to SAT, and NHGRI training grant T32 HG 9495 to AMH.

PB3490 Systematic analysis of the impact of short tandem repeats on gene expression

Authors:

A. Goren, S. Benton, L. Zhang, Q. Gong, M. Maksimov, S. Shleizer-Burko, E. Wang, C. Wang, M. Lamkin, M. Gymrek; UC San Diego, San Diego, CA

Short tandem repeats (STRs, 1-6bp) are an intriguing type of genetic variation given the diverse repeat units (e.g. $(A)_n$, $(AC)_n$) or the polymorphism in the number of repeats. We and others have linked STRs to variation in gene expression and complex traits. These studies suggested STRs may impact transcription via multiple mechanisms. To study STR involvement in transcription regulation, we optimized a massively parallel reporter assay (MPRA) with random barcoding to handle low complexity sequences. We focused on 3-4 variants each of ~30,000 unique human promoter-proximal STRs for a total of 100,000 fragments. Our MPRA captured ~83% of the library, with >2.1M unique barcodes. We transfected this array to three cell lines (HEK293, RPE1 and HeLa), each in triplicate. The reporter expression was highly correlated between the triplicates in the same cell line (R=0.98), and to a lesser extent between different lines (R=0.62).

Of the ~30K promoter STRs, 8K drove reporter expression ("active"). Motif analysis of the genomic context of the active STRs showed enrichment of key transcription factors (e.g. SP family (p=1e-55) and KLF family (p=1e-47) motifs near GC-rich STRs). Of active STRs, 6.7K (~84%) showed an association between repeat unit number and reporter expression ("eSTRs"). eSTRs were enriched for GC-rich repeats and were strongly biased toward showing positive associations between copy number and reporter expression (4K, ~60%, p=4.6e-57). Our MPRA results aligned with population level data, with ~500 active and ~120 eSTRs of the ~1.1K variants that overlapped STRs significantly linked ($p<0.05$) to transcription (Geuvadis) or blood traits (UKB).

To study the role of STR composition in regulating transcription we designed a second array where we perturbed each of the top 300 active STRs (e.g. by altering repeat sequence or strand orientation). Transfection of this array allowed us to identify key properties of active STRs, such as how directionality can be impacted by repeat unit composition or strand orientation. Our results suggest certain repeat units (e.g. GC-rich) consistently drive positive associations with expression, whereas others (e.g. GTTT) consistently drive negative association, while some repeats show more context-dependent effects.

Our study provides a first in depth interrogation of how sequence characteristics of STRs and their contexts impact transcriptional regulation. Notably, while our initial experiment focuses on promoter STRs, building on new advances in MPRA design (e.g. genomic integration) would allow extensions of our approach to study STRs in other genomic regions (e.g. enhancers) which may work by alternative mechanisms.

Session Title: Omics Technologies Poster Session II

PB3491 Systematic discovery of gene-environment interactions underlying the human plasma proteome

Authors:

B. Sun[1], R. Hillary[2], D. Gadd[2], Z. Kuncheva[3], T. Mangelis[4], T. Lin[1], K. Ferber[1], H. mclanghlin[1], H. Runz[5], Biogen Biobank Team, R. Marioni[2], C. Foley[6]; [1]Biogen, Cambridge, MA, [2]Univ. of Edinburgh, Edinburgh, United Kingdom, [3]Optima Partners Ltd, London, United Kingdom, [4]Optima Partners, London, United Kingdom, [5]Biogen Inc., Cambridge, MA, [6]Optima Partners, Edinburgh, United Kingdom

Understanding how gene-environment interactions (GEIs) influence the circulating proteome could foster biomarker discovery and validation. The presence of GEIs can be inferred from single nucleotide polymorphisms that associate with phenotypic variability - termed variance quantitative trait loci (vQTLs). Here, we conducted the first genome-wide vQTL association studies on plasma levels of 1,463 proteins in UK Biobank (N=53,752). We detected 683 vQTLs for 571 proteins, all newly described. Effect sizes were correlated 96% with a multi-ancestry independent subset of UK Biobank. We then tested for possible interactions that underlie each vQTL association using 114 candidate environmental exposures. We uncovered 1,400 GEIs between 142 proteins and 101 lifestyle and metabolic exposures. The proportion of vQTLs that participated in a GEI was five times greater than conventional protein QTLs (i.e. additive effects, 20% vs. 4%), highlighting the strength of this approach. Stratified analyses within UK Biobank clearly illustrated how age, sex and genotype alter associations between plasma proteins and environmental exposures. Specific examples included a GEI between glycodelin (a reproductive glycoprotein) and body weight, where women under 55 years of age showed negative correlations between protein and phenotype. Women over 55 years showed positive correlations. The opposing signed-effects would mask each other in non-stratified analyses, and the association was entirely absent in males. Furthermore, using knowledge from our GEIs, we pinpointed biological mechanisms that explain why some sites are vQTLs only and lack conventional additive effects on protein levels. This study leverages an unrivalled resource of open-access proteomics and genomics to establish the most comprehensive database yet of GEIs for the human proteome. Importantly, others will be able to use our catalogue of vQTL effects to investigate GEIs with environmental exposures of interest to them, which will expedite the identification of genetic mechanisms underlying a diverse array of disease states.

Session Title: Omics Technologies Poster Session III

PB3492 Systematic identification of silencers in the human genome

Authors:

B. Pang[1], M. Snyder[2]; [1]Leiden Univ. Med. Ctr., Leiden, Netherlands, [2]Stanford Dept. of Genetics, Palo Alto, CA

The majority of the human genome does not encode proteins. Many of these noncoding regions contain important regulatory sequences that control gene expression. To date, most studies have focused on activators such as enhancers, but regions that repress gene expression—silencers—have not been systematically studied. We have developed a system that identifies silencer regions in a genome-wide fashion on the basis of silencer-mediated transcriptional repression of caspase 9. We found that silencers are widely distributed and may function in a tissue-specific fashion. These silencers harbor unique epigenetic signatures and are associated with specific transcription factors. Silencers also act at multiple genes, and at the level of chromosomal domains and long-range interactions. Deletion of silencer regions linked to the drug transporter genes ABCC2 and ABCG2 caused chemo-resistance. Overall, our study demonstrates that tissue-specific silencing is widespread throughout the human genome and probably contributes substantially to the regulation of gene expression and human biology. <!--EndFragment-->

PB3493 Taming the Titans: Building an Ecosystem for Massive Scale Single-Cell RNA-Seq Data Analysis and Visualization

Authors:

Z. Ouyang; BioInfoRx, Inc, Madison, WI

The advent of single-cell (single-nuclei) RNA sequencing (sc/sn RNA-Seq) has revolutionized our understanding of cellular diversity, rare cell populations, and dynamic cellular processes. However, with the advancement of modern sc/sn RNA-Seq technologies, profiling millions of cells in a single experiment has become easily achievable, leading to massive datasets that pose challenges in storage, processing, and analysis. To address these challenges, the development of computational methods specifically tailored for analyzing massive-scale sc/sn RNA-Seq data is crucial to unlock the hidden biological insights within.

Previously, we published scRNASequest and CellDepot, an ecosystem for sc/sn RNA-seq data analysis, visualization, and publishing. This ecosystem has provided benefits to researchers across different domains, enabling biologists to gain insights, analysts to improve turnaround time, core facilities to host data projects, and publishers to examine data integrity. Here we present the next-generation development of this ecosystem to handle massive scale single-cell data.

One major hurdle encountered when analyzing massive scRNA-Seq datasets is the limitation of R sparse matrices, which do not support matrices with over 2 billion non-zero entries. To overcome this limitation, we have developed an updated solution that allows the analysis and visualization of tens of millions (and above) cells. The pipeline employs a novel split-combine approach. In this method, batch integration features were extracted after preprocessing all samples in multiple chunks, including quality control (QC), filtering and doublet prediction. Subsequently, various integration methods are applied on each sample chunk using these features, followed by harmonizing the data across all samples.

Effective visualization of massive sc/sn RNA-Seq data is equally important for interpreting complex biological insights. Building upon the cellxgene VIP data visualization platform, we introduce cellxgene VIP meta-cells. The new platform provides a simplified multi-level visualization on tens of millions of cells.

Through the continuous improvement of capabilities to analyze and visualize massive-scale scRNA-Seq data, the scRNASequest ecosystem empowers researchers to overcome computational challenges and extract valuable biological insights from these large complex datasets.

Session Title: Omics Technologies Poster Session II

PB3494 † Targeted long-read sequencing of *C9orf72* in multiple human tissues.

Authors:

E. Udine[1], N. A. Finch[1], M. DeJesus Hernandez[1], J. Jackson[1], T. Gendron[1], M. Ebbert[2], D. Dickson[1], L. Petrucelli[1], R. Rademakers[3], J. Shah[1], B. Oskarsson[1], M. van Blitterswijk[1]; [1]Mayo Clinic, Jacksonville, FL, [2]Univ. of Kentucky, Lexington, KY, [3]VIB Ctr. for Molecular Neurology, Antwerp, Belgium

The most frequently observed genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) is a non-coding hexanucleotide repeat expansion (GGGGCC) in the gene *C9orf72*. Little is known about how variation in the *C9orf72* expansion contributes to clinico-pathological heterogeneity across this disease spectrum. Advancements in long-read sequencing technologies now allow us to study repeat expansions at a greater resolution than traditional methods, like Southern blotting. Therefore, we aim to use long-read sequencing to uncover variation in the length, sequence content, and methylation levels of the *C9orf72* repeat expansion. Previously, we have used long-read sequencing to examine the *C9orf72* repeat expansion in the cerebellum and found that expansion length is associated with survival time and levels of dipeptide repeat (DPR) proteins, one of the hallmarks of *C9orf72*-related diseases. We are currently extending this targeted long-read DNA sequencing study that utilizes No-Amp sequencing to accurately examine the *C9orf72* repeat expansion in multiple brain regions and blood. No-Amp sequencing is being performed on genomic DNA and utilizes CRISPR-Cas9 to capture a specific genomic region. For this, we are extracting high-quality DNA from the human brain (n~40 per region), including frontal cortex, temporal cortex, motor cortex, and whole blood (n~30) and sequencing samples using the Sequel II (PacBio) at the Mayo Clinic Genome Analysis Core, enriching for the *C9orf72* repeat expansion. Raw data is being analyzed using PacBio's RepeatAnalysisTools. We have selected ALS and FTLD samples with detailed clinical and pathological information available, such as age at onset, age at death, *C9orf72* promoter methylation, *C9orf72* transcript levels, and measures of RNA foci and DPRs. Our work demonstrates that No-Amp sequencing can be used to sequence the entire *C9orf72* repeat expansion in single, long-reads. Thus far, we have detected a wide range of expansion sizes, ranging from less than 1kb to greater than 24kb. Initial analyses of longitudinal blood samples confirm that some individuals have expansions that are stable over time, while others are more dynamic. We have also validated the presence of paternally inherited contractions of the expansion. Our initial estimates of the sequence indicate that approximately 80% of the expansion is comprised of the pure GGGGCC motif and is methylated. Ongoing efforts are focused on further optimizing methylation analyses and identifying clinical and pathological associations.

Session Title: Omics Technologies Poster Session III

PB3495 Targeted sequencing of *ATM* for the genetic diagnosis of Ataxia Telangiectasia - A pilot evaluation of oxford nanopore technology

Authors:

H. Yeung, K-H. Tse; The Hong Kong Polytechnic Univ., Hung Hum, Hong Kong

Introduction Rare diseases (RDs) in childhood often exhibit catastrophic consequences with major neurological deficits. The infrequency of rare neurological disorders makes genetic screening difficult and clinical specialists scarce. Ataxia Telangiectasia (A-T) is one such disease with hundreds of possible pathogenic mutations on *ATM* (Ataxia Telangiectasia Mutated) gene. Targeted sequencing on the next generation sequencing (NGS) platform emerges as a cost-effective genetic diagnosis for A-T. Here, we evaluate if oxford nanopore technology (ONT)-based third generation sequencing may improve genetic diagnosis for A-T. **Methodology** Genomic DNA of A-T (n = 10, mean age = 26.2 years) and healthy control (n = 10, mean age =24.3 years) were isolated from frozen postmortem brain tissues kindly provided by NeuroBioBank, NIH. For Illumina-based NGS, fragmented gDNA (50 ng, 150 bp) was captured with TruSight Inherited Disease Sequencing Panel, and pooled library was sequenced on NextSeq 500 platform with established pipeline. For ONT, fragmented gDNA (1 µg, 1500 bp) was captured with Agilent ClearSeq Inherited Disease Panel and each captured library sequenced by a R9.4 nanopore flow cell on MinION Mk1b device. Real-time basecalling was conducted by Guppy (v6.5.7) on GPU. Reads from two platforms were then aligned to human reference genome (hg19) with genetic variants called by GATK (v1.6) and Clair3 (v1.0.2) respectively and annotated by ClinVar, COSMIC and dbSNPs database. **Results** For NGS, 2.71M reads (N50 = 103.6 bp) were obtained per sample with 1.03Gb reads aligned with targets with an average of 181.6x coverage. Among the A-T samples, 13 pathogenic variants were identified with missense indels or frameshift mutation. For ONT, an average of 3.72M reads (N50 = 1.55kb) was detected with 3.51Gb bases were called per sample. The average read depth aligned with targeted panel region was 67.5x. ONT was able to pin down the identical pathogenic variants in A-T found in Illumina-based NGS. The single nucleotide polymorphism identified in the *ATM* (including missense and frameshift variants) reported was consistent in A-T (80%) and control (66.7%) across the two platforms with comparable average read depth (ONT, 8x - 99x; NGS, 46x - 570x). Ongoing analyses are underway for genes responsible for RDs with deficits in DNA repair. **Conclusion** ONT-based targeted sequencing could identify pathogenic ATM variants in A-T. Targeted sequencing with NGS and/or ONT is useful for genetic screening of childhood RDs but warrants further investigations and standardization. **Funding** Health and Medical Research Fund (HMRF06173836), Hong Kong SAR Government; PolyU Start-up Fund: P0030307

Session Title: Omics Technologies Poster Session I

PB3496 Targeted single-cell transcriptome sequencing characterizes 1 million healthy and leukemic bone marrow mononuclear cells.

Authors:

B. Hariadi[1], E. Papalexi[1], G. Kim[1], A. Malinkevich[2], C. Roco[2], A. Rosenberg[2]; [1]Parse BioSci.s Inc., Seattle, WA, [2]Parse BioSci.s, Seattle, WA

In the thirteen years since its inception, single-cell RNA-sequencing (scRNA-seq) has rapidly spread across multiple fields of research, leading to many new discoveries. As technologies have matured, the number of cells that can be processed in a single experiment has seen exponential growth with workflows now assaying up to one million cells in an individual experiment. While high throughput sequencing methods have facilitated the discovery and characterization of various cell types, sequencing costs can be prohibitively high for routine use. Many applications of scRNA-seq are focused on cell type identification, gene regulatory networks, or biomarker discovery. These applications often do not require surveying the entire transcriptome, but rather require the interrogation of specific sets of well-characterized genes. In these cases, sequencing the entire transcriptome may be adding unnecessary costs. To increase throughput and minimize sequencing costs, the development of a targeted gene enrichment method is required. Here, we extend our whole transcriptome (WT) split-pool combinatorial barcoding technology to enrich a subset of genes representing hundreds of thousands of human bone marrow mononuclear cells (BMMCs) from three acute myeloid leukemia (AML), one acute lymphocytic leukemia (ALL), and four healthy donors. We used our Immune1000 panel to enrich genes representing canonical immune cell markers and pathways. Our method increased the percent of reads on target from as low as 7% in the whole transcriptome libraries to 75% in the targeted libraries. This enabled a nearly ten-fold reduction in sequencing reads between unenriched and enriched libraries, with the resulting clustering yielding high concordance of cell type identities and preserving leukemia-specific signatures such as FLT3, MKI67, and CD19. Overall, we demonstrate our modular enrichment strategy preserves biological structure and allows for deep characterization of gene signatures in health and disease. We envision our approach will enable researchers to simultaneously reduce sequencing costs while drastically scaling up the number of cells and samples across experiments.

Session Title: Omics Technologies Poster Session II

PB3497 Technical comparison between short-read and long-read RNA sequencing.

Authors:

Y. Song[1,2], Z. Chong[1,2]; [1]Dept. of Genetics, Heersink Sch. of Med., Univ. of Alabama at Birmingham, Birmingham, AL, [2]Informatics Inst., Heersink Sch. of Med., Univ. of Alabama at Birmingham, Birmingham, AL

The RNA sequencing technology, developed over a decade ago, has become an indispensable tool for analyzing the transcriptome. Next Generation Sequencing (NGS) typically produces short reads, which can present challenges in deciphering the full complexity of transcriptomes, particularly in repetitive regions. In contrast, long-read sequencing platforms, including Pacific Biosciences (PacBio) and Oxford Nanopore Technologies (ONT), have emerged as valuable tools for studying transcriptomes. These platforms provide full-length transcript sequences and enable more comprehensive analyses. This project investigated the transcriptome differences between long-read sequencing platforms and the Illumina short-read platform, focusing on gene coverage, comparing gene expression, and detecting isoforms. 12 samples from Human Genome Structural Variation Consortium (HGSVC) containing both PacBio Iso-seq and Illumina high-coverage RNA-seq data were selected. The top six regions from GRCh38.p13 annotation file were selected including protein-coding genes, lncRNA, retained introns, protein-coding CDS not defined, nonsense-mediated decay, and processed pseudogenes. The transcript numbers of these regions are 89305, 56049, 33947, 26468, 21234, and 10150, respectively. Long-read sequencing achieved nearly full coverage of selected regions based on the percentage of base pairs, while short-read sequencing fell short of reaching 80% coverage. When considering the extent of transcripts covered at over 95% of length, long-read sequencing demonstrated coverage rates of 21.6%, 4.3%, 13.6%, 6.6%, 10.5, and 3.7%; while short-read sequencing achieved coverage rates of 15.1%, 4.2%, 13.3%, 11.6%, 8.8%, and 5.58%. The correlation of gene expression between the long-read and short-read platforms was approximately 59%. Long- and short-read RNA sequencing can both identify known isoforms, but long-read RNA sequencing provides clearer results without noisy alignment. In conclusion, our investigation of these aspects will contribute to a better understanding of the strengths and limitations of long-read transcriptome sequencing platforms in comparison to the Illumina short-read platform, ultimately guiding researchers in selecting the most appropriate technology for their transcriptome studies.

Session Title: Omics Technologies Poster Session III

PB3498 Technical overview of machine learning pipelines used for assay predictions.

Authors:

T. Rajasekar[1], A. Musolf[2], B. Guo[2], K. Shkura[3], A. Vij[3], G. Bryman[2], K. Williams[4], C. Mann[5], J-H. Sul[2], S. Longerich[2], M. Kennedy[2], A. Tamburino[6], R. Mathew[2]; [1]Merck, Cambridge, MA, [2]Merck & Co., Inc., Cambridge, MA, [3]MSD, London, United Kingdom, [4]Merck & Co., Inc., Rahway, NJ, [5]Merck & Co., Inc., San Francisco, CA, [6]Merck & Co., Inc., West Point, PA

Machine learning (ML) in pharmaceuticals is becoming exceedingly popular, particularly for their predictive value. Through a cross-functional collaboration, our group has developed two automated machine learning pipelines. While these pipelines can be utilized to make predictions on multiple types of data, our initial validation used the results of a CRISPR assay to predict hits from the untested genome. CRISPR screens are useful in drug development for identifying targets and gene modulators, however, the screening process is time consuming. Our ML pipeline can streamline this process, enabling targeted genes (or selected targets) to be selected for testing with CRISPR assays based on results from predictive ML models.

We have developed two parallel pipelines (written in R and Python), utilizing 12 classification models in parallel on a dataset consisting of 40+ features derived from genetics, multi-omics, and known pathways. The pipelines are implemented on AWS using Databricks/MLFlow experiment tracker to optimize the pipelines and allow users to assess which model functions best at making predictions. Our implemented models were chosen as they covered a broad range of classifications algorithms, including random forest, gradient boosting, support vectors, and neural networks. An ensemble approach was chosen as it allows for data to be analyzed individually within each model, taking advantage of each model's inherent strengths/weaknesses for different datasets. It also allows for an effective way to compare multiple models using metrics such as precision, recall, and ROC. From these values, we can determine which of the models is most effective at making predictions. All models output feature importance metrics listing which attributes are most important for developing a predictive model. Simulation studies have shown this method to have high power under multiple scenarios and we present comparisons of models and the differences between the R and Python pipelines. Data science capabilities prove to be a beneficial addition to known genetic research practices, further expanding the scope in which the data can be used. This pipeline can also be leveraged for novel datasets across various therapeutic areas, including those using CRISPR assay data as well as other types of data for predictions.

Session Title: Omics Technologies Poster Session I

PB3499 Telomere dynamics in aging and cancer by nanopore long-read sequencing.

Authors:

T. Schmidt[1], C. Tyer[2], P. Rughani[2], C. Haggblom[1], J. Jones[1], J. Beaulaurier[2], X. Dai[3], S. Juul[3], S. Hickey[2], J. Karlseder[1]; [1]Salk Inst. for Biological Studies, La Jolla, CA, [2]Oxford Nanopore Technologies, Inc, Alameda, CA, [3]Oxford Nanopore Technologies, Inc, New York, NY

Telomeres are the protective, nucleoprotein structure at the ends of linear eukaryotic chromosomes. The accurate measurement of both telomeric length and composition of individual telomeres in mammalian cells has been challenged by the length and repetitive nature of telomeres. With Oxford Nanopore Technologies sequencing, it is now technically possible to sequence entire telomeres and map them to individual chromosome arms. Here, we report a reliable method to enrich, sequence and analyze human telomeres using native nanopore sequencing. To enrich for telomeric sequences, we combine the ligation of adapters complementary to the telomeric G-overhang with restriction enzyme digestion to sequence the telomeric C-strand and part of the adjacent subtelomere. The subtelomeric information is harvested to map individual telomeric reads to specific chromosome arms. We have measured bulk and chromosome-arm specific telomere length dynamics during cellular aging of cultured primary cells and in a patient-derived aging cohort. To address the impact of the telomere maintenance mechanism on telomere length and composition, we have sequenced five well-established telomerase- and ALT-positive cancer cell lines. Our results suggest that, based on nanopore telomere long-read sequencing, ALT-positive cells can be easily discriminated from normal and telomerase-positive cancer cells.
In summary, nanopore sequencing of telomeres grants a deeper understanding of individual telomere composition through telomere length measurement and mapping to specific chromosome arms. As such, telomere sequencing using our Oxford Nanopore enrichment method is a valuable tool to study telomere biology in aging and cancer.

Session Title: Omics Technologies Poster Session II

PB3500 The expression analysis using RNA-seq on human cerebellar tissues.

Authors:

K. Ishikawa; Tokyo Med & Dental Univ, Tokyo, Japan

Many neurological diseases are known to be caused by the expansion of RNA repeat sequences, and the number of such diseases is expected to increase in the future. In such repeat expansion disorders, abnormally expanded repeat sequences attract specific binding proteins, and in pathological states, binding of the specific protein to RNA repeats is accelerated that interferes protein functions. If the binding protein acts as a splicing factor, its binding to the repeat sequence may cause splicing dysregulation. In this study, we performed RNA-seq analysis in the cerebellum of SCA31, a repeat expansion disorder, where critical splicing factors such as TDP-43 are known to bind to the causative RNA repeat. We compared the result with the cerebellum of healthy subjects and SCA6 cerebellum as a control. The RNA-seq was performed using a 150 base-pair pair-end method as well as a long read sequencing. Data analysis was focused on genes such as *ITPR1* and *CACNA1A* that are particularly important in Purkinje cells, and mutations of both cause spinocerebellar ataxia in human. Of note that these genes are large in mRNA size (ITPR1: 9719 bp; CACNA1A: 8660 bp). In addition, it is easy to assume that the splicing abnormality causes severe damage to Purkinje cells, resulting in cerebellar ataxia. We mapped the RNA-seq results of healthy subjects and one subject each for SCA6 and SCA31, and compared their transcript counts. We first found that expression levels of *ITPR1* and *CACNA1A* were clearly lower in SCA31 than in healthy subjects, which is reasonable because the number of remaining Purkinje cells was lower in SCA31. On the other hand, the splicing pattern was very complex for both genes in the healthy subjects, and no significant difference in the splicing pattern was observed so far in an SCA31 patient. We are now checking long read sequencing results to identify if there is any splicing change is present in SCA31

PB3501 The molecular signature of restrictive cardiomyopathy - a multi-omics approach to diastolic heart failure.

Authors:

N. Hanafi[1], A. Turinsky[1], L. E. Wybenga-Groot[2], M. F. Moran[2,3,4,5], S. Mital[6,7]; [1]Ctr. for Computational Med., Hosp. for Sick Children, Toronto, ON, Canada, [2]SPARC BioCtr., Hosp. for Sick Children, Toronto, ON, Canada, [3]Program in Cell Biology, Hosp. for Sick Children, Toronto, ON, Canada, [4]Dept. of Molecular Genetics, Univ. of Toronto, Toronto, ON, Canada, [5]Princess Margaret Cancer Ctr., Univ. Hlth.Network, Toronto, ON, Canada, [6]Dept. of Pediatrics, Univ. of Toronto, Toronto, ON, Canada, [7]Ted Rogers Ctr. for Heart Res., Toronto, ON, Canada

Introduction: Diastolic dysfunction, the central cause of heart failure in restrictive cardiomyopathy, is a predictor of adverse clinical outcomes. However, it is under-diagnosed in cardiomyopathy, difficult to treat, and little is currently known about disease mechanism.
Methods: We did RNA-sequencing and tandem mass spectrometry on myocardial samples from 49 pediatric patients with cardiomyopathy, and performed differential gene expression and protein abundance analyses. We applied a range of unsupervised and supervised computational methods, including machine learning classifiers to clinical, echocardiographic and multiomic data to identify patterns associated with diastolic dysfunction.
Results: We identified molecular patterns associated with restrictive cardiomyopathy in both the transcriptomic and the proteomic components. Supervised principal component analysis of the transcriptomic data revealed two distinct clusters of patients, both of which were enriched for patients with diastolic dysfunction. The first cluster primarily included patients with either restrictive cardiomyopathy or arrhythmogenic cardiomyopathy involving the left ventricle and correlated with upregulation of lipid biosynthesis genes. Cluster 2 primarily included patients with hypertrophic cardiomyopathy and severe diastolic dysfunction and correlated with upregulation of the gene *CA3*. Proteomics was also able to cluster patients with diastolic dysfunction, but was correlated with upregulation of proteins in the coagulation regulation pathway. We used machine learning to generate a prediction model for diastolic dysfunction using clinical, imaging and 'omics' data. The model incorporating multi-omics with clinical components had a stronger classification accuracy for diastolic heart failure compared to a clinical only classifier.
Conclusion: Our study identified a unique molecular phenotype of restrictive cardiomyopathy and diastolic heart failure, which presents exciting opportunities for the development of new biomarkers and therapies for diastolic heart failure targeted to the dysregulated lipid metabolic pathways.

Session Title: Omics Technologies Poster Session I

PB3502 † The Office of the National Coordinator's Sync for Genes Program is delivering on standards-based genomics-EHR integration.

Authors:

B. Dolin[1], P. Paul[2], S. Garcia[2], R. Freimuth[3], S. Chamala[4]; [1]Elimu Informatics, Richmond, CA, [2]US Dept. of Hlth.and Human Services, Washington, DC, [3]Mayo Clinic, Rochester, MN, [4]Children's Hosp. Los Angeles, Los Angeles, CA

Standardizing genomic information and making it interoperable for use in health and research systems is a complex yet crucial endeavor. The Sync for Genes project, launched in 2017 by the Office of the National Coordinator for Health Information Technology (ONC) in partnership with the National Institutes of Health (NIH), aims to enable the sharing of standardized genomic information among laboratories, providers, patients, and researchers. From the onset of this project, it was evident that the complexities of precision medicine and genomic data presented many challenges in adopting, implementing, integrating, and using such data. Over several years, and with the help of stakeholders, demonstrations, and contributions to the Health Level Seven (HL7®) Fast Healthcare Interoperability Resources (FHIR®) standard, the Sync for Genes project has created a well-vetted set of publicly available resources to help health and research organizations tackle these challenges.

One focus area was standardizing genomic variant sharing and interpretation for clinical knowledge. Annotating variants with various pieces of information (e.g., diagnostic or therapeutic implications, predicted molecular consequences, population allele frequencies) is critical in next-generation sequencing (NGS) analysis and interpretation. Standardizing the sharing of annotated variants utilizing FHIR and the knowledge structures defined by the Global Alliance for Genomics and Health (GA4GH) standards organization resulted in a set of resources produced by the Sync for Genes project currently deployed in a large healthcare setting.

Utilizing the Sync for Genes resources to standardize methods for sharing statically annotated variants (e.g., those coming in a lab report) and building on these resources to develop methods for sharing dynamically annotated variants by applying GA4GH-encoded knowledge into a clinical health record resulted in a deployed solution in which healthcare providers can access this information at the point of care. Additionally, this information is provided with context and clinical relevance, making it easier for a caregiver to consider the information as part of patient care and more informed decision-making. By decoupling the update of knowledge from the reporting of sequencing results, the pipeline presents the most current annotations to clinicians.

Tools developed under the Sync for Genes program to support the communication of dynamically annotated variants can be found here [https://github.com/FHIR/genomics-operations].

PB3503 The Personal Genome: Evaluating Individual Sample *de novo* Genome Assemblies and Reporting Performance Benchmarks

Authors:

N. Duro[1,2], P. Schreiner[3,2], Y. Shi[2], X. Gong[2], A. Srour[2], S. Gautam[3], B. Gorman[3,2], S. Pyarajan[4,5]; [1]Booz Allen Hamilton, Tampa, FL, [2]VA Boston Hlth.care System, Jamaica Plain, MA, [3]Booz Allen Hamilton, Lexington, MA, [4]Partners Hlth.Care, Jamaica Plain, MA, [5]Harvard Med. Sch., Boston, MA

Individual human genomics is the key that will unlock the future of personalized diagnosis, prognosis, healthcare intervention, and precision therapeutics. Although, even after high-impact efforts have been made to better represent human diversity in a reference genome, significant challenges persist in the field that hinder personalized healthcare insights. We aim to produce new data, alongside novel analytics, to address some of these challenges by establishing high-quality references and QA/QC benchmarks for de novo genome assemblies.

We report the findings from our pilot study using PacBio HiFi reads that includes the assembly of 24 individual genomes in comparison to well-curated samples like HG002. Individual genomes are assembled using 1 to 4 SMRT cells on the PacBio Sequel IIe to provide insights into the breadth and depth of coverage as a function of the number of HiFi reads. We develop a fingerprinting method that is used to validate the identity of individual long read samples using signature SNPs. These same, deidentified individuals also have WGS data available that we use to compare short-read, long-read, and hybrid genomes. Further, we assess the amount of additional information achieved in a trio-based genome assembly. From these analyses, we observe de novo genome assembly metrics that are particularly descriptive and robust in the definition of high-quality genome assemblies.

We further detail benchmarks and relative performance describing long read-derived small & large variant identification and genome-wide DNA methylation. For small and large variant identification, we report benchmarks using DeepVariant and pbsv software, respectively. PacBio data also includes 5mc genome-wide methylation profiling, which we assess the relative concordance with respect to the Illumina Infinium MethylationEPIC microarray. The validity and consistency of targeted tandem repeat genotyping for these genomes is assessed using TRGT software. We anticipate that our work will provide insight that will help to establish standards, inform future research, and broadly drive continued research efforts in the field long-read sequencing.

Session Title: Omics Technologies Poster Session III

PB3504 The rate of RNA isoform discovery since 2015 and their expression in human frontal cortex brain tissue based on long-read sequencing.

Authors:

K. Dikobe[1], B. Aguzzoli Heberle[2], J. Brandon[2], K. Nations[2], M. Page[2], M. Wadsworth[2], S. Goodwin[3], E. Ghiban[4], R. Wappel[4], S. Mavruk Eskipehlivan[4], P. Nelson[2], J. Miller[2], J. Fryer[5], M. Ebbert[2]; [1]Univ. of Kentucky, Lexingthon, KY, [2]Univ. of Kentucky, Lexington, KY, [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY, [4]Cold Spring Harbor Lab, Cold Spring Harbor, NY, [5]Mayo Clinic, Jacksonville, FL

Intro: Most human genes produce multiple RNA isoforms, averaging 7 across all genes. These distinct mRNA transcripts result in different protein sequences, and potentially distinct functions. For example, two isoforms from the BCL-X gene have opposite functions: BCL-XL is anti-apoptotic while BCL-XS is pro-apoptotic. Due to inherent limitations in short read sequencing, RNA isoform expression has been understudied. Recent advances in long-read sequencing allow researchers to explore the full breadth of RNA isoform diversity. Here, we compare Ensembl annotations since 2015 to our deep long-read RNAseq from human brain to: (1) quantify the recent dramatic increase of annotated transcripts; and (2) highlight RNA isoform diversity and its importance in human health and disease.
Methods: We sequenced frontal cortex tissue from 12 postmortem human brain samples (50% female) using one Oxford Nanopore PromethION flow cell per sample. We analyzed the data using guppy, pychopper, minimap2, and bambu. We quantified the number of newly annotated human transcripts in Ensembl by year from 2015-2022 and measured the RNA expression in frontal cortex brain tissue for transcripts annotated between 2019-2022.
Results: Ensembl annotations gained 8075 transcripts from 2015-2018, but there was a much more significant increase from 2019-2022 with 45000+ newly annotated transcripts. This significant increase coincides with the expanded adoption of long-read sequencing, though it is unclear whether this increase was, in fact, directly because of long-read data. We further found that 2797 of these transcripts are expressed in our long-read human frontal cortex data with a median Counts per Million (CPM) > 1. Of the 2797 transcripts, 868 came from medically relevant genes with 598 having a new protein coding sequence. One example is KIF5A-a gene associated with amyotrophic lateral sclerosis (ALS)-that had 80% of its total gene expression originating from a transcript with newly annotated protein coding sequence since 2019.
Conclusions: Our results demonstrate that the number of annotated human transcripts in Ensembl has grown significantly since 2019, where a large proportion of them are from known medically relevant genes. Researchers studying a given disease need to be aware of all isoforms for a given gene, and their relative expression patterns, to properly understand the gene's involvement in disease and how to target the gene. Intriguingly, thousands of transcripts annotated between 2019-2022 are expressed in human frontal cortex, including brain disease relevant genes, making these results especially important for researchers studying brain related diseases.

Session Title: Omics Technologies Poster Session I

PB3505 Tilted-CCA: Quantifying common and distinct information in multi-modal single-cell data via matrix factorization

Authors:

K. Lin[1], N. Zhang[2]; [1]Univ. of Washington, Seattle, WA, [2]Univ Pennsylvania, Philadelphia, PA

Paired multi-modal single-cell data profile multiple modalities for each cell simultaneously, such as the transcriptome alongside either the surface antibodies or epigenome. This new type of data has been growing in popularity in many areas of biomedical research and provides unique opportunities to learn how different modalities coordinate within each cell. In this work, we develop the Tilted-CCA to learn this coordination via dimension reduction. This novel method estimates low-dimensional embeddings that separate the axes of variation shared between both modalities (i.e., the "common geometry," capturing the coordination between both modalities) from the axes of variation unique to a particular modality (i.e., the "distinct geometry"). This task fundamentally differs from existing methods, which capture all the axes of variation from either modality instead. Methodologically, Tilted-CCA combines ideas from Canonical Correlation Analysis (CCA) and density clustering. Our method first uses the nearest-neighbor graphs from each modality to infer the common geometry between both modalities and decomposes the canonical scores from CCA to approximate this geometry. Biologically, we demonstrate that Tilted-CCA can enable many downstream analyses for CITE-seq (measuring the transcriptome alongside surface antibodies) and 10x Multiome (measuring the transcriptome alongside accessible chromatin regions) datasets on various biological systems. We focus on two detailed analyses in this work. The first shows that Tilted-CCA aids surface antibody panel design for finding a concise set of antibodies that best compliments the transcriptome for CITE-seq instruments. The second shows that Tilted-CCA can unveil cellular dynamics in developmental systems based on the proportion of variation between the common and distinct embeddings for RNA-ATAC multiome datasets.

Session Title: Omics Technologies Poster Session II

PB3506 Trinity of chromatin architects - the coordination of CTCF, RNAPOL2 and Cohesin proteins in shaping the spatial landscape of human genomes

Authors:

D. Plewczynski[1,2], A. Agarwal[3], M. Chilinski[2], S. Korsak[2], A. Halder[2]; [1]Univ. of Warsaw, Warsaw, Poland, [2]Warsaw Univ. of Technology, Warsaw, Poland, [3]CENTRE OF NEW TECHNOLOGIES, Univ. OF WARSAW, Warsaw, Poland

The higher-order organization of chromatin within the nucleus can be deciphered through advanced high-throughput next-generation sequencing techniques like Hi-C, ChIA-PET, and HiChIP, providing insights into the spatial landscape of human genomes at the population scale. Structural proteins, including the CCCTC-binding factor (CTCF), RNAPOL2, and the cohesin complex, are instrumental in stabilizing the spatial arrangement of chromatin. These proteins play critical roles in establishing and maintaining the long-range chromatin interactions, forming chromatin loops and topologically associating domains, and coordinating communication between genes with their regulatory elements, such as enhancers. In our work, we explore the precise contributions of CTCF, RNAPOL2, and cohesin in shaping the multi-scale three-dimensional architecture of chromatin exploiting 3C-type experimental methods combined with the advanced Artificial Intelligence (AI) computational models. Specifically, we answer the question: how the static architecture defined by CTCF micro-condensation is transformed by the dynamic activity of cohesin via the loop extrusion model (LEM) and reorganized during transcriptional activity by RNAPOL2. Finally, we enhanced the previously proposed 3d-gnome algorithm by training a deep learning transformer model (BERT) on chromatin long-range interactions from ChIA-PET experiments mediated by all three protein factors. The Artificial Intelligence powered model of chromatin looping use only DNA sequence as an input, and can be used as the powerful tool to predict the 3D structure of chromatin at the population scale. This allowed us to study the impact of structural variations on genome topology for various human populations by exploiting the 1000 genomes project DNA sequences. By integrating high-throughput sequencing data with advanced computational techniques, 3DNBERT enables the identification and characterization of genomic structural variations, such as copy number variations (CNVs), insertions, deletions, and inversions, across diverse individuals. These structural variations have a profound influence on the three-dimensional organization of the genome, leading to alterations in chromatin looping, topologically associating domains (TADs), and higher-order chromosomal architecture.

Session Title: Omics Technologies Poster Session III

PB3507 TRuc: A GraphAligner based method to characterize tandem repeat expansions from Nanopore sequencing.

Authors:

M. Khan[1,2], S. Chaudhary[3], C. Pearson[1,2], J. Simpson[3,2], R. Yuen[1,2]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]The Univ. of Toronto, Toronto, ON, Canada, [3]Ontario Inst. for Cancer Res., Toronto, ON, Canada

Approximately 7% of the human genome is comprised of tandem repeats (TRs) - stretches of DNA sequence repeated adjacent to one another. These repeats are polymorphic in sequence and length across the population, and tandem repeat expansions (TREs) beyond a pathogenic length are associated with over 60 neurological, neurodevelopmental, and neuromuscular disorders. Larger TREs lead to earlier onset, increased severity, and faster progression of disease. DNA methylation and sequence purity within a repeat can also affect disease outcomes. Traditional PCR diagnostic methods are unable to effectively report sizes for large, GC-rich repeats, while southern blotting offers a lower resolution. Neither approach provides information on methylation, or specific sequence context. While next-generation sequencing overcomes some of these challenges, it is unable to correctly parse large, repetitive sequences.

Long-read sequencing by Oxford Nanopore Technologies (ONT) overcomes these limitations by providing base-pair sequence resolution and methylation information. Here, we present TRuc (Tandem Repeat unit counting), a novel GraphAligner-based method to estimate tandem repeat sizes from Nanopore sequencing data, given the repeat motif and coordinates. We demonstrate the utility of this method on sizing TREs in 11 repeat-containing plasmids, and 7 patient cell lines harbouring known disease-associated TREs of various unit sequence. This method can be used to accurately size repeats in low-coverage datasets, and identify mosaic expansions. Comparison of TRuc repeat size estimates to molecularly validated 'truth' sizes in our sample set results in Pearson correlation coefficients from R=0.82 to R=0.99 for plasmid and patient samples. We compare the accuracy of TRuc to three other existing TR-sizing methods, and demonstrate that TRuc performs as well as, or better than, other methods. We also demonstrate that sequencing with R9.4.1 ONT chemistry results in strand-bias and sequence errors, particularly in GC-rich repeats, and show that these are resolved with higher accuracy and modified ONT basecalling configurations.

This work highlights the benefit of Nanopore sequencing for characterization of TRs. We reveal how different ONT basecallers and configurations affect the accuracy of tandem repeat analysis from Nanopore sequencing data. We also demonstrate the utility of TRuc in sizing heterogenous and mosaic TREs; this can be similarly applied to study complex diseases, or microsatellite instability in cancer. Implications of such methods may also include more accurate prognosis, and faster clinical diagnosis of tandem-repeat associated diseases.

Session Title: Omics Technologies Poster Session I

PB3508 Two-stage Bayesian network (BN) causal structure learning for discovering ncRNA-gene regulatory network.

Authors:

H. Ke, T. Ma; Univ. of Maryland, Coll. Park, College Park, MD

Despite the fact that non-coding RNAs (ncRNAs) make up the majority of the human genome, their annotation and functional understanding are still generally under-studied compared to the coding region. Increasing evidence suggests that ncRNAs play important regulatory roles in various biological processes, such as gene expression. Nevertheless, the precise underlying regulatory mechanisms of most ncRNAs remain elusive.
The interaction between ncRNAs and genes is a complex phenomenon: it has various regulatory patterns, including up-regulation and down-regulation, and mixed-regulation; a single ncRNA can potentially regulate multiple genes simultaneously, while a single gene can also be regulated by multiple ncRNAs at the same time; the regulatory mechanisms are likely to vary under different physiological conditions. In addition, there also exists high ncRNA-ncRNA and gene-gene correlations that might create spurious correlation between ncRNAs and genes. While high-throughput technologies enable us to examine these relationships on a genome-wide scale, it also poses a challenge due to the high-dimensionality of both ncRNA data and gene expression data. In this paper, we propose a novel two-stage hybrid Bayesian network (BN) structure learning method for discovering ncRNA-gene regulatory network with both high-dimensional ncRNA and gene expression data. In the first stage, we employ fast iterative constraint-based screening algorithms to filter out irrelevant ncRNA-ncRNA, gene-gene as well as ncRNA-gene edges, thereby mitigating the confounding bias and reducing the search space of causal structure. In the second stage, we develop a score-based Markov Chain Monte Carlo (MCMC) sampling approach that fully utilizes the unique bipartite backbone structure of ncRNA-gene regulation and incorporate prior knowledge from previous studies or external databases to guide the final structure learning of ncRNA-gene regulatory network. Comparing to existing BN structure learning methods which deal with only one single type of node (e.g., genes only), our method considers two types of nodes and their unique structures and uses existing biological knowledge to guide structure learning and improve the computation efficiency.
Comprehensive simulation studies and real data applications have demonstrated the advantage of our method on both correct causal structure identification and computation efficiency. We also developed a user-friendly software with GUI interface to implement our method with interactive ncRNA-gene regulatory network visualization.

Session Title: Omics Technologies Poster Session II

PB3509 Uncovering isoforms modulating early endothelial cell differentiation via a system-scale approach

Authors:

M. Mehlferber[1], V. Pavelko[1], D. Wissel[2], E. D. Jeffery[1], M. D. Robinson[2], G. M. Sheynkman[1]; [1]Univ. of Virginia, Charlottesville, VA, [2]Univ. of Zurich, Zürich, Switzerland

Isoform variation is known to contribute to the earliest establishment of cell fates; however, the role of isoforms in the developing vascular system remains understudied. To characterize isoforms involved in the establishment of endothelial cells, we utilized an induced human pluripotent stem cell line to model early endothelial cell (EC) differentiation. To gain insight into temporal isoform expression patterns, in collaboration with PacBio, we collected cells on five days of differentiation for long-read sequencing; obtaining bulk MAS-Seq data across five days with biological triplicates for the first (Day 0) and last (Day 5) timepoints. We also performed mass-spectrometry analysis on the differentiated cells, thus forming the basis for an integrative long-read proteogenomic approach. MAS-Seq libraries were sequenced on the Revio SMRT Cell system, giving ~60 million full-length reads per sample, representing the most comprehensive repertoire of full-length transcripts from early primordial endothelial cell differentiation. To characterize the isoform drivers of EC differentiation, we surveyed differential isoform usage from Day 0 and 5, identifying 2,159 genes with statistically significant differential isoform usage from DRIMSeq. The top genes showing dramatic isoform switches were RBM7, PIAS1 and GNAS, previously implicated in endothelial processes. To confirm the expression of these isoforms at the protein-level, we utilized a deep coverage MS-based proteomics approach, collecting data from multiple proteolytic digestions (Trypsin, AspN, Chymotrypsin, and Lys-C) to expand the identification of protein isoforms within our collected mass-spectrometry samples. Focusing on the proteomics data collected from Day 0, we identified proteins from an average of 9,370 genes. Through the enhanced resolution of the MAS-Seq Revio system, in tandem with the proteomic data, we present one of the most comprehensive surveys of protein isoform expression evidence during early developmental pathways. The findings from this work lay the foundation to build a more comprehensive framework for defining functional isoform regulatory modules during development, and technical assessment of parallel RNA and protein data collection for iPSC and other tissue resources.

Session Title: Omics Technologies Poster Session III

PB3510 Unraveling disease-driving genes and cell types through optimized integration of single-cell transcription and genome-wide association studies

Authors:

X. He, Q. Li, X. Zhu; Penn State Univ, University Park, PA

How disease-associated SNPs confer disease risk remains unknown. Recent studies have begun to integrate GWAS with scRNA-seq to uncover genes and cell types by which SNPs drive diseases. These studies often used a single method to identify cell-type-specific genes from scRNA-seq (e.g., differential expression) or link them to SNPs in GWAS (e.g., proximity). However, relying solely on one method could be misleading, because a method that excels in one study might fall short in another, and determining the optimal method for a new study is often uncertain. Hence, there is a need for a framework that synergizes various approaches to automate the optimal integration of scRNA-seq and GWAS.

Here, we develop an automatic framework that optimizes the integration of scRNA-seq and GWAS to find disease-driving genes and cell types. First, we use 6 metrics of expression specificity (ES) to identify genes of the transcriptional signature for a cell type on scRNA-seq. Next, we link these genes to their regulatory SNPs through 5 strategies based on SNP-to-gene (S2G) proximity, bulk and single-cell epigenomes. Lastly, we quantify heritability enrichment of these SNP annotations in GWAS via stratified LD score regression, and we normalize the results to be comparable across datasets, ES metrics and S2G strategies. By optimizing the normalized results, our framework automatically selects the best combination of ES metric and S2G strategy for a given study, which advances over previous studies.

We applied this framework to 4 scRNA-seq studies of healthy human hearts (n=40; 741,907 cells) and GWAS for 20 cardiovascular traits. Our results recapitulated known disease-associated cell types, including cardiomyocytes (CMs) in atrial fibrillation (AF) and endothelial cells in coronary artery disease (CAD). Our results identified previously unexplored but plausible cell-disease relations, such as pericytes in CAD (9.9-fold, p=1.4e-4), demonstrating the hypothesis-generating potential. Our results showed the benefit of S2G via cell-type-matched single-cell epigenomes. For example, AF heritability enrichment in CM-specific genes increased from 21.3-fold (p=2.5e-7) to 41.8-fold (p=3.4e-7) when we switched S2G from bulk epigenomes of heart tissues to single-cell epigenomes of CMs. Given a disease, our results prioritized the same cell types on European and East Asian GWAS, highlighting the cross-population transferability.

While focusing on heritability, our framework identifies cell-type-specific gene sets that can aid gene prioritization and polygenic prediction. Though our framework was tested mainly on cardiovascular GWAS, it can be applied to study other diseases.

Session Title: Omics Technologies Poster Session I

PB3511 Unraveling dynamic enhancer-promoter interactions across neural differentiation using network analysis models

Authors:

A. Kreimer, **W. DeGroat**; Rutgers Univ., Piscataway, NJ

There is an emerging consensus that a substantial portion of the mutations associated with human diseases in genome-wide association studies (GWAS) likely occur in cis-regulatory elements, especially gene-distal enhancers, that mediate their effects by causing a change in the expression of a target gene. However, our understanding of how the variation in this 98.5% of the sequence that constitutes the human non-coding genome contributes to human disorders remains largely unknown. Here, we collected epigenetic and gene expression data from seven early time points during the differentiation of human embryonic stem cells (hECSs) into neural progenitor cells (NPCs). Focusing on this model system, we constructed an intricate network of enhancer-promoter (E-P) interactions which demonstrated characteristics suggesting dynamic network patterns across time points. Temporal analysis suggests timepoint-specific characteristics. Next, we collapsed all the time points into one network and performed enrichment analysis which showed relevant genomic annotations. We applied bi-clustering techniques by grouping enhancer and promoter regions together using a modularity metric, which unraveled various network sub-structures of interactions suggesting different transcriptional regulation programs. Finally, we identified overlap with variants from various neuropsychiatric and neurodevelopmental disorders within our constructed network with matching disease-associated target genes. Analysis of the transcription factors (TFs) predicted to bind to the enhancers in our network suggests a mechanism by which these variants can exert their effect. Overall, our results suggest a general framework for exploring gene regulation programs and their dynamics across developmental processes and a comprehensive approach to exploring the effect of disease-associated genetic variation on transcriptional networks.

PB3512 Unraveling Layers of Proteogenomic Complexity in Cancer through Multiomic Exploration of Archived FFPE Tissue

Authors:

H. Latif[1], Y. Han[1], D. Corney[2], Y. Fan[1], W. Wang[1], J. Matthew[1], Z. Ying[1], C. Mozdzierz[1], G. Zhou[1]; [1]Azenta, South Plainfield, NJ, [2]Azenta, South Planfield, NJ

Formalin Fixed Paraffin Embedded (FFPE) tissues are a staple in clinical diagnostics associated with solid tumor. The preserved tumor tissue can be interrogated using classical histopathology and complemented with molecular approaches to elucidate cancerous SNPs, indels, structural variants, repeat expansion, copy number expansions, and mutational burden. Increasingly, approaches are being deployed to interrogate tissue not only through individual datasets but through integrated approaches that provide spatial information that defines the tumor microenvironment. Here, we illustrate using FFPE blocks from various tissues a multiomic workflow that allows for deep exploration of the molecular underpinnings of cancerous tissue. FFPE blocks were serially sliced into various FFPE slides with a single slide H&E stained. Individual slides were then utilized to explore the genome, epigenome, single cell RNA-seq, and digital spatial profiling. Genome information was captured using hybrid capture based approaches followed by deep NGS on an Illumina platform and analyzed for a variety of variants and tumor mutational burden. DNA methylation was detailed using target capture probes targeting DNA methylation sites. Single cell approaches were applied to explore the transcriptome using 10X Genomics scRNAseq Flex kit, and digital spatial profiling was done using the NanoString GeoMx Whole Transcriptome Atlas and immunostaining. Aggregating these data illustrates the expanding landscape of information that can be extracted from FFPE derived tissue and the potential for novel discovery and diagnostic power integrating these complex data types holds.

Session Title: Omics Technologies Poster Session III

PB3513 Unravelling Myoblast Potential: A Breakthrough in CRISPR/Cas9 Efficiency.

Authors:

A. Rihoux[1,2], A. Gagné[1,2], L. K. Hamilton[1,2], M. Tétreault[1,2]; [1]Univ. of Montreal, Montreal, QC, Canada, [2]CRCHUM, Montreal, QC, Canada

Until now, the use of CRISPR/Cas9 in myoblast research has been challenging and has yielded low editing efficiency. In this study, we present a transformative protocol, effectively integrating Neon Transfection system with Single Cell Cloning on immortalized myoblasts. This cohesive approach magnifies the yield of viable clones nine-fold and triples the occurrences of successful knockout mutations. More clones translate to an increased likelihood of obtaining colonies with desired mutations, thereby significantly improving the success rate of CRISPR manipulations.

Our method's success is underpinned by the integration of the high-resolution melting (HRM) curve technique for clone screening, replacing the time-consuming and expensive sequencing processes. HRM reduces screening time from days to just a couple of hours and significantly cuts costs by minimizing cell culture resources.

This innovative protocol not only speeds up myopathy research but also proposes an alternative to patient biopsies. It eliminates lengthy paperwork and patient discomfort associated with biopsies, making the process both faster and more humane. The unified approach of Neon Transfection, Single Cell Cloning, and HRM screening promises a higher success rate while avoiding bulk effects, thus maintaining the purity of the clones. This breakthrough holds substantial potential to redefine myoblast research and offers exciting possibilities for future myopathy studies and treatments.

Session Title: Omics Technologies Poster Session I

PB3514 Unravelling the interplay between type 2 diabetes, genetics and metabolite levels

Authors:

O. Bocher, A. Singh, A. Arruda, P. Kreitmaier, A. Barysenka, W. Rayner, E. Zeggini; Helmholtz Zentrum Munich, Neuherberg / Munich, Germany

Type 2 diabetes (T2D) represents a major health burden and is forecast to increase dramatically in the upcoming years. The genetics of the disease have been successfully investigated in large GWAS but the remaining challenge lies in fully understanding the role of these variants in the biology giving rise to the disease. Metabolomics offers an opportunity to answer this question by giving insights into these biological mechanisms and into why certain patients progress to specific complications. We sought to investigate the interplay between genetics, metabolomics and T2D risk in the UK Biobank cohort. We first conducted a bidirectional Mendelian Randomization (MR) study using the UK Biobank to assess the effects of metabolites on T2D risk and the DIAMANTE GWAS meta-analysis results to assess the effects in the opposite direction. We found suggestive evidence for some metabolites to be causal of T2D, including glucose and metabolites linked to low-density lipoproteins. In the reverse direction, a lot more metabolites showed significance, possibly due to the higher statistical power reflecting the larger study size of the DIAMANTE meta-analysis. We find changes in half of the 164 absolute metabolite levels tested to be caused by T2D (with p-value down to 10^{-61}), including an increase in amino acids and glucose levels, and a decrease in metabolite levels from cholesterol classes. Some of these metabolite levels are also seen to be associated with specific T2D complications in the UK Biobank cohort such as HDL cholesteryl esters showing lower values in T2D individuals with kidney complications compared to T2D individuals without complications (β=-0.55, $p=3.66x10^{-8}$). Secondly, we assessed the interaction between T2D status and genetic variants through a differential metabolite QTL analysis. We find 22 metabolites that are differentially genetically regulated in individuals with and without T2D, including glycine (β=0.41, $p=5x10^{-25}$ for the most significant SNP) and low-density lipoproteins (β=0.53, $p=1.61x10^{-12}$) which show the most prominent signals. More than a third of these 22 metabolites were found to be caused by T2D. This work provides a better understanding of the metabolic changes induced by the occurrence of T2D. While further work is needed to confirm these results and better disentangle the underlying biology, they provide potential directions to investigate T2D consequences and subsequent complications.

PB3515 Unveiling novel actionable targets: Proteomic GWAS insights into 1790 largely unstudied proteins.

Authors:

J. Kuliesius, P. Timmers, P. Navarro, L. Klaric, J. Wilson; Univ. of Edinburgh, Edinburgh, United Kingdom

Genome-wide association study (GWAS) power lies in testing hundreds of thousands of single nucleotide polymorphisms (SNPs) across many genomes for associations with a trait. Recent technological developments in high-throughput proteomic assays allow simultaneous quantitative measurement of thousands of proteins in a single sample. In this study we investigated 6432 plasma proteins using the SomaLogic aptamer-based technology in the Viking Health Study - Shetland, an endogamous population with a relatively low genetic diversity.
A total of 505 significant independent protein quantitative trait loci (pQTL) were found for 455 proteins in human blood plasma (382 cis ($P < 5x10-8$), 123 trans ($P < 6.6x10-12$)). Of these, 31 cis-pQTL were for proteins previously unstudied in large-scale proteomic GWAS. We leveraged this new resource to perform causal inference using bidirectional Mendelian Randomization and Colocalization against complex traits of biomedical importance. Causality was established for 18 little-studied proteins, with hitherto undiscovered links to type-2 diabetes, prostate cancer, depression, and other disease outcomes.

Session Title: Omics Technologies Poster Session III

PB3516 Unveiling the Genomics of Refractory Epilepsy: Human Diploid Genome Assembly using Long-Read Sequencing Technologies (PacBio HiFi).

Authors:

J. Diaz[1,2], L. Guio[3], R. Naranjo[3], J. Gúzman[3], J. Pérez[3], Ó. Zorro[3], D. García[2], P. Siauchó[2], S. Maradei[2,3], J. Duitama[1]; [1]Univ. de los Andes, Bogotá, Colombia, [2]Biotecnología y Genética SAS Biotecgen, Bogotá, Colombia, [3]Fundación Hosp. Pediátrico De La Misericordia HOMI, Bogotá, Colombia

Refractory epilepsy (RE) is a debilitating condition which severely impacts the quality of life, and healthcare costs on patients. Epidemiological evidence reveals that 20% to 40% of individuals diagnosed with epilepsy will ultimately develop resistance to conventional treatments. Understanding the genomic basis of this condition is crucial to enhance the clinical diagnosis of RE. In this study, we employed PacBio HiFi sequencing, to build a phased genome assembly for a patient diagnosed with RE. A de novo assembly of the error-corrected reads using Hifiasm generated a primary genome assembly with median contig length (NG50) of 60 Mbp, and total length of 3.1 Gpb. The total lengths of the individual haplotypes generated by HifiAsm were found to be similar to those obtained for the primary assembly. (3.04 Gpb and 3.0 Gpb, respectively). However, the NG50 values reduced to about 30 Mpb, and 24 Mpb, respectively. All assemblies covered approximately 90% of the GrCh38 reference genome, according to statistics obtained with the Inspector software. Evaluation of the assemblies using BUSCO revealed a high level of completeness, ranging from 93.2% to 95.8% of conserved genes in the primate lineage. Moreover, we were able to recover and annotate ~96% of protein coding genes within each haplotype assembly. Among these genes, approximately 3.6% were identified as duplicated genes. Taking into account that structural variants (SVs) could have causal effects on neurological and psychiatric disorders, we identified and genotyped 33,360 SVs, comparing the reads with the T2T genome assembly. A total of 27,684 of these SVs (83%) were heterozygous and intersect 4,483 protein coding genes. Through the utilization of long-read sequencing techniques, this study seeks to enrich the growing body of knowledge pertaining to this multifaceted condition, with the potential to unveil novel insights into its genetic underpinnings.

Session Title: Omics Technologies Poster Session I

PB3517 Use of long read sequencing and optical genome mapping to solve unsolved rare Mendelian diseases.

Authors:

E. Wohler[1], C. Antonescu[1], M. Schatz[1], R. Martin[1], S. Raskin[2], N. Sobreira[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]GENETIKA, Curitiba, Brazil

Chromosomal disorders are the most frequent cause of intellectual disability in our population, however, deletions and duplications shorter than 300 kb and longer than 50 bp, inversions, and translocations are not easily identified by FISH, arrays or by short-read sequencing methods. Consequently, structural variants represent the largest unexplored reservoir of genetic variation. With average read lengths now over 10 kb and some reads exceeding 100 kb, the long-read technology has dramatically improved sensitivity over short-read sequencing, FISH, or arrays to detect structural variants. The new optical genome mapping (OGM) methodology also has the potential to address this important class of genomic variation and contribute to cases that fail to be solved by short-read sequencing. Here, we performed OGM on 5 probands. Three probands had known germline duplications of uncertain clinical significance identified by SNP array. SNP array could not detect if these duplications were in tandem or inserted elsewhere in the genome. Using OGM we found that all three duplications were in tandem. Next, we will use RNAseq to determine which affected genes are disrupted by these duplications and if they could be the cause of the phenotypes being investigated. We also performed OGM in two families with rare Mendelian diseases unsolved by WES, short-read and long-read WGS. In Family 1, 8 males in 2 generations were affected with an apparently X-linked Treacher-Collins-like phenotype. OGM identified a ~368 kb hemizygous tandem duplication with a partial inversion at Xq26.2 in the proband and his unaffected mother. SNP array is being used to confirm the segregation of this rearrangement in other family members. Family 2 is a non-consanguineous family segregating an apparently X-linked myopathy. The proband and 3 other males over 3 generations have a congenital progressive myopathy. OGM identified a tandem hemizygous duplication of ~807 kb at Xq22.1q22.2 in the proband and his affected maternal uncle. Further analysis of the long-read sequencing also identified this duplication, but the size was ~832 kb and now it included the *PLP1* gene. Duplications of this gene have been associated with Pelizaeus-Merzbacher disease that matches the phenotype of this family. Further SNP array analysis showed that this duplication is also present in the maternal great uncle. In summary, a combination of methodologies is necessary to precisely identify possible causative structural variants, determine their familial segregation, and understand the effect of these rearrangements on the transcription of the genes involved and their relationship with the diseases being investigated.

Session Title: Omics Technologies Poster Session II

PB3518 Using CUT&RUN/Tag with a portable nanopore sequencing device

Authors:

P. Hook, W. Timp; Johns Hopkins Univ., Baltimore, MD

Introduction: Many methods have been developed using DNA sequencing to measure protein-DNA interactions. Two recently developed methods, Cleavage Under Targets and Release Using Nuclease (CUT&RUN) and Cleavage Under Targets and Tagmentation (CUT&Tag), have become extremely popular. These assays are typically used with short-read sequencing platforms, but those platforms have limitations including high cost, limited read lengths, and time needed for sequencing runs. We sought to overcome these limitations by testing sequencing CUT&Tag and CUT&RUN libraries with Oxford Nanopore Technologies (ONT) minION single-molecule sequencer. Sequencing with ONT devices is ideal due to a small physical footprint, lack of read length limitations, the ability to perform real-time analysis, and the ability to measure primary sequence and DNA modifications simultaneously.
Methods: We performed both CUT&RUN and CUT&Tag on the GM12878 cell line including experiments targeting histone marks (H3K27me3 and H3K4me) and a transcription factor (CTCF) as well as negative control experiments (IgG). Libraries were prepared using PCR amplification as if they were to undergo sequencing on an Illumina platform. Additionally, purified DNA fragments from CUT&RUN experiments were directly sequencing without amplification. All libraries were sequenced on a minION device from ONT. Sequencing was compared to publicly available CUT&RUN and DNA methylation data.
Results: Amplified CUT&Tag and CUT&RUN libraries sequenced with ONT showed concordance with short-read datasets. Expected patterns were observed including H3K4me3 enrichment at promoters with negative controls displaying no such enrichment. With unamplified CUT&RUN, we found sequenced fragments displayed nucleosomal laddering including tetra- and pentanucleosomes (>600 base pairs), which cannot be sequenced on short-read platforms. Unamplified H3K4me3 and H3K27me3 samples showed high concordance with amplified profiles as well. DNA modifications (5-methylcytosine and 5-hydroxymethylcytosine), called on unamplified libraries, showed expected patterns such as hypomethylation in active promoters.
Conclusion: By combining CUT&RUN and CUT&Tag with nanopore sequencing, we have enabled affordable benchtop sequencing and measurement of protein-DNA interactions. We have also demonstrated that CUT&RUN can be transformed into a real-time, multimodal, single-molecule assay without the need for additional molecular biology manipulations. These advancements will expand the portability of protein-DNA binding assays, increasing accessibility to these assays in a range of environments.

Session Title: Omics Technologies Poster Session III

PB3519 Using interpretable machine learning to understand variation in the human genome.

Authors:

N. Dwarshuis[1], P. Tonner[1], N. Olson[1], F. Sedlazeck[2], J. Wagner[1], J. Zook[1]; [1]NIST, Gaithersburg, MD, [2]Baylor Coll. Med., Houston, TX

The Genome in a Bottle (GIAB) consortium generates variant benchmarks for a set of human genomes to enable evaluation and comparison of sequencing technologies and variant detection methods. While these technologies have advanced significantly, correctly calling variants in complex or repetitive regions remains a challenge. We generally understand that sequencing biases and short read lengths can lead to incorrectly-called variants; however, we lack a data-driven model that uses GIAB benchmarking metrics to link variant caller performance to quantifiable features of the context surrounding a given variant.

We made such a model using explainable boosting machines (EBMs) which fit data using a linear combination of arbitrary univariate and bivariate functions (a generalized additive model with interaction terms). Despite being flexible, the simplicity of EBMs allows a human to easily understand the functional relationship and relative contribution of each feature. We exploit this transparency by fitting EBMs to variant call errors as a function of genomic context, which enables understanding when and to what extent a given feature will impact performance.

We demonstrated this strategy with two use cases. First, we compared false positive rates for Illumina PCR-free and PCR-plus sequencing technologies. Within homopolymers, INDEL false positives were much more prevalent in PCR-plus, and the error rate for both methods began to increase after 8 bp for both A/T and G/C homopolymers. SNP errors in contrast were not different between the two technologies; however, the error rate increased beyond 10 bp for A/T homopolymers and any length in the case of G/C homopolymers. For our second use case, we compared the likelihood of callsets from Illumina PCR-free or PacBio HiFi data to miss clinically relevant variants. While most false negatives occurred in hard-to-map regions, some errors occurred in homopolymer regions.

Ultimately, this will provide a data-driven mechanism for understanding sources of error within different variant caller methods and sequencing technologies within difficult genomic regions. We also plan to use this model to improve genome stratifications for creating and using GIAB benchmarks. The code is available online.

Session Title: Omics Technologies Poster Session I

PB3520 Using single cell transcriptomics to identify endothelial cell senescence signature genes that correlate with atherosclerotic disease.

Authors:

P. Hejazi[1,2], M. Mehdizadeh[1,3], É. Thorin[1,4], M. Sirois[1,5], S. Nattel[1,2,3,5], G. Lettre[1,2]; [1]Res. Ctr. of Montreal Heart Inst., Montreal, QC, Canada, [2]Dept. of Med., Université de Montréal, Montreal, QC, Canada, [3]Dept. of Pharmacology and Therapeutics, McGill Univ., Montreal, QC, Canada, [4]Dept. of Surgery, Université de Montréal, Montreal, QC, Canada, [5]Dept. of Pharmacology and Physiology, Faculty of Med., Université de Montréal, Montreal, QC, Canada

Background- Endothelial dysfunction is one of the hallmarks of atherosclerosis and results in arterial stiffness and the weakening of vascular endothelium integrity. Cellular senescence is one of the many consequences of endothelial dysfunction in which cells remain metabolically active but do not die or divide. The accessibility of the skin circulation system makes it an attractive tissue to do an in-depth analysis of endothelial function. We hypothesized that the skin vasculature can be used, in combination with single-cell transcriptomics, as an easily accessible biosample to monitor endothelial cell dysfunction and senescence and that this information can be used to monitor atherosclerosis. **Aims and Methodologies** - We aimed to investigate the impact of senescence on endothelial cell gene expression in the skin of mice. We used INK-ATTAC mice for these experiments, in which senescent cells can be selectively eliminated upon treatment with the drug AP20187. The mice received twice-a-week treatment throughout the period from 12 months to 18 months of age. We used three different groups of this mouse model: (1) young and untreated animals (3 months), (2) old and vehicle-treated animals (18 months), and (3) old and AP-20187-treated animals (18 months). Afterward, we collected and snap-froze skin samples from three mice in each group. We used 10X Genomics to construct sequencing libraries with a target of 10,000 cells/animal. We applied standard software such as CellRanger and Seurat for scRNA-seq for data analysis. **Results**- The validation of p16 gene expression using qPCR did not reveal significant differences among the three groups, prompting us to employ single-cell RNA sequencing for a more comprehensive examination. Single-cell RNA-seq analysis of 47,441 cells identified relevant cell clusters, including endothelial cells, but no differentially expressed genes (DEGs) were found across the groups. Pathway analysis on approximately 300 genes with nominally significant expression at p-value< 0.05 did not yield significant results. We speculate that the aged group (18 months old) may not have been old enough to exhibit a striking difference in gene expression related to endothelial cell senescence. Future studies should consider alternative approaches, such as investigating older mice, to better understand the senescence signature in the vascular system and atherosclerotic disease.

Session Title: Omics Technologies Poster Session II

PB3521 Using single-molecule analysis for a deep investigation of Tau proteoform heterogeneity and proteome-wide changes in Alzheimer's Disease.

Authors:

G. Kapp[1], S. Guha[1], S. Tan[1], J. Joly[1], D. Park[1], R. Wang[1], B. Nortman[1], T. Gillies[1], V. Budamagunta[1], J. K. Robinson[1], T. E. Rinker[1], J. Sherman[1], T. Wiederhold[2], D. Kirkpatrick[3], J. Lipka[4], T. Wendorff[4], N. J. Pandya[4], A. Rohou[4], J. Egertson[1], P. Mallick[1]; [1]Nautilus Biotechnology, San Carlos, CA, [2]Cell Signaling Technologies, Danvers, MA, [3]Interline Therapeutics, South San Francisco, CA, [4]Genentech, South San Francisco, CA

Introduction: The Tau protein is known to be extensively post-translationally modified at a large number of sites on the protein. The protein isoforms (proteoforms) that result from splicing and post-translational modification and the molecular heterogeneity of Tau are critical contributors to Alzheimer's disease (AD) progression and pathology. Currently, very little is known about the prevalence or impact of the diversity of Tau proteoforms. Here, we detected and analyzed Tau proteoforms in the context of the broader proteome in model systems using a novel single-molecule proteomic analysis platform.

Methods: We used a single-molecule proteomic analysis platform that leverages affinity reagents combined with novel instrumentation, single-molecule biochemistry, and machine learning bioinformatics to enable deep proteoform and broad proteome analysis. We first evaluated the proteoform distribution of Tau using commercially available antibody reagents. Proteoform heterogeneity was compared (specifically splicing and phosphorylation variants) in both healthy and diseased samples. We additionally applied Protein Identification by Short-epitope Mapping (PrISM), for broadscale proteomics analysis. PrISM leverages proprietary multi-affinity probes designed to recognize short epitopes and a machine learning algorithm that decodes binding of hundreds of multi-affinity probes into protein quantifications.

Results: The approach was evaluated by first measuring defined mixtures of recombinant Tau proteins. Next, we examined Tau enriched from induced pluripotent stem cell (iPSC)-derived neurons and tau-expressing cell lines. The platform revealed the molecular heterogeneity of Tau proteoforms missed by bulk measurements and peptide-centric proteomics approaches. The proteoform data was then supplemented with broader proteome analysis in order to identify proteome-wide changes - differences in proteins and pathways due to or in combination with specific Tau proteoforms and disease.

Conclusion: Understanding the role of proteoforms in biology uncovers a level of additional biological complexity that complements the rich genomic and proteomic data from existing analytical methods. Single-molecule tools that can analyze proteoforms in depth and the proteome broadly and link molecular signatures to disease states are essential. These tools will enable improved biomarkers, improved understanding of disease, and improved therapies for diseases like Alzheimer's disease.

Session Title: Omics Technologies Poster Session III

PB3522 Utilizing long-read sequencing to decipher the genomic architecture of mitochondrial DNA in neurodegenerative diseases

Authors:

N. Tran[1], A. I. Soto-Beasley[2], Y. Ren[1], S. Basu[2], W. Springer[2], O. A. Ross[2]; [1]Mayo Clinic Graduate Sch. of BioMed. Sci., Jacksonville, FL, [2]Mayo Clinic, Jacksonville, FL

Mitochondrial DNA (mtDNA) integrity is crucial in the overall health and physiological function of the cells. Previous studies have shown that mtDNA variations are implicated in several neurodegenerative diseases including Early-Onset Parkinson's Disease (EOPD). mtDNA is a circular 16.5 kb molecule and each mitochondrion has multiple copies. Given that there are several mitochondria per cell, there exist hundreds to tens of thousands copies of mtDNA. mtDNA variations are predominantly captured using Short-read whole-genome sequencing (SR-WGS) which allows the accurate and high-yield capture of single nucleotide variants (SNV); however, more complex structural variants (SV) such as repeats, inversions, large deletions, etc. are unable to be detected. The recent development of long-read sequencing (LRS) has allowed us to capture more complex SV and copy number variation (CNV), thus addressing the limitations of conventional SR-WGS. LRS will allow us to better characterize mtDNA variation influencing disease onset and progression. Furthermore, given PacBio LRS generates Circular Consensus Sequence with optimal read length of 15-17kb, it gives us an unprecedented opportunity to examine each copy of the 16.5 kb mtDNA genome in one read. This will allow for a true quantification of heteroplasmy levels and characterize individual mtDNA genomes for variation. In our current study, we have generated SR-WGS and PacBio LR-WGS for a subset of EOPD patients (age of onset <39). We utilized existing bioinformatics tools (GoldenHelix, PacBio, etc) to determine SNV and CNV for each dataset, and compared our findings between the two methods. Our study provides a comprehensive method that allows for the integration of sequencing approaches, capture of mtDNA CNV/SV with high resolution and in-depth quantification of the mitochondrial genome species to resolve the role of mtDNA variation in the EOPD phenotypic presentation including disease onset and progression.

Session Title: Omics Technologies Poster Session I

PB3523 VizCNV: An integrated platform for CNV detection and analysis of genome sequencing data

Authors:

H. Du[1], M. Lun[2], M. Mehaffey[2], C. M. Grochowski[1], M. Gandhi[3], S. N. Jhangiani[4], D. M. Muzny[4], D. Pehlivan[1], F. Sedlazeck[4], Z. Coban-Akdemir[5], J. Posey[1], A. Lindstrand[6], I. K. Chinn[1], R. Gibbs[4], J. Lupski[1], C. M. B. Carvalho[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Pacific Northwest Res. Inst., Seattle, WA, [3]UT MD Anderson Cancer Ctr., Houston, TX, [4]Baylor Coll. Med., Houston, TX, [5]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [6]Karolinska Inst.t, Stockholm, Sweden

Copy number variation (CNV) is a class of structural variation that results in deviations from the diploid state and contributes to the pathogenicity of genomic disorders if dosage-sensitive genes are involved. Karyotyping was initially used to detect large CNVs (>5 Mb); however, in the past ten years, comparative genomic hybridization (aCGH) or SNP arrays, which have a resolution of 5-10 kb, have emerged. With the advancement of genome sequencing (GS) in the clinical diagnostic setting, CNV analysis using GS data has faced several challenges, including the overwhelming number of false-positive calls due to systemic biases from non-uniform read coverage and collapsed calls resulting from the abundance of paralogous segments in the human genome. To address these challenges, we developed VizCNV to facilitate CNV analysis using GS data. VizCNV normalizes read depth using the chromosomal median read depth information and leverages the shifting level model for segmentation. Using R Shiny, VizCNV generates aCGH and SNP array-like interactive graphs to facilitate the detection, visualization, and interpretation of CNVs at a resolution of 1-10 kb. Moreover, this platform incorporates tools to distinguish inherited and de novo CNVs, both of which are validated by B-allele frequency plots. VizCNV provides a genomewide view enabling pattern recognition of chromosomal abnormalities [e.g., aneuploidy, deletions, duplications] and mutational events such as chromothripsis/chromoanasynthesis, multiple de novo CNVs, and complex genomic rearrangements. To test the effectiveness of VizCNV, we analyzed 19 aCGH-positive trios using Illumina short-read GS (30x) data. This dataset includes 16 probands with MECP2 duplication syndrome and three probands with de novo marker chromosomes. VizCNV accurately identified nine dnCNVs and 10 inherited variations, including a triplication and a mosaic CNV. In contrast, combined output from three structural variant callers (Manta, Delly, and Lumpy) identified only 9 out of 19 aCGH-observed events. To further test the tool, VizCNV was utilized to screen for potentially pathogenic CNVs in 39 patients with a primary diagnosis of primary immunodeficiency disease. On average, 7 potential dnCNVs and 90 inherited CNVs >10 kb per trio passed the filter. In one family, a compound heterozygous combination of a paternal 12.8 kb exonic deletion and a maternal missense variant affecting DOCK8 explained the proband's phenotype. In conclusion, VizCNV provides a reliable method for CNV analysis at a higher resolution than traditional aCGH analysis. VizCNV is freely available online.

Session Title: Omics Technologies Poster Session II

PB3524 VPAP: A pipeline for proteomic analysis of genetic variants

Authors:

V. Magalhaes Borges[1], N. Teruel[2], A. Nato[1]; [1]Dept. of BioMed. Sci., Joan C. Edwards Sch. of Med., Marshall Univ., Huntington, WV, [2]Dept. of Pharmacology and Physiology, Faculty of Med., Université de Montréal, Montreal, QC H3T 1J4, Canada, Montreal, QC, Canada

Understanding the three-dimensional structure of proteins plays a pivotal role in unraveling the functional implications of genetic variants. Recent advancements in structural biology, led by AlphaFold, revolutionized our ability to explore the universe of protein structures and allowed us to integrate and complementarily connect genomics and proteomics. This work introduces a variant proteomic analysis pipeline (VPAP) that effectively evaluates the proteomic consequences of disease-associated genetic variants. The development of VPAP is driven by two conceptual motivations. First, the evaluation of the allele-specific impact of a nonsynonymous variant on the protein structure allows us to predict its potential effects on protein stability, folding, and interaction with other molecules. Second, the degree of interactions across residues flanking an amino acid mutation (e.g., protein-protein interaction, protein-ligand interaction) is useful in interpreting genomic data to identify disease-causing variants. Implemented in R, VPAP simplifies access to publicly available datasets (e.g., GWAS Catalog, Protein Data Bank) and incorporates a systematic approach to select the top genetic ancestry-specific variants associated with a specific complex disease. By integrating scriptable methods that are suited to high-throughput evaluations, VPAP identifies and scores the interactions between the wild-type protein (containing the reference allele) or the mutated protein (containing the alternate allele) with a ligand or another protein, employing (1) MODELLER, a software that generates the modified protein structures based on homology modeling and (2) Surfaces, a tool to quantify per-residue contributions to molecular interactions within and between proteins and ligands. Based on the interaction values calculated by Surfaces, VPAP estimates allele-specific impact scores, which may be used in downstream analyses. VPAP compares these impact scores with values from several variant annotations and prioritizers to evaluate and validate its robustness. VPAP therefore allows researchers to measure the magnitude of effect caused by a specific risk allele for a particular disease and visualize the molecular interactions occurring within these residues. This multi-omic approach leverages on the strengths of each field to elucidate the underlying mechanisms involved in the etiology of a disease and provide valuable information to explore therapeutical targets and ultimately guide drug design.

Session Title: Omics Technologies Poster Session III

PB3525 Whole-genome sequencing and metabolic profiling in Finns underscores the relevance of rare variants in blood metabolome regulation and disease risk.

Authors:

X. Yin[1], B. Ryan[2], J. Okamoto[2], J. Chiou[3], D. Bose[2], J. LI[2], A. Jackson[2], H. Stringham[2], S. Ripatti[4], A. Palotie[4], J. Morrison[2], X. Wen[5], C. Burant[2], E. Fauman[3], M. Laakso[6], M. Boehnke[2]; [1]Nanjing Med. Univ., Nanjing, China, [2]Univ. of Michigan, Ann Arbor, MI, [3]Pfizer, Cambridge, MA, [4]Inst. for Molecular Med. Finland FIMM, Helsinki, Finland, [5]Univ. of Michigan, Ann Arbor, MI, [6]Univ. of Eastern Finland and Kuopio Univ. Hosp., Kuopio, Finland

Metabolite levels reflect both environmental and genetic influences. GWAS have identified thousands of common (minor allele frequency [MAF]≥1%) genetic variants associated with metabolite levels. However, the contribution of rare genetic variation to metabolite levels is less studied. We profiled plasma levels of 1,540 metabolites in 10,188 Finnish men from the METSIM study using Metabolon HD4 untargeted mass spectrometry platform and sequenced genomes for 9,501 of the 10,188 individuals (average depth=25x). We quantified the contribution of common and rare (MAF<1%) variants to the single nucleotide variation (SNV)-based heritability (h2SNV) of blood metabolites. We found that common and rare variants accounted for on average 16.6% (median=14.1%, range=0.09-65.9%) and 9.6% (median=8.3%, range=0.17-77.5%) of the h2SNV for blood metabolites, respectively, with most of the rare variant heritability attributed to the variants with 0.1%<MAF<1%. We performed GWAS for each of the metabolites, identifying 3,890 independent association signals (metabQTLs) for 1,011 metabolites at P<5.0x10-9. To prioritize putative causal variants for each metabQTL, we conducted statistical fine-mapping analysis and identified signal-level posterior probability≥0.95 for 3,666 of the 3,890 metabQTLs. For 370 (9.5%) metabQTLs for 282 (27.9%) unique metabolites, we identified putative causal variants at 263 rare variants with variant-level posterior probability (VPIP)≥0.3. Notably, of the 263 variants with VPIP≥0.3, 193 showed MAF>10-fold greater in METSIM than in non-Finnish Europeans (NFE) for 355 metabQTLs of 291 metabolites. We performed colocalization analysis between the metabQTLs from the METSIM and GWAS for the 1,209 disease traits from the FinnGen release 9. We identified 6,561 metabolite-trait pairs having at least one locus with locus-level colocalization posterior probability (LCP) > 0.5, suggesting a pervasive role for blood metabolites in disease molecular mechanisms. For example, we suggested that Finns-enriched missense variant rs77273740 of the *DBH* gene affects the risk of type 2 diabetes through regulating plasma 3-methoxytyramine sulfate levels. We are integrating metabolites and disease GWAS with several other molecular traits including gene and protein expression to help understand disease molecular mechanisms.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4001 3D-4-BigData: 3D Printed Electronics enabled 4D Visualization of Big Data Networks in Human Genetics

Authors:

J. Kim[1], G. Manogharan[2], Y. Veturi[3,4]; [1]Schreyers Honors Coll., Pennsylvania State Univ., University Park, PA, [2]Dept. of Mechanical Engineering, Pennsylvania State Univ., University Park, PA, [3]Dept. of Biobehavioral Hlth., Pennsylvania State Univ., University Park, PA, [4]Dept. of Statistics, Pennsylvania State Univ., University Park, PA

Background: Current statistical/computational advances in network analysis lack the ability to understand the interconnectedness between network nodes in a tactile manner. Effective visualization of network graphs can not only identify underlying structure in the data but are also critical for dimension reduction and training. **Objectives:** The overall research goal is to design-develop-demonstrate-evaluate a novel data visualization method that brings together data analytics, augmented reality (AR), and 3D Printed Electronics (3DPE - embedded wireless electronics at nodes and LED strips at edges). This novel approach is demonstrated for genetic associations between neuroimaging phenotypes and diseases in electronic health records (EHR) across the phenome. Our approach can yield novel image-derived phenotype (IDP) biomarkers for complex diseases as well as provide pleiotropic gene targets for drug repurposing. **Methods:** We have established: (1) an open-source Python toolkit to drive the 3DPE-node and data network using open-source low-cost controllers (e.g., Arduino, Teensy 4.1), and (2) visualization of node-edges in mixed reality through AR lens modalities with physical model (e.g., Unity, Meta Quest Pro) to visualize 3D network models. We apply this to summary statistics from a transcriptome-wide association study on 2,124 IDPs (structural and diffusion MRI measuring cortical volume, cortical thickness, brain volumes, cortical grey-white contrast etc.) from UK Biobank (UKB) on 38K samples of European ancestry across 13 brain tissues from GTEx v8 followed by gene-based colocalization. We mapped the significant genes to fine-mapped eQTL from PredictDB (using multivariate adaptive shrinkage models). Finally, we conducted IDP-guided phenome-wide association study on 12,494 fine-mapped eQTL across 664 ICD-10 codes (n=452,595 samples). **Results:** We found that 3D-4-Big Data can seamlessly create mixed-reality 3D network models for GWAS and TWAS studies with preprocessed high dimensional data and is effective in mapping network models with multiple modalities (e.g., labeling of genes, drug pathway using AR, and dynamic networking - edge direction, LED intensity to identify strength of relationship). **Conclusions:** We have developed a novel immersive 3DPE enabled 4D visualization of big data networks to better understand the complexity of the high-density data networks in human genetics. This study demonstrates the utility of this approach as a powerful tool for interactively visualizing pre-processed high dimensional multilayered data (e.g., genomics, transcriptomics, EHR) for statistics education.

PB4002 A BAYESIAN NETWORK-BASED APPROACH FOR MULTI-OMICS INTEGRATION TO REVEAL UNDERLYING MECHANISMS OF HEALTHY AGING

Authors:

A. Leshchyk[1], S. Monti[1], P. Sebastiani[2]; [1]Boston Univ., Boston, MA, [2]Tufts Med. Ctr., Boston, MA

Previous studies of individuals who live to very old age have found that very old centenarians experience a significant delay in the onset of age-related diseases and disabilities such as Alzheimer's, dementia, and cardiovascular diseases compared to the general population. Genetic studies of long-lived individuals showed that carriers of the APOE e2 allele had increased odds of reaching longevity compared to the non-e2 allele carriers. Moreover, the APOE e2 allele is characterized by distinct serum proteomics and metabolomics profiles that could be useful to understand the mechanism of propagation of the genetic effect of APOE to the molecular level and eventually to phenotypes. We are developing a novel Bayesian network-based approach that integrates genetics, multi-omics, and multi-phenotypes to identify shared molecular profiles among the subjects with familial longevity that lead to compression of morbidity, disability, and mortality. This Bayesian network-based approach can be used to also make various predictions and probabilistic reasoning. For example, the preliminary analysis shows that the APOE e2 allele carriers have lower sphingolipids abundance than APOE e4 carriers and better cognitive performance (for SM:18 $-1.5<FC<1.5$ in APOE e2 carriers $P = 0.32$ for a high cognitive score in contrast to APOE e4 carriers with $P= 0.08$). Sphingolipids are fatty amino alcohols that regulate cell survival, inflammation, senescence, and apoptosis, which might impair the cognitive function of elderly adults and contribute to their disability and morbidity, thus affecting their aging.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4003 A cloud based pipeline for rare variant analysis using public summary counts for prioritizing disease predisposition genes in rare disease studies.

Authors:

S. Tithi, W. Chen, G. Wu; St. Jude Children's Res. Hosp., Memphis, TN

Sequencing data from rare disease cohorts often lack healthy matched individuals to serve as controls for association analysis to prioritize disease risk genes. In such cases, researchers often use public datasets as controls, but these public datasets are often assembled from different sources, using different pipelines, making it difficult to combine the control data with the disease cohort directly for genetic association analysis. Previously, we developed CoCoRV (consistent summary counts based rare variant burden test), which is a computational tool to help prioritize disease predisposition genes and genetic variants in rare diseases using public summary counts. CoCoRV implements consistent variant quality control and filtering, ethnicity-stratified rare variant association test, accurate inflation factor estimation and powerful FDR control, which minimize the chance of false positives due to batch effects between cases and controls. However, the full pipeline that applies CoCoRV involves multiple steps such as variant QC, annotation, and ethnicity inference, which can be either computationally intensive or demanding a large physical memory, such as preprocessing of the gnomAD control data. Here, we develop a cloud version of CoCoRV based on the popular workflow language nextflow and the docker container. Our cloud based pipeline includes already pre-processed and annotated gnomAD count data, and it is simple to run the full analyses once required parameters are specified. The nextflow based pipeline allows users to resume the execution from the last successfully executed step, so users do not need to re-run every step each time. The docker containerization of each step relieves the users from installing all dependencies for their specific platform, making it much easier to use the tool. The pipeline is deployed in a cloud platform called CAVATICA through a partnership with Seven Bridges. As CAVATICA hosts a large amount of sequencing data, including pediatric cancer data from Kids First Portal, researchers around the world can analyze these datasets using our tool to make potential discoveries on novel disease predisposition genes. The nextflow based pipeline is also portable and can be downloaded to run in a local environment, e.g., a high-performance computing cluster.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4004 A complete end-to-end workflow for implementing clinical polygenic risk scores

Authors:

G. Busby, S. Kulm, A. Bolli, J. Kintzle, P. Di Domenico, G. Bottà; Allelica, New York, NY

Polygenic Risk Scores (PRS) aggregate the effect of many variants into a single value that represents an individual's genetic liability of disease from common genome-wide variation. Over the last 5 years, interest in the clinical use of PRSs for a range of common diseases has grown, but challenges to widespread adoption and implementation remain. These include but are not limited to the attenuation of performance of the same PRS in different populations, the differential performance of different PRSs for the same disease in the same population, misunderstandings on what the output of a PRS actually represents and how it should be used, and uncertainty around how to standardize and regulate PRS tests.

Here we describe the development of a transparent and fully automated, genetic ancestry-aware bioinformatics pipeline that takes raw genotype data and turns it into a clinical assessment of an individual's disease risk via a PRS. Our pipeline is agnostic to the genetic technology used to generate the genetic data, and we discuss the need for essential quality control, genetic ancestry adjustment, clear definitions of reference risk distributions that are required to deploy PRSs, and how to convert and communicate a PRS into a measurement of disease risk. We also provide clarity on how the choice of PRS and reference distribution should be a key consideration when applying a PRS to a new population and how to match existing datasets to the intended use population. We provide metrics that can be used to objectively quantify potential discrepancies between different PRSs in order to transparently assess the application of a PRS to specific intended-use populations.

We illustrate this approach using cardiovascular disease, type 2 diabetes, breast and prostate cancer as examples. By documenting the end-to-end process of PRS generation, our study shows the key considerations necessary to generate clinical level risk predictions from genomic data and provides a framework for the reproducibility of PRSs in the clinic.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4005 A continuous local ancestry measure and efficient local-ancestry-aware association tests

Authors:

H. Sun[1], B. Yu[1], Q. Qi[2], A. Morrison[3], E. Boerwinkle[1], R. Kaplan[2], H. Chen[4]; [1]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Albert Einstein Coll. of Med., Bronx, NY, [3]Univ. of Texas Hlth.Sci. Cntr Houston, Houston, TX, [4]The Univ of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Population stratification is a well-known challenge in genetic association tests, due to the genetic heterogeneity between averaged ancestral proportions (global ancestry) and ancestry at specific regions (local ancestry), particularly for admixed populations. However, conventional approaches, like top ancestral principal components (PCs), may fail to correct the underlying population structure. Moreover, relying on reference panels, local ancestry inference is prone to misclassification with improper reference populations involved. To address the issues, we proposed Local Ancestry Coordinates (LACs), a continuous measurement aggregating population-specific local ancestry components into linear combinations. LACs can preserve local ancestry characteristics in fine-scale resolution, and is more robust against misclassification. We projected local ancestry probabilities onto a reference-based global PC-spanned space, to represent the demographic and geographical patterns of local ancestry across the genome. Specifically, we first established a standard reference panel comprising 3 African (ASW, LWK, YRI), 3 European (CEU, TSI, GBR), 3 American (PEL, CLM, MXL) populations from the 1000 Genomes project, which provided a constant projection canvas regarding their global PCs. We then simulated 5,000 independent 9-ancestry-admixed study samples and called their reference-dependent local ancestry probabilities using RFMix v1.5.4 with reference panels from 6, 9, or 12 ancestral populations. Study samples were then projected onto the same reference-based global PC-spanned space to compute their global PCs and LACs, using their global ancestry proportions and local ancestry probabilities, respectively. To evaluate LACs' efficacy and robustness, we computed the correlations between LACs inferred using various reference panels and the simulated true values. The mean correlations for the top 2 PCs across the genome for 6, 9, and 12-reference-population inferred LACs are 0.9489 and 0.9123, 0.9891 and 0.9816, 0.9879 and 0.9808, respectively. In our simulations, the LAC-adjusted association test effectively controlled type I error rates confounded by local ancestry, outperforming global PCs-adjusted tests. We also applied our local-ancestry-aware association test to real data from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). Our findings demonstrate LACs as a reliable proxy for characterizing local ancestry and mitigating the impact of local ancestry misclassification, and incorporating LACs into association tests shows promise in effectively accounting for population stratification effects.

PB4006 A framework to evaluate and validate polygenic risk models at scale.

Authors:

S. Moreno Grau[1,2], M. Vernekar[3], A. Lopez-Pineda[1,4], M. A. Nava-Aguilar[1,4], C. Quinto-Cortés[1], B. Moatamed[1], M. Lee[1], Z. Yu[3], K. Numakura[3], Y. Matsuda[3], J. D. Wall[1], A. Ioannidis[1,2], N. Katsanis[1], T. Takano[3], C. Bustamante[1,2]; [1]Galatea Bio, Hialeah, FL, [2]Dept. of BioMed. Data Sci., Stanford Univ. Sch. of Med., Stanford, CA, [3]Genomelink Inc, Berkeley, CA, [4]Amphora Hlth., Morelia, Mexico

Polygenic risk scores (PRS) are a promising approach to predict an individual's genetic risk to diseases. Thousands of PRS have been developed, but each new PRS is highly influenced by the characteristics of the discovery dataset. There is limited validation outside the training sets. A lack of standardized approaches to compare and select the best available PRS exists. To address this problem, we present a framework for harmonizing, testing, selecting and validating the best performing pre-existing PRS for 13 phenotypes of medical interest.

A harmonized set of unrelated European individuals from the UK biobank was used to test PRS models. Then, we validated the best performing PRS in an independent cohort of Europeans from the Biobank of the Americas-Genomelink (BBofA-GL) study (N=8,394), and tested them in non-European populations (N UKBB =18,846). Case counts ranged from 216 for T1D to 33,441 for high HDL levels in the UKBB, and from 151 for T1D to 2,283 for hypertension in the BBofA-GL. Phenotypes were extracted from UKBB phecodes (ICD10) and by self-reported questionnaires in the BBofA-GL. Genetic information was processed following standard methods. To select the best performing PRS model we estimated the variance explained by the PRS, which was calculated as the difference between AUC for the model with PRS and covariates (age, sex, 4PCs) versus the covariates-only model. Odds ratio for each outcome was estimated per percentile.

We evaluate a total of 401 PRSs downloaded from PGSCatalog for cardiac conditions (atrial fibrillation [AF], CAD, hypertension), metabolic (T1D, T2D, hypothyroidism), gastric (celiac disease [CD], ulcerative colitis [UC], hemorrhoids), inflammatory (gout), and lab values (LDL, HDL and TG measures). Our framework lets us replicate published PRS effectively. Selected PRS explained from 1.4% of disease variance for CAD to 25% for CD. The 90th percentile threshold showed 10 times more cases than the observed in the mid-percentile (40-60%) for T1D. Large case enrichment was also observed for CE (x3), CAD and TG levels (x2), conversely to other outcomes, where case enrichment was moderate (gout, T2D, hypertension, hypothyroidism and LDL) or limited (AF, UC, hemorrhoids, HDL, and VitaminD). We observed variation in the PRS distribution by ancestry, and a reduction in PRS accuracy from European sets to South, East asians and Africans.

Here we have developed a scalable framework to test, select and implement the best performing PRS, maximizing the comprehension of existing scores. We have validated PRSs in an independent cohort and highlighted conditions, where implementing risk-prioritization strategies could have a practical utility

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4007 † A framework to evaluate the utility of embeddings in genetic discovery

Authors:

S. Mukherjee[1], Z. McCaw[1], J. Pei[1], H. Somineni[1], T. Soare[1], B. Michael[2], C. O'Dushlaine[1], C. Probert[1], T. Karaletsos[1]; [1]Insitro, South San Francisco, CA, [2]Stanford Univ., Palo Alto, CA

Embeddings are a compressed representation of high content data modalities obtained through deep learning models. Embeddings have been thought to capture detailed information about disease states and have been qualitatively shown to be useful in genetic discovery. Despite their promise, embeddings are also known to have several downsides: i) they are often confounded by covariates, and ii) their disease relevance is hard to ascertain. In this work we aim to develop a framework to systematically evaluate the utility of embeddings in genetic discovery.
Our genetic validation workflow focuses on comparing phenotypes along two axes: i) heritability of the phenotypes, and ii) ability to identify 'disease relevant' variants. We use the number of genome-wide significant signals and mean/median chi-square statistic as a proxy for heritability of multivariate phenotypes. To evaluate disease relevance, we compute polygenic risk scores for each principal component (PC) of the embedding (or multivariate comparators) and evaluate their association with a held-out set of patients with high-confidence disease phenotypes. We use NAFLD as a case study and compare several embedding/non-embedding derived comparators using our framework: i) embeddings from a deep learning model trained to predict liver fat percentage from MRIs in UK Biobank, ii) 203 NAFLD-related traits comprising of circulating metabolites, blood biochemistry markers and abdominal composition variables, and iii) imputed NAFLD case/control status from biomarkers using machine learning. To keep our comparisons consistent, we perform the GWAS for each trait on the same set of samples (discovery cohort) and evaluate in a held-out set of samples with NAFLD case/control labels (test cohort).
We find that while embeddings had more genome-wide significant associations (442) than predicted NAFLD case/control status (6), a multi-trait analysis across all of the NAFLD-related traits had the greatest number of associations (4968). However, embedding-derived PRSs (p-value = 8.9e-18) show a much more significant association with gold-standard NAFLD case/control status than PRSs from non-embedding baselines (p-value for PCs of traits = 0.75, p-value for predicted case/control status = 0.15).
We propose a framework to evaluate the utility of embeddings in genetic discovery along two important axes. Using a case study and reasonable non-embedding baselines, we evaluate the utility of embeddings for genetic discovery in NAFLD. Our finding shows that embeddings derived from a model trained to predict liver fat percentage yields highly disease relevant associations when compared against our chosen baselines.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4008 A framework to improve the interpretation and prediction of variant effect sizes using non-linear functional models

Authors:

S. Cheng, S. Gazal; USC, Los Angeles, CA

Modeling the relationship between the effect sizes of common variants and their functional annotations is critical to accurately characterize the functional genetic architecture of human diseases and complex traits. Existing functional models rely on linear relationships between variants squared effect sizes (or per-variant heritability) and their functional annotations; this linear relationship is methodologically constrained by the fact that we are observing marginal effect sizes from genome-wide association studies (GWAS), and that true effect sizes are unobserved. However, linear models constrained our interpretation of functional architectures, and it is thus unclear if a non-linear structure would improve model prediction. Here, we aim to improve the interpretation and prediction of existing functional models by using machine learning approaches.Here, we developed a framework that leverage fine-mapping methods to 1) estimate the true allele effect sizes of each common variant, and 2) model per-variant heritability directly on these estimated effects (rather than marginal effects) using 96 functional annotations from the baseline-LD model (Gazal et al. 2017 Nat Genet). Using simulations, we observed that leveraging the fine-mapping method SuSiE with functional priors (estimated using an additive model of annotations) provides nearly unbiased functional enrichment estimates, even if the causal model includes interactions between annotations. We investigated decision trees and deep neural networks (DNN) on the fine-mapping results of 15 independent UK Biobank traits. Optimal hyper-parameters were estimated by looking at the mean squared error (MSE) using a leave-one-chromosome-out (LOCO) approach (to avoid overfitting). For decision trees, we observed that the functional genetic architecture of complex traits were dominated by annotations related to evolution (8/18 nodes) and continuous annotations (10/18 nodes) where we were able to optimize cutoff. The tree also highlighted constrained enhancers and recent constrained mutations as the most important leafs. By analyzing new annotations based on the 19 leaves of this tree with S-LDSC on 63 independent GWAS, we observed that 13 annotations had significant conditional effect over the existing annotations, demonstrating an improvement of model fit. Finally, we observed that DNN produced lower MSE than the linear model (used by S-LDSC), demonstrating the benefits of DNN annotations for future genetic analyses.In conclusion, we have developed and validated a framework using non-linear models that improve representation and prediction of existing heritability models.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4009 † A Functionally Informed Rare Variant Analysis Approach for Unbalanced Case-Control Ratios in Biobank-Scale Sequencing Data

Authors:

Z. Li[1], X. Lin[2], X. Li[3]; [1]Northeast Normal Univ., Changchun, China, [2]Harvard T.H. Chan Sch Pub Hlth, Boston, MA, [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Introduction
Large-scale sequencing studies have enabled the investigation of rare variants (RVs) associated with complex human diseases and traits. Functionally informed RV analysis represents a powerful approach for studying RV associations through the integrative analysis of sequencing data and functional annotations that predict the biological functionality of genetic variants. The existing STAAR method and its corresponding whole-genome sequencing analysis workflow, STAARpipeline, provide robust, scalable, and powerful functionally informed association analysis for quantitative and binary traits in biobank-scale sequencing data. However, these approaches have limited capacity to account for extremely unbalanced case-control ratios, such as <1:100, for binary traits.
Methods
We propose STAAR-B-SPA, an extension of the STAAR framework using the Burden test, to improve type I error control for significantly unbalanced case-control ratios. We integrated STAAR-B-SPA into the STAARpipeline, enabling scalable, flexible, and streamlined functionally informed genetic association analysis for biobank-scale sequencing data, including gene-centric analysis and genetic-region analysis for coding and noncoding variants. STAARpipeline implemented with STAAR-B-SPA is available in both offline and cloud computing environments, such as high-performance computing clusters, the UK Biobank research analysis platform and the NHLBI BioData Catalyst ecosystem. Through extensive simulation studies, we demonstrated that STAAR-B-SPA can efficiently analyze large datasets while maintaining well-controlled type I error rates.
Results
We applied STAAR-B-SPA to detect rare variants associated with five cancer traits (breast, colorectal, lung, prostate and ovarian) using the UK Biobank 200K whole-exome sequencing data. The control to case ration varies from 20 to 200. We detected 15 genome-wide significant associations while well protecting the type I error rate in the analysis of these five cancer traits. Notably, the significant findings include not only known genetic associations, such as protein-truncating variants in *BRCA2* with breast, prostate and ovarian cancer, but also potential new associations, such as synonymous variants in *IQCJ*, *PRSS16*, and *CACHD1* with lung cancer.
Summary
In summary, STAAR-B-SPA provides a comprehensive tool for studying coding and noncoding rare-variant associations in biobank-scale sequencing data with extremely unbalanced case-control ratios.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4010 A genetic risk profile classifies disease severity in children with sickle cell anemia from birth to six years of age.

Hosp., Memphis, TN, [5]Dept. of Diagnostic Imaging, St. Jude Children's Res. Hosp., Memphis, TN, [6]Div. of Epidemiology, Biostatistics, and Environmental Hlth., Sch. of Publ. Hlth., Univ. of Memphis, Memphis, TN, [7]Dept. of Oncology, St. Jude Children's Res. Hosp., Memphis, TN, [8]Div. of Hematology/Oncology, Dept. of Internal Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [9]Dept. of Pediatrics, Vanderbilt-Meharry Ctr. for Excellence in Sickle Cell Disease, Vanderbilt Univ. Med. Ctr., Nashville, TN

Sickle cell anemia (SCA) is an autosomal recessive disease caused by one major missense mutation in the *HBB* gene, which encodes the β-globin subunit of adult hemoglobin (HbA, $\alpha 2\beta 2$). Abnormal sickle hemoglobin (HbS, $\alpha 2\beta^S 2$) polymerizes at low oxygen tension, causing red blood cells (RBCs) to become sickle shaped and triggering a complex pathophysiology with vascular occlusion, inflammation, and hemolysis. Symptoms begin in early childhood with acute pain episodes and progressive multi-organ damage leading to early mortality. The onset and progression of organ damage in SCD vary according to genetic and environmental risk factors. Variants impacting HbS polymerization in RBCs, such as α-thalassemia and predictors of post-natal fetal hemoglobin (HbF) levels, are associated with many SCA-related outcomes. Hence, we developed a genetic risk profile (GRP) including eleven single nucleotide polymorphisms (SNPs) from *BCL11A*, *HBS1L-MYB*, and the extended β-like globin locus, which account for ~20-50% of HbF variance in SCD patients, and the most common α-thalassemia allele ($\alpha^{-3.7}$). Using 327 children with SCA (HbSS/HbSβ^0; 0-6 years old; 1,952 person-years of observation) enrolled in the Sickle Cell Clinical Research and Intervention Program (SCCRIP), we evaluated the effects of $\alpha^{-3.7}$ and an 11-SNP polygenic score for HbF (PGS^{HbF} = # HbF-increasing alleles) on six hematological traits (HbF, hemoglobin [Hb], mean corpuscular volume [MCV], reticulocyte [ARC], white blood cell [WBC], and neutrophil [ANC] counts) and four clinical events (elevated transcranial doppler velocity [TCD] or stroke, acute chest syndrome [ACS], single RBC transfusion [TXN], and acute splenic sequestration [ASS]). For all outcomes where $\alpha^{-3.7}$ or PGS^{HbF} were associated individually, the effects were independent, so we constructed a GRP with 3 risk categories: high ($\alpha\alpha/\alpha\alpha$ & $PGS^{HbF} \leq 7$; N=110/327), low ($\alpha\alpha^{-3.7}/\alpha\alpha$ & $PGS^{HbF} > 7$ or $\alpha\alpha^{-3.7}/\alpha\alpha^{-3.7}$; N=53/327), and intermediate (otherwise; N=164/327).

Compared to the intermediate and high groups, at a false discovery rate adjusted P (P_{FDR})<0.05, those with low-risk profiles had higher HbF and Hb and lower MCV, ARC, WBC, and ANC, all of which predict reduced disease severity. The high-risk group had increased rates of elevated TCD or stroke (β=1.50; $P_{FDR}=2x10^{-5}$), ACS (β=0.31; P_{FDR}=0.04), TXN (β=0.74; $P_{FDR}=3x10^{-4}$), and ASS (β=0.54; P_{FDR}=0.04). Results for HbF, Hb, MCV, WBC, and ACS were validated in the Silent Infarct Transfusion (SIT) cohort. While the GRP may not always be as strongly associated as the $\alpha^{-3.7}$ or PGS^{HbF} alone, it was associated with all outcomes, so it can be used to stratify infants by risk of severe disease agnostic of specific outcome.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4011 A joint model for transcriptome-wide association study analysis to dissect gene and pathway level contribution to complex polygenic traits

Authors:

N. Wang, T. Ma; Univ. of maryland, COLLEGE PARK, MD

Genome-wide association studies (GWAS) have identified tens of thousands of single nucleotide polymorphisms (SNPs) associated with human disease or complex traits in the past 10 years, however, their biological mechanisms remain largely unknown. Transcriptome-wide association studies (TWAS) were proposed as a tool for detecting associations at gene levels and potentially investigating the gene regulatory mechanisms. Existing TWAS methods are usually implemented in two stages, which first used the reference dataset (e.g. genotype and gene expression data from GTEx) and genotype data of the study to impute the gene expression data and then correlated the imputed expression data with the phenotype in the study. However, these methods failed to account for the uncertainty inherent to the imputing step and may lead to a potential loss in statistical power. In addition, all existing TWAS methods are strictly univariate without considering the gene-gene correlation and groups of genes (e.g. biological pathways) that might be jointly predictive of complex polygenic traits. In this paper, we proposed a joint model that accounts for the uncertainty in gene expression imputation and dissects genetic contribution to traits at both gene and pathway levels. A sparse group Lasso penalty was introduced into a penalized expectation-maximization (EM) framework to select both genes and pathways associated with a trait. Our method can be regarded as an polygenic extension of an existing joint model, collaborative mixed model (CoMM). Our extension elevates the analysis to a multivariate framework, enhancing its capacity to handle complex genetic data and providing better functional insight into the genetic architecture of traits. We conducted extensive simulations with varying group structures and signal strengths to evaluate the variable selection and prediction performance of our method as compared to two-stage TWAS, univariate and additive CoMM. We also applied our method to identify genes and pathways predictive of a polygenic trait blood pressure (BP) using UK Biobank data.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4012 A map of genetic and phenotypic associations across male reproductive phenotypes.

Authors:

J. Figueredo, Estonian Biobank research team, T. Laisk, **R. Mägi**; Inst. of Genomics, Univ. of Tartu, Tartu, Estonia

Male infertility is a common, complex disease, affecting ~7-10% of men, and manifesting in diverse phenotypes ranging from morphological and functional abnormalities in sperm to severe spermatogenic impairment. Epidemiological data indicates that male infertility is often not an isolated condition, and it is not only a concern related to failed fatherhood. Recent research has revealed that many of the molecular pathways and mechanisms involved in male reproductive traits are shared with chronic diseases such as diabetes, heart disease, and cancer. Therefore, understanding the underlying causes of male infertility and finding ways to improve overall male reproductive health can advance reproductive health outcomes and help identify and prevent other health issues. Here, we carry out the most extensive effort to map the genetic background of phenotypes related to male reproductive health and provide an atlas of genetic and phenotypic correlations. In a joint analysis of three large population-based biobanks [Estonian Biobank (EstBB), FinnGen and UK Biobank (UKBB)] we perform a genome-wide association study (GWAS) meta-analysis of up to 532,376 men across 53 phenotypes defined using International Classification of Disease 10 (ICD-10) classification and encompassing diagnoses related to cancers of the reproductive tract and diseases of the genitourinary system. In addition to ICD-10 codes, 12 EstBB lab measurements were used in the analyses. Besides annotating the GWAS findings from individual phenotypes, we estimated the heritability of analysed phenotypes. We explored the genetic correlations across phenotypes using the LDScore framework and to compare genetic and phenotypic associations, we also analysed associations amongst the studies reproductive diagnoses using a logistic regression framework adjusted for year of birth and 10 genetic principal components. Altogether, our analyses identify 146 genome-wide significant ($p<5\ 10^{-8}$) variants, including numerous novel findings, many of which tag coding variants. We provide the first large-scale map of shared genetic architecture for male reproductive health phenotypes with several estimated pairwise genetic correlations. Overall, we found the genetic and phenotypic correlations to be quite similar and reflecting shared biological background. In conclusion, our work represents the largest effort to comprehensively characterize and map the genetic determinants of different male reproductive health-associated diagnoses.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4013 A meta-analysis of genome-wide association studies of high-sensitive CRP in Korean.

Authors:

K. Oh, Y. Kwak, M. Yuk, S. Yang, J. Lee, J. Youn, N. Song; Chungbuk Natl. Univ., Cheongju, Korea, Republic of

[Introduction]
Circulating hs-CRP (high-sensitive C-reactive Protein) is a representative marker of systemic inflammation. Since chronic inflammation is known as possible risk factor for various chronic diseases such as cardiovascular diseases and metabolic syndrome, the association studies between hs-CRP and chronic diseases have been conducted widely. But genetic factors of high hs-CRP as well as their biological functions and pathways were not fully understood. Therefore, we conducted a meta-analysis of genome-wide association study (GWAS) to identify genetic variants associated with hs-CRP and downstream functional analysis in Korean population.
[Method]
Epidemiological and genome-wide genotype data of 71,020 subjects was collected from HEXA, CAVAS, and Ansan and Ansung study in Korean Genome and Epidemiology Study (KoGES). We performed GWAS using multivariable linear regression model adjusted for sex, age, body mass index, history of hypertension, smoking and regular physical activity. After that, we performed meta-analysis of 3 GWAS results on hs-CRP. Based on our meta-GWAS results, we conducted functional annotation using the 3 strategies (positional mapping, eQTL mapping and chromatin interaction mapping) in Functional Mapping and Annotation (FUMA). For the functional analysis, we also performed gene-based, gene-set and gene-property analyses using the Multi-marker Analysis of GenoMic Annotation (MAGMA).
[Result]
The 188 SNPs associated with hs-CRP were found in this meta-GWAS study ($P<5\times10^{-8}$). Through the FUMA functional annotation, we found 511 mapped genes. Using the MAGMA gene-based analysis, we annotated SNPs to 18,681 protein coding genes, of which 58 were Bonferroni significant ($P<2.68\times10^{-6}$). In total, FUMA annotation and MAGMA gene-based analysis found 514 unique genes significantly associated with hs-CRP. From the MAGMA gene-set analysis of 15,480 gene sets, 19 gene sets were prioritized at FDR <0.05 and the strongest gene set were involved in metabolites or immune and inflammatory response. The gene-property analysis identifying tissue specificity of hs-CRP related gene expression showed the prominent expression levels in 3 of 54 tissues ($P<0.05$, specifically in liver, cells cultured fibroblasts and artery aorta).
[Conclusion]
We found genetic variants associated with hs-CRP and identified functional downstream pathways such as metabolic and/or immune and inflammatory response pathways linking metabolic or cardiovascular diseases.

PB4014 A method for fine-mapping time-to-event phenotype based on "sum of single effects" model

Authors:

Y. Yang, K. Tayeb, C. Peter, M. Stephens; Univ. of Chicago, Chicago, IL

With the increasing availability of time-to-event (TTE) phenotypes such as age of onset, disease progression and lifespan, researchers are developing methods for genome-wide association studies(GWAS) based on TTE outcomes. These studies have shown that modeling TTE outcomes, rather than binary outcomes, can enhance the power to detect genetic risk factors (Staley et al, 2017). Having assessed support for genetic associations with a TTE outcome, the next question is which genetic variants are more likely to be causally related to TTE outcome. However, there is a lack of powerful methods for fine-mapping genetic associations based on TTE outcomes. Here, we propose a novel fine-mapping method for TTE phenotypes called the "proportional hazard Sum of Single Effects" (phSuSiE) model. It combines the Cox proportional hazard model, a commonly used model for survival analysis, together with the SuSiE model for fine-mapping quantitative traits (Wang et al, 2020). phSuSiE inherits attractive properties of SuSiE including computational efficiency and intuitive interpretation, and uses credible sets to summarize uncertainty in which genetic variants are the candidate causal variants. We performed simulations with real genotype data to benchmark phSuSiE against two Bayesian variable selection methods for survival analysis, bvsnlp (Nikooienejad et al., 2020) and survival.svb (Komodromos et al., 2022). Our results show that phSuSiE increases power to detect TTE causal variants over the other methods, and it is the only method that provides credible sets. Having demonstrated the benefits of phSuSiE for fine-mapping TTE outcomes, next we plan to develop a software implementation of phSuSiE that can handle “biobank-scale” data sets.

PB4015 A method to improve GWAS by combining cohorts across genotyping platforms.

Authors:

A. Greenberg[1], H. Kang[2], D. Lee[1]; [1]Boston Children's Hosp., Boston, MA, [2]Univ Michigan, Ann Arbor, Ann Arbor, MI

Many large-scale GWAS cohorts, such as UK Biobank (UKB), are used to improve the power of studies lacking sufficient controls. However, technical differences in array platform are a major obstacle to perform combined analysis. Here, we present 2-stage imputation (2SI), a novel method for merging multiple cohorts which reduces Type I error and batch effects. In brief, (1) cohorts are imputed separately to increase potential SNP overlap (S1), (2) then merged on high-quality SNPs present in both imputed genotypes, and (3) the merged cohort is imputed again to achieve genome-wide coverage (S2). We validate this method by analyzing platform-specific bias, imputation-derived error, and impact on Type I error and GWAS results using data from the 1000 Genomes Project (1KG), UKB, and a case-control psoriatic arthritis (PA) cohort. In initial analyses, we focused on European genetic populations (EUR) and later expanded to include East Asian (EAS). First, we compared allele frequency differences (AFD) after both S1 and S2 for the same 1KG samples genotyped on two different array platforms. In S1, 0.53% of SNPs (n=8,829,116) showed greater than 3% AFD between platforms compared with 0.01% in S2 (n=8,230,518) indicating that 2SI reduces platform-specific bias when combining cohorts. We also performed AFD analysis for imputed genotypes of 1KG samples and their WGS and found similar results for both stages of imputation (S1=5.9%, S2=5.8%) suggesting there is no additional imputation-derived error introduced by S2. Moreover, we applied 2SI and conducted GWAS for controls from PA (n=1355) and a UKB subset (n=12666) using cohort as outcome and found 1 genome-wide significant locus (hit) in S2 ($p = 5\times10\text{-}8$) compared with over 500 in S1 indicating our method controls for Type I error. We also conducted a chromosome 19 GWAS on the merged set of 1KG (n=475) and UKB (n=1787) for EAS using cohort as outcome and found no hits in S2 compared with 3 in S1 ($\lambda S1 = 1.07$, $\lambda S2 = 1.02$). To assess reproducibility of 2SI, we performed GWAS on PA in EUR. We applied 2SI to only PA cases (n=1263) and our UKB EUR subset, simulating a case-only cohort scenario. S1 results showed many hits outside previously known regions. In S2, we replicated 4/5 hits from the original GWAS of PA cases and controls, with the 5th reaching suggestive significance ($p = 4.5\text{x}10\text{-}7$), and no novel loci were found. The GWAS of the full PA cohort combined with UKB achieved similar results, likely due to saturation of the case-control ratio. With the plethora of large biobanks and publicly available control cohorts, 2SI provides an avenue for cohorts of previously understudied phenotypes and populations to be investigated in the expansive GWAS framework.

PB4016 † A multi-ethnic reference panel to impute classical and non-classical *HLA* class I alleles: Enhancing HLA imputation accuracy in admixed populations.

Authors:

N. Silva[1,2], S. Bourguiba-Hachemi[1], S. H. Y. Knorst[3], R. T. Carmo[3], C. Masotti[3], M. Naslavsky[4], P-A. Gourraud[1], S. Limou[1], E. Castelli[2], N. Vince[1]; [1]Nantes Université, INSERM, Ecole Centrale Nantes, Ctr. for Res. in Transplantation and Translational Immunology, UMR 1064, Nantes, France, [2]São Paulo State Univ., Molecular Genetics and Bioinformatics Lab., Sch. of Med., Botucatu, Brazil, [3]Dept. of Molecular Oncology, Hosp. Sírio-Libanes, São Paulo, Brazil, [4]Dept. of Genetics and Evolutionary Biology, BioSci.s Inst., Univ. of São Paulo, São Paulo, Brazil

The MHC class I region presents several genes related to immune response. Genome-wide association studies have identified many SNP associations within the MHC region. These associations miss the immunological significance of specific *HLA* alleles. To impute these *HLA* alleles from SNPs remains a challenge especially when studying admixed populations as *HLA* genes exhibit high levels of polymorphism, and reference panels consist mainly of Europeans. The SNP-HLA Reference Consortium (SHLARC) aims to enhance HLA association studies by improving HLA imputation.

We called SNP genotypes and *HLA* alleles of 1,000 Genomes (1KG, n=2,504) and SABE (Brazilians, n=1,170) from 30X WGS using a bioinformatics pipeline developed to minimize genotype errors for HLA genes (hla-mapper). We assessed HLA imputation for *HLA-A*, *HLA-B*, *HLA-C*, *HLA-E*, *HLA-F*, and *HLA-G*. Three reference panels were created using HIBAG: 1KG, SABE, and full (1KG+SABE) reference. We extensively tested each dataset by creating several pairs of reference panel + test set: we subsetted each super population of 1KG (Africans, Americans, East Asians, and Europeans) and SABE to obtain 10 random resampling (200 samples each). Individuals of the test set were excluded from the paired reference panel. Additionally, we compared HLA imputation of our reference panels with the Michigan Server (TopMed dataset, n=20,000) for *HLA-A*, *HLA-B*, and *HLA-C* genes in an independent Brazilian population (n=192), with SNP data and *HLA* calls from commercial kits.

Accuracy was assessed by the percentage of correctly predicted alleles. The full reference consistently outperformed the 1KG and SABE alone. When compared to SABE, the 1KG reference generally exhibited better performance, except for predicting subsets from SABE. Non-classical genes achieved around 100% accuracy. We also computed the F1 score, a metric averaging coverage of a specific allele, and the proportion of correct allele calls. For classical genes, the F1 score was lower for *HLA-B* due to its high variability. Among the non-classical genes, *HLA-E* had a lower F1 score in Africans due to the presence of rare and population-specific alleles. The SABE reference was the best to impute Brazilians for *HLA-A* and *HLA-B*. Here, the accuracy for *HLA-B* ranged from 84% (Michigan Server) to 90% (SABE). In conclusion, our findings highlight the influence of population-specific references and target genes on imputation accuracy. Multi-ethnic reference panels generally yield superior results; however, the absence of admixed populations in major reference panels (including TopMed) jeopardizes the imputation accuracy, particularly for highly polymorphic genes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4017 A multiomics Mendelian randomization study identifying novel therapeutic targets for alcohol use disorder and problem drinking in the cortical proteome

Authors:

D. Rosoff[1], J. Wagner[1], A. Bell[2], L. Mavromatis[1], J. Jung[3], F. Lohoff[4]; [1]NIH/NIAAA, Bethesda, MD, [2]NIH/NIAAA, Rockville, MD, [3]NIH / NIAAA, Bethesda, MD, [4]NIH, Bethesda, MD

Background Alcohol use disorder (AUD) is a common neuropsychiatric disorder that is a leading cause of morbidity and mortality worldwide; however, only a few pharmacological treatment options are currently available, highlighting the need for novel and safe drug development. While protein biomarkers with causal genetic evidence are promising novel drug target candidates for AUD, systematic scans of brain proteins have not been performed.
Methods We integrated genome-wide association summary statistics (GWAS) for AUD and alcohol consumption behaviors, i.e., problem items from the Alcohol Use Disorders Identification Test (AUDIT-P), binge drinking, and total drinks per week (DPW), and applied *cis*-instrument Mendelian randomization (MR) to perform a proteome-wide MR with data from >1,700 brain proteins within the dorsolateral prefrontal cortex (dlPFC) to investigate their relationships with the AUD and alcohol consumption behaviors. We performed replication and validation analyses in independent proteomic and transcriptomic datasets.
Results We identified 34 unique brain protein-alcohol associations that emerged as causal mediators of AUD and alcohol consumption behaviors. Novel proteins not previously implicated in alcohol consumption behaviors included *CAB39L*, *TESC* (P-value=1.9910^{-7} (AUD)), *ERLIN1* (P-value=2.3110^{-12} (AUDIT-P)), *CPS1* (P-value=6.910^{-6} (binge drinking)), *HDGF* (*SLC5A6* (P-value=1.5310^{-7} (DPW)). *CAB39L* was consistently associated with increased drinking across alcohol phenotypes (with P-values ranging from 8.6610^{-10} (AUD) to 1.6910^{-114} (DPW)). We were able to replicate proteins using independent dlPFC protein and gene expression datasets. 11 of the proteins also showed evidence of a shared causal variant between the brain protein and respective alcohol consumption behavior, including *CAB39L*, *HDGF*, and *SLC6A5* with DPW and *CPS1* with binge drinking. Single-cell enrichment was predominantly in excitatory neurons within the dlPFC. MR identified corresponding associations for 31 of the 34 alcohol-related proteins with 22 neuropsychiatric endpoints, highlighting pleiotropic associations. *TESC*, *SLC6A5*, *HDGF*, and *CPS1* were not associated with other neuropsychiatric endpoints, suggesting potentially specific roles in alcohol consumption.
Conclusions Our findings highlight the power of integrating genetics, proteomics, and transcriptomics in elucidating the underlying biology of AUD and alcohol consumption behaviors, linking them with neuropsychiatric disorders and identifying novel drug targets that may aid the development of new therapeutics aimed at reducing problematic drinking.

PB4018 A network-based evaluation of sex-specific genetic differences in cross-phenotype associations from the UK Biobank

Authors:

V. Sriram[1], Y-Y. Ahn[2], D. Kim[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Indiana Univ. Bloomington, Bloomington, IN

Across the human diseasome, genetic associations between complex diseases can lead to the onset of comorbidities and longer-term complications. Disease-disease networks (DDNs), graphs where nodes represent diseases and edges represent relationships between diseases, enable the unbiased investigation of genetic components in cross-phenotype associations. While previous studies have analyzed DDNs derived from individual biobanks to identify genetic variants linked to disease interactions, none of these publications have considered more than one DDN at a time. The comparison of multiple DDNs can reveal different patterns of genetic associations between diseases across populations. Additionally, studies over the past two decades have identified sex-specific genetic differences (GxS effects) in the onset of various phenotypes. Given that many diseases exhibit sex-specific differences in their genetic underpinnings, we aimed to determine if their interactions with each other also differ by sex. Thus, the objective of our study was to perform a biologically informed comparison of sex-specific DDNs to evaluate differences in genetics-based cross-phenotype associations between sexes. We built a male- and a female-specific DDN for 102 diseases using sex-specific phenome-wide association study (PheWAS) summary data from twhe UK Biobank (UKBB). We compared the two graphs using network topology, similarity of edge sets, clustering behavior, and node embeddings derived from graph representation learning with node2vec. Our analysis suggests that the diseasomes of males and females behave generally similarly to one another in terms of topology and key central diseases, with hypertensive, chronic respiratory, and thyroid-based diseases playing dominant roles in cross-phenotype associations for both networks. Conversely, autoimmune and inflammatory disorders including multiple sclerosis and osteoarthritis are centrally involved only in the female-specific DDN, while cardiometabolic diseases and skin cancer are more prominent only in the male-specific DDN. We also observed a Jaccard similarity of only 26.39%, indicating that the two networks display vastly different edge sets. These results indicate significant GxS effects in cross-phenotype associations when comparing sex-specific DDNs. Further work will involve an evaluation of clustering patterns in the two DDNs, an assessment of node embedding differences, and an interpretation of the specific genetic variants that contribute to contrasting disease connections across the networks.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4019 A new Approach to Identify Gene-Environment Interactions: Gene by cigarette smoking and alcohol consumption interactions for serum lipids in diverse populations

Authors:

X. Zhu[1], Y. Yang[1], N. Lorincz-Comi[1], G. Li[1], A. Bentley[2], P. De Vries[3], M. Brown[3], A. Morrison[3], C. Rotimi[2], W. Gauderman[4], the CHARGE Gene-lifestyle Interactions Working Group; [1]Case Western Reserve Univ., Cleveland, OH, [2]NIH, Bethesda, MD, [3]Univ. of Texas Hlth.Sci. Cntr Houston, Houston, TX, [4]Univ of Southern California, Los Angeles, CA

There is a long-standing disagreement to the magnitude of the contribution of gene-environment interaction (*G*×*E*) to phenotypic variations of complex traits. Part of the reason may be that very few interactions have been reported to date, presumably owing to the generally low statistical power to detect *G*×*E* by existing methods. To address this issue, the Gene-Lifestyle Interactions Working Group (GLI), as part of the Cohorts for Heart and Aging Research in Genetic Epidemiology Consortium (CHARGE), has been spearheading efforts to investigate *G*×*E* in large and diverse samples through meta-analysis. Here, we present a powerful approach to screen *G*×*E* interactions across the genome and the approach shares substantial similarity to the Mendelian randomization framework, which has been widely applied to infer causal relationships between exposures and disease outcomes. We identified and confirmed 5 loci (6 independent signals) that interacted with either cigarette smoking or alcohol consumption for serum lipids. We further estimated that the lower bound of the interaction and environmental mediated contribution with cigarette smoking or alcohol consumption ranges from 0.21% (LDL-C, regular drinking) to 1.66% (TG, regular drinking) of SNP heritability of serum lipids in Cross-Population data. Our study improves understanding of the genetic architecture and environmental contributions to serum lipids.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4020 A new genetic risk score model for incorporating Gene-Environment interactions

Authors:

E. Dor[1], N. Rappoport[2]; [1]Ben-Gurion Univ. of the Negev, Beer Sheva, Israel, [2]Ben-Gurion Univ. of the Negev, Beer-sheva, Israel

Gene-environment interactions (G×E), refer to how an individual's genetics interact with an environmental factor to influence their traits. These interactions can occur at various levels, from molecular to behavioral, and can have positive and negative effects. Understanding G×E is important because it can help inform the development of personalized interventions and treatments that consider an individual's unique genetic and environmental influences. However, unbiased methods to profile G×E genome-wide are nascent and poorly characterized. A polygenic risk score (PRS) is the overall risk score of an individual for a specific trait based on the individual's genetics. PRS is often computed as the sum of individual genetic loci effects estimated from genetic risk factors study. Existent G×E methods are not part of the PRS estimate. Instead, G×E is focused on detecting genetic loci associated with environmental factors. We developed a new PRS model (PRSG×E), which incorporates genetic data, environmental data, and G×E interactions. We used data of 500,000 subjects from the UK Biobank. We demonstrated the model for two phenotypes: Body mass index (BMI) and lung cancer, and three environmental factors: smoking status, alcohol consumption, and hypertension. We found that the predictive ability of the interaction-based model did not improve beyond that of the PRS model based on genetic variants analysis from GWAS alone. Our findings may suggest that a larger data set is required to uncover small effects of G×E interactions. However, our approach is practical in terms of computing resources and comparable to other PRS computing methods.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4021 A new method to quantify cell type-specific heritability in single cell gene expression data

Authors:

A. Dahl, M. Chen; Univ. of Chicago, Chicago, IL

Single-cell RNA-sequencing (scRNA-seq) has revolutionized our ability to explore cellular heterogeneity across cell types, microenvironments, and individuals. It is now feasible to collect scRNA-seq datasets spanning hundreds of individuals with paired genotype data, which enables studying genetic regulation of gene expression at the level of individual cells. Indeed, several recent papers have established that cell type-specific SNP effects on gene expression can be identified in scRNA-seq data and, moreover, that these effects can inform the causal genes and cell types underlying GWAS hits. However, prior studies have evaluated individual SNP effects on expression, which is less powerful than polygenic approaches which aggregate together many SNPs in a *cis* window near the gene. This is important because scRNA-seq datasets are small and because the causal genes and cell types are typically more biologically and clinically meaningful than the SNP effects. To improve the power of scRNA-seq to characterize genes and cell types driving GWAS effects, we have developed a polygenic model of cell type-specific heritability that applies to scRNA-seq data called GxCTMM. GxCTMM partitions the *cis*-heritability of a single gene's expression into cell type-specific and -shared components, which requires careful modelling of cell-level noise and the heritability of cell type proportion. Through simulations, we demonstrate that GxCTMM provides unbiased estimates of cell type-specific heritability, and in fact that modelling cell-level noise can remove bias in prior estimates of heritability using bulk RNA-seq. We apply GxCTMM to scRNA-seq data obtained from 1.27 million peripheral blood mononuclear cells (PBMCs) collected from 928 donors. Our analysis reveals generally low cis heritability per cell type (median~0.05 across genes), with almost all heritability being cell type-specific. This contrasts with results from bulk sequencing showing that heritability is mostly shared across tissues, clearly demonstrating the biological utility of studying cell types via scRNA-seq. GxCTMM is a powerful and robust tool for detecting and quantifying cell type-specific genetic effects in scRNA-seq data, which can better inform the causal genes and cell types driving GWAS loci.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4022 A novel approach for genetic association test identifies risk genes for dental caries.

Authors:

X. Xu[1], P. Wang[2], M. Li[3], X-Y. Lou[4], S. Xu[5], B. Wu[6], G. Gao[7], P. Yin[2], N. Liu[8]; [1]Indiana Univ. at Bloomington, Bloomington, IN, [2]Huazhong Univ. of Sci. and Technology, Wuhan, China, [3]INDIANA Univ. BLOOMINGTON, Bloomington, IN, [4]Univ. of Florida, Gainesville, FL, [5]Univ. of Hong Kong, Hong Kong, Hong Kong, [6]Univ. of Minnesota, Minneapolis, MN, [7]Univ. of Chicago, CHICAGO, IL, [8]Indiana Univ., Bloomington, IN

Dental caries, also known as tooth decay, is one of the most common chronic oral diseases. Studies suggested that dental caries are partially heritable. Besides, dental caries is influenced by shared genetic factors or close biological relationships which can introduce genetic dependencies. Although several genetic risk loci have been identified in previous genome-wide association studies (GWAS), association tests in these studies are limited to unrelated individuals. Challenges are still existed in detecting associations between genes and dental caries within family samples. Meanwhile, linear mixed model has been widely adopted in GWAS to account for the relatedness owing to its flexibility and effectiveness. In this study, we propose a novel gene-based approach, which integrats the advantages of linear mixed models, aiming at improving identification of genes associated with dental caries in family samples. Our approach utilizes the linkage disequilibrium matrix of SNPs to approximate the correlation between marginal Z scores from linear mixed model, assuming the internal block structure of kinship matrix. This approach enhances the power and accuracy of association signals by considering the intricate genetic mechanisms among samples with family structure. Further, it can also identify suspicious genes that may have been overlooked by prior GWAS in unrelated subjects. When the approach is applied to a dental caries dataset, few risk genes have been identified, which may provide deeper insight into the pathogenesis of dental caries.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4023 A Novel Fine-mapping Method for Multi-ancestry and Admixed Populations

Authors:

Z. Yang[1], I. Ionita-Laza[1], L. Liu[2]; [1]Columbia Univ., New York, NY, [2]Univ. of Pittsburgh, Pittsburgh, PA

One of the crucial steps in Genome-wide Association Studies (GWAS) analyses is conducting fine-mapping to prioritize putative causal variants. Fine-mapping can be achieved through a Bayesian statistical method that leverages linkage disequilibrium (LD) patterns between variants and nearby markers in risk regions identified by GWAS. While multi-ancestry (MA) GWAS have gained attention for discovering new susceptibility loci, existing MA fine-mapping methods assume universal causal variants across ancestries, potentially leading to reduced power and false positives. Additionally, current fine-mapping methods do not account for discrepancies among summary statistics and LD matrices from different reference panels, lacking robustness. Furthermore, no fine-mapping method has been proposed to tailor the unique situation of admixed individuals (e.g. African American), which offer a unique chance to investigate the effects of genetic variants across different ancestry backgrounds with control on environmental factors in contrast to outcomes from studies of cross-continental populations. In this study, we propose a novel MA fine-mapping method, "mCARMA", that utilizes a Bayesian adaptive prior (e.g. Horseshoe prior) to identify ancestry-specific or universal causal variants across MA. mCARMA also includes Bayesian hypothesis testing of MA to address discrepancies in summary statistics and LD matrices. Moreover, mCARMA is compatible with the summary statistics generated by GWAS methods like Tractor, which incorporates local ancestry information from admixed populations. We demonstrate that mCARMA offers increased power for identifying ancestry-specific causal variants, accommodates summary statistics and LD matrices from admixed populations, and exhibits robustness to outliers.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4024 † A novel meta-analysis of total mediation effect for high-dimensional omics mediators and cardiovascular traits in over 5800 TOPMed individuals

Authors:

Z. Xu, P. Wei; The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Motivation: Meta-analysis is used to aggregate the effects of interest across multiple studies, while its methodology is largely underexplored in mediation analysis, particularly in estimating the total mediation effect of high-dimensional omics mediators. Large-scale genomic epidemiology consortia, such as the Trans-Omics for Precision Medicine (TOPMed) program, comprise multiple cohorts with diverse technologies to elucidate the genetic structure and biological processes underlying complex human traits. We aimed to estimate the total mediation effects of the transcriptome on age/sex-related phenotypic variation in cardiovascular traits in over 5800 individuals in the TOPMed Framingham Heart Study (FHS) and Multi-Ethnic Study of Atherosclerosis (MESA) using our novel meta-analysis method for total mediation effect accounting for heterogeneity in technology (microarray or RNAseq) and diverse ethnicity.
Methods: Built on our recently established asymptotic standard error of the R-squared (Rsq)-based mediation effect estimation for high-dimensional omics mediators, we have developed a novel fixed-effect and random-effect-based meta-analysis framework requiring only summary statistics and allowing inter-study heterogeneity due to differences in, e.g., high-throughput technologies and ethnicities. We applied the developed method to 8 studies involving 5864 unique individuals: FHS-Offspring/Gen3-microarray/RNAseq and MESA-RNAseq-White/Black/Hispanic/Asian to estimate the mediation effects of gene expression on age-related variation in systolic blood pressure (SBP) and sex-related variation in high-density lipoprotein (HDL) cholesterol.
Results: Extensive simulations showed that the developed meta-analysis method yielded satisfactory efficiency and coverage probability comparable to the joint likelihood-based method requiring individual-level data. Application to the FHS and MESA studies revealed that gene expression explained 18.5% (95% CI=(13.2%, 23.7%) by fixed-effect meta-analysis with I^2=1%) of age-related variation in SBP and 47.2% (95% CI=(28.8%, 65.6%) by random-effect meta-analysis with I^2=69.4%) of sex-related variation in HDL. The proposed Rsq-based mediation effect estimation and meta-analysis will be available in the R package “RsqMed”.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4025 A novel multi-omics mendelian randomization method for gene set enrichment and its application to psychiatric disorders

Authors:

H. Gedik[1], S-A. Bacanu[2]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]Virginia Commonwealth Univ, Richmond, VA

Genome-wide association studies (GWAS) of psychiatric disorders (PD) yield numerous loci with significant signals, but often do not implicate specific genes. Because GWAS risk loci are enriched in expression/protein/methylation quantitative loci (e/p/mQTL, hereafter xQTL), transcriptome/proteome/methylome-wide association studies (T/P/MWAS, hereafter XWAS) that integrate xQTL and GWAS information, can link GWAS signals to effects on specific genes. To further increase detection power, gene signals are aggregated within relevant gene sets (GS) by performing gene set enrichment (GSE) analyses. Often GSE methods test for enrichment of "signal" genes in curated GS while overlooking their linkage disequilibrium (LD) structure, allowing for the possibility of increased false positive rates. Moreover, no GSE tool uses xQTL information to perform a mendelian randomization (MR) analysis. To make causal inference on association between PD and GS, we develop a novel MR GSE (MR-GSE) procedure. First, we generate a "synthetic" GWAS for each MSigDB GS by aggregating summary statistics for x-level (mRNA, protein or DNA methylation (DNAm) levels) from the largest xQTL studies available) of genes in a gene set. Second, we use synthetic GS GWAS as exposure in a generalized summary-data-based MR analysis of complex trait outcomes. We applied MR-GSE to GWAS of nine important PD. When applied to the underpowered opioid use disorder GWAS, none of the four analyses yielded any signals, which suggests a good control of false positive rates. For other PD, MR-GSE greatly increased the detection of GO terms signals (2,594) when compared to the commonly used (non-MR) GSE method (286). The uncovered signals mostly fall into synapse/neuronal, immune, cytoskeleton, RNA translation and chromatin accessibility, miRNA, apoptosis and "housekeeping" categories. Some of the findings might be easier to adapt for treatment, e.g., our analyses suggest modest positive effects for supplementation with certain vitamins and/or omega-3 for schizophrenia, bipolar and major depression disorder patients.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4026 A novel multi-view clustering approach for integrating genotypes and 3D facial images in the presence of confounders.

Authors:

Z. Li[1], S. F. Windels[2], M. L. Marazita[3], S. Walsh[4], S. M. Weinberg[5], M. D. Shriver[6], P. Claes[1], N. Malod-Dognin[2], N. Pržulj[2], K. Van Steen[7]; [1]KU Leuven, Leuven, Belgium, [2]Barcelona Supercomputing Ctr., Barcelona, Spain, [3]Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, [4]Univ. of Pittsburgh, Pittsburgh, PA, [5]Univ of Pittsburgh, Pittsburgh, PA, [6]Penn State Univ, University Park, PA, [7]Univ. of Liège / KU Leuven, Liège, Belgium

Human populations from distinct geographical locations possess unique genomic and facial patterns. By integrating these multi-view data, we can achieve a more comprehensive and complementary clustering of population structure. Among the various approaches for multi-view clustering, integrative nonnegative matrix tri-factorization (NMTF) has emerged as advantageous in learning low-rank representations of samples and features and straightforwardly interpreting them. When dealing with 3D image datasets, nonnegative Tucker decomposition (NTD) can be treated as a generalization of NMTF. Because confounders can also influence clustering within a population, it is essential to assess and deal with these confounding effects. Here we present a novel multi-view clustering method based on NMTF and NTD to find unconfounded subgroups of population structure from genotypes and facial images. The proposed method is evaluated on a real-life multi-view dataset to subgroup individuals with different population structures in a US cohort based on their genomics and 3D facial images. More specifically, the data consist of roughly 7M SNPs and 7K 3D facial landmarks collected from 4680 US individuals with European ancestry. Covariates, such as age, sex, weight, height, face size and camera system, are available and taken as confounders to population structure. The model generates three representation matrices separately for samples, SNPs and facial landmarks. We test whether the sample representation and its clustering are significantly associated with known covariates. For the SNP representation, K-Means clustering is initially performed and the clusters of SNPs show good enrichment of genes and Gene Ontology (GO) terms. Additionally, we apply hierarchical clustering to the facial representation to obtain a segmentation with improved cophenetic correlation score than a previously published segmentation of the same facial images. Out of all 48 vectors in the sample representation, 20 are not associated with confounders, from which we achieve the unconfounded clustering of population structure. The clusters of individuals are further characterized jointly by the most relevant GO terms and facial regions. In conclusion, this study introduces a novel multi-view clustering method that integrates genotypes and 3D images to derive unconfounded clustering. The evaluation via a real-life dataset demonstrates that the proposed model yields biologically meaningful representations for each data type and obtains unconfounded sample clustering for population structure with a comprehensive interpretation of the derived clusters.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4027 † A Phenome-Wide Systemic Approach to Large-Scale GWAS Meta-Analysis of More Than 1200 Traits in Over 30 Studies

Authors:

D. Jakubosky[1], J. Chen[1], T. Greene[1], B. Gonzalez[2], M. F. Ragsac[1], R. Avila[1], Z. Romer[1], G. McInnes[1], S. Bruse[2], B. Cajes[2], O. Gottesman[2]; [1]Empirico Inc, San Diego, CA, [2]Empirico Inc., San Diego, CA

In the past decade there has been a proliferation of increasingly large genome wide association studies (GWAS), most recently utilizing large-scale biobanks comprising genotyping and/or next generation sequencing data linked to rich phenotypic information, such as the UK Biobank, FinnGen and Biobank Japan. In order to address the lack of power and diversity in single studies, particularly for rare variants or diseases with a lower population prevalence, meta analyses have become an important tool for maximizing the utility of GWAS discovery. However, performing these analyses is difficult, requiring significant effort to curate studies and harmonize inputs, and most meta-analyses efforts consist of only one or a few traits. Here, we describe a phenome-wide systematic approach to large-scale meta-analysis, resulting in one of the largest meta-analyses performed to date. We combined primary GWAS results for thousands of binary and quantitative traits from the UK Biobank with publicly-available summary statistics from more than 30 studies, harmonizing their result formats and gathering detailed metadata about their associated cohorts, phenotypes and statistical methods. We then constructed a knowledge graph of cohorts and studies, and used OpenAI GPT3.5 and all-mpnet-base-v2 to estimate phenotype similarity, matching studies to a custom phenotype ontology. Using this knowledge graph, we algorithmically selected groups of study-trait pairs, requiring that (i) all studies in a group are independent with regard to samples and (ii) group composition is prioritized with regard to total case/sample count. We then performed inverse variance weighted and sample size weighted meta analyses on each group using a spark framework. We generated meta-analysis results for more than 1200 phenotypes with 2-8 studies per group, comprising over 200Million results spanning 12 million unique variants, and revealing a substantial number of previously sub-threshold associations that exceed genome-wide significance following meta-analysis. This study provides important insights into the strategies, methods and value of large-scale meta-analysis for maximizing the utility of GWAS from large and diverse cohorts for genetic discovery at scale. This research has been conducted using the UK Biobank Resource under Application Number 34229.

PB4028 A pipeline to curate GWAS summary statistics and identify independent traits

Authors:

C. Legros[1,2], A. Kim[1,2], S. Gazal[1,2]; [1]Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [2]Ctr. for Genetic Epidemiology, Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA

The public release of genome-wide association studies (GWAS) summary statistics have enhanced discoveries in the genetic architecture of human diseases and complex traits, such as understanding how causal variants are shared across traits. However, the first encountered issues in downstream GWAS analyses are 1) the lack of standardization of summary statistics file formats and 2) the high number of summary statistics from traits that correlate with each other while sharing samples.
To address these issues, we have developed a pipeline designed to facilitate 1) the integration of GWAS summary statistics with different file formats, and 2) the selection of independent summary statistics for further genetic analyses. The pipeline takes as input unprocessed GWAS summary statistics file and handles various input formats of variant information (chromosome, position, allele, variant identification code) and significance of effect sizes (e.g., beta coefficients, p-values, Z scores, Odds Ratio values) and outputs uniformly formatted summary statistics. It includes common quality-control steps such as checking for allele flipping, non-biallelic SNPs and removing duplicated information. Finally, it leverages LD score regression to provide a genetic correlation matrix across traits and define a set of independent traits by excluding genetically correlated traits in overlapping samples.
We leveraged our pipeline to curate hundreds of informative (heritability Z score > 5) GWAS summary statistics of European ancestry from individual publications, the panUK Biobank and Global Biobank Meta-analysis Initiative (GBMI). We defined a set of 130 independent GWAS (mean N = 429K), more than doubling the largest set of independent GWAS previously reported. Our set prioritized 60 disease GWAS, and includes 16 psychiatric diseases and 14 immune related traits.
We anticipate that our pipeline and curated list of independent GWAS summary statistics will be widely used in the GWAS community.

PB4029 A polygenic risk score of postoperative nausea and vomiting improves risk prediction and shows genetic correlation with CNS conditions including vertigo and motion sickness

Authors:

W. Wang, C. German, Y. Liang, 23andMe Research Team, J. Tung, S. Shringarpure, M. Holmes; 23andMe, Sunnyvale, CA

Postoperative nausea and vomiting (PONV) is a frequent side effect following surgical procedures. Improvement of PONV risk identification may benefit postoperative care. Conventional risk factors, such as sex, smoking status and motion sickness, have been widely studied and utilized in PONV predisposition. However, the polygenicity of PONV and contribution of polygenic risk to PONV remains unclear. 23andMe's large-scale genotype and phenotypic database offers unparalleled opportunities for discovery and evaluation of the polygenic basis and risk of PONV that may have potential implications for clinical practice.

We studied 1.98M participants from 23andMe, Inc research cohort with 659K PONV cases and 1.32M controls across 5 populations (1.65M Europeans, 228K in Latines, 64.4K African Americans, 26.1K East Asians and 6.2K South Asians). We divided participants into 3 non-overlapping datasets: discovery dataset to perform genome-wide association study (GWAS), polygenic risk scores (PRS) training dataset to build PRS, and testing data to evaluate the PRS contribution to PONV risk. We compared the PONV prevalence across risk groups stratified by genetic risk based on PRS and commonly used conventional risk factors, including sex, smoking status and motion sickness.

In the discovery cohort, we identified 185 independent loci associated with PONV in European population and 7 loci in Latino population. The genetic-only AUC of PONV PRS was 0.606 in Europeans; 0.589 in Latines; 0.555 in African Americans; 0.585 in East Asians; 0.594 South Asians. We evaluated the increased prevalence of PONV among European participants in the hold-out testing data, using conventional risk factors and PRS. Women were at 1.26-fold (95% CI: [1.25%, 1.28%]) higher risk of experiencing PONV, adding non-smoking: 1.30 (95% CI: [1.29%, 1.31%]); adding motion sickness: 1.46 (95% CI: [1.44%, 1.48%]), adding high PRS: 1.77 (95% CI: [1.74%, 1.81%]). We found a high genetic correlation of PONV with codeine-induced vomiting (rg: 0.81, P-value: 2.6e-11); and moderate genetic correlation with recurrent vertigo (rg: 0.41, P-value: 1.3e-78), carsick (rg: 0.39, P-value: 5.8e-64), severity of morning sickness (rg: 0.38, P-value: 2.2e-56), dizziness (rg: 0.35, P-value: 5.0e-65), migraine (rg: 0.33, P-value: 1.9e-69) and altitude sickness (rg: -0.33, P-value: 1.9e-37).

Large-scale GWAS reveal the polygenicity of PONV that is predictive of PONV susceptibility. PRS provides additional information beyond conventionally used clinical risk factors at identifying individuals at elevated risk of treatment-emergent side effects.

PB4030 A Predictive Machine Learning Pipeline for Functional Genomics Screens

Authors:

A. Musolf[1], B. Guo[1], K. Shkura[2], T. Rajasekar[1], A. Vij[2], G. Bryman[1], K. Williams[1], C. Mann[1], A. Stiemke[1], D. Jha[1], N. Raghavan[1], J. Sul[1], S. Longerich[1], M. Kennedy[1], A. Tamburino[1], R. Mathew[1]; [1]Merck & Co., Inc., Rahway, NJ, [2]MSD, London, United Kingdom

Within recent years the application of machine learning (ML) in pharmaceutical industry data science has increased rapidly, where ML has been used for target identification, image analysis, and drug development. We have constructed an ensemble ML pipeline for functional screening prediction. As a general concept, the results of initial assays, such as functional genomic screens, are used as training data to predict which perturbations would pass a future screen. Successful, data-driven prioritization of target selection for screening ultimately would increase efficiency of target selection and screening cost. We have performed testing of our ML method on publicly available data. ML requires predictive features associated with the training set. In consultation with biologists, we leveraged over 70 sets of features, bucketed into 11 categories. Features include genes associated with genetic risk for the disease of interest as well as potential adverse events; protein-protein interactions; key pathway features from cells and tissues of interest as well as potential biological pathways to avoid; transcriptomic and protein expression from tissue of interest, and differential expression in healthy controls versus individuals with disease. Further feature engineering designed to increase informativity include the creation of graph embeddings and the one-hot encoding of location features. Many of the initial features were quantitative values that were binarized based on a predetermined threshold; we plan to use quantitative features in future analyses. Data is analyzed by an ensemble-based pipeline consisting of different learning machines. Each machine analyzes the data in parallel without input from the other machines. Current simulations have shown high power (>80% F statistics) when varying the number of causal features and noise levels. Power decreases as the data becomes more unbalanced; we are currently evaluating techniques for increasing power in unbalanced datasets. All machines output feature importance metrics to identify which features are most predictive; simulations show that these metrics have correctly identified the causal features with high power. This approach is modular and can be utilized for further prediction beyond assays and screens.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4031 A resampling-based approach to share reference panels.

Authors:

T. Cavinato[1], S. Rubinacci[2], A. Malaspinas[1], O. Delaneau[3]; [1]Univ. of Lausanne, Lausanne, Switzerland, [2]Brigham and Women's Hosp., Boston, MA, [3]Univ. of Lausanne, Lausanne-Dorigny, Switzerland

For many genome-wide association studies, imputing genotypes from a haplotype reference panel is a necessary step. Over the past 15 years, reference panels have become larger and more diverse, leading to improvements in imputation accuracy. However, the latest generation of reference panels is subject to restrictions on data sharing due to concerns about privacy, limiting their usefulness for genotype imputation. In this context, we propose RESHAPE, a method that employs a recombination Poisson process on a reference panel to simulate the genomes of hypothetical descendants after multiple generations. This data transformation helps to protect against re-identification threats and preserves important data attributes, such as linkage disequilibrium (LD) patterns and, to some degree, Identity-By-Descent (IBD) sharing, allowing for genotype imputation. Our experiments on gold standard datasets show that simulated descendants up to eight generations can serve as reference panels without significantly reducing genotype imputation accuracy. We suggest that this specific type of data anonymization could be used to generate synthetic reference panels available under less restrictive data sharing policies

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4032 A robust cis-Mendelian randomization method with application to drug target discovery

Authors:

Z. Lin, W. Pan; Univ. of Minnesota, Minneapolis, MN

Mendelian randomization (MR) uses genetic variants as instrumental variables (IVs) to investigate a causal relationship between two traits, an exposure and an outcome. Compared to conventional MR using only independent IVs selected from the whole genome, cis-MR focuses on a single genomic region using only cis-SNPs. For example, using cis-pQTLs for each circulating protein as an exposure for a disease opens an economical path for drug target discovery. Despite the significance of such applications, only few methods are robust to (horizontal) pleiotropy and linkage disequilibrium (LD) of cis-SNPs as IVs. In this work, we propose a cis-MR method based on constrained maximum likelihood, called cisMR-cML, which accounts for LD and (horizontal) pleiotropy in a general likelihood framework. It is robust to the violation of any of the three valid IV assumptions with strong theoretical support. We further clarify the severe but largely neglected consequence of the current practice of modeling marginal effects, instead of conditional effects, of SNPs in cis-MR analysis. Numerical studies demonstrated the advantage of our method over other existing methods. We applied our method in a drug-target analysis for coronary artery disease (CAD), including a proteome-wide application, in which three potential drug targets, PCSK9, COLEC11 and FGFR1, for CAD were identified.

PB4033 A scalable variational inference approach for increased mixed-model association power.

Authors:

H. Loya, G. Kalantzis, P. Palamara; Univ. of Oxford, Oxford, United Kingdom

The rapid growth of modern biobanks is creating new opportunities for large-scale genome-wide association studies (GWAS) and the analysis of complex traits. Available GWAS algorithms, however, rely on modeling simplifications that reduce statistical power to improve computational costs. We developed a method, called Quickdraws, that simultaneously achieves state-of-the-art statistical power and computational efficiency. Quickdraws improves association power by modeling polygenicity and relies on highly efficient stochastic variational inference and GPU-based operations for parallel trait analysis.

We compared Quickdraws with current GWAS algorithms including Regenie (Mbatchou et al, *Nat Genet*, 2021), FastGWA (Jiang et al, *Nat Genet*, 2019/21), Saige (Zhou et al, *Nat Genet*, 2018), and BOLT-LMM (Loh et al, *Nat Genet*, 2015/18) on simulated and real data. Quickdraws consistently provided higher statistical power while being robust to population stratification, relatedness, and case-control imbalance. In an analysis of 50 disease traits in 404k UK Biobank samples, Quickdraws provided the highest association power, detecting 7.8% more independent associations than Regenie, and 15.8% more than FastGWA-GLMM. Similarly, applied to 50 quantitative blood-related traits, Quickdraws matched the statistical power of BOLT-LMM, the gold standard for quantitative traits, while finding 4.7% more independent associations than Regenie and 31.2% more than FastGWA. The gain in statistical power was higher in less polygenic traits (e.g. 23.3% and 22.2% increase over Regenie for Celiac disease and Hypothyroidism). Quickdraw's higher association power also results in a higher number of replicated associations in other cohorts (e.g. 3.2% and 14.7% more replicated associations compared to Regenie and FastGWA in Biobank Japan).

We compared the computational cost of Quickdraws and other algorithms using 404k UK Biobank samples on the RAP platform. We used 458k model SNPs and tested 13.3 million imputed SNPs across 50 quantitative and 50 disease traits, tuning the hardware configuration for each method. Quickdraws was 147x cheaper than BOLT-LMM, the only method with similar association power in quantitative traits, and was comparable to more cost-effective methods that have lower association power (50 disease traits: Quickdraws=£452.1, Regenie=£506.9, FastGWA-GLMM=£98.1, Saige≈£2803; 50 quantitative traits: Quickdraws=£50.8, Regenie=£24.2, FastGWA=£37.3, BOLT-LMM≈£7467).

These results highlight the promise of using modern machine learning methodology to reduce the costs of GWAS analyses without sacrificing statistical power and robustness.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4034 A simulation study comparing cognitive decline measures in Alzheimer's disease

Authors:

R. Shi, E. Feingold, M. Kamboh, K. Fan; Univ. of Pittsburgh, Pittsburgh, PA

Background: Cognitive decline in Alzheimer's disease (AD) can be assessed over time using neuropsychological tests such as the Mini-Mental State Examination (MMSE) score. Various functions of longitudinal decline can then be used as phenotypes for genome-wide association studies (GWAS). One difficulty in choosing the most appropriate measure is that there is significant missing data. Left censoring occurs when the diagnosis time is uncertain, while right censoring happens when patients are lost to follow-up as the disease progresses to a severe stage. This study proposes several different MMSE-based cognitive decline measures and evaluates their power for GWAS analyses. **Methods:** We evaluated the power of six alternative cognitive decline measures calculated from the longitudinal MMSE scores across various simulated scenarios. We built different simulated cognitive decline patterns using parameters estimated from linear mixed-effect models of two real datasets. We employed masking strategies to mimic random missing, left-, and right-censoring patterns on the simulated full trajectories. For each measure, we conducted analyses with and without adjusting for baseline MMSE score as a covariate. **Results:** Most measures showed increased power after adjusting for baseline MMSE score, except for the annual cognitive decline rate and percentage MMSE score changes that already incorporate the baseline level in the calculations. Among all six measures, a simple measure of the slope of cognitive decline was more powerful under all missingness-induced sigmoid-like decline patterns, which was estimated to be over 75%, followed by the time-to-reach MMSE10. The time-to-reach MMSE10 is more powerful in selected scenarios in which the censoring rate is lower and with a shorter time to reach that point. **Discussion:** Overall, our results suggest that a simple measure of slope and the time-to-reach MMSE10 may be most powerful for capturing the genetic effects underlying AD-related cognitive decline, particularly in datasets with significant left and right censoring. An additional advantage of these methods is that they are computationally faster than repeated-measures approaches. Adjusting for baseline MMSE score is very important, as it helps to reduce confounding and improves the accuracy of decline rate estimates.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4035 A statistical approach for detecting trends in underpowered genome-wide association studies

Authors:

M. MacMillan, S. Demiriz, T. Furneaux, B. Ballew; Sequence Bio, St. John's, NL, Canada

Genome-wide association studies (GWAS) have accelerated our understanding of the genetic landscape of complex human disease. A well-powered GWAS, a function of sample size and effect size, is required for reliable signal; the field benchmark for association is genome-wide significant results of $p<5 \times 10\text{-}8$. Genomics groups who are embarking on a new area of study or are developing new in-house bioinformatics capabilities may find it challenging to achieve sufficient power when attempting to confirm that their methods are functioning as expected. When developing NGS methods, we often rely on comparisons to high confidence call sets via the Genome in a Bottle Consortium, but an analogous method to verify that GWAS workflows are capturing known signals at relatively small sample sizes does not yet exist. Here, we present a statistical method for benchmarking GWAS pipelines in underpowered studies. This approach aims to determine if, although not at genome-wide significance, our association findings are enriched for putative true positive signals at lower p-values than would be expected by chance. We developed our trend detection pipeline using a cohort of around 2,000 genotyped and QC'd participants from the Newfoundland and Labrador population. Based on the phenotypes for which we had the largest sample size, we performed association testing on our cohort for each of the selected traits to derive experimental p-values for all SNPs that passed QC. We used the European Bioinformatics Institute GWAS catalog, filtered to $p<5x10\text{-}8$, to establish a benchmark "true positive" dataset of variants that have been previously associated with our traits of interest. Receiver Operating Characteristic (ROC) curves were generated to evaluate the performance of our association workflow, and the GWAS catalog was mined for known signals in ~independent traits to serve as expected null controls. If the rate at which we are correctly identifying true positive and true negative signals is greater than the rate at which we are misclassifying signals, we'd expect a curve into the upper left quadrant of the plot. We compared different approaches to try to ensure expected behaviour of the null model, including implementing LD clumping for experimental SNPs, improving variant joining precision and controlling for allele frequency matching. Our performance curve showed a statistical trend toward significance for our test trait associations, boosting confidence in the methodology of our GWAS workflow, sample processing and data integrity. This technique provides a potential benchmarking approach for assessing the validity of association workflows in underpowered studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4036 A stringent filter for putative NMD escape variants improves rare variant association tests.

Authors:

A. Holleman, A. Deaton, R. Hoffing, L. Krohn, P. LoGerfo, P. Nioi, M. Plekan, S. Akle, L. Ward; Alnylam Pharmaceuticals, Cambridge, MA

Genetic variants like frameshift and stop-gain mutations typically result in gene loss of function (LOF) through nonsense-mediated decay (NMD). However, if these variants are located near the end of a gene's coding sequence, the resultant transcript may escape NMD, in which case the variant does not cause LOF. Such variants may nonetheless be classified as high confidence predicted LOFs (HC pLOFs) by commonly used annotation algorithms like LOFTEE, and they may reduce power for identifying associations if included in LOF burden analyses. Using UK Biobank (UKBB) whole-exome sequencing data for ~407,000 participants with European ancestry, we first generated sets of rare (MAF < 1%), LOFTEE-designated HC pLOFs for all genes. These "standard" variant sets included 531,919 HC pLOFs. We then generated "curated" pLOF variant sets by taking the standard variant sets and removing variants located within the last exon and the last 25% of coding sequence for each transcript in which it was designated by LOFTEE as a HC pLOF. This removed 37,054 (7%) of the LOFTEE HC pLOFs. In total there were 11,300 genes with a reduced number of HC pLOFs in the curated versus standard variant sets. We used UKBB Olink proteomics data to examine whether the curated variant sets may be enriched for true LOFs. For 219 genes, we tested the burden of curated and standard set variants for association with levels of the gene's encoded protein. The curated set yielded a stronger estimated effect on decreased serum protein levels ($\beta_{curated} < \beta_{standard} < 0$) for 147 genes (67%; $p_{binom}=4.5x10^{-7}$), and for 5 of these 147 genes the 95% CIs for $\beta_{curated}$ and $\beta_{standard}$ did not overlap. Among 17 genes for which the curated set had ≤ 50% of the carrier count of the standard set, we observed $\beta_{curated} < \beta_{standard} < 0$ for 14 genes (82%; $p_{binom}=0.01$), and for 2 of these 14 genes the 95% CIs for $\beta_{curated}$ and $\beta_{standard}$ did not overlap. These results are consistent with the curated variant sets being enriched for true LOF variants. We then tested the 11,300 gene-based variant sets mentioned above for association with 607 UKBB quantitative traits (QTs), with the with the aim of finding associations not detected using the standard variant sets. Analyses of the curated variant sets identified 69 associations at $p < 1.25x10^{-6}$ not identified by the standard sets. These included novel associations between *PLIN1* and six cholesterol- and fat-distribution-related QTs, strengthening evidence for previously known associations between *PLIN1* LOFs and decreased visceral adiposity. This work helps to demonstrate that additional curation of pLOFs beyond the standard output of LOF-prediction algorithms may aid in the discovery of novel therapeutic targets.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4038 A Systematic Exploration of Phenotypic and Genetic Relationships Between Physical Activity and Brain Health

Authors:

Y. Guo[1], B. Zhao[2], P. Paschou[1]; [1]Purdue Univ., West Lafayette, IN, [2]Univ. of Pennsylvania, Dept. of Statistics and Data Sci., Philadelphia, PA

Physical activity, an essential lifestyle aspect, is associated with various health outcomes including mental health and brain functions. Using multiple data types from the UK Biobank and a variety of tools, we aimed to examine the phenotypic and genetic relationships between physical activity and brain health. We identified brain regions and networks that are strongly associated with the variation in daily physical activity volume and circadian rhythm. We also expect to quantify putative causality between them with the help of genetic instruments. This study is designed to advance our knowledge of the genetic architecture and biological networks involved in the beneficial effects of physically active and balanced lifestyle behaviors on brain health in a systematic way.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4039 A test of genotyping platform bias for multiethnic case/control association studies merging external controls

Authors:

T. Tu[1], R. Gbadegesin[2], A. Adeyemo[3], A. Ochoa[1]; [1]Computational Biology and Bioinformatics Program, Duke Ctr. for Statistical Genetics and Genomics, and Dept. of Biostatistics and Bioinformatics, Duke Univ., Durham, NC, [2]Dept. of Pediatrics, Div. of Nephrology, Duke Univ. Med. Ctr., Durham, NC, [3]NIH, Bethesda, MD

Every genotyping platform, including array, sequencing, and imputation, is known to have biased errors that vary between platforms. Merging data from different genotype platforms is a common step prior to conducting GWAS, especially in case-control studies where control samples from various sources are often combined to increase the sample size while reducing costs by reusing existing data. There is an increased risk of type I error when these platform-differential biases are correlated with a variable of interest, confounding the analysis.
We propose a framework for detecting platform-differential biases in case-control data from two genotyped datasets with different platforms and labeled ancestry. The two datasets must have control samples with one or more overlapping homogeneous ancestries. However, no cases are required, allowing analysis where one of the datasets is entirely control samples. Using control samples of the same ancestry only, we assume that allele frequencies are the same between datasets, and identify biased SNPs if allele frequencies are found to be significantly different. Our working model assumes Binomial distribution of genotypes and evaluates significance using a likelihood ratio test, but alternative models are also proposed. This method is extended to a joint ancestry test by treating each ancestry as independent data and considering the joint null hypothesis that all allele frequencies of each ancestry between the two datasets are equal. In a real data scenario where a mixture of cases and controls genotyped on an array are combined with 1000 Genomes sequencing data, which are all treated as controls, this approach successfully identifies for exclusion numerous false positive SNP associations without removing true signals. Additionally, this method can be applied to align reverse complement allele pairs between datasets, which are often misaligned due to strand ambiguity. The test is based on allele counts and can be applied to summary statistics, which we demonstrate on a replication study that uses gnomAD as the control group. Overall, this approach can allow us to safely increase study sample size by efficiently quantifying and controlling platform-differential SNP biases when controls of the same ancestries are available across platforms.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4040 A Transformer-Based Architecture for Cell Type-Level Analysis of Alzheimer's Disease Using Single-Cell RNA Sequencing Data

Authors:

X. Liu, J. Gu, R. R. Butler III, F. M. Longo, Z. He; Stanford Univ., Palo Alto, CA

Alzheimer's disease (AD) is a neurodegenerative disorder characterized by cognitive and behavioral impairments significantly impacting daily activities. Understanding the pathogenesis of AD is crucial for developing effective prevention and treatment strategies. Recent advances in single-cell RNA sequencing (scRNA-seq) technology have provided unprecedented insights into the molecular mechanisms underlying AD.
This study presents an end-to-end architecture based on the Transformer for analyzing scRNA-seq data for AD, focusing on cell type-level analysis. We train our models on fourteen different cell types with cell state classification as the objective to validate model fitting. The proposed model takes all the cells in a particular cell type as input and uses the Transformer-based architecture to effectively capture both linear and nonlinear patterns within the data. Notably, our method incorporates an essential feature extraction step that identifies and ranks genes based on their relevance to predicted cell states independently for each cell type. Additionally, our model constructs cell-type-specific gene-gene interaction networks and identifies gene modules that provide valuable insights into AD status. Results demonstrate superior performance compared to existing methods in identifying known AD-related genes. Moreover, the generated cell-type-specific gene interaction networks capture a higher representation of unique AD-related genes, surpassing traditional marginal association methods with minimal overlap observed between cell types. Furthermore, functional enrichments of the cell-type-specific AD modules reveal significant enrichment of biologically relevant pathways associated with AD, highlighting distinct functional characteristics specific to different cell types. Importantly, our model achieves accurate classification of AD versus control status for most cells across all cell types with AUC up to 0.97, underscoring the broad impact of AD across multiple cell types and genes. These findings suggest the potential utility of several cell types for disease diagnosis in the future.
In summary, our proposed method provides a robust framework for defining disease states and offers valuable insights into exploring causal genes in the context of AD. Beyond the scope of AD, the gene-feature-aware classification approach aware classification has considerable potential to impact various complex diseases—through diagnosis/stratification, the discovery of gene targets, and implication of cell types—hopefully leading to more personalized disease treatment and improved study of disease heterogeneity.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4041 A Two-stage Linear Mixed Model (TS-LMM) for Summary-data-based Multivariable Mendelian Randomization

Authors:

M. Ding; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Multivariable Mendelian randomization (MVMR) methods provide a strategy for applying genome-wide summary statistics to assess simultaneous causal effects of multiple risk factors on a disease outcome. In contrast to univariate MR methods that assumes no horizonal pleiotropy (genetic variants only associate with one risk factor), MVMR allows for genetic variants associate with multiple risk factors and models pleiotropy by including summary statistics with risk factors as multiple variables into the regression model. Here, we propose a two-stage linear mixed model (TS-LMM) for MVMR that accounts for variance of summary statistics not only in outcome, but also in all of the risk factors. In stage I, we apply linear mixed model to treat variance in summary statistics of disease as fixed-/random-effects, while accounting for covariance between genetic variants due to linkage disequilibrium (LD). Particularly, we use an iteratively re-weighted least squares algorithm to obtain estimates for the random-effects. In stage II, we account for variance in summary statistics of multiple risk factors simultaneously by applying measurement error correction methods that take into consideration LD between genetic variants and correlation between summary statistics of risk factors. We compared our MVMR approach to other approaches in a simulation study. When most of the instrumental variables (IVs) were strong, our model generated the highest coverage of true causal associations, the highest power of detecting significant causal associations, and the lowest false positive rate of identifying null causal effect for a range of scenarios that varied correlation (weak, strong) between summary statistics of risk factors and LD among genetic variants (weak LD [$2 \leq 0.1$], moderate LD [$0.1 < 2 \leq 0.5$]). When the proportion of strong IVs was reduced, our model showed performances comparable to MVMR-Egger and MVMR-IVW. The more accurate inference of our model in the presence of correlation among risk factors supports potential wide application to -omics data that are commonly multi-dimensional and correlated, as shown in application to determinants of longevity, where our method nominated a specific significant lipoprotein subfraction for causal association from a panel of 10 lipoprotein cholesterol measures. The robustness of our model to correlation structure suggests that in practice we can allow moderate LD in selection of IVs, thereby potentially leveraging genome-wide summary data in a more effective manner. Our model is implemented in ‘TS_LMM’ macro in R (https://github.com/mingding-hsph/TS_LMM).

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4042 A unified framework for phenome-wide genetic effect variance and correlation estimation utilizing GWAS summary statistics with applications to UK Biobank

Authors:

G. Chen, T-Q. Thach, P. Sham; The Univ. of Hong Kong, Hong Kong, China

Whilst pleiotropic SNPs are ubiquitous in the genome, we have also observed widespread correlations in the marginal effect estimates (Z-scores) of associated SNPs across numerous GWAS studies. This finding underscores the critical need to delve deeper into the complex architecture of the joint genetic effect matrix, encompassing multiple SNPs across hundreds of phenotypes. We're primarily interested in phenome-wide **genetic-effect variance and correlations**—relatively uncharted facets of genetic architecture, which quantify the functional relevance of a SNP and the functional commonalities between two SNPs, respectively. These perspectives parallel the heritability of individual traits and the genetic correlation between phenotypes, but are examined across the phenome instead. However, interpreting GWAS-wide variance and covariance components of summary statistics is complicated. These can inflate due to genuine genetic-effect relationships or be skewed by confounding factors, such as linkage disequilibrium (LD), shared population stratification, and GWAS non-independence. To distinguish true signals from potential bias using current methodologies, we've devised a unified statistical framework assuming **a point matrix normal distribution** of joint genetic effects. This framework enables two methods—**LRCP and LRCQ**—to respectively estimate genetic-effect correlations and variance. It leverages likelihood and regression-based approaches to analyze relationships in summary statistics and examines the connection between Z-score cross products and LD cross components.

When we applied LRCP to UK Biobank data, it revealed prevalent genetic-effect correlations within pleiotropic SNPs, presenting a fresh avenue to identify functionally-linked SNPs, gene clusters, and pathways. In contrast, LRCQ provided an innovative assessment of the functional significance of SNPs across different phenotypic categories in UK Biobank such as cardiometabolic and neuropsychiatric diseases. The detection of many "omni-SNPs" through LRCQ alludes to the possibility of identifying associated core genes and regulatory pathways. Meanwhile, "null SNPs"—those with a zero variance estimate and thus no discernable functional implications on any traits—may be disregarded in further analyses, reducing much analytical burden. Combined evidence from diverse functional annotation data further substantiates some of our findings. The combined use of LRCP and LRCQ allows for a nuanced interpretation of large-scale GWAS data, steering us towards a comprehensive comprehension of phenome-wide genetic architecture and its functional consequences.

PB4043 A unified model for cell-type resolution genomics from heterogeneous omics data

Authors:

Z. Chen[1], E. Rahmani[2], E. Halperin[2,1,3,4]; [1]Dept. of Computer Sci., Samueli Sch. of Engineering, Univ. of California Los Angeles, Los Angeles, CA, USA, Los Angeles, CA, [2]Dept. of Computational Med., David Geffen Sch. of Med., Univ. of California Los Angeles, Los Angeles, CA, USA, Los Angeles, CA, [3]Dept. of Anesthesiology and Perioperative Med., David Geffen Sch. of Med., Univ. of Califonia, Los Angeles, CA, USA, Los Angeles, CA, [4]Dept. of Human Genetics, David Geffen Sch. of Med., Univ. of Califonia, Los Angeles, CA, USA, Los Angeles, CA

INTRODUCTION: The vast majority of population-scale genomic datasets collected to date have been measured as "bulk" samples from heterogeneous tissues. The critical need for cell-type level analysis to enable discovery therefore calls for computational methods that can disentangle the convolution of cell-type signals in these population-scale bulk datasets. Such deconvolution methods exist, yet they neglect the fact that genomics is often different yet coordinated between cell types, which can provide additional information for deconvolution. Furthermore, existing methods are either heuristic or sensitive to violations of parametric assumptions.
OBJECTIVE: We aimed to develop a general framework for heterogeneous bulk omics that enables deconvolution of unknown cell-type level genomic profiles (samples by features by cell types) from bulk genomic data (samples by features).
METHODS: We present a non-parametric model, which, unlike previous work, explicitly models covariance across cell types, and an inference procedure that is theoretically justified for all heterogeneous omics. We benchmarked our method with CIBERSORTx and TCA, state-of-the-art (SOTA) methods for deconvolution of gene expression and DNA methylation.
RESULTS: We first benchmarked all methods in deconvolving in-silico mixtures of cell-type profiles we sampled from PBMC (n=118 donors) and lung (n=90) scRNA-seq data using a range of sample sizes and number of cell types. Our method consistently achieves substantial gain in the correlation between estimated and the true underlying cell-type level profiles by up to 37% and 35% over SOTA in PBMC and lung, respectively. We further confirmed the transferability of our model to other genomic modalities by demonstrating a 69% improvement in deconvolving bulk DNA methylomes for which corresponding cell-type methylation levels were experimentally available for validation. We next asked whether deconvolution can recapitulate differential expression (DE) in follicular lymphoma B-cells with CREBBP mutation that was previously found via experimental cell sorting. Strikingly, not only did our method outperform SOTA in identification of known DE genes, but it was also the only method that improved upon a straightforward analysis of the bulk data (p=8e-5; paired wilcox-test). Finally, we show that accounting for cell-type covariance establishes superior replication rates in identification of sex- and age-associated cell-type level differential methylation across four large whole-blood methylation datasets (average F1=0.94, 0.84 for sex and age, respectively, across pairs of datasets; ≤0.89 and ≤0.81 for SOTA).

PB4044 Accelerated Failure Time and Parametric Shared Frailty Model with the Application of Infant Mortality EDHS 2016 Data, 2023.

Authors:

A. Aragaw[1], E. Muluneh[1], A. Azene[2]; [1]Bahir Dar Univ., Bahir Dar, Ethiopia, [2]Dept. of Epidemiology and Biostatistics, Coll. of Med. and Hlth.Sci., Bahir Dar Univ, Bahir Dar, Ethiopia

Background: Infant mortality is a major public health issue in Ethiopia. The main objective of this study was to compare accelerated failure time with parametric shared frailty model and identify predictors of infant mortality in Ethiopia using EDHS 2016 data.
Methods: The study used data from the 2016 Ethiopian Demographic and Health Survey. Survival analysis techniques such as the Kaplan-Meier survival estimates, accelerated failure time model and parametric shared frailty models were employed to compare and analyze the data for survival time of infants.
Results: The clustering effect was significant and the Weibull-Gamma shared frailty model was best model for predicting survival time of infant in Ethiopia. Mothers educational level prolonged the survival time of infants by a factor of (AF =1.403 and AF =2.094) for primary and secondary and above education as compared to uneducated mothers. The acceleration factor for infants who were breastfeed was 6.307 times greater than those who were not breastfeed (reference) (AF=6.307, 95%CI= 4.976, 7.995), this indicates mothers who breastfeed their infants was prolonged the survival time of infants by the factor of 6.307 than the reference group.
Conclusion: Weibull-gamma shared frailty model was best for survival time of infants in Ethiopia. Considering the region and cluster variation, intervention should be given for who had not educated mother and fulfill the facilities for regions to achieve the target for Sustainable Development Goals (SDGs) by 2030, and one of the important components is to reduce the infant mortality rates. This study also implies that health professionals should give an emphasis on improve the awareness to increase birth spacing and encourage breastfeeding's to reduce infant mortality in the country.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4045 Accounting for cardiac cell composition in GTEx with single-nucleus reference profiles yields novel genetic-trait associations.

Authors:

B. Gural, C. Rau; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Heart failure (HF) is a heterogeneous condition defined by an inability of the heart to meet the circulatory needs of the body. HF is the result of a maladaptive response to chronic stressors during which the heart undergoes structural and cellular remodeling. For example, cardiomyocytes undergo apoptosis and necrosis after chronic overstimulation while fibroblasts proliferate to fill gaps left by the loss of larger cells. Although changes to the cellular makeup of the heart are known to mediate HF pathology, estimates of basal cardiac cellular composition vary widely. Moreover, despite our understanding of HF as a complex condition that is influenced by environmental and genetic factors, most studies on heart composition only examine small groups of individuals or inbred models. Recent efforts have used single-nucleus RNAseq (snRNAseq) to tally nuclear proportions as a proxy for cellular proportions. However, cellular dissociation biases for certain cell types and skews the resulting estimates. Furthermore, snRNAseq studies are expensive, making them infeasible and underpowered for population-scale analyses. To avoid these issues, we developed a method to estimate cellular composition of bulk RNAseq using cell-type-specific references defined in snRNAseq. Current deconvolution tools are designed for single-cell RNAseq inputs. Our method applies existing deconvolution tools, preprocesses the inputs to control for technical and biological differences when using snRNAseq, incorporates validation tests with appropriate compositional statistics, and allows for the inclusion of additional reference datasets. We apply our method to the Genome-Tissue-Expression atlas (GTEx), a multi-tissue database with bulk RNAseq from hundreds of subjects and snRNAseq from a small subset of those subjects. We estimated left ventricular cellular composition 386 individuals, revealing considerable heterogeneity. We found significant correlations between subject phenotypes and discrete cell populations. Further, we have used these estimates both as covariates in eQTL analysis and as a trait of their own in a cell-type QTL (ctQTL). To improve the rigor of our results, we have also conducted colocalization of these separate signals. This analysis demonstrates our ability to leverage existing, public datasets to accurately map the understudied variability of cardiac cell type variation across human populations.

PB4046 Accounting for distant relatedness with genealogical data in a multivariate analysis of eye disease and cognitive phenotypes

Authors:

M. Rakesh, A. Montazeri, K. Burkett, E. Freeman, M-H. Roy-gagnon; Univ. of Ottawa, Ottawa, ON, Canada

Background: Retinal diseases and cognitive phenotypes may share biological mechanisms. To explore this relationship, we investigate 36 candidate single nucleotide polymorphisms (SNPs) previously identified to be associated with either glaucoma, age-related macular degeneration (AMD), Alzheimer's, or cognitive decline in a cross-sectional study of 312 participants from the French Canadian founder population recruited in the Ophthalmology Clinics of the Maisonneuve-Rosemont Hospital, Montreal, Canada.
Methods: We tested for association between each candidate SNP and the multivariate phenotype of glaucoma (or AMD) and 6 continuous cognitive traits including the Verbal Fluency Test animal and letter versions, the Verbal Digit Span forward and backward versions, and the logical memory story with immediate and delayed recall. We used a multivariate analysis of variance approach and a reverse regression approach, where the SNP is set as the independent variable and the multivariate phenotype as the dependent variable, allowing for covariate adjustment. No genome-wide genotype data are available on these individuals. However, genealogical data from the BALSAC database are available for a subset of 227 individuals. In order to assess whether cryptic relatedness may cause spurious associations within our sample, we used these genealogical data to perform gene dropping simulations (1000 replicates of 2200 genome-wide SNPs 50kb apart) under the null hypothesis of no association with the R package GENLIB.
Results: Overall, our simulations did not indicate an inflated type 1 error (estimated over the 2200 SNPs) in the majority of the simulation replicates. However, in the specific replicates where type 1 error was elevated (n=38), mixed models with the genealogical kinship matrix as the covariance structure controlled the type I error rate. Our results replicate some of the previously identified associations with the selected candidate SNPs. In the multivariate analysis, we found a significant association ($p < 0.001$) with SNP rs11200638 in gene *HTRA1* involving the AMD and the logical memory story phenotypes.
Conclusion: We showed that, in the absence of whole-genome genotype data, using BALSAC genealogical data can adjust for cryptic relatedness in the French-Canadian founder population, which allowed us to find evidence of a multivariate association involving AMD and cognitive phenotypes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4047 Accurate Estimation of Genetic Admixture Proportions Via Haplotype Modeling

Authors:

S. Ko, E. Sobel, H. Zhou, K. Lange; Univ. of California, Los Angeles, Los Angeles, CA

Estimating admixture is essential for creating personal genealogies, studying human history, and conducting genome-wide association studies (GWAS). There are many computer programs available for determining the admixture proportions of individuals. Some employ Bayesian inference on the binomial model (such as STRUCTURE, fastSTRUCTURE, and TeraStructure), while others involve direct optimization of the modeled log-likelihood (like ADMIXTURE and OpenADMIXTURE). Yet, there are also programs that decompose the genotype matrix algebraically (such as ALStructure and SCOPE).

Over time, each of the approaches mentioned above has been scaled up to accommodate one million individuals and one million single nucleotide polymorphisms (SNPs). Although these methods often perform linkage disequilibrium (LD) filtering before analysis, unfortunately, this process loses some information and still retains some SNPs in LD. In this work, we explicitly incorporate haplotypes into ancestry estimation. Our latest program, HaploADMIXTURE, aims to improve ancestry accuracy by grouping nearby SNP pairs and jointly estimating their haplotype frequencies with admixture coefficients. This strategy takes advantage of the rich information present in haplotypes, resulting in improved admixture estimation and better identification of population clusters in real-world datasets.

Our simulations demonstrate superior inference on large datasets. Real data analyses also show better performance in clustering self-identified population labels compared to OpenADMIXTURE, SCOPE, and PCA. The number of populations can be determined using cross-validation or the Akaike information criterion. Both criteria accurately select the number of populations in simulated data and identify reasonable structures in curated real datasets.

By leveraging high-performance computing techniques such as GPUs and multithreading, we are able to run haplotype-based ancestry inference on several large contemporary datasets. For instance, it takes less than two hours to analyze 1000 Genome Project data with 1718 individuals and 1.8 million SNPs using 10 threads. Only SCOPE and OpenADMIXTURE yield shorter computing times, ignoring, of course, the extra information present in haplotypes.

Additionally, we consider unsupervised ancestry informative marker (AIM) selection through the sparse K-means with feature ranking (SKFR) method implemented in OpenADMIXTURE. Inferred ancestries demonstrate increased stability after AIM selection. In short, attempting to extract extra information from uninformative SNPs is actually counterproductive.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4048 Adapting the AD8 Dementia Screening Interview and the Clinical Dementia Rating (CDR) scale for use in Tongan

Authors:

B. Vaitohi[1], J. P. Tavana[1], R. J. Hansen[1], C. S. L. Pakalani[1], T. D. Packard[1], A. T. Perez[1], S. Polaapau[1], S. F. Funaki[1], F. Matthes[1], J. T. Tschanz[2], J. Kauwe[3], P. Ridge[1]; [1]Brigham Young Univ., Provo, UT, [2]Utah State Univ., Logan, UT, [3]Brigham Young Univ, Provo, UT

Native Hawaiians and Pacific Islanders (NHPI) are the least represented racial group in most Alzheimer's disease (AD) datasets (e.g., in NACC, the National AD Coordinating Center, there are only 36 total NHPI samples out of 50,000 total). Moreover, English language-based neuropsychological evaluations are ineffective for many NHPIs whose first language is not English.

The Clinical Dementia Rating (CDR) scale and the AD8 are robust tools for assessing dementia. The CDR evaluates individuals in six categories: memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. The AD8, derived from the CDR, is a concise screening instrument comprising eight questions designed to quickly determine whether or not an individual has even very mild dementia. However, the tests are only effective for people who speak English with native proficiency. Our objective in this study is to validate both CDR and AD8 in the Tongan language.

We modified and translated the CDR and AD8 into Tongan. We evaluated the accuracy of both the translations and assessments. A bilingual psychologist and expert translator back-translated the Tongan versions of the AD8 and CDR. The back-translated AD8 and CDR were nearly identical to the original versions, demonstrating that our translations to Tongan are accurate.

Next, we validate the Tongan version of the AD8 and CDR tools. We recruited 50 mono- and bilingual Tongans. NACC-certified bilingual examiners conduct the interviews. We are using the NACC neuropsychological test battery to validate our results. We will present our validation results at ASHG; our initial results indicate our Tongan tests are effective.

NHPIs account for 0.08% of NACC participants, despite being the second fastest-growing racial group in the USA, second only to Asian Americans. However, accurately diagnosing AD in NHPIs is imperative to building diverse cohorts and reducing the medical disparities in NHPIs generally and Tongans specifically. Our Tongan partners are eager to participate in ways to improve medical outcomes in their communities.

PB4049 Adjusting genetic confounders lead to detection of causal molecular traits underlying complex phenotypes

Authors:

S. Qian[1], W. Crouse[2], S. Zhao[3], K. Luo[1], M. Stephens[1], X. He[1]; [1]Univ. of Chicago, Chicago, IL, [2]Univ. of Chicago, Apex, NC, [3]Dartmouth Coll., Hanover, NH

While GWAS have identified many loci associated with complex traits, causal genes in these loci often remain unknown. A number of methods have been developed to leverage expression QTL data to nominate candidate genes, including Transcriptome-wide association studies (TWAS), colocalization analysis, and Mendelian Randomization (MR) methods that use cis-eQTLs as instrumental variables. All these methods, however, suffer from various issues, particularly false positive findings. For example, TWAS may find associations in non-causal genes when their eQTLs are shared with nearby causal genes or are in linkage disequilibrium (LD) with nearby causal variants.
The fundamental problem of existing methods is that, when assessing the role of one gene on the phenotype, nearby variants and nearby genetic components of expression can be correlated with the eQTL(s) of the test gene while also affecting the phenotype directly, thus acting as "genetic confounders". This motivates our approach, causal TWAS (cTWAS), which jointly models the effects of all nearby gene expression and nearby variants, which controls for potential genetic confounders. To make the model identifiable, we use a Bayesian variable selection strategy that learns parameters from genome-wide data.
In simulation, cTWAS produced calibrated false positive (FP) rates while existing methods all suffered from high FP rates. We applied cTWAS to GWAS summary statistics of several commonly studied traits, such as low density lipoprotein (LDL) cholesterol and Systolic blood pressure using eQTL data from GTEx. Genes identified by cTWAS are enriched with known risk genes, as well as relevant gene sets, and include novel genes and pathways, e.g. activin receptor signaling in LDL.
We have also extended cTWAS to perform joint analysis of multiple types of molecular QTLs and multi-tissue eQTLs. This extension greatly improves the power of detecting putative causal genes. By using both eQTL and splicing QTL (sQTL) data from liver in the analysis of LDL, we double the number of genes found, compared with using eQTL alone. In the case of multi-tissue eQTL analysis, by adding adipose as a secondary tissue to liver, the number of candidate genes of LDL increased by 50%, compared to using liver eQTL alone. These results thus demonstrate the great potential of gene discovery using the extended cTWAS.
In conclusion, cTWAS solves a fundamental challenge of integrative QTL-GWAS analysis, greatly reducing false positives. It also provides a framework for incorporating multi-tissue and multi-molecular traits data. cTWAS is available in easy-to-use R package.

PB4050 Aggregated best subset selection using summary statistics for polygenic risk prediction.

Authors:

T. Chen[1], H. Zhang[2], X. Lin[1], R. Mazumder[3]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Natl. Cancer Inst., Cambridge, MA, [3]Massachusetts Inst. of Technology, Cambridge, MA

Background: Polygenic risk scores (PRS) enhance population risk stratification and advance personalized medicine, with wide ranging applications from cancer to psychiatric disorders. However, existing methods face a tradeoff between predictive power and computational efficiency.
Method: We introduce ALL-Sum, an innovative approach that combines rapid L0Learn-based optimization, known for selecting sparse models, with an aggregation step to improve PRS prediction across varying penalty parameters. By combining estimates from multiple parameterizations, we can efficiently construct a highly accurate PRS.
Results: In extensive large-scale simulations with diverse polygenicity and genome-wide association studies (GWAS) sample sizes, ALL-Sum consistently outperforms popular alternative PRS methods, with up to 10% improvement in out-of-sample prediction accuracy. Our method further shows tremendous efficiency gains in runtime and memory usage compared to Bayesian computation. We further compare all methods on 27 published GWAS summary statistics for 11 complex traits from 9 reputable data sources, such as the Breast Cancer Association Consortium and Global Lipids Genetics Consortium, evaluated using individual-level data from the UK Biobank. In our analysis of published GWAS data, ALL-Sum typically achieves the highest or second-highest prediction accuracy, with particularly noticeable performance gains using GWAS with larger sample sizes.
Conclusion: With better prediction, faster computation, and easier implementation, ALL-Sum stands as a promising clinic tool and a foundation for future developments in PRS methodology. We provide ALL-Sum as a user-friendly command-line software with pre-computed reference data for streamlined user-end analysis.

PB4051 Allelic series-based analyses of rare variants are enhanced by sequence models.

Authors:

K. Fletez-Brant, T. Bhangale; Genentech, Inc, South San Francisco, CA

Genome-wide association studies on common variants have yielded thousands of associations providing novel insights into biological processes driving common diseases. By contrast, despite large-scale sequencing-based datasets enabling gene-level rare variant (RV) aggregation based analyses, RV studies have not been as successful. Two major challenges in RV analyses are (i) determining which variants in a gene actually affect the phenotype i.e. large proportion of variants do not directly impact phenotypes and (ii) determining the effect size of causal variants. Recent advances can potentially assist in addressing these: (i). applications of deep-learning models for variant effect prediction [e.g. EVE, ESM1b] substantially outperform traditional approaches, and may help identify relevant rare variants in a gene (ii). application of allelic-series models to variants in a gene can outperform traditional approaches for RV-aggregation analyses. We propose a Bayesian latent variable model that (i) assigns a posterior inclusion probability (PIP) to each variant and (ii) estimates an average effect of all variants tested. We leverage variant effect predictions from a recent protein sequence model, ESM1b, as prior information on variant PIP. Our test of average effect is implicitly a test on the presence of an allelic series, where the variant effect on the phenotype is a function of the prediction from ESM1b. We operationalize this model by extending the method of Logsdon et al, and deploy on all rare (MAF < 1%) protein coding variants genome-wide in cohorts of Parkinson's disease (PD) patients from both 23andMe and the UK Biobank. We recover the known relationship between rs76763715 (a rare coding variant in GBA; PIP = 91%) and PD, as well as the known lack of relationship to rs75548401 (also in GBA; PIP = 39%). We find the average variant effect in GBA to be an odds ratio (OR) of 13.9, with 4 variants with PIP > 0.6. Additionally, we find an association with POU3F3 (OR = 12.4), through a deletion at chr2:104856391 (PIP = 84%); POU3F3 has previously been described to have a role in PD pathogenesis via its function in autophagic-lysosomal system. Our approach accommodates multiple sources of prior information, and can be extended to include gene level features such as constraint scores (e.g. pLI) that affect the power to detect gene associations or variant level features such as MAF or protein structure based spatial information from Alphafold2 predictions. Through the integration of machine learning predictions into rare variant analysis, this work meaningfully extends our ability to interrogate rare coding variation to both effect size estimation and variant inclusion.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4052 Alzheimer's disease and herpes simplex virus type 1 - gene-viral interactions

Authors:

K. Lopatko Lindman[1], B. Weidung[2], J. Olsson[1], S. Eriksson[1], G. Hallmans[1], F. Elgh[1], H. Lövheim[1]; [1]Umeå Univ., Umeå, Sweden, [2]Uppsala Univ., Uppsala, Sweden

Background: Alzheimer’s disease (AD) risk is influenced by a combination of genetic and environmental factors. Herpes simplex virus type 1 (HSV-1), a virus capable of infecting the central nervous system, represent an environmental factor that has been implicated in certain forms of AD and especially in individuals carrying the APOE4 allele [1] Here, we aimed to explore the interactions between genes and HSV-1 in the context of AD. To achieve this, we created a polygenic risk score (PRS) for AD and evaluated its association with HSV-1 in relation to AD risk. Methods: PRS quantifies the aggregate risk of genetic variants. This approach can reveal interactions with environmental exposures such as HSV-1, by linking the environmental exposure to genetic predisposition of disease severity or susceptibility. The AD PRS was calculated as the sum of effect alleles weighted by their log odds, using summary statistics from a genome-wide association study of AD [2]. In the case-control sample, the participants underwent serological testing for anti-HSV-1 IgG. Subjects were classified into genetic AD risk tertiles: low (lowest score, 1/3), intermediate (middle score, 1/3) and high (highest score, 1/3) based on their PRS. All analyses were adjusted for population structure by inclusion of the first five principal components.Results: A total of 326 cases and 1022 sex- and age-matched controls passed quality control. The mean age at the time of the event was 71 years, and 74 % of the participants were female. On average, the blood samples were drawn 9.7 years before the AD diagnosis date. The odds ratio (OR) for AD was 1.8 per 1 standard deviation increase in the PRS (95 % confidence interval [CI] 1.54 - 2.01, $p < 0.001$). We found that anti-HSV-1 IgG was associated with an increased risk of AD (OR 2.3 per HSV-1 seropositivity, 95 % CI 1.47 - 3.52, $p < 0.001$). This association was stronger in individuals having high and intermediate genetic AD risk (OR 2.8, 95 % 1.15-6.73, $p = 0.023$ and OR 3.2, 95 % CI 1.04-9.70, $p = 0.042$), compared to those with low genetic AD risk (OR 1.7, 95 % CI 0.28-10.75, $p = 0.55$). No interaction was observed between the PRS and anti-HSV-1 IgG seropositivity ($p = 0.30$). Conclusion: The association between HSV-1 infection and AD appears to be greater in individuals with intermediate and high genetic AD risk, indicating that HSV-1 infection might play a role in those with a genetic predisposition to AD.1. Linard, et al., Interaction between APOE4 and herpes simplex virus type 1 in Alzheimer's disease. Alzheimers Dement, 2020. 16(1): p. 200-208.2. Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4053 An accurate machine learning model trained on clinically curated variants to predict the variant pathogenicity score

Authors:

R. Gupta; MedGenome Labs Ltd., Bangalore, India

Whole genome and exome sequencing data generates several thousands of variants including many rare variants. Identifying and prioritizing the disease-causing variants for diagnosis of rare disorders in clinical labs is a manual and time-consuming process. Ranking the rare variants based on pathogenicity will help in speeding up the report generation and improve the accuracy and consistency of clinical reporting. Models trained on variants obtained from public databases such as ClinVar have not been so successful because of the presence of noisy data. Recent studies have shown that the model built on variants identified from clinical labs in patients would perform better.
On a similar concept we have developed a machine learning model trained on manually curated and reviewed disease-causing variants from a cohort of 100,000 clinical samples. This covers more than 4,000 different symptoms and several diseases. We have also devised a unique approach to select a list of benign variants which are rare in nature and share similar variant type and genes with that of pathogenic variants to avoid feature bias and overfitting. We studied more than 200 variant features derived from sequence, population database frequencies, in-silico predictions, disease databases and other features. After performing the feature selection and ranking, we identified 33 features that suited best for scoring of the variants.
We built a random forest model and trained on 44,978 variants (9,009 disease-causing, 35,969 benign) covering 10,000 genes. Our model obtained F1 and sensitivity value of 0.98 on 15,000 unseen variants that covers 6,000 genes. We further evaluated our model on 166 cases which were diagnosed and resolved through manual interpretation in our laboratory. These cases were obtained from different diseases including metabolic (28%), nervous system diseases (22%), hereditary cancer (16%), development disorders (11%). Our model ranked the manually selected variant in Top20 for 89% of cases and after applying the patient phenotype filtering our model ranked the prioritized variants in Top20 for 95% of cases. We also compared the VaRTK model on a recent study published variants and could classify 98% of the pathogenic variant correctly. We believe that the VaRTK model will help the clinical laboratories in prioritizing variants quickly and accurately.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4054 An association study on adolescent cases of BNT162b2 vaccine-induced myocarditis in Hong Kong.

Authors:

L. She, H-W. Tsang, S. Tsao, X. Yang, G. Chua, S. Chan, W. Yang, M. Kwan, P. Ip; The Univ. of Hong Kong, Hong Kong, Hong Kong

Vaccine-induced myocarditis is a rare complication of BNT162b2 vaccine and is more commonly reported in male adolescents in Hong Kong [1]. Although the clinical presentation of mRNA vaccine-induced myocarditis was well documented [2-5], its underlying mechanism and whether genetics played a role remained unclear. In this study, we performed an association analysis on a cohort of 43 Hong Kong Chinese diagnosed with vaccine-induced acute myocarditis after administration of BNT162b2 mRNA vaccine (Fosun Pharma-BioNTech; BNT162b2 vaccine) from July 2021 to June 2022 and 481 controls. Whole-genome sequencing data was acquired for all individuals and a clustering approach (ClusterAnalyzer) was developed in-house to extract genomic regions with significant association signals that are also supported by multiple SNPs in linkage disequilibrium, to more or less overcome the false positive issue caused by the small sample size. We provided summary statistics of SNPs in 2,156 selected regions based on the strength of the association signals and analysis by ClusterAnalyzer. We illustrated in 3 regions (chr4:81,892,037-81,965,272; chr4:86,019,317-86,219,034; chr11:40473809-40585162) that true signals are enriched with reduced noise in the selected regions, as variants associated with COVID severity were found in each of the 3 regions (rs56038305, rs2575679 and rs1001952 respectively). Our results provide useful information on elucidating the potential genetic contribution on mRNA vaccine-induced myocarditis and valuable data for future replications.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4055 An atlas of gene regulatory variants mediating the association between brain morphology and obesity.

Authors:

D. Fusco[1], L. Troiani[1], M. Noè[1], F. Pizzagalli[1], D. Marnetto[2], P. Provero[1]; [1]Università di Torino, Torino, Italy, [2]Univ. of Turin, Torino, Italy

Given the support for a role of the central nervous system in susceptibility to obesity, several studies examined the correlation between obesity, often quantified as body mass index (BMI) and brain structural features. While there is evidence that increased BMI is associated with reduced gray matter volume, the related neurobiological mechanisms have yet to be characterized. In addition it is not clear what are the specific brain regions whose morphology is associated with BMI, whether such associations subtend causal relationships, and which are the genes mediating their genetic relationships at the molecular level.

We analyzed genome wide association studies (GWAS) data on structural brain magnetic resonance imaging (sMRI) from 33 thousands UK BioBank samples. By using LD score regression we estimated the genetic correlation with BMI of 437 sMRI-derived traits, including multiple cortical measurements for Desikan-Killiany parcellations and subcortical volumes and intensities.

We then performed three-way colocalization analysis for BMI- and sMRI-associated loci, adding as a third trait the expression in brain tissues of the genes located near the relevant locus, based on the GTEx dataset.

Overall, the genetic correlation analysis showed significant, typically negative correlations between brain sMRI phenotypes (such as those related to cortical area and volume, and subcortical volume) and BMI, in agreement with previous studies, suggesting that genetic factors associated with an increased BMI are also related to reduced volume of brain structures.

Moreover, we identified several loci for which the SNP putatively causal for both sMRI traits and BMI is also affecting the expression of a gene in brain tissues, thus providing a potential molecular mechanism that explains the common genetic basis of the two traits and might suggest new preventive and therapeutic strategies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4056 An augmented reference panel with 22,134 haplotypes enhances GWAS analysis and the rare variants detecting power of hip bone mass density.

Authors:

M. Yang, J. ZHONG, H. Zheng; Westlake Univ., HangZhou, China

The Westlake BioBank for Chinese (WBBC) cohort has established a population-specific reference panel and an online imputation server (https://wbbc.westlake.edu.cn/), promising significant improvements in imputation performance for the Chinese population. In an effort to enhance genome-wide association study (GWAS) analyses and the detection of rare variants, we integrated the WGS data from multiple sources, including SG10K project (13.7×, 4,563 samples), GenomeAsia (GAsP) project (36×, 1,031 samples), WBBC pilot (13.9×, 4,480 samples), and 1000 Genomes Project (1KGP) phase 3 (30×, 993 East and South Asian from 3,202 samples) to create a combined panel, boasting the highest diversity of populations within South and East Asia. The no-singleton version of this combined panel includes 22,134 haplotypes and 80,367,720 variants. For imputation in Human Genome Diversity Project (HGDP) populations, the combined reference panel consistently exhibited the highest average non-reference (NR) allele concordance rate for East Asian populations compared with 1KGP panel. When imputing the Chinese population data (5,679 samples), the combined reference panel successfully imputed a total of 7,976,019 well-imputed sites ($R^2 > 0.8$), surpassing the SG10K panel, which ranks second with 6,725,695 sites. Across nine MAF bins for rare and low-frequency variants, the combined reference panel demonstrates the highest number of well-imputed variants compared with SG10K, WBBC, 1KG and GAsP panel. Moreover, within 12,923 Asian GWAS catalog association sites, the combined panel exhibits the highest number of well-imputed variants, amounting to 4,424. Its main advantage over the other four panels lies in the imputation of low-frequency and rare variants, encompassing a total of 356 low-frequency variants and 133 rare variants. Finally, we applied two hip bone mineral density (BMD) cohorts from the WBBC to the augmented reference panel to conduct a discovery (n = 2,322) and replication (n = 3,037) association study. In downstream analysis, including meta-analysis and fine-mapping, we identified three BMD-related genome wide significant (GWS [$P < 5 \times 10^{-8}$]) signals, which were annotated to one novel gene *SNTG1* (rs60600379, MAF = 0.009: $P_{discovery} = 1.15 \times 10^{-3}$, $P_{replication} = 2.26 \times 10^{-6}$, $P_{meta} = 4.77 \times 10^{-8}$) and two known genes (*FMN2* and *SOX4*). In summary, we generated a reference panel for the South and East Asian populations, significantly improving the imputation performance for rare and low-frequency variants, thereby enhancing the utility and precision of GWAS analysis.

PB4057 An ensemble machine learning method for phenotypic refinement from binary symptom data.

Authors:

R. Danning, X. Lin; Harvard T.H. Chan Sch Pub Hlth, Boston, MA

The clinical heterogeneity of complex neuropsychiatric disorders presents a significant challenge for gene discovery. In the absence of consistent biomarkers, many neuropsychiatric conditions are diagnosed based on broad symptomatic criteria, leading to noisy phenotype definitions. The ability to refine these phenotypes is thus critical to the unmasking of genetic associations. Autism spectrum disorder is one such potentially noisy phenotype; despite evidence of heritability, its genetic etiology remains largely unknown. Given the diversity of behavioral presentations of autism, it is possible that the autism phenotype comprises several latent subtypes, each of which may have a distinct genetic profile. However, statistical methods for phenotypic subtype detection in autism and other complex neuropsychiatric conditions are hindered by the prevalence of binary symptom data representing the presence or absence of a specific behavior. Existing methods for clustering binary data have various drawbacks, including the necessity of pre-specifying the number of subtypes, bias in the presence of extraneous symptoms, and the assumption that there is no correlation of responses within an individual. We have developed an ensemble machine learning method for detecting subtypes from binary symptom data that does not require prespecifying the number of subtypes, is robust to the inclusion of extraneous symptoms, and is likewise robust to the violation of conditional independence of symptoms within individuals. The method ensembles latent class analysis, a model-based clustering method; principal components analysis, a mathematical dimensionality reduction algorithm; and UMAP, a cutting-edge model-free dimensionality reduction algorithm. In simulation studies, this method outperforms gold-standard techniques across a variety of scenarios, including in the presence of local symptom correlation structure within individuals, as well as when extraneous symptoms that are unrelated to the phenotype are included in analysis. We apply this method to the parent-report Social Communication Questionnaire data from the Simons Foundation's SPARK study of autistic individuals and find three distinct subtypes of communication skills and social functioning. We propose methods for synthesizing subtypes across the various diagnostic dimensions of complex disorders, address the potential impact of phenotype refinement on gene discovery for autism, and discuss the broader implications for psychiatric genetics and precision medicine.

PB4058 An individualized Bayesian inference framework for detecting genomic variantsandtheir interactions for complex diseases.

Authors:

J. Liu[1], M. Rahman[1], C. Cai[2], N. Bo[2], D. McNamara[2], Y. Ding[2], G. F. Cooper[2], X. Lu[2]; [1]Missouri Univ. of Sci. and Technology, Rolla, MO, [2]Univ. of Pittsburgh, Pittsburgh, PA

Population-based genome-wide association studies (GWAS) have been successful in discovering genomic variants associated with diseases, but they may not capture all factors that contribute to disease risk of individual subjects. In addition, it is challenging for GWAS to detect with sufficient power the association of rare or low-frequency genomic variants without a very large sample. As a complement to GWAS, we propose an individualized Bayesian inference (IBI) algorithm that can estimate genomic variants underlying complex traits such as hypertension at the level of an individual (e.g., a patient) and their "patients-like-me" subgroup. By modeling at the individual and their subgroup levels, IBI aims to identify genomic variants that provide a plausible explanation of the phenotype observed in each individual. We applied IBI to the whole-genome genotyping and blood pressure data from the Framingham Heart Study (FHS). Our results support IBI as a promising approach for complementing GWAS, especially in detecting low-frequency genomic variants as well as learning personalized genomic variants of traits and diseases to help advance personalized medicine. To tackle the challenge of understanding the interactions among variants or genes in complex diseases, we further extended IBI to develop an IBI Decision Tree (IBI-DT) learning algorithm, which allows for the detection of variant-variant or gene-gene interactions that act disjunctively or conjunctively to influence a trait of interest. IBI-DT builds subpopulations with distinct genomic heterogeneity using a tree and derives statistics across these subpopulations to reveal the influence of single variants/genes or variant/gene interactions. We applied IBI-DT to the cancer domain by utilizing The Cancer Genome Atlas data across 16 cancer types. The results demonstrate that IBI-DT not only outperforms expression quantitative trait loci (eQTL) analysis in identifying well-known cancer drivers responsible for differential gene expression in cancer patients but also uncovers biologically significant interactions among these cancer drivers. Our results provide support that IBI-DT has the potential to help identify signaling networks underlying cancer and other diseases and could be a valuable tool in advancing precision medicine.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4059 An integrative framework mapping the functional effects of rare noncoding variation in autism spectrum disorder leveraging high-resolution enhancer annotation

Authors:

Y. Zhang[1], J. Tian[2], A. Sun[1], Y. Jin[1], S. R. Shah[1], M. I. Paramo[1], S. Dong[3], L. Yao[1], V. Fangal[1], S. Sanders[3], K. Roeder[2], B. Devlin[4], H. Yu[1]; [1]Cornell Univ., Ithaca, NY, [2]Carnegie Mellon Univ., Pittsburgh, PA, [3]Univ. of California San Francisco, San Francisco, CA, [4]Univ. of Pittsburgh, Pittsburgh, PA

Damaging *de novo* coding variants are found in 10-20% of individuals diagnosed with autism spectrum disorder (ASD), and these variants are assumed to confer substantial liability. Inherited rare coding variation also plays a role, although how much is difficult to determine. It is reasonable to speculate that rare noncoding variants, both *de novo* and inherited, also play some role, although identifying their contribution is challenging due to insufficient functional annotation of the noncoding genome. In this study, we analyzed rare noncoding variants derived from whole-genome sequencing data of a cohort comprising 17,882 individuals, alongside rare coding variations sourced from a cohort of 63,237 individuals. We employed 20,736 high-resolution enhancer elements defined by gene-distal transcription events in neuronal progenitor cells to prioritize functional rare noncoding variants. Subsequently, we linked the prioritized noncoding variants to the target genes and developed a gene-based statistical model to integrate coding and noncoding signals. This model offers insight into the relative effect sizes of rare variants in coding and noncoding regions. In theory it should have better power to identify genes associated with ASD relative to using rare coding variants only, and our analyses support this conjecture. Next, we used an integrative framework that combines gene-specific test statistics, rare coding variation affecting protein-protein interactions (PPIs), as revealed by the presence of damaging *de novo* missense variants on the 3D structural interfaces, and a PPI network to delve further into ASD etiology. This holistic approach aids in enhancing the discovery of ASD genes as well as identifying relevant dysregulated cellular subnetworks. Overall, our study explores the potential of utilizing high-resolution enhancer annotation strategies to prioritize functional rare noncoding variations, and strives for effectively integrating this information with multiple complementary data sources to gain a more comprehensive understanding of ASD.

Hosp. for Children, Boston, MA, [16]Lourie Ctr. for Pediatric Multiple Sclerosis, Stony Brook Children's Hosp., Stony Brook, NY, [17]Dept. of Neurology, Univ. of Utah Sch. of Med., Salt Lake City, UT, [18]Dept. of Pediatrics, Univ. of Utah Sch. of Med., Salt Lake City, UT, [19]Mellen Ctr., Cleveland Clinic, Cleveland, OH, [20]Regional Pediatric MS Ctr., Neurology, Univ. of California, San Francisco, San Francisco, CA

The genetic basis of multiple sclerosis (MS) in adults has been extensively studied and more than 230 susceptibility variants have been identified to date through GWAS; less is known about genetic contributions to MS occurring in children (<18 years, 'pediatric-onset' MS) which comprises ~5% of patients. MS prevalence is higher in regions farther from the equator, supporting the hypothesis that vitamin D exposure has a protective effect on MS risk. Mendelian randomization studies have identified causal associations between lower serum vitamin D and increased risk of MS. Vitamin D is important for many biological processes. After being ingested or absorbed, serum vitamin D is first converted to 25-hydroxyvitamin D [25(OH)D], its more stable form, and then to 1,25-dihydroxy vitamin D [1,25(OH)2D]. Previous studies have established that 25(OH)D signals through the nuclear vitamin D receptor (VDR), a ligand-regulated transcription factor that modulates vitamin D-regulated gene expression. Directly testing for associations between VDR binding and disease phenotypes in large-scale human studies poses many challenges. SNPs associated with genetic variation in VDR binding affinity (VDR binding variants or 'VDR-BVs') have been recently identified using ChIP-exo data from calcitriol-stimulated lymphoblastoid cell lines. We recently studied these VDR-BVs as genetic instrumental variables in adult-onset MS and identified strong evidence for association between several VDR-BVs and MS. The objective of this study was to study adult-onset MS VDR-BVs candidates for a role in pediatric-onset MS. We utilized a multiethnic pediatric cohort comprised of 1,303 pedMS cases and 984 controls from the U.S. Network of Pediatric MS Centers. Genotyping was performed using Illumina Infinium 660K OmniExpress and OmniExpressExome BeadChip arrays and imputed against reference haplotypes from the 1000 Genomes Project Phase 3 using IMPUTE4. After quality control measures, VDR-BVs were excluded if minor allele frequency (MAF) <5%. This resulted in 17 candidate VDR-BVs for analysis. Associations between VDR-BVs and pediatric-onset MS were tested using logistic regression in *PLINK* and adjusted for the first six genetic principal components. In the full multiethnic cohort, three VDR-BVs were associated with pediatric-onset MS at $p<0.05$: rs10995246 (OR: 0.86, 95% CI: 0.75-0.99), rs11729497 (OR: 1.15, 95% CI: 1.01-1.30), and rs2531804 (OR: 1.25, 95% CI: 1.10-1.42). rs2531804 is located on chromosome 6 and is upstream of *TEC*. These findings provide further evidence that VDR-BVs associated with adult-onset MS are also implicated in pediatric-onset MS.

Hlth., Madison, WI, [16]Univ. of Wisconsin, Madison, WI, [17]Johns Hopkins Univ. Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [18]Rush Univ., Chicago, IL, [19]Lab. of Behavioral NeuroSci. Natl. Inst. on Aging NIH, Baltimore, MD, [20]Harvard Med. Sch., Boston, MA

Apolipoprotein E4 (*APOE*-ε4) is the most influential common genetic risk factor for late-onset Alzheimer's disease (AD). However, the impact of *APOE*-ε4 carrier status on the genetic architecture of cognitive decline remains unclear. Here, we sought to uncover genetic associations with cognitive decline via stratified genome wide-association analyses (GWAS), thus exploring differences in *APOE*-ε4 carriers and non-carriers, as well as across two racial/ethnic groups, non-Hispanic Whites (NHW) and non-Hispanic Blacks (NHB). We leveraged a harmonized cognitive dataset from 10 aging and AD cohorts, encompassing a large multi-ancestry population (Ntotal= 36,483, NHW_ε4pos = 12,047, NHW_ε4neg = 20,253, NHB_ε4pos = 1,810, NHB_ ε4neg = 2,373). The mean age at baseline was 73 years, with 58% females and 65% cognitively normal. Adjusting for age, sex, and the first 5 principal components of genetic ancestry, GWAS were performed for each neuropsychological domain (memory, executive function, and language) at baseline and for longitudinal decline. Each GWAS was conducted in a cohort-specific manner within each ancestry group by *APOE*-ε4 status, followed by fixed-effect meta-analysis. We saw 14 novel associations among E4 carriers including variants near *GRIN3A* and *NME7* genes among NHW and variants near the *WDPCP* gene among NHB participants. In contrast, we saw 10 associations among E4 non-carriers including variants near *LOC101927668* gene in NHW and *GALNT7* genes among NHB. Interestingly, eQTL evidence for the association on chromosome 9 among NHW E4 carriers/non-carriers implicates *GRIN3A* gene. Sensitivity analyses, excluding comorbidities and subsetting individuals aged 60 and above, were performed to confirm our findings. These preliminary findings have potential implications for precision medicine approaches targeting cognitive impairment and AD prevention. Future work will extend these preliminary findings to incorporate cross-ancestry analysis, gene-based tests, and genetic correlation.

PB4062 † Application of network-based heterogeneity clustering for investigation of genotype-phenotype correlations in BioMe BioBank

Authors:

M. Kars, Y. Wu, C. Bayrak, B. Gelb, Y. Itan; Icahn Sch. of Med. at Mount Sinai, New York, NY

The genetic basis for many human diseases often exhibits heterogeneity, resulting in different genes in the same or related biological pathways being responsible for the same or similar phenotypes. Conventional gene burden methods, which are used to identify genetic signals in case-control studies, lack the power to detect these signals in the presence of genetic heterogeneity and small cohorts. To address this issue, we have previously developed a computational method called network-based heterogeneity clustering (NHC) that can detect physiological homogeneity within genetically heterogeneous cohorts with small sample sizes, and demonstrated that our method can effectively converge genes that are biologically related on a protein-protein interaction network and accurately identify gene clusters with potentially deleterious rare variants. Here, we utilized NHC to analyze three disease cohorts from the Mount Sinai BioMe BioBank, where previous gene burden approaches were ineffective in identifying candidate genes. The cohorts comprised 50 individuals with lactation disorders (agalactia or hypogalactia) and 500 controls, 71 patients with severe COVID-19 and 390 controls with mild-moderate disease, and 431 children with food allergy and 2,155 controls, which was also analyzed in a population-specific manner using data from individuals of Ashkenazi Jewish (AJ, n = 826) and non-AJ European (n = 1,760) ancestries. NHC analysis in the lactation disorders cohort identified gene clusters involved in intra-golgi vesicle transport, mammary stem cell differentiation and proliferation, and trans-differentiation of white adipocytes in the mammary gland during lactation. NHC also uncovered two gene clusters potentially related to increased risk for severe COVID-19, including genes that preserve endothelial barrier function and genes involved in snRNA processing, which have previously been implicated in susceptibility to HSV-1 infection. Furthermore, NHC facilitated the identification of candidate gene clusters in the food allergy cohort with population-specific signatures, including genes proposed to be associated with allergic asthma and food allergies, such as *DYNC1H1*, toll-like receptor encoding genes, genes involved in IL-17 signaling and cell adhesion, and genes encoding mitochondrial ribosomal proteins. These findings indicate that NHC is a useful approach for uncovering candidate genes in disease groups with genetic heterogeneity, especially in smaller population-specific subgroups, outperforming traditional case-control studies for such cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4063 Applying local genetic covariance of functional annotations to increase the power of multi-trait association test to identify pleiotropic loci

Authors:

W. Choi[1], C. Lee[2], B. Han[3]; [1]Seoul Natl. Univ. Graduate Sch., SEOUL, Korea, Republic of, [2]Columbia Univ. Med. Ctr., Fort Lee, NJ, [3]Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

The identification of pleiotropic loci is important because the interpretation of them can provide us with valuable information to understand the common etiology of diseases or complex traits. Our previous method, PLEIO, effectively identifies pleiotropic loci by accounting for genetic architecture information, such as genetic covariance and heritability. However, PLEIO utilizes global genetic architecture information. If the genetic covariance differs by genomic region, accounting for the region-specific genetic covariance may improve the results. It is well known that some sub-genomic regions (a subset of SNPs belonging to an annotation group) may exhibit different genetic covariance compared to the global covariance in terms of direction and magnitude. If this is the case, applying the sub-genomic regional genetic covariance to PLEIO can increase the power. To verify how much the power can increase theoretically, we first simulated extreme situations where sub-genomic regions have significantly different genetic covariances among themselves. In these simulations, as expected, we observed a clear improvement in the performance of Stratified-PLEIO (PLEIO applied to the SNPs in the annotation region with the annotation-specific genetic covariance). For example, given 3 disjoint regions with largely disparate local correlations, S-PLEIO identified 423 significant signals out of 3,000 causal markers while PLEIO identified no signals at all. Next, we wanted to examine whether S-PLEIO will outperform PLEIO in real datasets, similar to the simulations. We used the real summary data of the 18 cardiovascular disease phenotypes and 33 annotations from the baseline-LD model(v2.2, 1000 Genome phase3) of S-LDSC. For simplicity, we focused on each annotation separately. For each annotation, we partitioned the whole genome (global region) into the annotation region and non-annotation region (the complement of the annotation region). We compared the genetic covariances of the annotation and non-annotation regions and chose the top 3 annotations that showed the most significant difference. For each of the top 3 annotations, we ran PLEIO and S-PLEIO and compared the results of the two methods, limiting our scope to the SNPs belonging to the annotation. Contrary to the expectation, S-PLEIO did not outperform PLEIO even for these top 3 annotations. The majority of the association p-values obtained with S-PLEIO were less significant than those obtained with PLEIO across all 3 annotations. Therefore, we suspect that the difference in true genetic covariance among annotations may not be large enough to confer higher performance of S-PLEIO for association mapping.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4064 Artificial Intelligence and Geographic Analysis of Clinical Genetic Data in California's Central Valley

Authors:

J. Woods; Valley Children's Hosp., Madera, CA

Introduction
Clinical genetic data is often unstructured and rarely applied outside of the context of an individual patient encounter. Therefore, there is a need for the development of data science methodologies to ascertain and analyze this real-world data. Comprehensive utilization of clinical genomic data can be leveraged to drive clinical decision-making and precision medicine at minimal cost to healthcare organizations.
Methods
Germline variant allele data were obtained over a five-year period from all genetic testing sent to reference laboratories from Valley Children's Hospital, which has a catchment area of 1.4 million patients. Data were obtained from integrated testing results in the electronic health record as well as directly from testing laboratories, as available. The variants were automatically reinterpreted utilizing the Franklin© Artificial Intelligence (AI) to flag cases for reinterpretation/reconsideration to drive appropriate follow-up. Genetic disorder counts were inferred from the data by sorting variants by gene, inheritance pattern, pathogenicity interpretation, sex, and zygosity. Utilizing PowerBI©, the variant data were matched to patient demographic data in the Electronic Health Record (EHR) to generate a data table and map variants as a choropleth at the resolution of Zip Code Tabulation Area (ZCTA).
Results
Three-thousand-sixty-five variants were identified and 98% were matched to patients in the EHR. The Franklin© AI changed the interpretation for 27% of variants. The top half of variant reinterpretations were Variant of Uncertain Significance (VUS) > Likely Benign (114 or 21.7%), VUS > Likely Pathogenic (110 or 20.9%) and Pathogenic > Likely Pathogenic (98 or 18.6%). A total of 723 genetic disorders were identified with 176 structural variant disorders, 543 monogenic disorders, three methylation disorders and one repeat expansion disorder. Mapping of variants demonstrated geographic hot-spots for pathogenic genetic variation such as *PEX6*-associated Zellweger Spectrum Disorder. Seven patients were identified with Bardet-Biedl syndrome and seven patients with Rett syndrome who were all amenable to newly FDA-approved therapeutics. Outreach programs were developed for underserved communities, tailored to genetic disease most prevalent locally, both to educate the patient and provider population.
Discussion
Utilizing common software, we developed a database and Exploratory Data Analysis (EDA) methodology enabling us to systematically reinterpret variants, estimate variant prevalence, identify patients amenable to new treatments, and localize geographies enriched for pathogenic variants.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4065 Assembling unified disease trajectories from sparse longitudinal molecular data.

Authors:

R. Thompson, G. E. Hoffman, D. M. Del Valle, The Mount Sinai COVID-19 Biobank Team, S. Kim-schulze, R. Sebra, M. Merad, S. Gnjatic, S. E. Eric, A. W. Charney, N. D. Beckmann; Icahn Sch. of Med. at Mount Sinai, New York, NY

Modeling the natural history of disease from onset to resolution is an essential prerequisite to understanding disease and optimizing interventions at actionable points in the disease course. Densely sampled longitudinal cohorts are ideal for this but rarely (if ever) achievable in practice given limited access to relevant tissues, long timespans of chronic diseases, high costs, and ethical issues. Cross-sectional cohorts, which are not constrained by longitudinal sampling burdens, lack temporal information. A growing number of research cohorts are hybrid in nature, with sparse longitudinal, high-dimensional data being generated. The short, disjointed sampling periods across the individual disease courses in these cohorts are not directly comparable due to the lack of a common time axis, limiting the ability of existing methods to accurately model natural disease histories. With more sparse longitudinal data sets being generated all the time, there is thus an urgent need for new methods to analyze these data. We devised a basic statistical framework to test the ability of a method to reproduce the correct ordering of samples within each individual in a cohort and used this framework to implement a proof of concept to show the feasibility and accuracy of this approach in a large cohort of patients hospitalized with COVID-19 with sparse longitudinal whole blood molecular profiling data. In the RNA-seq data, we assembled a common time axis (analogous to assembly of a contig from individual DNA sequence reads) using an elastic net and showed that this time axis correctly ordered 73.6% of within-patient sample pairs in 5-fold nested cross-validation, significantly more than the 50% expected by chance. Predicting time of COVID-19 symptom onset in a holdout set of patients using this RNA-seq time axis yielded a significant correlation with the patient-reported day of symptom onset ($p = 1.0E-4$). We also assembled a common time axis from Olink data for the same blood samples with a cross-validated correctly ordered fraction of 77.2%. These time axes from two different data modalities were strongly positively correlated ($R^2 = 0.37$, $p=8.9E-92$). Furthermore, the RNA-seq and Olink time axes both showed strong differential expression in the RNA-seq data, with 13241 and 7593 differentially expressed genes (DEGs) respectively (adjusted $p < 0.05$), even when controlling for time since first sample (339 DEGs). Our work demonstrates that reconstructing disease trajectories is indeed feasible in sparse longitudinal data sets and provides a straightforward and widely applicable method for assembling a cross-validated common time axis for any disease or biological context.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4066 † Assessing Risk in Complex Human Disease Using Polyexposure Scores in the Multiethnic Personalized Environmental Gene Study Cohort

Authors:

D. Lloyd[1], F. Akhtari[1], J. House[1], S. Schurman[2], C. Schmitt[1], J. Hall[3], A. Motsinger-Reif[4]; [1]NIEHS, Durham, NC, [2]Natl. Inst on Aging, NIH, Baltimore, MD, [3]niehs, Durham, NC, [4]NIH, Durham, NC

Common complex diseases such as asthma, diabetes and hypertension present enormous burdens on healthcare systems, and more importantly, on patients. Polygenic scores (PGSs) have emerged as reliable predictors of genetic risk of complex diseases, with emerging possibilities for early disease screening and prophylactic recommendations. However, etiologies of complex diseases and individual susceptibility involve both genetic and environmental components. Comparison of the predictive power of these two components of disease risk is important in understanding and recommending personalized prevention and treatment options. Prior research has shown that development of polyexposure scores (PXSs) that consider a wide array of environmental exposures have higher predictive power for type II diabetes. In the current study, we compare the predictive power of PXS and PGS for common complex traits in the Personalized Environment and Genes Study (PEGS). PEGS is a diverse North Carolina based cohort, representing a multiethnic population with an extensive collection of health, genetic and exposure data. We selected a subset of disease phenotypes to study including asthma, migraines, and hypertension. The environmental exposure data in PEGS includes results from three large surveys that ask about an extensive array of occupational, hobby, and lifestyle exposures as well as geospatial exposure estimates such as distance from environmental bads, the Social Vulnerability Index or the Environmental Justice Index from residential history. We developed PXS for each phenotype to compare to published PGSs. We used LASSO regression to select a weighted sum of exposures for each disease phenotype. For asthma, a PXS built using survey exposome data had an AUC of 0.71, while published PGSs AUC results ranged from 0.50 to 0.70 on multi-ancestral populations. For hypertension, our PXS had an AUC of 0.79, compared with published PGSs AUCs ranging from 0.57 to 0.73. For migraines, our PXS exhibited an AUC of 0.73 versus published a PGS AUC of 0.60. These results highlight the potential PXSs have to complement PGSs, allowing for increased disease screening without the increased costs associated with genomic sequencing. Future work in our group will combine both PGSs and PXSs to allow for identification of high-risk individuals for preventative early treatment and recommended lifestyle changes.

PB4068 Bayes factors for linear mixed models in genetic association tests

Authors:

Y. Guan[1], D. Levy[2]; [1]Natl. Heart, Lung, and Blood Inst., Framingham, MA, [2]Framingham Heart Study, NHLBI, Framingham, MA

Using linear mixed models in genetic association tests is now a standard practice to effectively control for population stratification and (cryptic) relatedness. Several software packages are available to compute p-values, but none can compute Bayes factors. Bayes factors have many advantages over p-values as evidence for association. For example, p-values are not directly comparable unless they have the same power, while Bayes factors are comparable because the alternative hypothesis is incorporated in the Bayes factor calculation; Bayes factors penalize SNPs of low minor allele frequencies, due to their relatively small information content, to reduce false positives. In addition, we show that Bayes factors can be computed efficiently for the linear mixed model. We first recasted the linear mixed model as Bayesian linear regression with a special prior, where the random effect is replaced by eigenvectors of the genetic relatedness matrix as nuisance covariates, whose priors for effect sizes are proportional to their respective eigenvalues (by a factor η). We then used the standard normal-inverse-gamma conjugate priors on other parameters, which allows us to compute Bayes factors in a closed form. Instead of specifying prior on η, which determines the (relative) size of the random effect, we seek its MAP (maximum a posterior) estimate (one estimate for each SNP) and plug in Bayes factor calculations. We devised a novel iterative procedure to efficiently estimate η. For a given η, we demonstrate that Bayes factors can be evaluated as efficiently as the p-values for a given η. The cohorts in the Framingham Heart Study (FHS), funded by the National Heart, Lung, and Blood Institute (NHLBI), include many independent three generational pedigrees, nuclear families, trios, duos, and singletons. This is an ideal setting in which to apply linear mixed models to control for relatedness among the participants. We analyze samples with whole genome sequencing data and multi-omics phenotypes through NHLBI's TOPMed program and demonstrate the advantage of the having both Bayes factors and p-values in genetic association tests.

PB4069 Bayesian genome-wide TWAS with reference transcriptomic data of brain and blood tissues identified 93 risk genes for Alzheimer's disease dementia

Authors:

S. Guo, J. Yang; Emory Univ., Atlanta, GA

Background: Transcriptome-wide association study (TWAS) is a powerful tool for identifying novel genes associated with complex diseases whose genetic effects are potentially mediated through transcriptome. TWAS leverages reference genetic and transcriptomic data to estimate genetic effect on expression quantitative traits of target genes sizes (i.e., a broad sense of expression quantitative trait loci, eQTL, effect sizes). Estimated effect sizes will then be taken as variant weights in burden gene-based association test statistics to map risk genes of complex phenotypes using GWAS data. However, existing TWAS of Alzheimer's disease (AD) dementia only considered *cis*-eQTL while neglecting potential *trans*-eQTL. To overcome this limitation, we applied the Bayesian Genome-wide TWAS (BGW-TWAS) method to leverage both *cis*- and *trans*- eQTL of brain and blood tissues to improve mapping risk genes for AD dementia. **Methods:** We first applied BGW-TWAS to the Genotype-Tissue Expression (GTEx) V8 dataset to estimate *cis*- and *trans*- eQTL effect sizes of prefrontal cortex, cortex, and whole blood tissues. Second, estimated eQTL effect sizes were integrated with the summary data of the most recent GWAS of AD dementia to calculate BGW-TWAS (i.e., gene-based association test) p-values of AD dementia per tissue type. Third, we used the omnibus aggregated Cauchy association test (ACAT-O) to combine TWAS *p*-values across three tissues to obtain omnibus TWAS *p*-values per gene. **Results:** We identified 37 genes in prefrontal cortex, 55 in cortex, and 51 in whole blood that were significantly associated with AD dementia. By combining BGW-TWAS *p*-values across these three tissues, we obtained 93 significant risk genes including 29 genes primarily due to *trans*-eQTL and 50 novel genes. With these 93 significant risk genes, we detected 5 functional clusters comprised of both known AD risk genes and novel genes by protein-protein interaction network analysis, and 7 enriched phenotypes by phenotype enrichment analysis. **Conclusion:** In this study, we applied BGW-TWAS and ACAT-O methods to integrate both *cis*- and *trans*- eQTL data of brain and blood tissues with GWAS summary data to identify risk genes of AD dementia. Both known and novel risk genes provide novel insights into the genomic etiology of AD dementia.

PB4070 BayesKAT: A powerful Bayesian framework to detect combined phenotype-associations of genetic variant groups.

Authors:

S. Das Adhikari, Y. Cui, J. Wang; Michigan State Univ., East Lansing, MI

Although GWAS approaches can help to identify individual SNPs that are significantly associated with specific phenotypes, many complex diseases are polygenic and are controlled by multiple genetic variants that are usually non-linearly dependent. These genetic variants are marginally less effective and remain undetected in GWAS analysis. Kernel Based tests (KBT), which evaluate the joint association effects from a group of genetic variants, are therefore critical for complex disease analysis. However, choosing different kernel functions in KBT can significantly influence the power and accuracy, and automatically selecting the optimal kernel is statistically challenging. A few existing methods suffer from inflated type 1 errors, limited scalability, inferior power, or issues of ambiguous conclusions. Here, we present our Bayesian framework, BayesKAT, which overcomes these kernel specification issues by selecting the optimum kernel adaptively from the dataset while testing genetic associations simultaneously. Furthermore, BayesKAT implements a scalable computational strategy to boost its applicability, especially for high-dimensional cases where other methods become less effective. Based on a series of performance comparisons using both simulated and real large-scale genetics data, BayesKAT outperforms the available methods in detecting complex associations and controlling type I errors simultaneously, leading to new insights into the genetic basis of complex diseases.

PB4071 Block LASSO for the genome: speeding up the training of polygenic scores in the age of whole genomes and costly computation

Authors:

T. Raben[1], L. Lello[2,1], E. Widen[2,1], S. Hsu[1,2]; [1]Michigan State Univ., East Lansing, MI, [2]Genomic Prediction, Inc., North Brunswick Township, NJ

We develop the "block" LASSO (*blockLASSO*) to generate polygenic scores (PGS). PGS generated with the traditional LASSO use the entire autosome/genome. The L1 penalty in the regression enforces sparsity by minimizing the inclusion of highly correlated SNPs. LASSO based PGS methods have consistently performed amongst the best methods for generating single-ancestry PGS with results validated out of sample, within families, and in longitudinal studies.

However, LASSO based methods are historically, computationally intensive. Genetic databases have typically used array sequencing and recruited upwards of a million participants. Genetic matrices are typically stored as memory mapped instances, but loading a million SNPs for a million participants can take ~8TB of memory. Running a LASSO algorithm requires holding in memory at least two matrices this size. This requirement is so large that even most large high performance computing clusters cannot perform these calculations. To circumvent this issue, most analyses use subsets: e.g., taking a representative sample of participants and filtering SNPs via pruning and thresholding. High end LASSO training uses ~500GB of memory (e.g., ~400k samples and ~50k SNPs) and takes 12-24 hours to compute.

Fortunately, the correlation structure of the human genome is largely block diagonal, that is, SNPs are generally only correlated with other SNPs on the same chromosome (and conservatively within a few million base pairs). We take advantage of this and perform LASSO based regression on subsets of sequencing data and stitch them back together. The main challenge is developing a scheme to find relative normalizations between segments (e.g., the BASIL algorithm by Qian et. al.). We show that simple regression methods can find relative weights that stitch together sub-LASSOs which then match or outperform traditional LASSO PGS as judged by AUC (area under receiver operator curve) and correlation. For example, an asthma PGS, for SNPs alone, leads to an AUC ~0.615 which is a 7% increase from traditional LASSO. We show that the example job above (~400k participants and 50k SNPs) can run in <10 minutes and use ~15 GB of memory using *blockLASSO*. Expanding ten-fold to ~500k SNPs takes 24-48 hours and uses ~150 GB of memory.

Ctr., Atlanta, GA, [18]Vanderbilt Univ. Med. Ctr., Brentwood, TN

Diabetic retinopathy (DR) is a highly prevalent microvascular complication of diabetes mellitus and is associated with vision loss. High blood pressure and impaired kidney function often co-occur with DR. Prior epidemiological studies identified hypertension and impaired kidney function as strong risk factors for DR, but it is unclear if these are predictors or have an actual causal role. We used two-sample Mendelian randomization (MR) to assess if BP traits (systolic blood pressure (SBP), diastolic blood pressure (DBP), pulse pressure (PP)) or kidney function traits (estimated glomerular filtration rate (eGFR), urine albumin-creatinine ratio (UACR), blood urea nitrogen (BUN)) are causally associated with risk of DR in European-ancestry individuals. We used statistically significant (P-value $<5x10^{-8}$) uncorrelated (R^2 <0.01) single nucleotide variants (SNVs) from published GWAS as genetic instruments for blood pressure traits (N-SNVs: 213 for SBP, 270 for DBP, and 225 for PP) and kidney-function traits (N-SNVs: 310 for eGFR, 57 for UACR, and 61 for BUN) as exposures, individually. Summary statistics for the same SNVs for DR were generated with logistic regression model in 38,944 DR cases and 69,416 controls from the Million Veteran Program while adjusting for age, sex, duration of diabetes, HbA1c, and ten genetic principal components. We used inverse variance weighted (IVW) random-effects analysis as the primary analysis, followed by MR-Egger, MR-mode, MR-weighted median, and multivariable MR as sensitivity analyses. As a positive control, we performed MR analyses with type 2 diabetes mellitus (T2DM) as exposure for DR. Genetically predicted blood pressure traits were not associated with a higher risk of DR (SBP: OR, 1.01; 95% CI, 1.00-1.01; *P* = 0.089; DBP: OR, 1.00; 95% CI, 0.99-1.01; *P* = 0.47; PP: OR, 1.00; 95% CI, 1.00-1.01; *P* = 0.359) in IVW analysis. Similarly, there was no significant association for genetically determined eGFR (OR, 1.26; 95% CI, 0.76-2.07; *P* = 0.37), UACR (OR, 1.09; 95% CI, 0.90-1.32; *P* = 0.379), or BUN (OR, 0.97; 95% CI, 0.61-1.53; *P* = 0.89) with increased risk of DR. These findings were supported by sensitivity analysis. Moreover, BP and kidney function traits were not associated with proliferative DR. In contrast, T2DM exposure as a positive control, on the other hand, was significantly associated with a higher risk of DR (OR, 1.21; 95% CI, 1.16-1.27; *P* < 0.001). Evidence guided by instrumental genetic variables shows T2DM is causally associated with DR. However, contrary to existing epidemiologic studies, the evidence does not support a role for elevated blood pressure or impaired kidney function as causal factors for DR.

GRAD. SCHOOL OF MED., Suita, Japan, [6]Graduate Sch. of Med., the Univ. of Tokyo, Bunkyo-ku, Japan, [7]The Univ. of Tokyo, Minato-ku, Japan, [8]Ctr. for Advanced Intelligence Project, RIKEN, Tokyo, Japan, [9]Toranomon Hosp., Tokyo, Japan, [10]Osaka Univ. / The Univ. Tokyo / RIKEN, Osaka, Japan

Type 2 diabetes (T2D) is a heterogeneous subtype composition with different body mass index (BMI) sensitivity. These subtype compositions are an essential factor of exacerbating polygenic prediction across populations. We performed stratified random sampling based on BMI to isolate highly heritable subtypes and to maintain case-control ratios for BMI-related diseases, namely T2D and cardiac artery disease (CAD). Thus, using >97,000 individuals (N_{T2D} = 27,642, N_{CAD} = 22,650) from each of BioBank Japan (BBJ) and UK Biobank (UKBB), we obtained datasets stratified into two or three groups and BMI-unstratified datasets. Comparing two BMI-stratified groups, T2D heritability in the low BMI group was 84.5% and 64.7% greater than for high BMI in BBJ and UKBB, respectively. Polygenic predictions of T2D toward low BMI targets showed 22.2% increased pseudo-R^2 for BBJ and 23.5% for UKBB over predictions for unstratified targets. Using a pathway-specific clustering model, we showed that the improved T2D predictions in low BMI groups were due to biological contributions from multiple pathogenic pathways. By combining BMI stratification and a method integrating cross-populational effects, T2D predictions showed a 37.4% and 47.0% improvement for BBJ and UKBB over unstratified matched-populational predictions, respectively. The improved T2D predictions at low BMI were confirmed when comparing three BMI groups and evaluating odds ratios and net reclassification improvement. The low BMI T2D cases showed higher rates of neuropathy and retinopathy, suggesting that the appropriate medication for low BMI cases could prevent complications. We also replicated the results of improved T2D prediction in the low BMI group with two independent cohorts, Tohoku Medical Megabank Project (N_{T2D} = 6,000, $N_{control}$ = 20,000) and the second cohort of BBJ (N_{T2D} = 11,236, $N_{control}$ = 21,860). In contrast, CAD predictions showed no improvements, suggesting that T2D subtyping improved the predictions. Our results suggest the utility of target stratification based on existing traits for polygenic prediction of heterogeneous diseases.

PB4074 Boosting SNP discoverability: How the selection of traits affects the power of multi-trait GWAS

Authors:

Y. Suzuki[1], H. Menager[1], B. Brancotte[1], R. Vernet[2], C. Nerin[1], C. Boetto[1], R. Torchet[1], P. Lechat[1], L. Troubat[1], M. Cho[3], E. Bouzigon[2], H. Aschard[1], H. Julienne[1]; [1]Inst. Pasteur, Paris, France, [2]INSERM, Paris, France, [3]Brigham and Women's Hosp., Duxbury, MA

Modern human datasets provide access to hundreds of phenotypes, including quantitative traits and diseases and a range of high throughput molecular data. This plethora of data has fostered the development and application of multi-trait genome-wide association studies (GWAS). Extensive works have optimised the power of those approaches and investigated their robustness and computational efficiency. Conversely, little has been done regarding the strategy to select traits to be analysed jointly, leaving investigators with overwhelming combinatorial possibilities. For example, from a set of ten traits, there are over 1,000 possible sets of 2 to 10 traits that can be analysed jointly. Here, we investigated to what extent genetic architecture can inform the ability of multi-trait approaches to identify new associations missed by univariate GWASs. We used JASS, an efficient Python package, to perform a standard joint analysis of ~20K randomly selected sets of 2 to 12 traits, pulled from a curated database of 72 quantitative traits and common human diseases GWASs. For each set, we derived the gain of the multi-trait test over univariate tests and measured single GWAS features (e.g. heritability, sample size, etc) and GWAS set features (genetic correlation, sample overlap, etc) associated with that gain. We identified four features driving the power gain of the multi-trait test relative to univariate GWAS: mean genetic effect size (P=2e-57), the number of traits analysed jointly (P=3e-20), the genetic covariance across the traits (P=7e-23), and the unaccounted heritability (the difference between common variants heritability and heritability explained by GWAS hits) (P=5e-47). Altogether these parameters carry a substantial predictive power with a predicted versus observed gain measured as squared Pearson's r=0.19 (r=0.4). We also identified multiple scenarios where the proposed data-driven selection approach outperformed clinically based selection (e.g. the power gain in the joint analysis of two sleep-related traits, chronotype and mean least active 5-hour period after previous midnight (L5) was 0.28, while the power gain with L5 and waist-hip ratio was 0.77). Overall, this demonstrates that trait GWAS characteristics can be used to guide the selection of relevant sets of traits for multi-trait analyses in order to maximise the identification of variants with low discoverability in univariate GWAS. (Funding: ANR-20-CE36-0009)

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4075 Breast cancer family history in participants with BRCA variants: A study in*All of Us*Research Program.

Authors:

L. Sulieman[1], C. Chen[1], R. Cronin[2]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Ohio State Univ. Med. Ctr., Columbus, OH

BRCA pathogenic variants are associated with an increased risk for breast cancer (BC). Most studies that investigated BRCA mutations and family history (FH) had small sample sizes or lacked diverse underrepresented populations. Moreover, the scope of most studies was limited by cohort selection that exclusively focused on estimating the prevalence of BRCA mutations in cohorts exhibiting breast cancer family history (BCFH). To close the knowledge gaps, we estimated the prevalence of BCFH in those with BRCA mutation and the prevalence of BRCA mutation in those with BCFH in the *All of Us* Research Program, a large longitudinal cohort from historically underrepresented populations. We used the latest data release (CDR-7) from *All of Us* to identify female participants with BRCA1 and BRCA2 pathogenic variants and completed FH surveys. We identified a control cohort of those that completed FH surveys without BRCA mutations. Using the control population as a reference, we applied the proportion test to check if the BCFH proportions in BRCA1 and BRCA2 cohorts are significantly different from the control population. Among 248,135 female participants, 118,008 completed FH, 145,563 had genome data, and 85,256 completed the FH survey and had genome data. Of those with FH survey and genome data, 16073 (18.9%) reported BC in their family, 411 (2.6%) had BRCA1 and 1054 (6.6%) had BRCA2. In group of multiple family members with BC, 11.2% had BRCA variants. 1130 (77%) BRCA carriers did not have BCFH. In BRCA1 carriers, the prevalence of BCFH was 29.9%. Among BRCA2 carriers, the prevalence of BCFH was 20.1%. The number of female BRCA1 and BRCA2 carriers who reported multiple BCFH were 94 (22.9%) and 153 (14.5%) respectively. Among BCFH members, 134 BRCA1 and 184 BRCA2 carriers reported Grandparent history with BC, which was the most common family member with BC history. In the control cohort that had 83798 participants, the prevalence of BCFH was 18.8% and 12.9% reported multiple family members with BC. BCFH was significantly more prevalent in participants with BRCA variants than in the control cohort (P-val < .00001 for BRCA1/BRCA2). The prevalence of BRCA variants in participants with FH was lower than 7%, which was like a study that calculated BRCA prevalence in cohort with FH, but different than another study found that BRCA mutation prevalence was 21% in 195 patients with BCFH. BCFH was significantly more prevalent (p-val =0.02) in females with BRCA1 variants. Our study was the first large scale that calculated BRCA mutation prevalence in relation to BCFH. The results show that BRCA mutations increase the likelihood of having BCFH, especially for participants with multiple family members with BC.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4076 † BTS: efficient Bayesian framework for functional evaluation of GWAS results against large-scale, heterogeneous functional genomics data collections

Authors:

P. Kuksa[1], M. Ionita[1], K. Clark[2], L. Carter[1], O. Valladares[1], Y. Leung[1], L-S. Wang[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Univ. of Pennsylvania, Baltimore, MD

Summary statistics from genome-wide association studies (GWASs) are often used in downstream analyses such as identifying tissue/cell context or causal variants/genes underlying GWAS signals, e.g., via fine-mapping or colocalization analyses. The growing number of loci identified by GWASs and available functional genomic (FG) annotation provide a unique opportunity to perform large-scale, systematic functional analyses of GWAS results. It is critical to have scalable algorithms that can integrate thousands of genome-wide FG annotations to identify putatively causal variants, affected tissue/cell types, regulatory mechanisms.

To this end, we propose BTS, a novel, highly efficient algorithm for joint estimation of potentially causal variants, loci, and their relevant functional context. BTS uses large-scale FILER FG database (Kuksa et al 2022) and performs systematic evaluation and prioritization of GWAS variants/loci across >1,000 tissues/cell types and >40,000 enhancer, open chromatin, transcription factor binding, epigenetic marks and other FG tracks. BTS scales well with the number of input annotations and GWAS loci, achieving its efficiency by 1) pre-computing GWAS/LD Bayes factors (BFs) for use across annotations, 2) improved evaluation of annotation-dependent priors, and 3) combining priors/precomputed BFs into annotation-specific models. Compared to state-of-the-art functional fine-mapping method (fastPaintor), BTS estimates a genome-wide Bayesian model for each input cell type/tissue-specific annotation *>2,000x* faster. BTS on average only needs 43s on a 387-loci GWAS and EpiMap/ENCODE enhancer/DNase-seq tracks as opposed to 90,401s using fastPaintor.

We demonstrated BTS utility and performance in discovering and prioritizing relevant tissue context, loci and variants by analyzing GWAS summary statistics on inflammatory bowel disease (IBD), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), coronary artery disease (CAD). BTS identified and analyzed 387 IBD, 331 RA, 262 SLE, and 385 CAD loci. BTS prioritized tissues/cell types, genes and variants such as ETS2, DAB2 in digestive/blood/immune cell types in IBD; LPL, PLG, SLC22A in blood vessel/lung in CAD, and these findings align with known/putative biological mechanisms.

To conclude, BTS is a joint GWAS variant and functional context mapping framework with greatly improved efficiency and is valuable for researchers to explore tissue and cell-type context in the gene-phenotype association architecture. BTS is available online.

PB4077 Calibrated prediction intervals for polygenic scores across contexts in diverse populations

Authors:

K. Hou[1], Z. Xu[2], Y. Ding[1], B. Pasaniuc[1]; [1]UCLA, Los Angeles, CA, [2]Univ. of California, San Diego, Los Angeles, CA

Polygenic scores (PGS) have emerged as the tool of choice for genomic prediction of complex traits in a wide range of fields from agriculture to personalized medicine. A critical barrier for their adoption in humans is their context-specific accuracy—variable performance across contexts (e.g., genetic ancestries and/or social determinants of health) raising equity concerns of their applications.

We propose that context-specific prediction accuracy can be captured using prediction intervals that are allowed to vary across contexts; trait prediction intervals denote the range within which the true trait value is likely to be at a pre-specified confidence level (e.g., 90%). Therefore, well-calibrated prediction intervals can properly inform context-specific uncertainties associated with the point predictions to be leveraged in subsequent applications.

We analyzed 72 PGS in UK Biobank (UKBB) and All of Us (AoU) data to find widespread context-specific accuracies; many contexts, including age, sex, and income, impact PGS accuracies with similar magnitude as genetic ancestries. For example, PGS accuracy differed by 50% for individuals across “education years” contexts averaging across 11 PGSs when applied to AoU. In addition, patterns of context-specific PGS accuracy were similar for single-ancestry as well as multi-ancestry PGSs.

We introduce CalPred, a statistical method that uses calibration data to estimate context-specific prediction intervals as a function of each individual's context information. CalPred yields well-calibrated context-specific intervals in simulations and real data analysis of diverse populations from UKBB and AoU. Using CalPred, we show that trait prediction intervals need to be increased by up to 40% to maintain proper calibration across contexts. Overall, our results highlight the need to account for context-specific PGS accuracies in genomic prediction of complex traits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4078 CARTaGENE reference panel improves genotype imputation in Québec

Authors:

M. Sayahian Dehkordi[1,2,3], R. Laflamme[4,5], K. Sin Lo[5], S. Gravel[1,3], G. Lettre[4,5], C. Bhérer[1,2,3], D. Taliun[1,2,3]; [1]Dept. of Human Genetics, Faculty of Med. and Hlth.Sci., McGill Univ., Montreal, QC, Canada, [2]Canadian Excellence Res. Chair in Genomic Med., McGill Univ., Montreal, QC, Canada, [3]Victor Phillip Dahdaleh Inst. of Genomic Med. at McGill Univ., Montreal, QC, Canada, [4]Université de Montréal, Montreal, QC, Canada, [5]Montreal Heart Inst., Montreal, QC, Canada

CARTaGENE (CaG) is a population-based biobank and a prospective health study containing genotyping data from 29,330 individuals recruited in the province of Québec, Canada. 87% (25,681) of these individuals are of European ancestry, mainly from the French-Canadian founder population, which formed by immigration of ~8,500 mostly French settlers in the 17th century. In this project, we built the first public Québec reference panel for genotype imputation using 2,173 whole genomes (at ~30X coverage) from CaG and showed that it outperforms TOPMed, the largest publicly available reference panel, when imputing rare population-specific genetic variants.

We conducted imputation experiments comparing the performance of the CaG panel (N=2,073), the TOPMed panel (N=97,256), and meta-imputation using three evaluation sets of 100 individuals each.

The CaG panel covered more true alternate alleles (AA) per individual than TOPMed, 99.81% vs 87.25%. On average, TOPMed imputed 99% of AA present in this panel concordantly with true AA, while CaG concordantly imputed only 96.07% of its AA. But in absolute numbers, the CaG panel concordantly imputed on average ~300,000 more AA per individual than TOPMed. The meta-imputation improved the coverage of true AA (99.89%) while maintaining high concordance (96.19%). Meta-imputation had lower concordance than TOPMed due to the inclusion of panel-specific variants from the CaG panel.

With the CaG panel, we concordantly imputed 478,704 (94% with R2>0.6) and 364,259 (95.5% with R2>0.6) rare variants (AF < 0.01) which were absent from or discordantly imputed in TOPMed, respectively. 50.8% of rare variants absent in TOPMed were >5-fold enriched compared to gnomAD non-Finnish Europeans. 39.2% of rare variants discordantly imputed by TOPMed were >5-fold enriched. Meta-imputation recovered all the rare variants that were absent from TOPMed, as well as 357,936 (98.2%) variants that were discordantly imputed by TOPMed.

The CaG panel concordantly imputed all known French-Canadian founder mutations implicated in Mendelian diseases and present in the evaluation set (N=12, e.g. Leigh Syndrome). Three of them were absent from TOPMed, and one was discordantly imputed by TOPMed. Additionally, 4%(8,394 out of 218,337) of variants reported in the GWAS Catalog, were concordantly imputed by CaG in all individuals but were discordantly imputed by TOPMed in at least one individual in the evaluation set or absent from TOPMed.

Our findings highlight the benefits of local reference panels for the imputation of rare population-specific variants.

PB4079 Casebase analysis for two-phase failure time studies

Authors:

D. Soave[1], K. Kwan[2], C. Greenwood[3], N. Cheng[4], P. Awadalla[4]; [1]Wilfrid Laurier Univ., Waterloo, ON, Canada, [2]McGill Univ., Montreal, QC, Canada, [3]Jewish Gen. Hosp., Montreal, QC, Canada, [4]Ontario Inst. for Cancer Res., Toronto, ON, Canada

Two-phase study designs are ideal for executing targeted sub-studies based on large prospective cohorts when the outcome of interest is a rare event in the full cohort, and additional covariates are expensive or difficult to measure. However, when analyzing such studies, individuals must be properly weighted to account for biased case/control sampling. To address this issue, we propose a weighted casebase framework using logistic regression to obtain unbiased estimates of relative and absolute risks. The benefit of this approach is that it provides smooth-in-time absolute risk functions. To obtain standard errors for the parameter estimates, bootstrapping can be used. We conducted a simulation study to examine the performance of the proposed methodology, and we then used the modelling procedure to predict breast cancer using cell-free DNA methylation profiles derived from blood samples from the Ontario Health Study (OHS).

PB4080 Catch me if you can: Genome-wide fine mapping with knockoff e-values

Authors:

P. Gablenz, C. Sabatti; Stanford Univ., Stanford, CA

A common goal in GWAS is to identify DNA variants that carry distinct information on a trait of interest. However, linkage disequilibrium between nearby variants makes it challenging to distinguish which of the many correlated SNPs most directly influence the phenotype. A common solution is then to identify sets of variants that cover the truly important ones. Depending on the signal strengths, local fine mapping strategies allow individual variant contributions to be resolved with more or less precision. However, assuring false discovery rate (FDR) control on the reported findings with these multi-step approaches is often impossible. We design a procedure that, operating on the entire genome, maximizes the number of independent discoveries and their precision, while controlling the FDR. Analysis of data from the UK Biobank illustrates the power of our adaptive approach.

PB4081 Causal effect of recurrent mild malaria on dyslipidemia in African Ancestry Individuals: A Mendelian randomization study.

Authors:

M. Traore[1,2], H. Sangare[2], O. Diabate[2], C. Cissé[2], O. Nashiru[3], J. Li[4], J. Shaffer[4], M. Wélé[2], S. Doumbia[2], T. Chikowore[5], O. Soremekun[6], S. Fatumo[1]; [1]MRC/UVRI & LSHTM Uganda Res. Unit, Entebbe, Uganda, [2]African Ctr. of Excellence in Bioinformatics of Bamako, Bamako, Mali, [3]H3Africa Bioinformatics Network (H3ABioNet) Node, Ctr. for Genomics Res. and Innovation, NABDA/FMST, Abuja, Nigeria, Abuja, Nigeria, [4]Sch. of Publ. Hlth.and Tropical Med., Tulane Univ., USA, New Orleans, LA, [5]Univ. of Witwatersrand, Johannesburg, South Africa, [6]MRC/UVRI $ LSHTM, Entebbe, Uganda

Dyslipidemia is becoming prevalent in Africa, where malaria is endemic. Observational studies have documented the long-term effect of malaria on lipid metabolism; however, these studies are vulnerable to confounding factors. Therefore, we used Mendelian randomization (MR- a method robust to confounders and reverse causation) to determine the causal effect of recurrent mild malaria (RMM) on lipid traits. We performed two-sample Mendelian randomization Genome Wide association study (GWAS) summary statistics for RMM conducted in Benin, (N=775) and lipid traits from African ancestry individual in Million Veteran Program (N= 57,332). We found a linear association between RMM and levels of low-density lipoprotein cholesterol (LDL-C) (Beta = -0.025, 95% CI, -0.042 to -0.007 p-value=0.005) and total cholesterol (Beta = -0.019, 95% CI, -0.035 to -0.002, p-value= 0.028). No significant association was obtained with High-density lipoprotein cholesterol (HDL-C) and levels of triglycerides. The finding of this study supports a causal relationship between RMM and levels of LDL-C and total cholesterol. We believe that larger studies on the link between malaria and dyslipidemia in Africa will help to manage the burden of both diseases better.

PB4082 cellSTAAR: Incorporating single-cell-sequencing-based functional data to boost power in rare variant association testing of non-coding regions

Authors:

E. Van Buren[1], Y. Zhang[2], X. Li[3], Z. Li[4], H. Zhou[5], G. Peloso[6], J. Rotter[7], P. Natarajan[8], X. Lin[9], NHLBI Trans-Omics for Precision Medicine (TOPMed)Consortium, TOPMed Lipids Working Group; [1]Dept. of Biostatistics, Harvard T.H. Chan Sch. of Publ. Hlth., CAMBRIDGE, MA, [2]Dana-Farber Cancer Inst., BOSTON, MA, [3]Dept. of Biostatistics, Harvard T.H. Chan Sch. of Publ. Hlth., Cambridge, MA, [4]Indiana Univ. Sch. of Med., Indianapolis, IN, [5]Harvard T.H. Chan Sch. of Publ. Hlth., BOSTON, MA, [6]Boston Univ., Boston, MA, [7]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [8]Massachusetts Gen. Hosp., Boston, MA, [9]Harvard T.H. Chan Sch Pub Hlth, Boston, MA

Introduction: Whole genome sequencing (WGS) studies have cumulatively identified hundreds of millions of rare variants, the majority of which are in non-coding regions and of unknown function. Given this large number of genetic variants, existing methods for gene-centric Rare Variant Association Tests (RVATs) in WGS studies have identified relatively few associations between candidate Cis-Regulatory Elements (cCREs) and complex human diseases. Because the regulatory landscape of many cCREs varies across cell types, it is of substantial interest to incorporate single-cell sequencing data into RVATs to capture the functional variability that exists across cell types in the non-coding genome and boost statistical power in the process. **Methods**: We propose cellSTAAR to address two opportunities to improve existing gene-centric RVAT methods as applied to genetic variants in cCREs. First, cellSTAAR integrates single-cell ATAC-seq data to capture variability in chromatin accessibility across cell types via the construction of cell-type-specific variant sets and the upweighting of relevant variants using cell-type-specific functional annotations. Second, cellSTAAR links cCREs to their target genes using an omnibus framework that aggregates results from a variety of linking approaches, each of which uses differing kinds of genomic data and computational approaches, to reflect the uncertainty in element-gene linking. We applied cellSTAAR on Freeze 8 (N = 60,000) of the NHLBI Trans-Omics for Precision Medicine (TOPMed) consortium data to three quantitative lipids traits: LDL, HDL, and TG. **Results**: In at least one cell type, genome-wide significant promoter and enhancer associations were found in several known lipids loci, including *APOE*, *APOA1*, and *CETP*. Unlike existing methods, cellSTAAR reveals variability in the significance of these loci across a variety of cell types and uncertainty in the target gene for significant enhancers. For example, out of 19 cell types analyzed, the significant enhancer near *APOE* was found in only 6 cell types. Included in these 6 are 5 cell types known *a priori* to be highly relevant to lipids: hepatocytes, fetal hepatoblasts, adipocytes, liver endothelial cells, and enterocytes from the small intestine. Although the associated enhancer is contained with the *APOE* gene, 3D-based evidence from SCREEN suggests possible regulation of nearby genes *APOC2* and *APOC4.* This uncertainty in target gene is not reflected in existing RVAT methods. Using a weakened genome-wide significance threshold, the most discoveries using cellSTAAR are found in cell types that are the most relevant to lipids such as those mentioned above.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4083 Characterising polygenic risk for glaucoma in genetically admixed individuals

Authors:

J. Ong[1], W. He[2], Y. Wu[2], X. Han[3], P. Gharahkhani[2], S. MacGregor[2]; [1]QIMR Berghofer Med. Res. Inst., Herston, Australia, [2]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [3]Massachusetts Inst. of Technology, Boston, MA

Polygenic risk scoring is a common technique to characterise the aggregation of genetic liability on human complex diseases. In the context of glaucoma genetics, we have shown how profiling one's polygenic risk score (PRS) on glaucoma can achieve reasonable risk stratification, where patients at the top-most glaucoma PRS decile on average was diagnosed with glaucoma ten years earlier than the bottom-most group. However, to date there are limited resources to investigate how our findings translate to patients of admixed ancestry - especially those with African ancestries since the baseline glaucoma prevalence among Africans is much higher.

We first derived theoretical distributions of glaucoma PRSs for individuals with varying degrees of admixture and compare them with real-life genetic data. Using 1000Genomes reference datasets, we simulate bi-ancestry haplotypes. Haplotypes from two local ancestries are randomly mixed to specified admixture fractions [e.g. 50% European (EUR), 50% African (AFR)] across five generations. This process is repeated to generate genotypes at different admixture fractions and pairings of five super-populations. We then map the distribution of European-derived glaucoma PRSs onto the admixed population, finding strong similarity to PRS distributions obtained empirically from the UK Biobank cohort.

During the meeting, we will demonstrate simple heuristics on how to estimate glaucoma genetic risk in UK Biobank individuals with (inferred) AFR-EUR admixed ancestries. We compared two approaches: jointly modeling PRSs in local ancestries with PRS-CSx and adjusting for genetic distance by regressing top ancestral PCs. PRS-CSx slightly improved predictions for moderately admixed groups but performed worse for homogeneous Europeans (reduction in log(OR) from 0.70 to 0.35 per unit SD change). Predicting South Asian and East Asian admixtures using the EUR-AFR joint model resulted in lower overall prediction, indicating a potential shift in genetic architecture among Africans. Our study provides insights for delivering PRS findings to admixed individuals and emphasizes the need for larger GWASs in understudied ancestries for better prediction.

PB4084 Characterization of mitochondrial phenotypes across 28 tissues among four genetically diverse mouse strains as a foundation for QTL mapping

Authors:

M. Lancaster, D. J. Acri, A. Fischer, N. Olchawa, S. Dosunmu, C. Elliott, P. Gillespie, J. Kim, B. Graham; Indiana Univ. Sch. of Med., Indianapolis, IN

Mitochondrial diseases are a common form of multisystem disease (combined prevalence of 1 in 4,300) with limited treatment options. They are typically marked by defects in oxidative phosphorylation (OXPHOS), leading to a failure of the mitochondria to produce enough cellular ATP to meet energy demands. In addition to primary mitochondrial disease, mitochondrial dysfunction is also implicated in chronic and complex diseases, such as cardiovascular and neurodegenerative diseases, cancer, and diabetes. Mitochondrial disorders are also notable for wide clinical, genetic, and tissue-specific heterogeneity. The genetic architecture underlying tissue specific mitochondrial phenotypic variability remains incompletely understood. The first goal of this project, therefore, was to characterize mitochondrial phenotypic variation across 28 tissues within four genetically diverse inbred mouse strains: C57Bl/6J, WSB/EiJ, CAST/EiJ, PWK/PhJ. Specifically, the activity of citrate synthase (CS), the first enzyme within the tricarboxylic acid cycle, as well as the copy number of the mitochondrial genome (mtDNA) was measured in all tissues. CS activity is commonly used as a biomarker of intact mitochondria, with perturbations of mitochondrial content observed in disease states commonly associated with alterations in CS activity. Additionally, mtDNA is located within the mitochondrial matrix and encodes for 37 genes essential for mitochondrial function, including 13 protein coding genes encoding subunits within the electron transport chain (ETC). MtDNA copy number varies broadly over different cell types; however, little is known about tissue-specific mtDNA content regulation. The characterization demonstrates distinct patterns of variation between strains across tissues. Of the 28 tissues analyzed, 16 had significant differences in mean CS activity between strains, and 19 had one or more strains with significant differences in mean mtDNA copy number, suggesting genetic contribution in regulating these traits. The chosen strains are four of the eight founders of the Diversity Outbred (DO) mouse model and capture significant variability that can be utilized for genetic mapping. Using three tissues identified as highly variable in our original founder experiment, we performed quantitative trait locus (QTL) mapping and identified a known cis-coding variant for CS. These results provide validation for a larger future study, and in its completion, this project will aid in the identification of genetic modifiers of tissue-specific CS activity and mtDNA content and provide candidate targets for mitochondrial dysfunction and disease therapies.

PB4085 Characterization of non-coding variants associated with transcription factor binding through ATAC-seq footprinting in liver.

Authors:

M. F. Dudek[1], B. M. Wenz[1], S. F. Grant[2,1], C. D. Brown[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Chronic liver disease (CLD) represents a massive healthcare burden worldwide, most commonly due to non-alcoholic fatty liver disease (NAFLD). A better understanding of CLD genomic etiology can inform the development of novel treatments. The polygenicity of CLD and related traits has been confirmed by genome-wide association studies (GWAS), which have revealed multiple associated loci. Most of these loci reside in non-coding regions with unknown effects on gene regulation, limiting their utility in elucidating the biological mechanisms of liver disease. Further studies have detected quantitative trait loci (QTLs) with a genetic association for a molecular trait such as gene expression or chromatin accessibility. However, identifying the causal variant within trait-associated loci remains challenging due to linkage disequilibrium (LD), which limits the genomic resolution of both GWAS and QTL studies.

Non-coding GWAS variants are enriched at the binding sites of transcription factors (TFs), suggesting a link between disease association and the disruption of cis-regulatory sequence. TF binding can be detected in ATAC-seq experiments, where bound TFs block the DNA-cleaving transposase Tn5, leaving a pattern of relatively depleted Tn5 cutsites known as a “footprint”. Here we used computational tools to scan ATAC-seq reads from 189 human liver samples, both separated and combined, and quantified TF binding likelihood as *footprint scores* at variants genome-wide.

We observe that when reads across samples were combined, footprints were significantly enriched at liver eQTLs, caQTLs, disease-associated variants, and promoter-interacting regions from Capture-C. Analyzing samples separately according to genotype, we detected in excess of 9,000 variants significantly associated with footprint-inferred TF binding at 5% FDR, known as footprint QTLs (fpQTLs). In particular, we observed fpQTLs at the obesity-associated *FTO* locus (rs8050136), the NAFLD-associated *IFT172* locus (rs2303370), and the triglyceride-associated *CELSR2* locus (rs7528419). Given that variant footprint scores are not in LD, fpQTLs can aid GWAS fine-mapping by precisely locating TF activity within broad disease-associated loci which typically includes several candidate variants. fpQTLs can therefore be leveraged to study the role of TF binding site disruption in disease, and provide functional interpretations for non-coding variants.

PB4086 Characterizing proteomic and transcriptomic features of missense variants in amyotrophic lateral sclerosis genes

Authors:

A. Dilliott[1,2], S. Kwon[3], G. A. Rouleau[1,2], S. Iqbal[3,4], S. M. K. Farhan[1,2]; [1]Montreal Neurological Inst.-Hosp., Montreal, QC, Canada, [2]McGill Univ., Montreal, QC, Canada, [3]Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Massachusetts Gen. Hosp., Boston, MA

Within recent years, there has been a growing number of genes associated with amyotrophic lateral sclerosis (ALS), resulting in an increasing number of novel variants, particularly missense variants, many of which are of unknown clinical significance. Here, we leveraged the sequencing efforts of the ALS Knowledge Portal (3,864 individuals with ALS and 7,839 controls) and Project MinE ALS Sequencing Consortium (4,366 individuals with ALS and 1,832 controls) to perform proteomic and transcriptomic characterization of missense variants in 24 ALS-associated genes.

The two sequencing datasets were interrogated for rare missense variants in the 24 genes, and variants were annotated with protein sequence features, including Uniprot functional site annotations and PhosphoSitePlus post-translational modification (PTM) site annotations; protein structural features from AlphaFold predicted monomeric 3D structures; and transcriptomic expression levels from Genotype-Tissue Expression (GTEx). We applied missense variant enrichment and gene-burden testing following binning of variation based on the selected proteomic and transcriptomic features to identify those most relevant to pathogenicity in ALS-associated genes.

Using predicted human protein structures from AlphaFold, we determined that missense variants carried by individuals with ALS were significantly enriched in β-sheets and α-helices, as well as in core, buried, or moderately buried regions. We also identified that hydrophobic amino acid residues, compositionally biased protein regions, and protein-protein interaction regions are significantly enriched in missense variants carried by individuals with ALS. Assessment of expression level based on transcriptomics revealed significant enrichment of variants of high and medium expression across all tissues and within the brain. We further explored enriched features of interest using burden analyses and identified individual genes were indeed driving certain enrichment signals. We performed a case study of *SOD1* to demonstrate proof of concept of how enriched features align with the consequences demonstrated by experimentally solved structures of *SOD1* variants and how the features may aid in defining variant pathogenicity.

Our work demonstrates that proteomic and transcriptomic features are important indicators of missense variant pathogenicity in ALS and are distinct from features associated with neurodevelopmental disorders. Incorporating gene-specific features into variant classification may offer the ability to better identify true pathogenic missense variants in ALS clinical cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4087 Characterizing substructure via mixture modeling in large-scale summary statistics

Authors:

H. Wolff[1], A. Price[1], N. Scribner Trout[2], K. Crooks[1], N. Rafaels[1], N. Pozdeyev[1], S. Tifour[2], K. Marker[1], C. Gignoux[1], A. Hendricks[2,1]; [1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO, [2]Univ. of Colorado, Denver, CO

Genetic summary data are both broadly accessible and highly useful. Nevertheless, collapsing individual-level data into groups masks intra- and inter-sample heterogeneity (e.g., population structure), biasing results especially in admixed or understudied populations. We address this gap with the development of *Summix v2* (available on GitHub/Bioconductor) that estimates, adjusts for, and even harnesses substructure in summary level data. The suite of methods includes local-ancestry estimation and a statistical test to identify regions of selection; fine-scale ancestry estimation and visualization; allele frequency harmonization for secondary data analysis; and estimation of genetic risk of disease enabling adjustment for differences in ascertainment and sampling.

We evaluated over a comprehensive set of simulation scenarios and application in publicly-available data, including gnomAD v3.1.2 and Genome Wide Association Study summary statistics. In simulations, *Summix v2* produced precise and accurate local-ancestry proportion estimates (≥ 99%) of continental ancestry similarity (African, East Asian, European, Indigenous American, South Asian) using as few as 250 genetic variants. Our test of selection (i.e., ancestry deviance) controlled type I error and had 92% power to detect 400kb regions with 5% difference in local vs global ancestry. For finer-scale ancestry, minimum accuracy of proportion estimates is related to reference group pairwise F_{st}: 89% for F_{st} =0.005; 97% for F_{st} =0.009. Median accuracy over reference groups is always high, >99%. In application to gnomAD v3.1.2, we replicated signatures of selection at the *HLA* locus in the gnomAD African/African-American, (FDR=6.5x10-11) and Latinx (FDR=6.68x10-9) groups and 1p33 in the Latinx group containing *CYP4A11*, a candidate gene in pharmacogenetics (FDR=9.63x10-6). After a Bonferroni correction, we identified 8, 6, and 2 regions containing putative signatures of selection in African/African-American, Latinx, and both, respectively, identifying genes relevant to innate immune response and multiple cancers. Finally, to highlight the ability of *Summix v2* to identify other types of substructure, we estimated the genetic risk of prostate cancer in the Colorado Center for Personalized Medicine Biobank from 146 previously-associated variants, reproducing the observed proportions of cases for those ≥60 years and identifying yet to be realized risk for those 40-60 years and ≤40 years. Through multiple functionalities, *Summix v2* enables a breadth of substructure estimation and improves data harmonization ultimately increasing the robust use of publicly available summary data.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4088 Circulating metabolite levels vary by genetic ancestry in individuals of African ancestry.

Authors:

O. Agasaro[1,2], H. Xu[3], X. Sheng[4], H. Fuller[1], D. Albanes[5], D. V. Conti[4], C. A. Haiman[4], C. Chiang[4], K. Ye[3,6], B. Darst[1,7]; [1]Publ. Hlth.Sci., Fred Hutchinson Cancer Ctr., Seattle, WA, [2]Inst. of Publ. Hlth.Genetics, Univ. of Washington, Seattle, WA, [3]Dept. of Genetics, Univ. of Georgia, Athens, GA, [4]Ctr. for Genetic Epidemiology, Dept. of Population and Publ. Hlth.Sci., Univ. of Southern California, Los Angeles, CA, [5]Natl. Cancer Inst., NIH, Bethesda, MD, [6]Inst. of Bioinformatics, Univ. of Georgia, Athens, GA, [7]Dept. of Epidemiology, Univ. of Washington, Seattle, WA

BACKGROUND: The majority of metabolomic epidemiology investigations have been limited to individuals from European ancestry populations and as such, little is known about how metabolites vary by diverse genetic ancestries. We evaluated whether circulating metabolites vary by genetic ancestry in individuals of African ancestry. METHODS: Participants included 706 men of African ancestry from the Multiethnic Cohort (MEC) with serum metabolomic data measured using mass spectrometry and 6,750 men and women of African ancestry from the UK Biobank (UKB) with plasma metabolomic data measured using nuclear magnetic resonance. Genetic ancestry proportions were calculated using ADMIXTURE with unsupervised K=4 and 15,115 common independent SNPs in 4,765 individuals from West African, South African, East African, and European ancestry populations. The learned population structure was then used to project ancestry proportions in MEC and UKB participants. Linear regression models were used to evaluate the association between each metabolite and genetic ancestry proportions, adjusting for age at blood draw, batch (MEC only), and sex (UKB only). In MEC, enrichment analyses were performed to determine if any pathways were over-represented by metabolites associated with genetic ancestry. To investigate the potential implications of metabolites associated with genetic ancestry, identified metabolites were also tested for association with body mass index (BMI) and for mediation of the association between genetic ancestry and BMI. RESULTS: Of the 1,098 metabolites tested in MEC, 81 were associated with genetic ancestry, including 53 associated with West African ancestry, 9 with South African ancestry, 5 with East African ancestry, and 76 with European ancestry. These metabolites were enriched for diacylglycerols and plasmalogen phospholipids, with metabolites associated with West African ancestry uniquely enriched for xenobiotics involved in xanthine metabolism. Seven of these metabolites, including three phospholipids, were associated with BMI and mediated the relationship between genetic ancestry and BMI. In the UKB, of the 249 metabolites tested, 44 were associated with genetic ancestry, including 37 associated with West African ancestry, 1 with East African ancestry, and 30 with European ancestry, with the strongest association suggesting that West African ancestry was positively associated with total omega-3 fatty acids and particularly, docosahexaenoic acid (DHA). CONCLUSION: These findings suggest that metabolite levels vary by genetic ancestry and that such metabolites could have important implications in health and health disparities.

PB4089 Classification of gene functional properties using evolutionary constraint.

Authors:

Y. Duan[1], T. Hayeck[2], A. Allen[1]; [1]Duke Univ., Durham, NC, [2]Children's Hosp. of Philadelphia, Bryn Mawr, PA

The identification of genes subject to purifying selection has important applications to disease genetics. The rapid increase in the number of human genomes available has resulted in a large increase in the power of population genetics analyses to detect such genes. In a linear regression-based model (RVIS, 2013), the deviation of common functional variants per gene from genome-wide average was taken as a measure of purifying selection on gene. This approach does not explicitly model the mutation rate per site, which can be different due to the local genetic context, but conditions on the total number of variants observed in the gene as a proxy for this rate. In this work, we explicitly model sequence context dependent mutation rates and directly compare the standing variants of genes to neutral expectations given the mutation rate. In addition, selection on different classes of mutation types depends on the functional mechanism of the gene. Some genes tolerate loss-of-function (LOF) mutations but not missense mutations, e.g., genes that are not dosage sensitive but are affected by protein structural changes.
We developed a likelihood ratio test (LRT) based on a multinomial model involving five classes (non-functional, codon-optimality-change, benign missense, pathogenic missense, LOF) to test the deviation of observed composition of variant types from expectation for each gene. The p-value of the LRT was taken as the measure of purifying selection on the gene. By comparing constraint across variant classes, we categorized genes into different mechanistic functional groups. The results were validated by AUC analyses of several functional and disease relevant gene sets. We found our LRT outperform RVIS in all gene sets. For example, a stillbirth gene set AUCs improve from 0.77 to 0.90 and a ClinGen haploinsufficient gene set AUCs improve 0.78 to 0.87. Also, genes belonging to distinct super gene families exhibit varying patterns of enrichment for constraint in different variant types. Important for diagnostic applications, we find that genes that are more constrained in missense variants than LOF variants, are more likely to contain more ClinVar pathogenic missense variants than LOF variants. Differences in missense and LOF constraint are correlated with the differences in the pathogenic missense and LOF variant counts in ClinVar (spearman's r = -0.45, p-value < 2.2e-16). Finally, we show eGenes from GTEx have greater intolerance to LOF variants compared to non-eGenes, suggesting the potential for identifying causal regulatory variants.

PB4090 Cluster based approach for deciphering complexity in individuals with neurodevelopmental differences

Authors:

M. Leclercq; CHU de quebec, Québec, QC, Canada

This study aims to assess the use of two different clustering approaches, agglomerative and divisive, in order to group individuals with global developmental delay (GDD) for future basket trials and identify disease related genes. Basket trials have shown success in oncology but have not yet been used in GDD due to the heterogeneity of individuals with neurodevelopmental disorders. The study used the largest cohort of individuals with GDD, the Deciphering Developmental Disorders (DDD), and extracted genotypic and phenotypic information from 6,588 individuals. K-means clustering (divisive) and hierarchical agglomerative clustering (HAC) were used to identify subgroups of individuals. Gene network and molecular function information about the clusters were then extracted. The HAC based on phenotypes identified 16 clusters in individuals with GDD, each presenting one dominant phenotype and other minor phenotypes. The most common phenotypes were delayed speech, absent speech, and seizure. Each phenotypic cluster had several sub-clusters of more closely related genes with diverse molecular functions. K-means clustering also segregated individuals with these phenotypes, but the genetic pathways identified were different from the ones identified by HAC. This study highlights the potential of using in a complementary manner both divisive and agglomerative clustering to group individuals with GDD for basket trials. The results suggest that phenotypic clusters should be subdivided into molecular clusters for increased likelihood of successful treatment and that a combination of both clustering approaches may be necessary for comprehensive treatment development.

PB4091 Clustering Algorithms for Rare Variant Association Studies: Generating effective therapeutic hypotheses for Complex Traits

Authors:

M. Rivas; Maze Therapeutics, Newburyport, MA

Rare variants play a crucial role in the understanding of complex human diseases and traits. With advancements in sequencing technologies, there has been an increasing interest in studying the association between rare genetic variants and phenotypic outcomes. However, the identification and interpretation of rare variants present unique challenges due to their low frequency and the need for specialized statistical methods. Here, we present an approach we call the Multiple Rare variants and Phenotypes Mixture Model (MRPMM), which clusters rare variants into groups based on their effects on the multivariate phenotype and makes statistical inferences about the properties of the underlying mixture of genetic effects. Using summary statistic data drawn from Genebass in UK Biobank across 30 renal, liver, and sex hormone biomarkers from 394,841 individuals, we demonstrate that our mixture model can identify clusters of variants responsible for significantly disparate effects across a multivariate phenotype. We estimate (1) the proportion of non-null variants, (2) whether variants with the same predicted consequence in one gene behave similarly, and (3) whether different annotations differ in the magnitude of their effects. We find examples of three clusters of rare protein truncating variants in *UMOD* consistent with protection against chronic kidney disease, i.e. lowers creatinine levels, and a second cluster of rare protein truncating variants that tag an ADTKD inframe deletion haplotype that increases creatinine levels. We detect three clusters of effects for protein altering variants in *ANGPTL8* and triglyceride levels showcasing a bidirectional effect profile. However, challenges remain in the application of clustering algorithms for rare variant association studies. These include the selection of appropriate genetic variants due to the reduction of power to detect signals when including neutral alleles when analyzing protein altering variants. Here, we will present approaches for addressing some of those challenges.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4092 COLOC-Boost: A new gradient boosting informed colocalization algorithm improves the identification of functional disease causal variants

Authors:

X. Cao[1], H. Sun[1], R. Mazumder[2], K. Dey[3], G. Wang[1]; [1]Columbia Univ., New York, NY, [2]Massachusetts Inst. of Technology, Cambridge, MA, [3]Sloan Kettering Inst., Mem. Sloan Kettering Cancer Ctr., New York, NY

Background
1. Expression quantitative trait locus (eQTL) studies have had considerable success in understanding the regulatory function of disease variants; recent efforts expand QTL studies to molecular phenotypes beyond expression, like histone acetylation, methylation, protein abundance. 2. Colocalization methods like COLOC, eCAVIAR (Wallance 2021, Hormozdiari et al. 2016) have been widely used to identify variants and loci with shared causal variant underlying a molecular phenotype and trait. 3. The expansive types and nature of the QTL studies demand a colocalization method that can accurately pinpoint the functional disease causal variant from tagging variants, and that can be easily extended to multiple phenotypes.
Method
1. We propose a new colocalization method, COLOC-Boost, that uses coupled gradient boosting algorithm to automatically distinguish colocalized sets of variants from un-colocalized variants with superior precision and recall compared to existing approaches.2. Though inherently a locus-level colocalization method, COLOC-Boost assigns a probabilistic grade to each variant in a colocalized set, that can be used to perform variant-level colocalization.3. The conceptual gradient boosting framework of COLOC-Boost can be easily extended to multiple phenotypes and even to a single phenotype fine-mapping.
Results
1. We performed a systematic comparison of COLOC-Boost against SuSiE-COLOC for a broad range of simulation settings where the causal variants are in varying levels of linkage disequilibrium (LD) from 0.1 to 0.9 and the phenotype heritability varies from 0.2 to 0.7. 2. For locus-level colocalization, COLOC-Boost exhibited 1.08x-1.83x significant higher power than locus-level version of SuSiE-COLOC at high levels of LD (LD>0.5; p-value<0.001) and similar power at low LD levels, while had similar false discovery rate (FDR). 3. Locus-level colocalization methods (COLOC-Boost and locus-level version of SuSiE-COLOC) reduced FDR to 2.9%-58.1% of SuSiE-COLOC, and improved 1.27x-6.08x power across all settings (p-value<0.001). 4. The fine-mapping equivalent of COLOC-Boost, term FINE-Boost, had comparable performance to SuSiE at low to moderate levels of LD, but slightly outperformed the latter for high LD (LD>0.9) scenarios.5. Currently, COLOC-Boost is being applied to integrate an emerging multi-omics QTL and AD GWAS resource developed by the FunGen-xQTL Project, yielding promising preliminary evidences of propagation of xQTL on the etiology of complex diseases.6. Overall, COLOC-Boost provides a novel framework to identify colocalized disease-critical functional signals for varying number of phenotypes.

PB4093 Common Genetic Variants are Associated with Plasma and Skin Carotenoid Metabolism in Ethnically Diverse US Populations

Authors:

Y. Han[1], S. Mwesigwa[2], M. N. Laska[3], S. B. Jilcott Pitts[4], N. E. Moran[5], N. A. Hanchard[1]; [1]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Dept. of Med. Microbiol., Coll. of Hlth.Sci., Makerere Univ., Kampala, Uganda, [3]Div. of Epidemiology & Community Hlth., Sch. of Publ. Hlth., Univ. of Minnesota, Minneapolis, MN, [4]Dept. of Publ. Hlth., East Carolina Univ., Greenville, NC, [5]USDA/ARS Children's Nutrition Res. Ctr., Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX

Carotenoids, natural pigments found in plants and lower organisms, possess antioxidant and anti-inflammatory properties with potential benefits against oxidative disorders, arteriosclerosis, obesity, and certain cancers. Blood and skin carotenoid levels are reliable biomarkers for assessing carotenoid dietary intake. However, the impact of genetic variability on carotenoid metabolism in diverse populations, and the generalizability of findings from European populations regarding the genetic control of carotenoid metabolism in other populations remains understudied. To address this, we investigated the association between genetic variation and plasma carotenoid species and total skin carotenoid concentrations in a diverse cohort of 207 US adults. Genome-wide genotyping used the H3Africa microarray, complemented by targeted sequencing of 35 genes reportedly important in carotenoid metabolism. Principal Component Analysis effectively grouped individuals self-reporting as 'white' and 'African American' with 'European' and 'African' ancestry, respectively. Self-reported 'Asian' clustered with both Indian/South Asians and East Asians, while Hispanic clustered with admixed Mexican and Latino groups from 1000 Genomes. With 7,467,403 imputed SNPs (MAF $\geq$ 0.5%) from the Michigan Imputation Server ($r^2 \geq 0.3$), we conducted multivariate logistic regression analysis including covariants (age, sex, BMI, race-ethnicity and carotenoids intake), identified a novel genome-wide significant association between *ATF6* variants (lead SNPs *rs11579627*) and plasma total carotenoids (*p*=2.5x10e-8; *Beta*=0.34). Two common missense variants in *PKD1L2* (*rs4889261 and rs7194871*) from targeted sequencing showed significant associations with plasma beta-carotene levels (*p*=9.2 x10e-5, adjusted *P*=0.04, *Beta*=-0.3; *p* = 1 x10e-4, adjusted *P*=0.04, *Beta*=-1.3, respectively). Pathway analysis revealed a link between suggestive SNPs (p < 5x10e-6) and lipid metabolic pathways, highlighting the lipid-soluble nature of carotenoids. We also found that allele frequency differences primarily drove variation in skin carotenoid metabolism between ancestry populations. Our research enhances the understanding of genetic factors in carotenoid metabolism, revealing a novel role for lipid metabolism-related variants. It emphasized the need for diverse genetic ancestries in genomic studies and considering genetic and environmental variables for carotenoid biomarkers. Overall, our study contributes to advancing precision nutrition and precision health.

PB4094 Comparative analysis of fine-mapping methods at loci with multiple association signals

Authors:

R. Walters[1], J. Sidorenko[2], K. Lin[1], A. Pozarickij[1], K. Young[3], S. Berndt[4], Y. Lu[5], S. Vedantam[6], L. Yengo[2], C. Spracklen[7]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Inst. for Molecular BioSci., Brisbane, Australia, [3]Univ North Carolina, Chapel Hill, NC, [4]Natl. Cancer Inst., Rockville, MD, [5]Vanderbilt Univ. Med. Ctr., Nashville, TN, [6]Boston Childrens and Broad Inst., Boston, MA, [7]Univ. of Massachusetts, Amherst, MA

Genome-wide association studies (GWAS) have proved highly effective at identifying loci associated with diseases and complex traits. A critical step in translating these findings into precision medicine is pinpointing the underlying causal variant(s). Fine-mapping to single variant resolution remains challenging, especially at loci with >1 distinct association signal, and multiple statistical methods have been developed for identifying and characterizing distinct signals from a combination of summary statistics and a linkage disequilibrium (LD) reference dataset.

LD between variants at a locus is a key factor limiting identification of causal variants, and the performance of fine-mapping methods is recognised to be optimal when the LD reference closely matches the GWAS population. However, achieving a closely matched LD panel is challenging for association signals derived from large multi-cohort (and potentially multi-ancestry) meta-analyses, and it is unclear how sensitive these approaches are to the extent of mismatch or size of the LD panel.

To investigate the sensitivity of commonly-used fine-mapping methods to variation in the size of the provided LD panel, we performed a GWAS of height in 456K European-ancestry individuals in the UK Biobank and selected 7 loci of varying complexity: 4 ‘simple’ loci with 1-2 signals within 1 Mbp (at *TANC1, RBMS1, FAM178B, UGGT1*); and 3 ‘complex’ loci with 6-8 signals (at *ZFAT, LTBP1, DIS3L2*). We then compared the results from analyses of these loci using Stepwise Exact Conditional Analysis (SECA), GCTA-cojo, FINEMAP, and SuSiE, with varying LD references of unrelated UK Biobank individuals, one of 350K, and triplicate randomly-selected subsets of 80K, 40K, and 10K.

Compared with SECA, GCTA-cojo produced near-identical results at all 7 loci when using the 350K LD panel and was the method most robust to reductions in LD panel size; nevertheless, it gave more disparate results for complex loci as panel size decreased. By contrast, even with the 350K panel, lead variants and credible sets for the association signals identified by FINEMAP and SuSiE differed substantially, not only from SECA but also from each other, with only limited agreement even in the number of identified signals; for instance, even at the ‘simple’ *FAM178B* locus, SECA and GCTA-cojo identified 2 signals, but FINEMAP and SuSiE identified 5 and 9 signals, respectively. The extent of these differences increased with decreasing panel size. The substantial disagreement between these approaches, as well as their high sensitivity to the size of even a well-matched LD panel, emphasises the need for continued development of fine-mapping methods for complex loci.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4095 Comparing imputation quality in two distinct Latin American populations: Influence of super population exclusion

Authors:

J. French-Kwawu[1], V. Borda Pua[2], R. Laboulaye[2], T. Peixoto Leal[3], I. Fernandez Mata[4], T. O'Connor[2]; [1]Univ. of Maryland Baltimore, Baltimore, MD, [2]Univ. of Maryland Sch. of Med., Baltimore, MD, [3]Cleveland Clinic, Cleveland, OH, [4]Cleveland Clinic Fndn., Cleveland, OH

GWAS are a powerful tool for identifying potential associated between variants and phenotypes. However, GWAS rely on imputation and many existing imputation reference panels are mainly on individuals of European ancestry, making it difficult to reach the same levels of imputation quality in non-European populations. Specifically for Latin Americans (LatAms), historical events have led to sex-biased admixture generating differences in ancestry composition between the autosomes and sex chromosomes (chrs). It is also important to include chr X as sex is a risk factor for many phenotypes. We aim to analyze how the composition of the imputation reference panel affects imputation quality in LatAm populations. Two of the many ways to explore this is by excluding one of three super populations (African, European, or predominantly Native American) in the reference panel, and including LatAms with increasing proportions of Indigenous American (IA) ancestry. To address this, we created imputation panels for both chrs X and 7, since chr 7 is most similar in size to chr X.

We created 4 panels for each chr with 12,000 individuals from the Genetics of Latin American Diversity (GLAD) Project and the Trans-omics for Precision Medicine (TOPMed) program, each containing: 1) Europeans and LatAms (EL), 2) Europeans and Africans (EA), 3) Africans and LatAms (AL), and 4) individuals from all 3 populations (ALL). To compare the effects of increasing IA ancestry, we ordered the 20,079 LatAm individuals by IA ancestry proportion and selected the first 4,000 individuals and joined them with 4,000 African and European individuals. We repeated this step, sliding the window of LatAm individuals by 2,000, until 10 panels were created.

We included two target populations: the Latin American Research Consortium on the Genetics of Parkinson's Disease (LARGE-PD, predominantly South American) and the Columbia University Study of Caribbean Hispanics with Familial and Sporadic Late-Onset Alzheimer's Disease (AD). We limited genotyped SNPs to those with an $R^2 \geq 0.8$, and compared empirical R^2 values, which estimate the correlation between true genotypes and imputed dosages for only genotyped SNPs, between cohorts and chrs.

In the AD cohort, we observed that EL outperformed AL on chr 7, but performed similarly on chr X. In LARGE-PD, EL outperformed AL on chr 7, but AL outperformed EL on chr X. The differences between results in the cohorts can relate to different admixture dynamics between Caribbeans and South Americans, suggesting that population structure and sex-biased admixture may affect the quality of imputation. We expect to find differential effects with increasing the IA ancestry proportions.

PB4096 Comparison of ancestry calibration methods for colorectal cancer polygenic risk score to ensure equity in the clinic.

Authors:

E. Rosenthal[1], L. Hsu[2], M. Thomas[3], U. Peters[4], C. Kachulis[5], K. Patterson[6], G. P. Jarvik[7]; [1]Univ. of Washington Sch. of Med., Seattle, WA, [2]Fred Hutchinson Cancer Res. Ctr., Seattle, WA, [3]Fred Hutch, Redmond, WA, [4]Fred Hutchinson CA Res Ctr, Seattle, WA, [5]Broad Inst., Cambridge, MA, [6]Univ. of Washington, Seattle, WA, [7]Univ Washington Med Ctr., Seattle, WA

Colorectal cancer (CRC) is the 3rd most common cancer in the U.S., and is associated with the 2nd most deaths from cancer. CRC is a complex disease with monogenic, polygenic and environmental/lifestyle risk factors. Polygenic risk scores (PRS), which aggregate low risk variants across the genome, are currently being developed to identify individuals at high risk of developing CRC due to a polygenic component, and to inform the starting age of preventive screening. As causal loci, linkage disequilibrium and minor allele frequencies vary across ancestral groups, PRS must be developed using diverse ancestral data to be equitably applied in the clinic. Similarly, the distribution of raw PRS varies by ancestry, necessitating calibration so that risk stratification is valid regardless of genetic ancestry. We compared 4 calibration methods using the All of Us Research Program Whole Genome Sequence data (N=98,256) for a CRC PRS previously developed in participants of European and East Asian ancestry. Case (N=348) and control (N=12,378) status was determined using a validated algorithm (PheKB #514). Methods 1 and 2 use linear models and the entire dataset to center the raw PRS. Methods 3 and 4 train a linear model to estimate the expected mean and variance on an ancestrally diverse subset of the unassigned participants, which is then applied to case/control data. Methods 1 and 3 use the first 5 principal components of ancestry; methods 2 and 4 use admixture estimates for global ancestries: African (AFR), Admixed American (AMR), European (EUR), East Asian (EAS), Middle Eastern (MID), and South Asian (SAS). Participants were grouped into ancestral clusters based on admixture estimates: AFR (23%), AMR (9.5%), EUR (45%), MID (4.1%) and other (OTH) (16%). Participants clustering with EAS and SAS made up < 3% of the sample and did not have power for statistical testing. The AUC (95% bootstrap C.I.) of the PRS were > 0.5 in AFR 0.59 (0.51,0.67), AMR 0.71 (0.60,0.83), EUR 0.63 (0.59,0.67) and OTH 0.63 (0.56,0.70) but not for MID 0.53 (0.50,0.67). Calibration method 4 had the best performance overall, resulting in distributions that were closest to standard Normal with accurate upper tail frequencies for each ancestry. Sample size was sufficient only in the EUR cluster to show that participants with PRS in the top 20% had higher risk of CRC than participants in the middle (40-60%) with OR=2.3, C.I.=(1.5,3.4). Larger, more diverse datasets are required to further develop and validate the PRS. Ultimately, a more comprehensive ancestrally calibrated risk that includes environment, genetics, and social determinants of health is necessary for equitable application in the clinic.

PB4097 Compound heterozygous effects across common phenotypes in the UK Biobank.

Authors:

F. Lassen[1], S. Venkatesh[1], N. Baya[1], A. Bloemendal[2], B. Neale[3], B. Kessler[1], W. Zhou[3], C. Lindgren[4], D. Palmer[5]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Broad Inst., Cambridge, MA, [3]Massachusetts Gen. Hosp., Boston, MA, [4]Big Data Inst., Oxford Univ., Oxford, United Kingdom, [5]Univ. of Oxford, Big Data Inst., Oxford, United Kingdom

Exome-sequencing association studies have successfully linked rare protein-coding variation to risk of thousands of diseases. However, whilst heterozygous and homozygous variants have been well-studied, the phenotypic impact of rare deleterious compound heterozygous variation has not been investigated at scale.

Here, we leverage advances in statistical phasing to accurately phase rare variants (minor allele frequency (MAF)~0.001%) in exome sequencing from 175,587 UK Biobank participants. We then systematically annotate putatively deleterious compound heterozygous coding variation. We show that 6.5% of individuals carry such damaging variants in the compound heterozygous state, with 90% of variants occurring at MAF<0.34%.

Using a logistic mixed model framework, systematically accounting for relatedness, polygenic risk, nearby common variants, and rare variant burden, we investigate recessive effects in common complex diseases. We discover 8 gene-trait associations at 'exome-wide significance' ($P<1.68x10^{-7}$). These include well-established recessive gene-trait pairs with recessive mode of inheritance, including *MUTYH* and colorectal cancer ($\beta=10.8$, $P=2.5x10^{-12}$). We further incorporate age-at-diagnosis information from primary care electronic health records, to show that genetic phase influences lifetime risk of disease across 20 gene-trait combinations (FDR < 5%). Our findings show that for certain gene-trait pairs, individuals with a single disrupted gene copy have a risk of developing disease that is virtually indistinguishable from that of wildtypes, suggesting clear non-additive gene dosage effects. Through statistically shuffling haplotypes across cases and controls, we provide the first large scale cohort evidence that genetic phase is indeed the primary determinant of disease susceptibility for a range of gene-trait pairs, including *FLG*-asthma ($P=0.0027$).

Taken together, we demonstrate the utility of phasing large-scale genetic sequencing cohorts for robust identification of the phenome-wide consequences of compound heterozygosity.

PB4098 Comprehensive evaluation of CNV detection leveraging SV support on Illumina DRAGEN™ Bio-IT platform v4.2 using high quality human genomes and clinical samples

Authors:

Y. Gao, M. Fleharty, E. Malolepsza, D. Toledo, N. Lennon; The Broad Inst. of MIT and Harvard, Cambridge, MA

Copy Number Variations (CNVs) significantly contribute to human genetic diversity and disease predisposition, necessitating the development of precise and efficient detection methodologies in genomics research and clinical diagnostics. In this context, we present a study that evaluates the CNV detection performance of the CNV caller that leverages both depth and structural variant signals in the latest Illumina DRAGEN™ Bio-IT Platform v4.2. For the evaluation, we utilized high-quality data from the Telomere-to-Telomere (T2T) sequenced human genome HG002 and its associated dipcall variant calling results as a benchmark. Comparing CNV calls from DRAGEN™ for HG002 against this ground truth, we assessed the platform's ability to detect deletion (copy number losses) and duplication (copy number gains) events across an extensive range of CNV sizes. Further extending the robustness of our study, we incorporated a set of samples featuring known clinically significant chromosomal aberrations. This added dimension of real-world clinical data allows for a deeper examination of the platform's potential performance in a diagnostic context. To evaluate the platform's precision and potential for erroneous calls, we sequenced CHM13 using the NovaSeqX™ platform and aligned the data to the CHM13-T2T reference. As part of our evaluation process, we considered the CHM13-T2T reference to encompass all true CNV events. Consequently, any calls made in relation to this reference were classified as false positives. Our evaluation, stratified by CNV type and length, provides a nuanced understanding of the sensitivity and specificity of CNV detection from Illumina DRAGEN™ Bio-IT Platform v4.2. The insights drawn from this study offer valuable guidance for researchers and clinicians dealing with high-throughput genomic data and contribute to the continued enhancement of CNV detection methodologies. Please note that the results of this study are intended for research purposes only and are not for use in diagnostic procedures.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4099 † Comprehensive polygenic prediction of respiratory diseases: a cross biobank multi-trait and multi-ancestry approach

Authors:

Y. He, Y. Wang, K. Tsuo, A. Martin; Massachusetts Gen. Hosp., Boston, MA

Polygenic risk scores (PRS) are poised to become valuable risk prediction tools for improving precision medicine and health outcomes. However, they demonstrate poor trans-ancestry portability, thus hindering their clinical utility and potentially exacerbating disparities. To date, most PRSs have been developed for single traits and single ancestry groups without considering genetic correlation between traits or ancestry specific linkage disequilibrium (LD) and allele frequency patterns. Here, we develop PRS-xtra (cross TRait and Ancestry), a stepwise approach to model multi-trait and multi-ancestry features. We demonstrate its greater predictive ability compared to existing approaches for respiratory illnesses.

Respiratory diseases such as chronic obstructive pulmonary disease (COPD) and lung cancer are leading causes of morbidity and mortality globally and share many comorbidities and risk factors. We thus jointly modeled genome-wide association studies (GWAS) for 7 strongly correlated traits-COPD, asthma, lung cancer, FEV1, FVC, smoking status, and cigarettes/day-in African (AFR), Admixed American (AMR), East Asian (EAS), and European (EUR) ancestry groups. We leveraged the largest and most diverse GWAS from the Global Biobank Meta-analysis Initiative, Pan UK Biobank, and GWAS & Sequencing Consortium of Alcohol and Nicotine use. We employed the multi-trait analysis of GWAS (MTAG) method to model genetic correlation between traits, then PRS-CSx to model LD within and between populations. Altogether, we derived 56 PRSs in 120614 individuals from the All of Us research program (AoU). We synthesized PRS-xtra using elastic net regularization to penalize number of PRSs and their effects. We evaluated PRS-xtra in held out test sets from AoU and Mass General Brigham Biobank.

All traits were significantly correlated with each other, with the strongest correlations being between asthma and COPD ($rg=0.705$, $p<0.0001$) and lung cancer and cigarettes/day ($rg=0.614$, $p<0.0001$). PRS-xtra demonstrated significant improvements in predictive performance, especially in non-EUR populations. For example, PRS-xtra significantly improved predictive accuracy of COPD in AMR and AFR populations, with AUC increasing from 0.522 to 0.654 and from 0.504 to 0.535, respectively.

We conducted the most powerful multi-trait and multi-ancestry genetic analysis of respiratory diseases and auxiliary traits to date. We propose PRS-xtra as a method to model genetic correlation across traits and LD differences between ancestry groups that demonstrate significantly better disease prediction, thereby advancing more equitable and generalizable prediction models.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4100 Computational algorithms for phenotypic patient matching to achieve diagnoses in rare disease cohorts.

Authors:

I. Cooperstein[1], A. Ward[1,2], G. Marth[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]Frameshift Genomics Inc, Boston, MA

Introduction: Patients with rare monogenic diseases often lack a clear disease-causing variant or mutation following sequencing. Computational approaches that efficiently identify functionally import variants for analysis are essential. However, incomplete knowledge of gene associations and diverse clinical phenotypes, which rarely perfectly align with disease descriptions in databases, limit the power of many existing variant prioritization tools. We present a computational approach that utilizes real patient data from deeply genotyped and phenotyped rare disease databases. Our algorithmic and visualization tools automate the identification of patients with similar genetic mutations and disease phenotypes, which can be crucial to inform diagnoses and significantly advance knowledge of a rare disease. **Methods:** The hierarchically organized Human Phenotype Ontology (HPO) terms describing patients' disease presentations enable calculations of phenotypic similarity scores between patient pairs. We apply a Bayesian statistical framework to determine the significance of high-scoring patient pairs. Our method prioritizes candidate variant lists of new or previously unsolved cases based on the diagnostic genes of high-scoring diagnosed patient matches. Furthermore, our algorithms identify clusters of phenotypically similar undiagnosed patient matches, then search for high-impact variants within shared genes across all cluster members to discover novel disease genes. **Results:** Applying our methods to the difficult-to-diagnose patient cohort within the NIH's Undiagnosed Diseases Network (UDN) demonstrate that patient pairs with matching clinical diagnoses exhibit significantly higher phenotypic similarity scores than when scoring the patients against the Orphanet disease description of their diagnosis. Further, patients with diagnoses in the same gene exhibit significantly higher phenotypic similarity scores than those with diagnoses in different genes. We have identified compelling candidate variants for undiagnosed UDN cases based on their phenotypic and genotypic similarity to other UDN patients. **Conclusion:** Our approach leverages the power of phenotypic and genomic data in existing datasets to automate patient matching, offering a promising pathway to improve diagnostic rates and generate new insights into gene function in rare monogenic diseases. This development is part of the larger Calypso project, which aims to provide longitudinal support to genomic medicine. Applying our algorithms to reanalyze data over time will allow us to continually revisit patient cohorts to discover new impacting and relevant genes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4101 Contribution of rare variants to heritability of a disease is much greater than conventionally estimated: modification of allele distribution model

Authors:

Y. Nagao; Tokai Univ. Hosp., Isehara, Japan

Missing heritability is a current problem in human genetics. I previously reported a method to estimate heritability of a polymorphism (h_p^2) for a common disease without calculating the genetic variance under dominant and the recessive models. Here, I extended the method to the co-dominant model and carry out trial calculations of h_p^2. I also calculated h_p^2 applying the allele distribution model originally reported by Pawitan et al. for a comparison. Unexpectedly, h_p^2 calculated for rare variants with high odds ratios was much higher. I noticed that conventional methods use the allele frequency (AF) of a variant in the general population. However, this implicitly assumes that the unaffected are included among the phenotypes: an assumption that is inconsistent with case-control studies in which unaffected individuals belong to the control group. Therefore, I modified the allele distribution model by using the AF in the patient population. Consequently, the h_p^2 of rare variants was quite high. Recalculating h_p^2 of several rare variants reported in the literature with the modified allele distribution model, yielded results were 3.2 - 53.7 times higher than the original model. These results suggest that the contribution of rare variants to heritability of a disease has been considerably underestimated.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4102 Coordinated Epistasis reveals Symptom-Specific Polygenic Pathway Interactions in Major Depressive Disorder

Authors:

J. Rietkerk[1], L. Huang[1], V. Appadurai[2], V. Trindade-Pons[3], H. van Loo[3], L. Garvert[4], S. van der Auwera[4], M. Adams[5], H. J. Grabe[6], A. Schork[7], B. Müller-Myhsok[8], A. Dahl[9], N. Cai[1]; [1]Helmholtz Munich, Neuherberg, Germany, [2]Inst. of Biological Psychiatry, Roskilde, Denmark, [3]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [4]Univ. of Greifswald, Greifswald, Germany, [5]Univ. of Edinburgh, Edunburgh, United Kingdom, [6]Univ. of Greifswald, Greifwald, Germany, [7]Res. Inst. for Biological Psychiatry, Roskilde, Denmark, [8]Max-Planck Inst. of Psychiatry, Munich, Germany, [9]UChicago, Chicago, IL

Major Depressive Disorder (MDD) is a highly heterogeneous disorder; patients often exhibit very diverse symptom profiles, some of which have no symptoms in common. Mounting literature suggests that MDD is likely the common outcome of many different etiological pathways. In this project, we aim to identify polygenic pathways that contribute to symptom heterogeneity in MDD. We do this through identification of interactions between their genetic effects on the disorder using Coordinated Epistasis (CE). CE tests for interactions between polygenic effects of etiological pathways by aggregating the effects into Polygenic Risk Scores (PRS). For a polygenic disorder like MDD, CE assumes that those genetic effects are distributed across the genome. Therefore, we approximate these pathways with random genome partitions. We validate this assumption through simulation: we randomly partition the genome into halves 100 times. The resulting 100 interaction effect estimates (γ) constitute a distribution over the different partitions and its standard deviation varies with polygenicity. Next, we apply this 100-partition test to MDD and its 14 worst-episode symptoms in the UK Biobank. We find that their γ distributions capture both the pathways' polygenicity and their interaction effects. To further characterize these, we test for CE between PRS of all chromosome pairs. We find 2 significantly interacting chromosome pairs in MDD and 64 significantly interacting chromosome pairs in 13 out of 14 MDD symptoms (at 10% FDR). We then follow-up on significantly interacting pairs through SNP-PRS interaction tests and identified 102 chromosome-wide significant loci. Strikingly, we find that the significant SNP-PRS interactions for specific worst-episode symptoms of MDD align with previously found GWAS hits for MDD and other MDD-related phenotypes. For example, chromosomes 1 and 11 show significant PRS interactions for the worst-episode symptom hypersomnia (P = 3e-04); the locus involved (rs4245154, SNP-PRS interaction test P = 1.2e-06) is in an intron of the gene DRD2, which has previously been associated with MDD and neuroticism. We identify, for the first time, polygenic pathway interactions in MDD and its worst-episode symptoms. Our simulations show that γ forms a distribution over partitions of the genome, and simultaneously indicates interaction effects and pathway polygenicity. We further find specific loci that contribute to pathway interactions for symptoms of MDD. These loci are previously found associated with MDD and a variety of MDD-related phenotypes. This demonstrates the relevance of these symptom interactions as part of MDD genetic architecture.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4103 Copy number variants associated with neuropsychiatric traits differ in prevalence across ancestry groups.

Authors:

L. M. Schultz[1], G. Huguet[2], M. Jean-Louis[2], Z. Saci[2], J. Mollon[3], E. Knowles[3], D. C. Glahn[3], S. Jacquemont[2], L. Almasy[4,1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]CHU Sainte-Justine, Montréal, QC, Canada, [3]Boston Children's Hosp., Boston, MA, [4]Univ. of Pennsylvania, Philadelphia, PA

Rare copy number variants (CNVs) have been associated with a variety of health outcomes and neurodevelopmental traits. We previously found that CNV prevalence varies across the European, African, and South Asian ancestry groups in the UK Biobank (UKBB). We now replicate these findings in SPARK, a United States cohort of individuals diagnosed with autism spectrum disorder (ASD) and their families, and we extend our analyses to examine the prevalence of recurrent CNVs in individuals of admixed American ancestry. We used PennCNV and QuantiSNP to call CNVs (≥ 50 kB pairs) for European (EUR; *n* =46,971), African (AFR; *n* = 3,697), and admixed American (AMR; *n* = 7,882) SPARK participants whose genetic ancestry we inferred using KING. Then, we subsampled two cohorts of EUR individuals who were propensity-score matched on age, sex, and ASD diagnosis to either the AFR cohort (EUR-AFR; *n* = 3,697) or the AMR cohort (EUR-AMR; *n* = 7,882). We calculated odds as the number of recurrent CNV carriers divided by the number of non-carriers for each of 11 recurrent CNVs that we previously selected for analyses in the UKBB. Then, we calculated AFR odds ratios (ORs) as the AFR odds / EUR-AFR odds and AMR ORs as AMR odds / EUR-AMR odds. Despite smaller sample sizes and ascertainment differences, we replicated our previous findings of reduced prevalence of *CRYL1* DEL (AFR OR = 0; 95% confidence interval:[0, 0.693]), 15q13.1 BP4.5-BP5 DUP (AFR OR = 0.248; [0.0988, 0.551]), and 16p13.11 DUP (AFR OR = 0.315; [0.103, 0.82]) as well as increased prevalence of 2q13 *NPHP1* DUP (AFR OR = 17.1; [2.67, 711]) in AFR- as compared to EUR-ancestry individuals. Additionally, the *NRXN1* DEL was less prevalent in the SPARK AFR cohort than in the matched EUR cohort (AFR OR = 0.055; [0.001, 0.351]). We also found that 4 of the 11 recurrent CNVs were less prevalent in the SPARK AMR cohort as compared to the matched EUR cohort: 15q11.2 DEL (AMR OR = 0.546; [0.334, 0.875]), *NRXN1* DEL (AMR OR = 0.436; [0.215, 0.842]), 16p13.11 DUP (AMR OR = 0.512; [0.278, 0.915]), and 1q21.1 TAR DUP (AMR OR = 0.071; [0.002, 0.469]). By establishing that ancestry-related differences in CNV prevalence are present in both unselected community populations (UKBB) and cohorts enriched with ASD-diagnosed individuals (SPARK), our results suggest that genetic ancestry should be a key consideration when probing associations between CNVs and neurodevelopmental outcomes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4104 Cox proportional hazards mixed model enables accurate estimation of heritability for time to event outcomes

Authors:

K. Taraszka[1], S. Sankararaman[2], A. Gusev[1]; [1]Dana-Farber Cancer Inst., Boston, MA, [2]UCLA, Los Angeles, CA

Heritability is defined as the variance in disease susceptibility attributed to genetics and is a fundamental parameter for interpreting disease architecture and polygenic prediction. Multiple methods have been developed for estimating the heritability of continuous or case-control phenotypes (under the liability threshold model, LTM), however, the heritability of time-to-event (TTE) outcomes has been largely unstudied. This has limited the characterization of age-of-onset and treatment response phenotypes, the latter particularly relevant for clinical studies. Here, we propose and evaluate a Cox proportional hazard mixed model (COXMM) to enable accurate estimation of heritability for TTE phenotypes with censoring. We apply these methods to real data from the UK Biobank.

We implemented an efficient COXMM with a random effect modeled by the genetic relatedness across individuals, and benchmarked its performance in extensive simulations. We simulated phenotypes according to generative models reflecting either LTM or TTE models. For TTE phenotypes, data followed various Weibull distributions with independent censoring. Across TTE simulations, COXMM produced unbiased estimates of heritability while classic case-control heritability estimators (Haseman-Elston regression, HE-reg under the LTM) showed significant downward bias. Likewise, restricting only to cases and estimating heritability of age-of-onset as a normalized continuous phenotype with HE-reg produced biased estimates, due to the artificial exclusion of controls. For example, for an exponential distributed age-of-onset with heritability of 0.8 and 40% of individuals in the study being cases, COXMM inferred heritability was 0.80 (0.007), compared to 0.32 (0.004) for case-control HE-reg, and 0.09 (0.02) for case-only age-of-onset HE-reg.

In the UK Biobank, we analyzed ten cardiovascular related age-of-onset traits. Interestingly, we found that the TTE estimate was higher for eight traits while the other two traits better reflect the LTM. For example, myocardial infarction (N=275,841 with 6% as cases), the COXMM heritability was 0.38 compared to 0.05 for case-control HE-reg, and 0.26 for case-only age-of-onset HE-reg. Ultimately, disease susceptibility is a well studied phenomenon while the heritability of TTE phenotypes such as age-of-onset or progression remain understudied due to poor performance of existing methods.

PB4105 Craniofacial enhancers are enriched for *de novo* mutations in trios with orofacial clefts

Authors:

S. Curtis[1], J. Murray[2], E. Feingold[3], T. Beaty[4], S. Weinberg[3], M. Marazita[5], M. Epstein[1], D. Cutler[1], J. Cotney[6], A. Visel[7], E. Leslie[1]; [1]Emory Univ., Atlanta, GA, [2]U of Iowa, Iowa City, IA, [3]Univ of Pittsburgh, Pittsburgh, PA, [4]Johns Hopkins Univ, Sch PubHlth, Baltimore, MD, [5]Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, [6]UConn Hlth., Farmington, CT, [7]Lawrence Berkeley Natl Lab., Berkeley, CA

Identifying the contribution of non-coding variants to human disease is challenging due to the increased number of genetic variants relative to coding variants and the cell-type and timepoint specific function of non-coding elements, which are incompletely catalogued. Although it is well established that common genetic variants associated with human diseases are enriched in non-coding regions of the genome, less is knowns about the role of rare non-coding variants, including de novo mutations (DNMs). We investigated the role of non-coding DNMs in a cohort of 1,114 trios with orofacial clefts (OFCs), a common birth defect, sequenced by the Gabriella Miller Kids First Research Program. We developed a novel algorithm to estimate the expected mutation rate in any defined region of the genome based on mutation rates from gnomAD, and validated its performance for coding regions using existing software tools ($r = 0.88$, $p<2.2x10-16$). We then called 73,284 high confidence DNMs and curated a set of 316,823 enhancers active in embryonic human craniofacial tissue. A total of 10,346 unique DNMs occurred in 8,421 of these enhancer regions. After correcting for multiple tests, 8 enhancers showed a significant burden of DNMs ($p < 5.9$ x 10-6). The enhancer with the greatest enrichment of DNMs was a 250kb super enhancer region with 20 DNMs ($p=1.35$ x 10-7), located 200kb upstream of PTK2, a tyrosine kinase (FAK) involved in focal adhesions between growing cells. While PTK2 is ubiquitously expressed, the conditional knockout in neural crest cells in mice was previously found to cause cleft palate and other structural anomalies. We next tested whether the DNMs in the 8 significant enhancers disrupted any transcription factor (TF) binding sites. 62 of the DNMs were predicted to alter the binding of TFs, with 144 TF binding sites predicted to be destroyed in the presence of the mutation, including binding sites for TFAP2A, TWIST1, SOX9, and ZBTB7A, all TFs known to be involved in craniofacial development and/or OFCs. To demonstrate tissue relevance, we repeated the analysis using DNMs in 301 healthy trios from the 1000 Genomes Project and >21 million non-craniofacial enhancers from the Roadmap Epigenomics Consortium. None of the OFC-enriched enhancers were enriched for DNMs in the control trios. Six of the Roadmap enhancers were enriched for DNMs in OFC trios ($p < 5$ x 10-8), and further analysis showed they overlapped enhancers active in fetal and craniofacial development. Our overall results demonstrate that craniofacial enhancers are enriched for DNMs found in OFC trios and suggests a mechanism by which these variants could alter gene regulation and affect developmental pathways leading to OFCs.

PB4106 Creating a Simulation Framework and Testing Methods to Adjust for Fine-Scale Population Structure in Rare Variant Analyses

Authors:

K. Marker[1], R. Shemirani[2], M. Lin[1], E. Kenny[2], G. Belbin[3], C. Gignoux[1]; [1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Gencove Inc., New York, NY

When there is a difference in average trait value or disease prevalence between subpopulations, fine-scale genetic differences in rare variants can induce population structure that cannot always be guaranteed to be corrected with traditional approaches. This is increasingly a problem as very large sample sizes are needed to detect rare variant associations. Fine-scale ancestry differences between cohorts will induce population structure bias that can confound rare variant association studies if the fine-scale population structure is not properly adjusted for. We aim to compare four methods for capturing and adjusting for fine-scale population structure under varying phenotypic and environmental structure to identify the best method/s for various scenarios. These methods include identity-by-descent (IBD) clusters, kinship clusters, rare variant PCA, and Uniform Manifold Approximation and Projection (UMAP) projections. We developed a genetic simulation framework to generate 9 populations from a continental European demographic model with stepping-stone migration using msprime and tskit. We first simulate four outer populations from an ancestral population, and the inner populations are admixed from those original four populations and add continuous migration between adjacent populations. For our phenotype simulations we extend prior work on simulating ancestry-by-environment interactions (APRICOT). We extend the method to allow for complex multi-way admixture, in addition to adding isolation by distance models. This allows us to model and control the fine-scale population structure to test various confounding scenarios. Using this simulation framework, we run rare variant association tests to compare adjustment by IBD clusters, kinship clusters, rare variant PCA, and UMAP projections under varying phenotypic structures.

PB4107 Credible set is sensitive to imputation quality and missing variants

Authors:

Y. Liang, 23andMe Research Team, A. Auton, X. Wang; 23andMe, Sunnyvale, CA

Performing Bayesian fine-mapping to obtain credible sets has been widely applied in GWAS to pinpoint causal variants. With most GWASs relying on genotype imputation, the imputed genotypes are often represented by genotype dosages that may contain errors resulting from imperfect imputation. Besides, the imputation panel may not include the causal variants. However, these uncertainties resulting from imputation are usually not taken into account in downstream fine-mapping analyses.

In this work, we consider a common use case in which a GWAS study is performed using a minority of genotype calls that originate from a genotyping chip and a majority of variants that are imputed as genotype dosages using a reference whole genome sequencing panel. We designed a simulation study to look into the effect of genotype imputation on the quality of fine-mapping results. In particular, we focused on the observed coverage of the credible set and how well the credible set could tag a missing causal variant. We found that the coverage is expected or better when the association p-value is around 1e-8 to 1e-10 or the causal variant is rare. In contrast, when the association p-value < 1e-10 and the causal variant is common, the observed coverage is significantly smaller than the expected coverage as a result of attenuation due to imputation error and linkage disequilibrium. We further show that this miscalibration is due to the fact that the posterior inclusion probabilities overly concentrate on nearby variants that are in high LD with the causal variant while the posterior probability of the causal variants is low. This miscalibration is exacerbated by low imputation quality. To resolve this calibration problem, we explored potential post-GWAS solutions that explicitly take imputation quality into account by weighting the summary statistics on the basis of imputation quality and the true LD of the locus.

In summary, this work highlights the usefulness of including imputed variants in fine-mapping analyses and points out the potential miscalibration of fine-mapping results due to the uncertainty introduced by genotype imputation. To maximize the utility of the fine-mapping analysis in the context of genotyping in combination with genotype imputation workflow, we suggest methodological improvements for considering imputation error in fine-mapping analyses in the future.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4108 † Cross-ancestry genetic architecture influences estimation of heritability and genetic correlation in diverse populations

Authors:

S-K. Jang[1], N. Zaitlen[2], TOPMed consortium, S. Vrieze[3], S. Basu[3]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]UCLA, Los Angeles, CA, [3]Univ. of Minnesota, Minneapolis, MN

With global initiatives for diverse genomic research, diverse genetic data will be increasingly available. Understanding the extent to which genetic architecture overlaps across populations and its impact on SNP-based heritability (h^2_{SNP}) and cross-ancestry genetic correlation are important to leverage these datasets to advance the genetic etiology of complex traits. Here we examined behaviors of different analytic approaches in estimating h^2_{SNP} and cross-ancestry genetic correlation estimates in diverse populations, considering various cross-ancestry genetic architecture scenarios with varying allele frequency (AF) and allelic effects of causal variants across ancestries.Using up to 55,724 diverse whole-genome sequence data from the TOPMed consortium, we compared four approaches and different ways to standardize genotype in simulation and real anthropometric phenotype analysis: 1) single ancestry approach: Genomic Restricted Maximum Likelihood (GREML) /Haseman-Elston (HE) regression applied to individual ancestry, 2) combined ancestry approach: GREML/HE regression applied to ancestry- combined sample, 3) bivariate approach: bivariate GREML to estimate h^2_{SNP} and cross-ancestry genetic correlation, and 4) GxE approach: GxEMM to estimate h^2_{SNP} for shared and ancestry-specific genetic effects. In the simulation, we found that heterogeneity in AF and allelic effects significantly affect heritability and genetic correlation estimates. Enriching causal variants in variants with lower cross-ancestry AF difference than that of randomly chosen SNPs led to a downward bias in h^2_{SNP} estimates due to the overall low LD level of these variants. Additionally, enriching causal variants in variants with larger cross-ancestry AF differences led to an underestimation of cross-ancestry genetic correlation across all ancestry pairs. Overall, bivariate and GxE approaches using within-ancestry standardized GRM yielded robust estimates in a relatively wide range of cross-ancestry architectures than other methods. In real phenotype analysis, we observed that h^2_{SNP} of height in the AFR population is enriched in variants with larger AF differences with European ancestry even after accounting for overall allele frequency and LD level in individual ancestry (h^2_{SNP} estimates=.10 (.04) v.s., .19 (.04) for smaller v.s. larger AF difference). This study provides guidance for estimating h^2_{SNP} and cross-ancestry genetic correlation using diverse ancestry data and highlights the importance of considering cross-ancestry genetic architectures in interpreting the results of existing methods.

PB4109 Data-driven trait heritability-based extraction of human facial phenotypes in genome-wide association studies

Authors:

M. Yuan[1], S. Goovaerts[1], H. Hoskens[2], O. D. Klein[3], R. Spritz[4], B. Hallgrimsson[2], S. Richmond[5], S. Walsh[6], M. D. Shriver[7], J. R. Shaffer[8], S. M. Weinberg[8], H. Peeters[1], P. Claes[1]; [1]KU Leuven, Leuven, Belgium, [2]Univ. of Calgary, Calgary, AB, Canada, [3]Univ. of California, San Francisco, San Francisco, CA, [4]Univ Colorado Hlth Sci Ctr, Aurora, CO, [5]Cardiff Univ., Cardiff, United Kingdom, [6]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN, [7]Penn State Univ, University Park, PA, [8]Univ. of Pittsburgh, Pittsburgh, PA

Genome-wide association studies (GWAS) of complex, multi-dimensional traits, such as the human face, typically rely on predefined and simplified phenotypic measurements like inter-landmark distances and angles. These measures are predominantly designed by human experts based on biological or clinical knowledge. To circumvent manual crafting, alternative phenotypic descriptors, such as features derived from dimension reduction techniques (e.g., principal component analysis), are employed. While the features generated by computational algorithms capture the geometric variations of the biological shape, they are not necessarily genetically relevant. Therefore, genetically informed data-driven phenotyping is desirable. Here, we propose an approach where phenotyping is done by a data-driven optimization of trait heritability or estimates of the degree of variation in a phenotypic trait in a population that is due to genetic variation. The resulting phenotyping process consists of two steps: the first step involves constructing a feature-space that models shape variations using dimension reduction techniques, while the second step entails searching for directions in the feature-space where trait-heritability are high using a genetic search algorithm. This heritability-dependent optimization enables the extraction of phenotypes assumed to have a higher genetic value. We trained and validated our proposed phenotyping process using 3D facial surface scans of father-offspring pairs (n=770) and an independent cohort of unrelated European individuals (n=8,426) with genome-wide SNP data, respectively. The phenotypes resulting from the heritability-optimized training demonstrated higher mean trait heritability (0.399+/-0.088) compared to that of principal components (0.265+/-0.126), as expected. More notably, trait-heritability optimized phenotypes exhibited higher SNP-based heritability (0.36+/-0.062) compared to principal components (0.214+/-0.087). Furthermore, a smaller number (n=30) of effective heritability-optimized traits was sufficient to identify the same number of independent genetic loci (n=11) compared to using all principal components (n=70), that together explain 98% of the facial shape variation. Our results demonstrate that data-driven trait heritability-based optimization enables the automatic extraction of genetically relevant phenotypes, shown by their increased power in GWAS.

PB4110 *De novo* germline variants associated with congenital heart disease and neuroblastoma: Evidence of pleiotropic genetic effects from 1,320 parent-offspring trios.

Authors:

A. Renwick[1], Y. Yu[2], R. Harris[1], P. J. Lupo[1], C. Huff[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Univ. of Texas M.D. Anderson Cancer Ctr., Houston, TX

There is emerging evidence that children with congenital heart disease (CHD) are more likely to develop neuroblastoma when compared to children without these conditions. While there are some lines of evidence to support these associations (e.g., common cells of origin), there have been few efforts to evaluate the genetic overlap between these phenotypes. Therefore, we evaluated pleiotropic effects of *de novo* variants in CHD and neuroblastoma parent-offspring trios.

Whole genome sequencing (WGS) data on CHD trios (n=711) and neuroblastoma trios (n=609) was obtained from the Gabriella Miller Kids First Data Resource Center as trio VCFs. Our filtering criteria to identify *de novo* variants included the number of high-quality reads, the fraction of alternative alleles, and likelihood ratio in both parents and probands. We excluded common variants and variants from genomic repeat regions. Following filtering, we tested for an enrichment of *de novo* single nucleotide coding variants in each cohort using the VARPRISM software. We then computed an omnibus p-value across the two cohorts using Fisher's method, and then manually inspected the BAM alignments of variants contributing to significant enrichments. We also incorporated findings from a previously reported exome study of the CHD cohort.

Probands in the neuroblastoma cohort were 54% male and 81% Non-Hispanic White, with a median age at diagnosis of 16 months. Probands in the CHD cohort were 59% male and 60% Non-Hispanic White. The most frequent CHD phenotypes were ventricular septal defects (46%), tetralogy of Fallot (32%), hypoplastic left heart syndrome (28%), atrial septal defects (25%), and right aortic arch (25%). In our trio-based analysis, we tested 18,662 genes and found six genes were nominally (but not genome-wide) significant for an enrichment of *de novo* variants in both cohorts: *CIC* ($p=2.2x10^{-3}$), *FAM76A* ($p=2.3x10^{-4}$), *IREB2* ($p=6.4x10^{-4}$), *PCDHGB5* ($p=3.8x10^{-4}$), *PELO* ($p=1.5x10^{-3}$), and *POGZ* ($p=8.2x10^{-6}$).

While our results do not suggest that de novo variants play a strong role in the overlap between CHD and neuroblastoma, we did identify genes that are involved in development and carcinogenesis. For example, *FAM76A*, *IREB2*, *PCDHGB5*, and *PELO* are all involved in gene regulation, while *CIC* is involved in between-cell communication. Additionally, *CIC*, *IREB2*, *PCDHGB5*, and *POGZ* are known to be involved in neurodevelopmental disorders, phenotypes which have been reported among children with CHD and neuroblastoma. Our assessment demonstrates the utility of evaluating the genetic underpinnings of these associated conditions.

PB4111 Decoding the genetic architecture of hearing acuity in a family-based design

Authors:

J. Duran[1], S. Mansour[1], D. Neklason[2], L. Jorde[1]; [1]Univ. of Utah Dept. of Human Genetics, Salt Lake City, UT, [2]Univ of Utah Dept. of Internal Med., Salt Lake City, UT

Genetic studies of hearing impairment and deafness have revealed over 223 genes that negatively impact hearing. The genetics of natural variation in hearing acuity is less studied and poorly understood. Identifying genetic variation responsible for an individual's hearing ability would provide future avenues to explore novel targets for treating hearing loss. In addition, it may identify genetic variation that contributes to exceptionally acute hearing and offer insight into protective variants. We report the first pedigree-based assessment of heritability and genetic correlations of hearing ability across a range of frequencies. Whole-genome sequencing and audiometric data from 39 three- and four-generation Utah CEPH families were used to examine the genetic architecture of hearing acuity. The narrow-sense heritability of hearing acuity within the CEPH cohort decreased from 56% at 250Hz to 35% at 8000Hz. The single nucleotide polymorphism (SNP) heritability decreased from 35% to 15% across the same frequency range. These patterns are consistent with a larger non-genetic component for high-frequency hearing acuity. To explain the effects of familial transmission on SNP heritability we estimated the SNP heritability of unrelated individuals in our cohort. As expected, the SNP heritability of unrelated individuals was lower than that of related individuals, with an average decrease of 8%, $p = 0.01$. A bivariate analysis was performed to understand the genetic correlation between any two frequencies. We found that the closer frequencies are in pitch, the more significant the genetic correlation between those frequencies, suggesting distinct genetic effects contribute differentially to low- and high-frequency acuity. Previous studies of overall hearing acuity, based on twin data, have provided heritability estimates that may be upwardly biased. Thus far they have been limited to values averaged across frequencies. A Swedish twin study estimated the narrow-sense heritability averaged across four high frequencies at 75%. Similarly, a twin study of U.S. veterans reported hearing acuity heritability upper limits of 73% for mid-range frequencies and 72% for high frequencies. By comparison, our family-based heritability estimates are 51% for mid-level frequencies and 43% for high frequencies. This difference suggests that previous studies may have overestimated the genetic contribution to hearing acuity, and highlights the importance of considering frequency-specific differences. Continued work on the genetic architecture of hearing acuity may open avenues for investigating protective variation and novel targets to treat hearing impairment.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4112 Deep multilayer proteomics and multi-omics integration reveal molecular networks related to Alzheimer's disease in diabetic brains

Authors:

V. Sarsani[1], A. Capuano[2], S. Tasaki[2], Z. Arvanitakis[2], L. Liang[1]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Rush Alzheimer's Disease Ctr., Chicago, IL

Type 2 diabetes mellitus (T2D) and Alzheimer's disease (AD) are two complex diseases that are prevalent in the aging population. Recent research suggests that insulin resistance, a key feature of T2D, is associated with AD pathology, including amyloid-β deposition and cognitive impairment. To better understand the molecular mechanisms of insulin resistance in the brain and periphery and its relationship to AD neuropathology and cognitive function, we performed a phosphoproteome and proteome profiling study using a multi-omics integration approach. We examined 192 post-mortem brain and muscle samples from individuals with and without T2D and with varying levels of AD pathology. We quantified 11,726 phosphopeptides and 29,955 non-phosphopeptides from 3,537 protein groups in frozen brain tissue (dorsolateral prefrontal cortex). In muscle, we quantified 7,801 phosphopeptides and 14,940 non-phosphopeptides from 1,383 protein groups. Our analysis revealed that subjects with higher levels of AD pathology exhibited hyperphosphorylation in proteins like MAPT, regardless of T2D status. Diabetic proteome exhibited hyperphosphorylation in c*ytochrome* oxidases subunit proteins like NDUFA4 and COX7B. We also identified 105 phosphorylation changes in proteins, including MAP2, SLC43A2, and GIT1, that were common to both AD and T2D. We then integrated GWAS, methylation, metabolomics, and transcriptomic profiles of matched samples to build predictive omics signatures using a novel semi-supervised machine learning (ML) framework. To examine the generalizability and utility of our results, we tested our framework-generated signatures on primarily peripheral blood omics data from AD and T2D subjects in UK Biobank. In conclusion, with our multilayer proteomics data and novel ML omics integration framework, we built predictive signatures and molecular network maps of AD and T2D phosphorylation signaling events, thus filling knowledge gaps in metabolism, insulin signaling, and AD research.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4113 DeepRVAT: Joint modelling of rare variant genetic effects using deep learning and data-driven burden scores.

Authors:

E. Holtkamp[1], B. Clarke[2], H. Öztürk[2], F. Brechtmann[1], F. Hölzlwimmer[1], J. Gagneur[1,3,4], O. Stegle[2,5,6]; [1]Technical Univ. of Munich, Garching bei München, Germany, [2]German Cancer Res. Ctr., Heidelberg, Germany, [3]Helmholtz Ctr. Munich, Neuherberg, Germany, [4]Inst. of Human Genetics, Munich, Germany, [5]European Molecular Biology Lab., Heidelberg, Germany, [6]Wellcome Sanger Inst., Hinxton, United Kingdom

Population-scale genome sequencing data provides unprecedented opportunities to survey the effect of rare variants on human traits, with relevance for effector gene detection and extreme phenotype predictions. Existing methods for rare variant association genetics require *a priori* assumptions about the variant categories that exhibit phenotypic effects, thus limiting their efficacy. Recent variance-based methods incorporating multiple annotations lack the ability to jointly consider all variant annotations, instead performing post-hoc combination of individual tests into meta-models.

Here, we propose DeepRVAT (Deep Rare Variant Association Testing), an end-to-end deep-learning model that jointly estimates gene impairment from rare variants and annotations to explain trait variation. DeepRVAT employs a set neural network architecture to flexibly handle varying numbers of rare variants per gene and individual and learns an unbiased, gene- and phenotype-agnostic rare gene impairment scoring function in a data-driven manner. It leverages rich variant annotations, can score variants unseen at training time, accounts for nonlinear and epistatic effects, and can be combined with classical statistical tests to maintain rigorous control over type I error rates.

We first applied DeepRVAT to exome sequencing data for 21 quantitative UK Biobank (UKBB) traits (N=167k). Using the generic DeepRVAT gene impairment score yields substantial power gains for gene discovery, from 9-27% compared to meta-modelling methods that use an entire panel of mixed effect tests, up to 124% compared to the methods most commonly used in practice. Strikingly, these gains come together with improved replication rates in hold-out data.

Moreover, unlike meta-models, which have limited applicability beyond association testing, DeepRVAT gene impairment scores empower the creation of polygenic rare variant risk scores. By complementing common variant polygenic risk scores (PRS) with DeepRVAT scores to stratify high-risk individuals (extreme one-percentiles) in the UKBB cohort, we achieve a relative improvement of up to 52% in AUPRC compared to using the common PRS alone, thereby significantly outperforming recently proposed rare variant PRS strategies based on single annotations. Altogether, using deep learning and rich variant annotations, DeepRVAT summarises rare variant effects into a generic gene impairment score, enabling substantial improvements to multiple downstream applications such as gene-based association testing and high-risk individual stratification.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4114 Deriving computationally-defined latent phenotypes from medical images and genetic data.

Authors:

J. Wang[1], R. Border[2], O. Avram[1], B. Durmus[1], J. Mefford[1], E. Halperin[2], S. Sankararaman[1], N. Zaitlen[1]; [1]UCLA, Los Angeles, CA, [2]Univ. of California Los Angeles, Los Angeles, CA

Medical images are a fundamental component of clinical care and contain a large number of basic and informative biomarkers. Many of these image-derived biomarkers are defined a priori by domain experts and measure clear physical quantities such as surface areas or volumes of various brain regions. However, these quantities are not necessarily the most predictive of desired outcomes, nor are they the most genetic. Indeed, SNP-based heritability estimates have been computed for many of these traits, but even with large cohorts, most studies have produced estimates less than half of those from twin studies. Among the potential drivers of this missing heritability and the ensuing difficulty of identifying causal variants is one of particular interest: extensive genetic overlaps between related image phenotypes. Multivariate modeling approaches have emerged as an effective way of mitigating this problem, but this strategy is not entirely satisfactory, as multivariate methods sacrifice computational efficiency and interpretability.

Here, we propose a framework to define and compute univariate latent phenotypes which are more heritable and have a more discoverable architecture. This is accomplished by using recent extensions of convolutional neural networks in two ways. In the first, we predict externally defined phenotypes such as BMI or psychiatric disorders from organ scans, thus obtaining the portions of these broad phenotypes related to particular organs; here, our objective function is squared error loss against the true phenotype. In the second, we output, in an unsupervised fashion, a phenotype which is maximally heritable; here, our objective function is the Haseman-Elston regression estimate of heritability. To support the latter approach, we verify that heritability is a tractable objective function by recovering geometric features from simulated images and genetic data, without prior knowledge of said features. To support the former approach, we obtain good estimates of BMI (R2=0.82) from UK Biobank liver MRIs (n=7230) and perform comparative GWAS analyses against the true BMI, identifying rs1642763 and rs74543191 as SNPs which may be related to BMI through liver-specific mechanisms (waist circumference and diabetes-associated liver disease, respectively). This evidence suggests that our method may be a useful alternative for genetic analysis of medical images.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4115 Detecting D4Z4 repeat contraction with 4qA haplotypes from short-read whole genome sequences

Authors:

J. Choi[1,2,3], O. D. King[4], L. M. Kunkel[1,2], E. A. Lee[1,2,3]; [1]Boston Children's Hosp., Boston, MA, [2]Harvard Med. Sch., Boston, MA, [3]The Broad Inst. of Harvard and MIT, Cambridge, MA, [4]Univ. of Massachusetts Chan Med. Sch., Worcester, MA

Facioscapulohumeral Muscular Dystrophy 1 (FSHD1) is a common form of muscular dystrophy caused by the reduced copy (1-10 copies) of D4Z4 tandem repeats at 4q35, along with a 4qA polymorphism distal to the repeat. D4Z4 repeats have a long repeat unit (RU) of 3.3 Kbp that conventional short sequencing reads (100-150 bp) cannot cover. Additionally, there are two alleles distal to D4Z4 (4qA and 4qB), only one of which (4qA) is pathogenic leading to FSHD1 with D4Z4 contraction. Moreover, there are nearly identical D4Z4 repeats on chromosome 10, which do not contribute to FSHD1 pathogenicity. Thus, it is extremely challenging to detect pathogenic contraction of D4Z4 repeats using short-read whole-genome sequencing (WGS) data.

To address these challenges, we propose a new method that utilizes two different types of loci: chromosome separating loci (CSL) and allele separating loci (ASL). These loci have different genotypes according to their chromosomes and distal alleles (4qA vs 4qB), allowing us to estimate the RUs of D4Z4 repeats on the 4qA haplotype. To evaluate our method, we applied it to WGS data from 34 FSHD1 patients and compared the estimated RUs with those measured through classical western blots. Additionally, we applied our method to nine samples with both short-read WGS and Bionano data where single-molecule optical mapping enables precise measurement of D4Z4 RUs. We observed a high correlation between our estimated RUs and those independent measurements confirming the accuracy of our method. Then, we applied our method to ~30X WGS data of 2,504 individuals across 26 populations from the 1000 Genome Project (1KGP). Our analysis revealed population-specific characteristics of D4Z4 repeats. Notably, African populations exhibited a lower frequency of the 4qB haplotype that has recently appeared in the evolution, consistent with the literature. Furthermore, we identified 126 asymptomatic individuals from the 1KGP cohort with predicted pathogenic D4Z4 contraction by our method. Through our preliminary Genome-wide Association Study (GWAS) analysis, we identified two clusters of variants enriched in those asymptomatic carriers. Although more investigation is warranted, this approach might be useful to identify potential disease-modifying or protective variants against FSHD1.

Overall, our study presents a novel methodology to estimate D4Z4 repeat units on a pathogenic haplotype from short-read WGS data and provides a comprehensive characterization of D4Z4 repeats across different populations. These findings enhance our understanding of genetic architecture of FSHD1 and may offer insights into potential protective variants against the disease.

PB4116 Detecting Perturbation Effects of Gene Expression in Single-cell CRISPR Screening

Authors:

X. Wang, M. Lalli, J. Buxbaum; Icahn Sch. of Med. at Mount Sinai, New York, NY

We present a novel method for detecting perturbation effects of gene expression in single-cell CRISPR screening using low MOI CRISPR data. Our method utilizes subspace perturbation modeling to capture the effects of CRISPR perturbations and identifies consistent cell type shifts for a subset of Autism risk genes. In our study, we performed single-cell RNA-sequencing (scRNA-seq) on human-induced neural progenitor cells (iNPCs) that were subjected to CRISPR perturbations at a low multiplicity of infection. By analyzing the scRNA-seq data, we observed distinct subgroups of cells, including glial progenitor cells, neuronal progenitor cells, and maturing neurons. However, these changes in cell compositions can obscure the effects of CRISPR perturbations on gene expression. To overcome this challenge, we developed a method that separates the effects on cell composition from the effects on gene expression. By modeling the subspace perturbations, we were able to capture the specific changes in gene expression caused by CRISPR perturbations. Our method detected consistent shifts in cell types for a subset of Autism risk genes, providing valuable insights into their functional roles. Overall, our method enables the detection of perturbation effects of gene expression in single-cell CRISPR screening, even with low MOI CRISPR data. By utilizing subspace perturbation modeling, we can uncover the underlying effects of CRISPR perturbations and identify consistent cell type shifts for Autism risk genes. This approach contributes to our understanding of gene function in the context of neuro-psychiatric disorders.

PB4117 Developing prediction model for the age at natural menopause with the population-based Health Examinee cohort study

Authors:

M. Yuk, S. Yang, K. Oh, Y. Kwak, J. Lee, J. Youn, N. Song; Coll. of Pharmacy, Chungbuk Natl. Univ., Cheongju, Korea, Republic of

BACKGROUND: Most women experience menopausal transition inducing various physical and emotional changes that could even cause diseases. Hence, predicting the timing of menopause helps women prepare and cope menopausal transition-related diseases. In this study, we developed a prediction model for age at natural menopause and assessed its predictive performance.
METHODS: The study subject was drawn from the Korean Genome and Epidemiology Study_Health Examinee (KoGES_HEXA) study. Among women with genome-wide single-nucleotide polymorphism (SNP) data, after excluding women who experienced natural or artificial menopause at baseline of the study, total 10,729 (4,009 postmenopausal, 6,720 premenopausal) women who also had the follow-up data were included in the analysis. Cox proportional hazards regression, accelerated failure time (AFT), artificial neural network (ANN), XGBoost, and support vector machine (SVM) models were applied to determine the optimal model to predict age at natural menopause. The 52 variables of health screening-related data including anthropometrics, reproductive health, biochemistry, and diseases history, and 41 SNPs (31 known and 10 identified by genome-wide association studies) were used as predictors for age at natural menopause. The performance of five models was evaluated using mean absolute error (MAE) and R-squared (R^2) for all models and additional concordance index (C-index) for time-dependent models.
RESULTS: Cox model was presented as the most appropriate model for predicting age at natural menopause with the lowest MAE and the highest R^2 (MAE=0.71, R^2=0.86, AFT model; 2.07, 0.30, ANN; 1.16, 0.78, XGBoost; 1.12, 0.79, SVM; 1.24, 0.71) among the five models. In this time-dependent model, mean corpuscular hemoglobin concentration (MCHC) had the most significant effect on the age at natural menopause (HR=4.22, CI=3.67-4.86). When the Cox model was also evaluated with the genetic biomarkers, the predictive performance was better compared to the baseline model without genetic biomarkers (Harrell's C-index difference *P*=0.001).
CONCLUSION: The time-dependent Cox model was developed to predict age at natural menopause based on clinical and/or genetic data from the population-based Health Examinee cohort study. This time-dependent prediction model for age at natural menopause would be utilized to support making clinical and personal decisions related to menopausal transitions.

PB4118 † Differential cell-type-specific gene expression by type 2 diabetes status in human skeletal muscle

Authors:

D. Ciotlos[1], S. Hanks[1], A. Varshney[1], M. Erdos[2], N. Manickam[1], A. Jackson[1], H. Stringham[1], N. Narisu[2], L. Bonnycastle[2], P. Orchard[1], M. Laakso[3,4], J. Tuomilehto[5], T. Lakka[3], K. Mohlke[6], M. Boehnke[1], H. Koistinen[5], F. Collins[2], S. Parker[1], L. Scott[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]NHGRI/NIH, Bethesda, MD, [3]Univ. of Eastern Finland, Kuopio, Finland, [4]Kuopio Univ. Hosp., Kuopio, Finland, [5]Finnish Inst. for Hlth.& Welfare, Helsinki, Finland, [6]Univ North Carolina, Chapel Hill, NC

Skeletal muscle tissue plays a role in regulation of body glucose, and skeletal muscle insulin resistance is a hallmark of type 2 diabetes (T2D). Previous skeletal muscle bulk RNA-seq studies have identified association of gene expression with T2D status; however, these studies could not distinguish gene expression changes that differed between fast twitch (types 2A and 2X) and slow twitch (type 1) muscle fiber types.
To understand the relationship between T2D status and gene expression in different cell types, we performed single nucleus RNA-sequencing of skeletal muscle biopsied from 282 Finnish adults (41.5% female, 25.9% T2D) from the FUSION Tissue Biopsy Study. We observed 12 main cell- and subcell- type clusters including muscle fiber types. We tested for associations between cell-type composition and T2D-related traits using a negative binomial model. Individuals with T2D, higher fasting glucose, or higher fasting insulin had greater proportions of neuromuscular junction nuclei than individuals with normal glucose tolerance (min p=0.0020).
For each cell type, we tested for associations between gene expression and T2D using a negative binomial model (n genes tested=23,766). In each muscle fiber type, we found 4 to 9 genes differentially expressed by T2D status. However, using gene set enrichment analysis, we observed 6.4-10.1% of 5641 gene ontology gene sets were enriched for different levels of gene expression by T2D status across muscle fiber types. For most but not all GO terms, muscle fiber cell types and bulk RNA-seq data show concordant enrichment of expression differences between individuals with T2D or normal glucose tolerance (NGT). In each muscle fiber type and bulk skeletal muscle, genes associated with cellular respiration were enriched for higher expression in individuals with NGT than those with T2D (OR=0.51-0.65, min p=6.7e-6). In contrast, in type 2X muscle fibers, genes associated with positive regulation of vasoconstriction were enriched for higher expression in individuals with T2D than those with NGT (OR=2.84, p=3.84e-4) but this difference was not observed in bulk tissue (OR=1.01, p=0.93).
Overall, T2D-associated differences in gene expression in bulk RNA-seq are detected in all muscle fiber types, indicating similar biological processes across muscle fiber types. However, we also identified gene sets for which enrichment of expression differences are only detected in one muscle fiber type and not in bulk skeletal muscle, suggesting potential fiber-type-specific biology.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4119 Discovery of core genes for systemic lupus erythematosus via genome-wide aggregation of*trans*-effects.

Authors:

A. Iakoviev[1], O. Castellini-Pérez[2], M. Alarcón-Riquelme[2], P. McKeigue[1], E. Carnero-Montoro[2], A. Spiliopoulou[1]; [1]Univ. of Edinburgh, Edinburgh, United Kingdom, [2]GENYO. Ctr. for Genomics and Oncological Res. Pfizer/Univ. of Granada/Andalusian Regional Government, Granada, Spain

Aim: Systemic lupus erythematosus (SLE) is an autoimmune disorder in which defective degradation and clearance of DNA lead to upregulation of Type 1 interferon signaling and a B-cell mediated autoimmune response. The objective of this study was to test whether the genetic architecture of SLE fits an "omnigenic" model in which the polygenic *trans*-effects of common SNPs coalesce on a relatively sparse set of "core" effector genes. **Methods**: Using expression and protein level quantitative trait loci (eQTL and pQTL) summary statistics from 31,684 samples in eQTLGen and 35,559 samples in deCODE respectively, we computed genome-wide aggregated *trans*-scores to predict gene expression and levels of circulating proteins in a case-control GWAS of SLE cohort consisting of 5267 SLE cases and 4909 controls. We identified putative core genes based on strength of association of the genome-wide *trans*-score with SLE, the effective number of *trans*-eQTLs contributing to the genome-wide score, and specificity of the association (lack of correlation with scores for other genes). **Results**: SLE was strongly associated with *trans* scores for at least 12 co-expressed Type 1 interferon-stimulated genes (ISGs); these genes share a common set of five *trans*-eQTLs, so that the aggregated *trans*-scores are correlated ($r > 0.8$). Of these ISGs, *MX1* has the strongest effect (Log OR=0.13, $P = 4 \times 10^{-10}$), *ISG15* (Log OR=0.1, $P = 1 \times 10^{-6}$) and *RABGAP1L* (Log OR=-0.1, $P = 6 \times 10^{-7}$) are known monogenic causes of SLE. The score for *STAT1* was also associated with SLE (Log OR=0.1, $P = 2 \times 10^{-6}$) but uncorrelated with detected ISGs. From pQTL analysis, *LGALS2* ($P = 2 \times 10^{-14}$), *TNFRSF17* ($P = 2 \times 10^{-17}$), *ALKBH2* ($P = 1 \times 10^{-12}$), *CRTAM* ($P = 2 \times 10^{-11}$) and *CD5L* ($P = 6 \times 10^{-15}$) were identified as putative core genes. **Conclusions**: Some genetic effects on SLE risk are mediated via *trans*-effects on basal expression of a cluster of ISGs. These do not appear to be mediated by effects on the JAK/STAT signaling pathway. Of the other putative core genes, *TNFRSF17* encodes a receptor for a therapeutic target for SLE. *LGALS2*, *CD5L* and *CRTAM* are in immune-related pathways, and *ALCBH2* is a DNA repair enzyme. These results support the conclusion of a recent study of type 1 diabetes that genome-wide aggregated *trans*-QTL analysis is able to identify core genes for disease that are not detected in a conventional SNP-by-SNP GWAS analysis.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4120 Discovery of kidney function loci and MR-based associated causal effects of lipid traits in 80k African ancestry individuals

Authors:

C. Kintu[1], S. Opeyemi[2], M. Richard[1], J. Daudi[3], C. Tinashe[4], F. Segun[5]; [1]MAKERERE Univ., Kampala, Uganda, [2]The African Computational Genomics (TACG) Res. Group, Entebbe, Uganda, [3]Makerere Univ. Coll. of Hlth.Sci., Kampala, Uganda, [4]The African Computational Genomics (TACG) Res. Group, Kampala, Uganda, [5]Dept. of Non-Communicable Disease Epidemiology, London Sch. of Hygiene and Tropical Med. (LSHTM), United Kingdom, London, United Kingdom

Background: Estimated glomerular filtration rate (eGFR) is a proxy for kidney function and lower eGFR (<60ml/min/1.73m^2) is indicative of chronic kidney disease (CKD). Although people of African ancestry (AA) have a greater burden of CKD, most genome-wide association studies (GWASs) have been conducted in Europeans. These findings might not be transferable to Africans due to genetic differences. We therefore set out to perform a meta-analysis of African-ancestry datasets to identify novel loci associated with CKD in Africans, and to determine the causal effects of lipid traits on kidney function in this population. **Methods:** We conducted a meta-analysis of creatinine-based eGFR in 80,027 AA participants from three global population-based cohorts: The Chronic Kidney Disease Genetics Consortium (CKDGen, n = 16474), UK Biobank (UKBB, n = 6217), and the Million Veteran Program (MVP, n = 57336). A fixed-effect inverse-variance weighted meta-analysis was performed using METAL software. We used the Bayesian fine-mapping approach to localize putatively causal variants. We further performed a Two-sample MR; instrument variables (IVs) for the predictor (lipid traits) were derived from a meta-analyzed African lipids GWAS (MALG, n = 24,215). The outcome IVs were computed from the MVP dataset. A random-effects inverse variance method was used as our primary analysis while adjusting for pleiotropy.
Results: The meta-analysis identified 403 significant Single Nucleotide Polymorphisms (SNPs) (at $p<5x10^{-8}$), 8 SNPs were lead variants and 3 of these were novel. The novel variants; rs200950799, rs10084572 and rs77408001 mapped to genes: Solute Carrier Family 15 member 5 (*SLC15A5*), 1-acylglycerol-3-phosphate O-acyltransferase 3 (AGPAT3), and Frizzled Class receptor 9 (*FZD9*) respectively. SLC15A5 and AGPAT3 are both diferentially expressed in the kidney-medulla and kidney-cortex. The rs200950799 variant was the putatively causal variant with a 71% posterior probability.
Our univariable MR analysis indicated a significant association between low-density lipoprotein (LDL) cholesterol and eGFR in African ancestry individuals (β= 1.1, 95% CI = [0.411-1.788]; p=0.002). The multivariable (MVIVW) method indicated similar evidence for LDL and TC with eGFR (β = 1.228 [0.477-1.979]; p=0.001) and (β = 1.357 [0.444-2.27]; p=0.004) respectively. A protective effect of Triglycerides on eGFR was observed in the MVIVW analysis (β = -1.412 [-2.714— -0.109]; p=0.034). **Conclusion:** We report ancestry-specific genetic variants associated with kidney function and show evidence of a possible causal effect of lipid traits on eGFRcrea in Africans.

PB4121 Disease-Aware Machine Learning Pipeline for Drug Target Prediction

Authors:

A. Stiemke[1], A. Musolf[1], B. Guo[1], T. Rajasekar[1], K. Shkura[2], J. Sul[1], S. Longerich[1]; [1]Merck & Co., Inc, Rahway, NJ, [2]MSD, London, United Kingdom

Identifying effective and safe drug targets in drug development is a long, arduous, and expensive process. Recently, machine learning (ML) techniques have been deployed for drug development leading to increased throughput and decreased failure rates of drug discovery. ML methods have been applied to identify and prioritize high quality, druggable gene targets for multiple diseases. However, these methods and their predictive features are usually built specifically for an indication; utility beyond the indication is limited. The goal of this study is the construction of a ML-based pipeline that can be utilized across diverse disease indications.

To create adaptability across disease, our pipeline takes advantage of disease-agnostic features like cellular location/function and druggability/tractability of targets. To improve predictability, we incorporate several disease-specific features which are automatically generated when applied to different diseases. One major component of our approach is incorporation of genetic evidence for diseases, which is largely absent from other ML methods. Genetic evidence is important because the probability of successfully developing a drug is much higher when the target is supported by human genetic evidence. This new ML pipeline containing disease-specific and disease-agnostic features is termed “disease-aware”.

We analyze our array of features through a new ML ensemble method. This ensemble approach uses 11 different machines (random forest, neural networks, etc.) to select the best predictive machine and achieves optimal prediction across many diseases. This overall model adapts and uses the appropriate features and best-fit machine based on the disease of interest. Simulations show that our method is robust and maintains high power while varying the number of causal features and noise factors. We demonstrate this ensemble method matches and surpasses the individual models and can be used effectively across disease types to identify new, high-confident druggable gene targets in multiple disease areas, such as glaucoma and autism.

PB4122 Disentangling the shared genetic aetiology of type 2 diabetes and schizophrenia.

Authors:

A. Arruda[1], L. M. Huckins[2], E. Zeggini[3]; [1]Helmholtz Zentrum München, Neuherberg, Germany, [2]Yale Univ. Sch. of Med., New Haven, CT, [3]Helmholtz Zentrum Munich, Neuherberg / Munich, Germany

Multimorbidity represents an increasing public health challenge with far-reaching implications for health management and policy. Among adults, the coexistence of metabolic and psychiatric diseases is a commonly observed comorbidity. In this study, we leverage summary statistics from large-scale trans-ancestry genome-wide association studies to investigate the genetic intersection between type 2 diabetes and schizophrenia, two positively epidemiologically associated conditions. We perform colocalization analysis and identify robust evidence of shared association signals at 11 genomic loci, six of which have opposing directions of effect for type 2 diabetes and schizophrenia. To elucidate these colocalizing signals, we integrate multi-omics data from bulk and single-cell data from disease-relevant tissues (pancreatic islets, adipose tissue, liver and brain), along with functional information. We identify high-confidence effector genes, each of which is supported by at least four orthogonal lines of evidence for their involvement in the diseases. The top-ranking effector gene is *NUS1*, which plays a role in lipid trafficking regulation. Mendelian randomization analysis suggests that increased expression of *NUS1* in the brain is causal for schizophrenia liability and protective against type 2 diabetes liability. This causal evidence is supported by data from differential expression analysis in the brain, indicating overexpression of *NUS1* in schizophrenia patients. The result also aligns with observations from *NUS1* knockout mice, displaying elevated levels of circulating triglycerides, which are associated with an increased risk of type 2 diabetes. Our findings offer insights into the underlying biological mechanisms contributing to the co-occurrence of type 2 diabetes and schizophrenia, shedding light on the complex nature of this comorbidity.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4123 Dissecting the shared aetiology of immunologically-driven disease through genetic correlation analysis

Authors:

M. Boyton[1], T. Gaunt[1], T. Richardson[2], V. Walker[1]; [1]Univ. of Bristol, Bristol, United Kingdom, [2]MRC Integrative Epidemiology Unit (IEU), Bristol, United Kingdom

Numerous comorbidities and altered risk profiles exist between prevalent immunologically-driven disorders in the observational literature. However, little is known of the underlying genetic basis for these diverging relationships between often complex phenotypes. We investigated the shared global and local genetic architecture of a spectrum of immune-associated diseases via Linkage Disequilibrium Score Regression (LDSC) and Local Analysis of (co)Variant Association (LAVA). In LDSC, the heritability and genome-wide genetic correlation between pairs of phenotypes is computed through cross-trait LD-score regression, whereas in LAVA, the bivariate analysis of region-specific genetic correlations is calculated. Our results demonstrate the existence of shared global and local genetic correlations between immunologically-relevant disorders, with diverging relationships spanning autoimmune, allergic and cancer phenotypes. Early results indicate a shared genetic basis for diseases such as Lupus and Rheumatoid Arthritis ($rG = 0.523$, $p < 0.001$) and Kidney Cancer and Sepsis ($rG = -0.892$, $p < 0.001$), as well as numerous loci of bivariate genetic importance spanning known inflammatory genes such as BACH2 and IL6R. Further investigation into the local genetic contributions to these relationships is ongoing, with the aim of identifying gene and protein instruments to guide drug target prioritisation and repurposing opportunities.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4124 Dissection of a known gene-physical activity interaction using metabolomics

Authors:

K. Westerman[1], M. Sevilla[1], C. Gu[2], T. O. Kilpelaïnen[3], J. I. Rotter[4], D. I. Chasman[5], A. K. Manning[1], CHARGE Gene-Lifestyle Interactions Working Group; [1]Massachusetts Gen. Hosp., Boston, MA, [2]Washington Univ., St. Louis, MO, [3]Univ. of Copenhagen, Copenhagen, Denmark, [4]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [5]Brigham & Women s Hosp., Boston, MA

Improved molecular understanding of gene-environment interactions (GEIs) from large-scale discovery efforts is necessary to facilitate often-elusive replication and create the confidence necessary for clinical implementation. Here, we aimed to use metabolomics to refine the relevant exposures and outcomes for a previously discovered GEI modifying the relationship between physical activity (PA) and HDL-cholesterol (HDL-C). We explored this GEI, originally identified by Kilpeläinen et al. (PMID: 30670697), in the Women's Genome Health Study (WGHS; the strongest cohort-specific GEI signal from the original meta-analysis), the UK Biobank (UKB), and the Multi-Ethnic Study of Atherosclerosis (MESA). In each cohort, we retrieved self-reported PA (MET-hrs/wk) and genotypes at rs295849 (nearest gene: *LHX1*). Plasma metabolomics data were available from NMR (WGHS, N=23,000 women; UKB, N=67,738) and LC/MS (MESA, N=877) platforms. As initially reported, minor allele carriers of rs295849 in WGHS had a stronger positive association between PA and HDL-C (p_{int}=0.002). To refine the HDL-C outcome, we tested the effect of this interaction on 45 NMR metabolites (primarily lipoprotein and lipid subfractions), finding a stronger effect on medium-sized HDL particle concentrations (M-HDL-P; $p_{int}=1.0\text{x}10^{-4}$) than HDL-C. In the UKB, the basic GEI was not significant for HDL-C or M-HDL-P. However, GEI effects were stronger both in females (consistent with the female-only WGHS cohort) and using vigorous PA as the specific exposure. Taken together, the rs295849-vigorous PA interaction in females reached $p_{int}=3.7\text{x}10^{-4}$ for M-HDL-P. Having narrowed the relevant PA subtype, lipoprotein quantity, and cohort subgroup, we examined the interaction in MESA. While lipoprotein particle concentrations were not available, the rs295849-vigorous PA interaction for HDL-C replicated in females (p_{int}=0.008). This replication was weaker in the full (male and female) population and not significant using a combined PA measure. Further exploring potential molecular pathways mediating the GEI, we found 8 LC/MS metabolites associated with vigorous PA. Of these potential molecular proxies for PA, 2 (both unknowns) showed significant interactions with rs295849 for HDL-C, with mass-to-charge ratios pointing to a bacterial lipopolysaccharide component and a very long-chain fatty acid. Our work demonstrates an improvement in replication of a GEI by refining the exposure, outcome, and relevant population subgroup. Such omics-based follow-up is critical to bridge the gap between large-scale GEI discovery and downstream experimental studies and clinical translation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4125 † DNA language models: A new paradigm for predicting the impact of human genome variation

Authors:

G. Benegas, C. Albors, A. Aw, C. Ye, Y. Song; Univ. of California at Berkeley, Berkeley, CA

Introduction: Remarkable progress (e.g., ChatGPT) has been made in natural language processing by training large neural network models on massive text corpora. This notion of "self-supervised" learning has emerged as a powerful paradigm in biology as well; e.g., protein language models have proven to achieve outstanding performance in missense variant effect prediction. Regulatory non-coding variants also underlie numerous complex traits and diseases, but the existing DNA language models for the human genome have not yet demonstrated a competitive edge in predicting the effects of genetic variants at a genome-wide scale. These models often grapple with a number of challenges such as the diverse nature of genomic regions and the high prevalence of repetitive sequences, while requiring extremely large GPU resources. To address these challenges, we have developed a novel DNA language model that incorporates several key innovations to reduce the compute resource requirement by several orders of magnitude while achieving state-of-the-art results on genome-wide variant effect prediction.
Results: We have evaluated our model on three distinct metrics relevant to human genetics:
1. Classification of ClinVar variants.
In the case of missense variants (3 stars and above), our unsupervised model achieves an AUROC of 92.4%, comparable to CADD (AUROC=92.0%), which is a supervised model trained on proxy-deleterious and proxy-neutral variants. In contrast, the Nucleotide Transformer, a 30 times larger DNA language model trained using 4800 times more GPU hours than our language model, achieves an AUROC of only 53.2%.
2. Assessment of deleterious score enrichment in rare versus common gnomAD variants.
The top 1% of most likely functional variants predicted by our model are substantially more enriched in rare variants compared to CADD, suggesting that our model has an improved ability to detect variants under purifying selection.
3. Enrichment of UK BioBank GWAS hits in regions of extreme scores.
The top 0.1% of most likely functional variants predicted by our model are 15-fold enriched in GWAS hits, improving over CADD's 9-fold enrichment.
Conclusion: Our research underscores the promise of DNA language models for genome-wide variant effect prediction, bridging advancements in natural language processing with important insights from evolutionary biology. Our unsupervised model substantially improves genome-wide variant effect prediction over state-of-the-art methods, and it has the potential to benefit a number of statistical tasks in human genetics, including genome-wide rare variant burden testing, fine-mapping, and polygenic risk score prediction.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4126 DNA methylation GrimAge version 2.

Authors:

A. Lu[1], Q. Yan[1], S. Horvath[1,2,3]; [1]Altos Labs, SDI, San Diego, CA, [2]Dept. of Human Genetics, David Geffen Sch. of Med., Univ. of California Los Angeles, Los angeles, CA, [3]Dept. of Biostatistics, Fielding Sch. of Publ. Hlth., Univ. of California Los Angeles, Los angeles, CA

We previously described *DNAm GrimAge*, a DNA methylation-based biomarker of human mortality risk. In this study, we present version 2 of GrimAge (trained on individuals aged between 40 and 92),which leverages two new DNAm-based estimators of (log transformed) plasma proteins: high sensitivity C-reactive protein (logCRP) and hemoglobin A1C (logA1C). We evaluate GrimAge2 in 13,399 blood samples across nine study cohorts. After adjustment for age and sex, GrimAge2 outperforms GrimAge in predicting mortality across multiple racial/ethnic groups (meta $P=3.6x10^{-167}$ versus $P=2.6x10^{-144}$) and in terms of associations with age related conditions such as coronary heart disease, lung function measurement FEV1 (correlation= -0.31, $P=1.1x10^{-136}$), computed tomography based measurements of fatty liver disease. We present evidence that GrimAge version 2 also applies to younger individuals and to saliva samples where it tracks markers of metabolic syndrome.DNAm logCRP shows a positive correlation with morbidity count ($P=1.3x10^{-54}$). DNAm logA1C is highly associated with type 2 diabetes ($P=5.8x10^{-155}$). DNAm PAI-1 outperforms the other age-adjusted DNAm biomarkers including GrimAge2 in correlating with triglyceride (cor=0.34, $P=9.6x10^{-267}$) and visceral fat (cor=0.41, $P=4.7x10^{-41}$). Pedigree based polygenic models of GrimAge2 adjusted for age and gender, yielded significant narrow sense heritability estimates (=0.30, *P*=0.03), comparable with the previous version GrimAge (=0.29, *P*=0.02). Finally, we applied the blood-based mortality clock, GrimAge2, to a previously published reprogramming dataset in Human Dermal Fibroblasts (HDFs). Notably, we observed a decrease in GrimAge2 in partially reprogrammed cells after day 7, mirroring observations with Horvath's epigenetic pan tissue clock. Similarly, several estimates from GrimAge2 components, including DNAm logA1C, changed with different phases of reprogramming to reflect aging reversal post-OSKM transduction. Overall, we demonstrate that GrimAge version 2 is an appealing epigenetic biomarker for assessing human mortality and morbidity risk.

PB4127 DNA structural information underpins mutation rate variations and regulatory site polymorphisms in the human genome

Authors:

Z. Liu, M. Samee; Baylor Coll. of Med., Houston, TX

Single nucleotide mutation rates have critical implications for human evolution and genetic diseases. Importantly, the rates vary substantially across the genome and the principles underlying such variations remain poorly understood. A recent model explained much of this variation by considering higher-order nucleotide interactions within sequence contexts around mutated nucleotides. This model's success implicates a connection between DNA shape and mutation rates. DNA shape, i.e., structural properties like helical twist and tilt, is known to capture interactions between nucleotides within a local context. Thus, we hypothesized that changes in DNA shape features at and around mutated positions can explain mutation rate variations in the human genome. Indeed, DNA shape-based models of mutation rates showed similar or improved performance over current nucleotide sequence-based models. These models accurately characterized mutation hotspots in the human genome and revealed the shape features whose interactions underlie mutation rate variations. DNA shape also impacts mutation rates within putative functional regions like transcription factor binding sites where we find a strong association between DNA shape and position-specific mutation rates. This work demonstrates the structural underpinnings of nucleotide mutations in the human genome and lays the groundwork for future models of genetic variations to incorporate DNA shape.

PB4128 Efficient Bayesian inference of genome-wide genealogies for large samples

Authors:

Y. Deng[1], R. Nielsen[2], Y. Song[1]; [1]UC Berkeley, Berkeley, CA, [2]Univ California Berkeley, Berkeley, CA

The Ancestral Recombination Graph (ARG) is a structure that describes the joint genealogies along DNA sequences. Accurate inference and sampling of the ARG, especially for large datasets, has the potential to substantially improve analyses in population genetics. Several previous methods have been developed for this purpose (e.g. ARGweaver, Relate, and tsinfer), but they are either not computationally scalable or do not allow accurate sampling of both topology and time. Here we provide a new method, SINGER (Sampling and INference of GEnealogies with Recombinations), for ARG inference and sampling based on Sequentially Markovian Coalescent (SMC) model. Our method provides a balance between inference accuracy and computational speed, and can also allow full sampling of ARGs in terms of both coalescence time and topology. The new method has better inference accuracy than Relate and tsinfer, while achieving a significant speedup over ARGweaver, and with more efficient MCMC convergence and mixing.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4129 Elucidating genetic susceptibility to orofacial clefting within a multi-ancestry cohort

Orofacial clefting (OFC) is one of the most prevalent birth defects, affecting 1 in 700 births globally. It is characterized by the abnormal formation of the lip and/or palate during prenatal development. Though previous OFC studies have identified several associated loci, they have not fully characterized the genetic architecture across heterogeneous phenotypes.

We have harmonized genetic and phenotypic data from a large multi-ancestry OFC cohort collected across 30 global sites. The cohort comprises 7,896 cases and 16,299 unaffected family members and controls from 5 genetic ancestry groups, including 3,653 East Asians, 4,408 South Asians, 5,183 Admixed Americans, 6,050 Europeans, and 4,901 Africans. We focused on nonsyndromic OFC, which accounts for the majority of cases but has a less clear delineation of their etiology than syndromic cases. We performed pre-imputation quality control and genotype imputation using GWASpy, a scalable and open source pipeline that we recently developed using the SHAPEIT/EAGLE and IMPUTE5 algorithms. Next, we are using GWASpy to infer genetic relatedness among individuals, which uses the pc_relate method that adjusts for population structure using principal components analysis (PCA) while inferring relatedness. Then, we are assessing population structure, identifying potential outliers within the dataset, and characterizing ancestry patterns by performing PCA. Furthermore, to more comprehensively understand the genetic architecture, we are estimating single nucleotide polymorphism (SNP)-based heritability using the genome-based restricted maximum likelihood method, allowing us to quantify the contribution of genetic variation to the observed phenotypic variance based on individual-level genotype data. Then, we will employ linear mixed models implemented in the SAIGE software to identify genetic loci associated with isolated OFC through genome-wide association study (GWAS), which offers robust and accurate association testing while accounting for relatedness of the dataset.

By conducting comprehensive analyses integrating genetic and phenotypic data from a diverse multi-ancestry OFC cohort, we aim to enhance our understanding of the genetic underpinnings of isolated OFC and contribute valuable insights into the etiology of this complex craniofacial anomaly. We anticipate that our study will have the potential to improve risk stratification via polygenic scores and enhance understanding of risk across diverse populations.

PB4130 Enhancing Genome-Wide Association Meta-Analysis in Multi-Ancestry and Admixed Population for Tobacco and Alcohol Use Phenotypes using 3.2 Million Individuals

Authors:

X. Wang, GWAS and Sequencing Consortium of Alcohol and Nicotine Use; Penn State Coll. of Med., Hershey, PA

Genome-wide association meta-analysis (GWAMA) has been instrumental in identifying genetic variants associated with various complex traits and diseases. As we push the boundaries of knowledge, it becomes crucial to explore beyond European populations and include individuals with diverse ancestries, including those of admixed origin. However, existing methods fail to adequately account for ancestry heterogeneity and the unique mosaic local genetic structure found in admixed populations. We propose improved GWAMA methods that account for global and local ancestry information. By harnessing principal components (PCs) of allele frequencies from each study as a proxy for global ancestry, we capture the nuanced variations in genetic effects. As for local ancestry, we model allele frequencies in admixed ancestry as a weighted combination of allele frequencies from continental ancestry backgrounds, reflecting the admixed population proportions. A grid-search window-based method is proposed to estimate these proportions by comparing the admixed population with reference panels from the 1000 Genome Project and Human Genome Diversity Project. Our approach provides a comparable estimation of ancestry proportion compared to individual-level local ancestry estimation method RFMix. We then model the genetic effects from each study as a mixture of models, incorporating PCs and ancestry proportion information, thus accounting for varying degrees of heterogeneity and local genetic structure. Additionally, considering ancestry proportion effects allows for a more accurate estimation compared to results obtained through ancestry stratification results. Our methods exhibit controlled type I error and enhanced power across diverse simulation scenarios. Applying them to the GSCAN study, encompassing 24 cohorts (78% European, 9% East Asian, 9% Admixed American, 4% African American), we unveil 838 and 830 significant loci using global and local ancestry information, respectively. Notably, 162 of these loci are novel compared to other commonly used methods, including FE, RE, RE2, BE, MR-MEGA, and TransMeta. Furthermore, we identify genetic signals exhibiting differences in effect sizes by comparing the ancestry proportion effects with ancestry stratified results. Collectively, our findings represent a significant advancement in comprehending the genetic architecture underlying tobacco and alcohol use in multi-ancestry samples and admixed populations.

PB4131 Ensemble Polygenic Risk Score Development for Coronary Heart Disease in Middle Eastern Populations

Authors:

M. Saad[1], K. Nahin[1], K. Kunji[1], A. El-Menyar[2], E. Ullah[1], I. Kullo[3], J. Al Suwaidi[2]; [1]Qatar Computing Res. Inst., Hamad Bin Khalifa Univ., Doha, Qatar, [2]Hamad Med. Corp., Doha, Qatar, [3]Mayo Clinic, Rochester, MN

Background: We previously validated four existing polygenic risk scores (PRSs) for coronary heart disease (CHD) in Middle Eastern (ME) populations using whole genome sequencing (WGS). Here, we aim at developing ME PRSs, and integrating them with existing PRSs to obtain an ensemble PRSs that outperforms individual PRSs.
Methods: Our cohort comprised of 1014 CHD patients and 6009 controls with 30x WGS in a Middle Eastern cohort. We split the data into training and testing datasets (70% and 30%). We developed PRSs using pruning and thresholding (P+T), LDpred2, and machine learning models (e.g., XGBoost). We downloaded 35 PRSs from the PGS catalog and evaluated their performance in the testing dataset. We combined developed and existing PRSs into an ensemble PRS using summing and machine learning techniques.
Results: P+T model performed better than LDpred2 (OR=1.8, AUC=0.664 vs OR=1.7, AUC=0.656). The 3 existing PRSs that performed the best in our data were PGS000337 (OR=1.8, AUC=0.657), PGS003356 (OR=1.6, AUC=0.64), and PGS003355 (OR=1.6, AUC=0.637). Summing these 3 PRSs improved the performance (OR=1.9, AUC=0.667). Summing these 3 PRSs, and our P+T and LDpred2 improved the performance further (OR=2.2, AUC=0.698). The best XGBoost model outperformed P+T and LDpred2 (OR=1.8, AUC=0.67).
Conclusions: Our ME PRSs performed better than existing PRSs to predict CHD. Machine learning models showed good performance but not strikingly better than P+T and LDpred2. Combining PRSs developed with different datasets and methods improved prediction performance, which suggests a greater transferability across ancestries.

PB4132 Estimating association effects of Copy Number Variants using penalized regression with Lasso and weighted fusion penalties.

Authors:

Y. Si[1], W. Lu[2], A. A. Tucci[1], H. Wang[3], Y. Cheng[1], L-S. Wang[3], G. Schellenberg[3], W-P. Lee[3], J-Y. Tzeng[1,2]; [1]Bioinformatics Res. Ctr., North Carolina State Univ., Raleigh, NC, [2]Dept. of Statistics, North Carolina State Univ., Raleigh, NC, [3]Penn Neurodegeneration Genomics Ctr., Dept. of Pathology and Lab. Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Background: Copy number variants (CNVs) are DNA gains or losses involving at least 50 base pairs. By analyzing one CNV locus at a time, genome-wide scanning of CNVs has provided valuable insights into their association with complex traits and diseases. However, accurately estimating the effect size of CNVs on disease risks requires considering several factors. First, the variations in CNV dosage and CNV length need to be addressed. CNVs can involve duplications or deletions with lengths ranging from a few hundred base pairs to several kilobases. The dosage and length of a CNV can impact gene expression, influencing its functional impact on the disease. Second, it is crucial to incorporate all CNV events in a genomic region and simultaneously assess the joint effect of multiple CNVs to gain a more comprehensive understanding of their combined effects. **Methods**: We propose a statistical framework that treats CNVs as consecutive events over the genome. Specifically, we model an individual's CNVs as a piecewise constant curve, which allows us to naturally account for CNV length and dosage and capture the CNV effects as a continuous function over the genome. To perform joint modeling of all CNVs in a genomic region and select CNVs associated with the outcome of interest, we adopt penalized regression with a Lasso penalty. Additionally, we integrate a weighted fusion penalty to encourage genomic regions impacted by the same CNV events to have similar effects when supported by the data. This framework avoids the arbitrary definition of a CNV locus, allows for adjusting potential confounding factors, and accommodates both continuous and binary outcomes. We conduct numerical studies using simulations and real data analysis to evaluate the performance of the proposed framework. **Results and Conclusion**: The simulation studies show that the proposed framework can more effectively identify outcome-associated CNVs (i.e., higher true positive rates) without introducing additional noise signals (i.e., comparable false positive rates) compared to the baseline methods (standard Lasso regression). Moreover, the proposed methods yield more precise effect size estimation (i.e., smaller mean squared errors in the true signal regions and equivalent mean squared errors in the non-signal regions). Real data analyses further indicate that the proposed framework provides a useful tool to detect and estimate CNV effects. In conclusion, the proposed statistical framework, modeling an individual's CNVs as a piecewise constant curve and adopting Lasso and weighted fusion penalties, demonstrates better variable selection and effect size estimation performance for CNV association studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4133 Estimating family-to-offspring effects from genetic data of first-degree relatives

Authors:

L. Darrous[1,2,3], Z. Kutalik[1,2,3]; [1]Univ. of Lausanne, Lausanne, Switzerland, [2]Univ. Ctr. for Primary Care and Publ. Hlth., Lausanne, Switzerland, [3]Swiss Inst. of Bioinformatics,, Lausanne, Switzerland

Motivation: While past studies investigated direct genetic effects of complex trait, we aimed at estimating the parental/family effects that arise when the genetics of an individual affect the trait of a family member. These parental/family effects also allow the estimation of parent-to-offspring causal effects via Mendelian Randomization (MR).
Methods: Using data from the UK Biobank, we estimated the direct and family genetic effects by regressing an individual's phenotype jointly onto its own genotype and that of its first-degree relatives. As a proof of concept, we examined educational attainment (EDU) and body mass index (BMI) and distinguished their direct and parental genetic basis via contrasting their genetic correlation to ~200 representative traits. To understand the parental determinants of EDU and BMI, we estimated the multivariable causal effects of >100 parental traits (proxying rearing environment) on these two focal traits by employing MR.
Results: We meta-analyzed the family effect estimates from parent-offspring and sibling pairs (N = 39'000) across ~8.5 million SNPs. As expected, the heritability of the family effects for EDU (0.06, se = 0.02) and BMI (0.01, se = 0.02) were modest since they represent environmental rearing.
Interestingly, we see no genetic correlation between offspring and parental obesity. On the other hand, high offspring BMI is genetically anticorrelated with healthy parental dietary habits (increased dried fruit/cereal, reduced beef/pork/poultry intake). In contrast to BMI, parental and offspring education extensively share genetic basis. While parental intelligence is not, parental longevity is strongly genetically correlated to offspring EDU (rG=1.33, P=2.2E-4).
MR revealed no parent-to-offspring transmission of BMI, but rather parental dietary habits and socio-economic status being the causal drivers of offspring obesity. Intriguingly, MR revealed that both parental BMI ($\boldsymbol{\alpha}$;=-0.04, P=2.5E-6) and leisure time habits (Time spent watching TV: $\boldsymbol{\alpha}$;=-0.08, P=3.7E-4) have a significantly negative causal effect on offspring EDU.
Conclusion: Using samples from the UK Biobank, we were first able to dissect direct and family genetic effects acting on BMI and EDU. These estimates fed into genetic correlation and causal inference analyses shed light onto the aspects of the rearing environment that play a key role in shaping an offspring's BMI and education level. These results highlight that a high socioeconomic environment and healthy parental diet have a favorable effect on offspring BMI, and other family habits, such as excessive TV watching, tend to decrease the offspring's educational attainment.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4134 Estimating genetic prevalence of autosomal recessive disorders in the Korean population using 5,000 genome sequencing data.

Authors:

W. Jeong, S. Ryu, G. Seo, C. Keum, H. Lee; 3billion, Seoul, Korea, Republic of

Patients with rare genetic conditions (RGC) could go through a long diagnostic odyssey when the symptoms overlap with common disorders. Oftentimes, this is due to healthcare providers not considering the patients may have an RGC either because of unawareness or because they think the disease prevalence (DP) is too low. However, DP may not be as low as there are many RGCs with underestimated DP. To break this negative cycle, it is important to accurately estimate DP. DP is measured by sampling individuals with a certain condition but estimating DP for RGCs is challenging due to the limited number of patients. However, with large genomic population data becoming available, it is now possible to calculate genetic prevalence (GP) instead, which may be more accurate than the estimated DP. GP is based on carrier frequency (CF) of the pathogenic variants of a condition. CF varies by populations so it is important to use the appropriate sub-population data to calculate.
Here, we calculated CF/GP for rare OMIM AR diseases in 5,000 'healthy' South Koreans using 102 million variants from genome data obtained through the Korean Genome and Epidemiology Study (KoGES). Using an internally developed ACMG guideline-based variant classification system, EVIDENCE, 6,099 putative pathogenic variants were identified in 1,899 genes. CF was calculated from allele frequency data for each variant. GP was calculated by aggregating the product of all possible homozygous and compound heterozygous variant combinations.
We compared our results to published data of 5 RGCs prevalent (CF>=1/200) in South Korea: Wilson Disease, Glycogen Storage Disease Ia, Phenylketonuria, Congenital hypothyroidism and Congenital lipoid adrenal hyperplasia. CF concordance was high at r=0.94 but the concordance between our GP and reported DP was r=0.25 with GP being higher than DP for 3 RGCs and vice versa for 2. Another example is cystic fibrosis, a tier 1 disorder in the ACMG carrier screening guideline. The published data in 2011 showed that there are 10 patients in South Korea diagnosed with cystic fibrosis. However, our calculated CF was 1/250, consistent with the published CF 1/261 for Asians. From this, we could estimate GP to be 1/250,000. Since the South Korean population in 2011 was ~50 million, there should have been ~200 patients with cystic fibrosis, which is 20 times more than reported.
These findings highlight the utility of population-matched large-scale genomic data in calculating GP to estimate DP and how with more accurate DP, each sub-population would be able to develop more customized healthcare plans to increase RGC awareness and diagnostic rate and develop appropriate carrier screening programs.

PB4135 † Estimating SNP-pair effect correlations across functional annotations.

Authors:

M. Zhang[1], A. Durvasula[2], C. Chiang[3], P-R. Loh[4], S. Gazal[5], S. Sunyaev[6], A. Price[7]; [1]Harvard Univ., Roxbury Crossing, MA, [2]Harvard Med. Sch., Cambridge, MA, [3]Boston Children's Hosp., Boston, MA, [4]Brigham and Women s Hosp. / Harvard Med. Sch, Boston, MA, [5]USC, Los Angeles, CA, [6]Harvard Med. Sch., Boston, MA, [7]Harvard Sch Pub Hlth, Boston, MA

Inferring genetic architectures of disease and partitioning heritability across functional annotations are fundamental goals with far-reaching implications. However, virtually all published studies assume that nearby SNPs have independent causal effects on disease—an assumption that warrants careful scrutiny. Here, we propose a method, LD SNP-pair effect correlation regression (LD-SPEC), to estimate correlations of causal effect sizes (of derived alleles) for pairs of nearby SNPs, depending on their functional annotations. Roughly, LD-SPEC determines that a SNP-pair annotation has positive (resp. negative) correlation of causal effect sizes if SNPs with concordant signed LD to pairs of SNPs in the SNP-pair annotation have higher (resp. lower) chi-square statistics than SNPs with discordant signed LD. LD-SPEC produces robust estimates across a wide range of genetic architectures in simulations with real genotypes.
We applied LD-SPEC to 29 UK Biobank diseases/traits (avg. *N*=298K), estimating effect correlations for common (MAF>5%) and low-frequency (0.5%<MAF<5%) SNP pairs depending on their functional annotations. We reached 3 conclusions. First, low-frequency SNP pairs had significantly negative effect correlations that decayed with distance (e.g., −0.39±0.09, −0.14±0.04, −0.06±0.01 for 0-100bp, 0-1kb, and 0-10kb low-frequency SNP pairs; non-significant for common SNP pairs). The negative SNP-pair effect correlations can potentially be explained by linkage masking, whereby linked SNPs with opposite effects on disease have reduced effects on fitness and escape negative selection. Second, positive-LD SNP pairs had significantly more negative effect correlations than negative-LD SNP pairs (e.g., −0.18±0.05 vs. +0.19±0.06 for common 0-100bp SNP pairs and -0.38±0.10 vs. +0.21±0.18 for low-frequency 0-100bp SNP pairs), consistent with linkage masking; forward simulations under an evolutionary model involving stabilizing selection recapitulated these findings. Third, SNP pairs with shared functional annotations had significantly more negative effect correlations (e.g., −0.22±0.04 for low-frequency same-exon SNP pairs vs. -0.02 for random distance-matched low-frequency SNP pairs; avg. distance of 3.7kb), consistent with a model in which SNP pairs with shared function and opposite effects on disease are likely to have opposite effects on pleiotropic traits driving fitness. Overall, our results advocate against models in which nearby SNPs have independent causal effects on disease, and motivate new directions in modeling the impact of selection on genetic architectures and improving fine-mapping.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4136 † Evaluating genetically-predicted causal effects of lipoprotein(a) in human diseases: a phenome-wide Mendelian randomization study

Authors:

J. Shi[1], S. Shringarpure[1], 23andMe Research Team, A. Auton[2], M. V. Holmes[1]; [1]23andMe, Inc., Sunnyvale, CA, [2]23andMe, Inc., South San Francisco, CA

Lipoprotein(a) (Lp(a)) is a circulating plasma lipoprotein that is emerging as an important risk factor for vascular disease. Lp(a) levels are 75-95% heritable and predominantly determined by SNPs at the LPA gene. As such, genetic variants at the LPA locus can serve as instrumental variables for investigating the potential causal effects of circulating Lp(a) levels.
In 6.5M individuals from the 23andMe database, we constructed a weighted Lp(a) genetic risk score (GRS) using instrumental variables identified to be GWAS significant for Lp(a) from the UK Biobank data. Using the Lp(a) GRS, we conducted two-stage least square phenome-wide MR analyses across a spectrum of 448 phenotypes from the 23andMe database. In addition, we compared effects of genetically-predicted higher Lp(a) to the equivalent standardized difference in LDL-C using LDL-C instruments derived from the UK Biobank data.
Our phenome-wide MR analysis identified strong effects of genetically-predicted higher Lp(a) on multiple cardiovascular endpoints. Higher genetically-predicted Lp(a) increased the risk of coronary artery disease, with the magnitude of effect being very similar to that for a comparable standardized increase in LDL. Compared to LDL-C, we found genetically-predicted Lp(a) to have a directionally consistent and yet larger magnitude of effect on risk of heart failure, aortic stenosis and peripheral vascular disease. Both Lp(a) and LDL-C increased the risk of aortic aneurysm to a similar extent. Interestingly, genetically-predicted Lp(a) was found to lead to a higher risk of arrhythmia, specifically atrial fibrillation whereas such a relationship was not seen for LDL-C. Consistent effects of Lp(a) with LDL-C were identified for risk of stroke and transient ischemic attack.
Our findings demonstrate genetically-predicted deleterious effects of Lp(a) on a broad range of cardiovascular endpoints, including some traits (e.g atrial fibrillation) that are not impacted by LDL-C. Future work will explore the independent effects of Lp(a) and LDL-C using multivariable approaches, and estimate the non-linear effects of these potential causal relationships.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4137 Evaluating the contributions of rare and common variants in disease risk

Authors:

Z. FULLER, W. Wang, K-H. Lin, J. O'connell, A. Auton, X. Wang; 23andMe, South San Francisco, CA

Over the last decade, the dramatic increase of sample sizes in genetic association studies have demonstrated the clear polygenic role of common variants in complex disease risk. While individually any associated common variant tends to have a very small effect size, the contribution of many such variants across the genome in aggregate explains a much larger fraction of the observed heritability for many complex traits. At the same time, these large sample sizes have also enabled the discovery of rare variants (e.g. < 1%) with individually large effect sizes on complex traits, yet it remains unknown how such variants contribute to population trait variance. How the combination of common and rare variants influences human disease remains an open question. Here, taking advantage of over 6 million samples from 23andMe research participants, we quantify the contributions of common and rare variants to phenotypic variance for several quantitative and case-control human traits as a proof-of-principle, including height, body mass index, and obesity. We first construct polygenic risk scores based on common variants and then generate per-gene risk scores for rare loss of function variants based on estimates from gene-based burden tests. While overall rare variants do not explain a large amount of phenotypic variance and tend to yield minimal increases in predictive accuracy (incremental AUC < 10^{-3}), we find that they tend to be enriched in individuals whose true phenotype deviates the most from their predicted phenotype based on common genetic variants. Moreover, we find that although incremental AUC tends to be small, there is a significant proportion of individuals who are successfully reclassified with the addition of a per-gene rare variant polygenic score. Finally, we demonstrate how detecting genes enriched for large effect rare variants in individuals who deviate from their common variant derived predicted phenotype may be a useful approach for identifying therapeutic targets. Together, these results shed light on the joint influences of rare and common genetic variants on human traits and provide a framework for interpreting their contributions under a liability-threshold model.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4138 Evaluating therapeutic targets for Nonalcoholic Fatty Liver Disease using human genetic and phenotypic data from the UK Biobank

Authors:

M. Luth, G. McInnes, Y. Han, D. Jakubosky, B. Cajes, S. Bruse, O. Gottesman; Empirico Inc., San Diego, CA

Nonalcoholic Fatty Liver Disease (NAFLD) is a chronic and potentially life-threatening liver condition that affects more than 25% of the global adult population. Though many investigational therapies for NAFLD are the subject of active clinical development or have been previously evaluated in clinical trials, no drugs have yet been approved specifically to treat NAFLD. Given the attrition rate in clinical development across all therapeutic indications is approximately 90% and that previous studies have demonstrated a two-fold increase in drug approval rates if the drug target for an indication is supported by human genetics evidence, we sought to evaluate whether there was supportive human genetic evidence for multiple NAFLD targets that have entered clinical trials using the genetic and phenotypic data from 452,401 individuals in the UK Biobank. We evaluated associations between nonsynonymous variants in each target gene, either individually or in aggregate, and phenotypes associated with liver disease. Specifically, we assessed the associations between individual genetic variants and gene burdens with quantitative measures of liver function or composition and diagnosis codes pertaining to NAFLD or its sequelae. While we found supportive human genetics evidence for many of the targets of investigational NAFLD drugs, particularly in the form of associations with liver enzymes, we were unable to find supportive human genetics evidence for several targets that have failed in clinical development. For example, we observed no significant associations with NAFLD-related traits for variants or burdens in MAP3K5 (ASK1), the target of Selonsertib, which failed to meet its primary efficacy endpoints during Phase 3 clinical trials in patients presenting advanced liver fibrosis due to NAFLD. We also conducted phenome-wide association studies to predict potential adverse effects related to pharmacological modulation of each target. This study provides valuable insights into possible efficacy and safety concerns for potential NAFLD targets and highlights the utility of incorporating human genetics data early in the drug discovery and development process. This research has been conducted using the UK Biobank Resource under Application Number 34229.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4139 Evaluation of epistasis detection methods in simulated quantitative phenotype data.

Authors:

S. Listopad, Q. Peng; Scripps Res., San Diego, CA

Background: Epistasis, that is gene-gene interaction, plays a role in susceptibility to common human diseases such as Alzheimer's. There are two types of epistasis: biological epistasis and statistical epistasis. Biological epistasis involves physical interaction between two or more biological components. Statistical epistasis refers to the departure from additive effects of genetic variants at different loci with regard to their global contribution to the phenotype. There are different types of statistical epistasis: dominant, recessive, multiplicative, and exclusive or (XOR). The former two are considered biologically plausible, while the latter two are not. Epistasis detection tools detect statistical epistasis. There are many epistasis detection tools currently available. Several publications have compared the performance of epistasis detection methods suitable for case-control data. However, little is known about the performance of epistasis detections tools suitable for quantitative phenotype data. **Methods:** We have identified seven implemented epistasis detection tools suitable for quantitative phenotype data: Matrix Epistasis, MIDESP, Plink Epistasis, WISH-R, SNPassoc, FRGEpistasis, and EpiSNP. Three of these methods were well documented, easy to use, and highly optimized: Matrix Epistasis, MIDESP, and Plink Epistasis. In order to evaluate these tools, we have generated 46 simulated datasets using EpiGEN: 8 dominant, 8 recessive, 20 multiplicative, 4 XOR, and 6 control datasets. All interactions were second order, that is between pairs of disease SNPs. Each dataset contained 1000 SNPs, 1000 individuals and 1-8 pairs of interacting disease SNPs. Half of the datasets were pure, that is they had no marginal effects, and half were impure, that is they had marginal effects. The strength of interaction effect was also varied across datasets. **Results:** Plink and Matrix Epistasis tools excelled at detecting dominant epistasis with 100% detection rate. They also detected 50% of recessive epistasis pairs, 16%-18% of multiplicative epistasis pairs, and 0% of XOR epistasis pairs. MIDESP detected 50% of XOR, 41% of multiplicative, 33% of dominant, and 0% of recessive epistasis pairs. All three tools were able to process a single 1000 SNP dataset in less than a minute. All three tools exhibited better detection rates for datasets with stronger interaction effects and pure interaction. **Conclusion:** Plink and Matrix Epistasis were most effective at detecting dominant and recessive epistasis, while MIDESP was most effective at detecting multiplicative and XOR epistasis. All three tools were well documented, easy to use, and highly optimized.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4140 Evaluation of input data modality choices on functional gene embeddings

Authors:

F. Brechtmann[1], T. Bechtler[1], S. Londhe[1], C. Mertes[2], J. Gagneur[1]; [1]Technical Univ. of Munich, Garching, Germany, [2]Technical Univ. of Munich, Garching bei München, Germany

Functional gene embeddings, numerical vectors capturing gene function, provide a promising way to integrate functional gene information into machine learning models. These embeddings are learnt by applying self-supervised machine-learning algorithms on various data types including quantitative omics measurements, protein-protein interaction networks, and literature. However, downstream evaluations comparing alternative data modalities used to construct functional gene embeddings have been lacking. Here we benchmarked functional gene embeddings obtained from various data modalities for predicting disease-gene lists, cancer drivers, phenotype-gene associations, and scores from genome-wide association studies. Off-the-shelf predictors trained on precomputed embeddings matched or outperformed dedicated state-of-the-art predictors, demonstrating their high utility. When predicting curated gene lists, embeddings derived from genome-wide experimental data (transcriptomics, deletion screens, and protein sequence) were outperformed by embeddings based on literature and protein-protein interactions inferred from low-throughput experiments and manual curation. However, they performed similarly for predicting genome-wide association signals and were not biased towards highly-studied genes. These results indicate that embeddings derived from literature and low-throughput experiments may appear favourable in many existing benchmarks because they are biased towards well-studied genes and should therefore be considered with caution. Altogether, our study and precomputed embeddings will facilitate the development of machine-learning models in genetics and related fields.

Hlth., Baltimore, MD

Background
Rare inborn errors of metabolism have revealed many genes underlying metabolic homeostasis. We hypothesized that systematic, exome-wide genetic studies of paired plasma and urine metabolomes can reveal known and novel metabolite-associated genes and variants, differentiate between systemic and kidney-specific effects, and establish connections to related diseases.
Methods
We performed gene-based burden tests using whole-exome sequencing data, focusing on the effects of rare (MAF <1%), putatively damaging variants on the levels of 1,294 plasma and 1,396 urine metabolites (781 overlapping) from 4,737 participants of the GCKD study. Two masks reflecting different genetic architectures were defined to select qualifying variants (QVs). Identified gene-metabolite associations were integrated with common variant signals from the respective GWAS to investigate allelic series, and related to health outcomes using database annotations and PheWAS. The contribution of individual QVs was prioritized via forward selection.
Results
We identified 192 significant gene-metabolite associations across plasma (P<5.04e-9) and urine (P<4.46e-9), with 43 overlaps. Overall, 73 unique genes were involved, where 22 and 17 were detected exclusively in plasma and urine. Whereas plasma-specific signals predominantly arose from lipids, urine-specific signals mainly arose from amino acids. For instance, carriers of putative loss-of-function variants in *SLC7A9* showed significantly altered levels of urine amino acids that are transported by the encoded protein in the kidney. GWAS detected common-variant associations for 68% of the respective gene-metabolite pairs, enabling the generation of allelic series. QVs revealed different genetic architectures across genes and their associated metabolites, as well as for heterozygous and hemizygous carriers. For example, male compared to female carriers of QVs in X-chromosomal *TMLHE* showed markedly higher plasma and urine levels of the encoded enzyme's substrate N6,N6,N6-trimethyllysine. The identified genes and variants were associated with many traits and diseases in the UK Biobank, including kidney-enriched transporters with kidney function measures, implicating conditions for which their cognate metabolite(s) can serve as intermediate readouts of effect sizes across the allele frequency spectrum.
Conclusion
This genetic study identified known and novel gene-metabolite relationships, differentiated between systemic and kidney-specific processes, prioritized rare damaging variants involved in disease-causing processes, and established molecular links between genes and diseases.

PB4142 Exome-wide assessment of pediatric rhabdomyosarcoma suggests a novel susceptibility gene related to telomere function

Authors:

Y. Yu[1], S. Pagna[2], A. Sabo[2], J. Kim[3], M. Scheurer[4], S. Dugan-Perez[2], D. Marquez-Do[2], R. Gibbs[4], J. Khan[5], J. F. Shern[5], D. Malkin[6], C. Linardic[7], B. D. Crompton[8], R. Venkatramani[2], D. Hawkins[9], S. Plon[4], D. Stewart[3], C. Huff[10], C. Huff[11], P. Lupo[2]; [1]UT MD Anderson Cancer Ctr., Houston, TX, [2]Baylor Coll. of Med., Houston, TX, [3]Natl. Cancer Inst., Rockville, MD, [4]Baylor Coll. Med., Houston, TX, [5]Natl. Cancer Inst., Bethesda, MD, [6]Hosp for Sick Children, Toronto, ON, Canada, [7]Duke Univ. Sch. of Med., Durham, NC, [8]Harvard Med. Sch., Boston, MA, [9]Univ. of Washington, Seattle, WA, [10]U.T. MD Anderson Cancer Ctr, Pearland, TX, [11]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

While previous studies have characterized the frequency of pathogenic variants in established cancer predisposition genes (CPGs) among children with rhabdomyosarcoma (RMS), there have been few attempts to evaluate gene-level estimates of relative risk or to discover novel RMS susceptibility genes. Exome sequencing from two previously published RMS cohorts (n = 689) was combined and compared to population-based controls (n = 2,218). Following an extensive data harmonization and QC procedure we utilized VAAST 2.1 to integrate predicted variant function and frequency differences between cases and controls in gene-level association tests across rare variants (MAF < 0.5%). Analyses were conducted by ancestry group (non-Hispanic European [NHE], African, and Hispanic) and then meta-analyzed. Gene-level ORs and 95% CIs were calculated among those of NHE ancestry based on sample size. Results were also stratified by RMS histology (embryonal, alveolar). We observed significant associations for established CPGs including *TP53* (meta-p = 5.9 x 10^{-5}), *NF1* (meta-p = 0.001), *BRCA2* (meta-p = 0.002), and *HRAS* (meta-p = 0.02). When considering gene-level ORs for rare coding variants irrespective of known pathogenicity, we observed associations for *NF1* (OR = 2.5, 95% CI: 1.3-4.8) and *HRAS* (OR = 4.9, 95% CI: 1.1-21.6), which were driven by variants in those with embryonal RMS. We also observed a strong association for *TP53* (OR = 5.7, 95% CI: 2.0-16.1), which was consistent for those with embryonal RMS (OR = 5.5, 95% CI: 1.7-17.9) and alveolar RMS (OR = 7.1, 95% 1.7-29.6). We also identified a potentially novel RMS susceptibility gene, *ACD* (meta-p = 3.2 x 10^{-5}), which was significant across ancestry groups and encodes the telomere protein TPP1. It was strongly associated with RMS risk (OR = 5.5, 95% CI: 2.3-13.5) and was consistent for embryonal RMS (OR = 6.4, 95% CI: 2.4-17.6) and alveolar RMS (OR = 5.7, 95% CI: 1.5-22.1). In a sensitivity analysis of *ACD* ORs by ancestry, we observed similar trends for those of Native American ancestry (OR = 1.8, 95% CI: 0.5-6.1) and African ancestry (OR = 2.4, 95% CI: 0.5-10.3), but the 95% CI included the null. Overall, our findings further characterize the role of rare germline variants on RMS susceptibility. Specifically, our exome-wide assessment 1) confirmed the contribution of CPGs on RMS risk, including *TP53*; 2) demonstrated subtype specific effects, including *NF1* and embryonal RMS; and 3) implicated a potentially novel RMS susceptibility gene - *ACD*. Notably, *ACD* is involved in telomere function, which is emerging as an important predisposing factor for other sarcomas. Additional analyses are underway to further explore and validate our findings.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4143 Exploiting latent gene-environment Interaction in the analysis of binary traits

Authors:

Z. Zhang[1], J. Lawless[2], A. Paterson[3], L. Sun[1]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Univ. of Waterloo, Waterloo, ON, Canada, [3]Hosp for Sick Children, Toronto, ON, Canada

In genome-wide association studies (GWAS), it is desirable to include and test the interaction effect (GxE) between single-nucleotide polymorphism (SNP,G) and environmental variable (E). However, directly accounting for this interaction effect is often infeasible, because the environmental variable E is latent. The latent GxE, however, can be identified through *indirect* interaction analysis. For quantitative traits (Y) that are approximately normally distributed, it has been shown that indirect testing on GxE interaction can be done by testing the heteroskedasticity of Y between genotypes. However, when traits are binary, the existing methodology based on testing for the heteroskedasticity between genotypes cannot be generalized. In this work, we propose a solution for indirect testing hence leveraging latent (GxE) interaction effects for binary traits. Through numerical experiments, we show that the proposed approach can better detect associated SNPs compared to the traditional additive testing method. We illustrate the use of the proposed method by applying it to the UK Biobank dataset for a complete GWAS study. Our method reveals potential latent interaction effects in various SNPs and genes, which would not be detected using the traditional GWAS method.

PB4144 † Exploring plateau and saturation of PRS accuracy in the multi-populations and multi-trait model

Authors:

Y. Ruan[1], H. Zhang[2], A. Rodriguez[3], R. Madduri[4], W. Hornsby[1], P. Natarajan[5]; [1]Broad Inst., Cambridge, MA, [2]Natl. Cancer Inst., Cambridge, MA, [3]Argonne Natl. Lab., Lincolnwood, IL, [4]Argonne Natl. Lab., Naperville, IL, [5]Massachusetts Gen. Hosp., Boston, MA

Background: Polygenic risk score (PRS) is a valuable tool for basic research and its accuracy increases with increasing sample size of discovery Genome-wide association studies (GWAS). PRS is typically based on common Single Nucleotide Polymorphisms (SNPs), and its accuracy of PRS will theoretically be saturated when it reaches the level of common SNP heritability. Previous studies have projected the risk-prediction ability of PRS across sample sizes for naive clumping and P-value thresholding methods and single discovery GWAS scenario. However, contemporary PRS utilize GWAS from multiple populations and more complex Bayesian methods, potentially leading to different saturation estimates. **Methods:** To evaluate efficient schemes for future GWAS data collection and PRS methodology development, we simulated genotype data for up to 1 million individuals across five populations (African, American, East Asian, European, and South Asian) using 1000 Genome linkage disequilibrium references. The performance of prevalent Bayesian PRS methods (e.g. PRS-CS and LDpred2) in single-GWAS and multi-trait/population scenarios was benchmarked usingthe simulated data and large-scale real-world cohorts. **Results:** Our results showed that for within-trait prediction, combining GWAS from multiple populations requires less overall sample size to reach saturation than single-population GWAS. Even when the target data and the single-population GWAS are of the same population, the combination of different population discovery GWAS holds a marginal advantage. Particularly, this is notable when the trait is under strong selection. For example, when predicting adjusted LDL-C in a subset of UKBB EUR samples, partial R^2 of PRS based on the combination of GWAS of 4 populations is close to the estimated common SNP heritability when overall N= 672k while the PRS based on only EUR data is below this level when N> 1M. Besides, our results show the usefulness of the cross-trait PRS model, particularly for binary-traits with low prevalence, where discovery GWAS might be sparse or unavailable. The PRS model leveraging multiple trait GWAS and including additional information such as annotation and local genetic correlation can further increase PRS accuracy when the PRS sample size is limited. This study offers valuable insights for the future development of PRS methodologies and efficient schemes for GWAS data collection.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4145 Exploring prevalence and cancer risk in adult individuals with pathogenic and likely pathogenic variants in RASopathy genes.

Authors:

G. Ney[1], J. Kim[1], M. Frone[1], E. Astiazaran-Symonds[1], J. Haley[2], U. Mirshahi[2], G. Urban[2], H. Rao[2], M. Shadrina[3], A. Pemov[1], A. Gross[4], M. Yohe[5], D. Carey[2], B. Gelb[3], D. Stewart[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]Geisinger Clinic, Danville, PA, [3]Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Natl. Cancer Inst., Bethesda, MD, [5]Natl. Cancer Inst., Frederick, MD

RASopathies are clinical syndromes due to germline pathogenic variants in the RAS/mitogen-activated protein kinase (MAPK) pathway, leading to clinical sequelae including cardiac anomalies, neurologic conditions and failure to thrive. Notably, some of the RASopathies, such as Costello syndrome, have increased cancer incidence in childhood but very little is known about cancer risk later in life. To investigate cancer incidence in adults with germline pathogenic or likely pathogenic (P/LP) variants in canonical RASopathy genes, variants were extracted from exome data using the UKB, DiscovEHR and BioMe cohorts and clinical phenotypes were compiled. Variants were filtered and annotated with snpEFF, ClinVar (retrieved 12/08/2022) and InterVar (v.2.1.2). Variants with a read depth ≤ 10, ABHet ≤ 0.25, alternate allele read ≤ 3, or predicted loss-of-function (except for *SPRED1*) were removed. Variants were then classified by ClinVar and/or InterVar as P/LP and reviewed by a member of ClinGen's RASopathy Expert Panel. If there was consensus for P/LP, the variant was included. For analyses, non-carriers were selected as individuals with any variant status in any gene but did not harbor any P/LP variants in RASopathy genes. The most common variants identified were in genes associated with Noonan syndrome (1:2669, 1:1321, and 1:1406 in UKB, DiscovEHR, and BioMe, respectively), with *PTPN11* accounting for ~ 45% of the variants. Cancer incidence in *CBL*-associated Noonan syndrome, Noonan syndrome (NS) and cardiofaciocutaneous syndrome was similar in carriers compared to non-carriers across the UKB and DiscovEHR biobanks. However, a roughly 4-fold increased cancer incidence was observed in *SPRED1* carriers in UKB (OR 4.54; p = 4.61E-4) with earlier cumulative cancer risk than non-carriers, while no difference was observed in NS. Notably, individuals with P/LP germline variants in Noonan-associated genes had inferior survival compared to non-carriers, with a decrease in mean age of about three years (Cox p value = 8.84E-5). Surprisingly, while there was no difference in cancer incidence or cumulative incidence of cancer in NS, cancer-cause mortality was significant (Cox p-value = 0.0013), and remained after removing individuals with P/LP variants in *PTPN11* (cox p-value = 1.02E-5). Individuals who harbor germline P/LP variants in Noonan-associated genes do not have increased cancer incidence in adulthood, while data in *SPRED1* carriers in UKB suggests increased cancer incidence and earlier onset. However, carriers of germline P/LP variants in Noonan syndrome-associated genes demonstrate earlier all-cause mortality as well as cancer-cause mortality.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4146 Exploring the genetic background of facial variation in genetic disease to investigate the genotype to phenotype relationship, using achondroplasia as a model.

Authors:

K. Tran[1], H. Hoskens[1], D. J. Aponte[2], C. Unger[1], P. Claes[3], C. Rolian[4,1], B. Hallgrimsson[1]; [1]Univ. of Calgary, Calgary, AB, Canada, [2]Deep Surface AI, Calgary, AB, Canada, [3]KU Leuven, Leuven, Belgium, [4]McGill Univ., Montreal, QC, Canada

The complexity of the genotype-phenotype (GP) relationship poses a major issue in developmental biology and quantitative genetics; that is, changes in gene expression do not necessarily translate into changes in the phenotype. One trait that demonstrates this complexity is craniofacial shape, which is extraordinarily variable and is determined by interactions between thousands of genes. Craniofacial dysmorphism is characteristic among 30-40% of Mendelian diseases. Due to expressivity and penetrance, genetic diseases present with a wide range of craniofacial variability. This suggests that non-pathogenic genetic background variants interact with the disease-causing mutation, producing a continuum of phenotypic severity within the same disease. Craniofacial diseases thus offer a powerful tool to disentangle the role of background variants in the complexity of the GP relationship. One such disease is achondroplasia, the most common form of skeletal dysplasia. Patients with achondroplasia and mouse models present with shortened stature, macrocephaly, and an underdeveloped midface. Interestingly, the Longshanks mouse model, which has enhanced bone growth, has been shown to have opposite craniofacial features to achondroplasia mice. It is thus possible that the same gene networks might produce this long axis of phenotypic variability, from the Longshanks to the achondroplasia phenotype. Similarly, these genes likely contribute to the range of phenotypic severity in achondroplasia. To investigate this, I will map variants associated with the achondroplasia and the Longshanks phenotype in mice. Using geometric morphometrics, I will identify the facial shape axis associated with each phenotype and map a population of Diversity Outbred (DO) mice onto the shape axes. A genome-wide association study will reveal non-pathogenic background variants that may contribute to the achondroplasia and/or Longshanks phenotype. To confirm these effects, I will model the joint contribution of these genes to craniofacial shape using the process-MGP, a tool developed by our lab. This work will identify background variants that likely contribute to the severity of genetic disease and ultimately, improve our current understanding of expressivity, and penetrance, and the GP relationship.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4147 Expression QTL informed genetic risk score prediction in different genetic ancestries.

Authors:

S. Chhetri[1], D. Dutta[2], A. Omdahl[1], G. Qi[1], M. Arvanitis[1], A. Battle[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Natl. Cancer Inst., Rockville, MD

Polygenic risk scores (PRS) estimate genetic predisposition for complex traits using weighted sums of trait-associated alleles and, with improved estimates based on recent large genome-wide association studies (GWAS), offer the potential to be incorporated into clinical applications in the near future. However, their limited predictive performance for populations that differ in genetic ancestry remains a substantial obstacle to accuracy and equitable usage, as most current well-powered GWAS are biased toward individuals of European ancestry.
To mitigate the poor generalizability of PRS performance, we asked whether including multi-ancestry expression quantitative trait loci (eQTL) as a functional annotation in PRS would improve portability. Using eQTLs from European and African genetic ancestry, we determine, for each regulatory locus, whether the underlying genetic architecture is shared between ancestries and prioritize shared causal signals in the genetic risk score calculation. Using lymphoblastoid cell lines eQTLs from the GENOA consortia, we applied Bayesian colocalization to identify the shared causal variants responsible for the association in both cohorts. We identified 2256 regions with colocalizing cis-genetic effects across both ancestries and 298 cis-loci with distinct causal eQTL variants with posterior probability > 0.7.
To determine the trait heritability captured by GWAS loci with different patterns of eQTL causal variant sharing, we applied stratified-linkage disequilibrium score regression on 102 immunological, hematological, and anthropological traits. We hypothesize that GWAS effect sizes, and thus PRS weights, should be shared between ancestries more strongly at loci where eQTLs also share causal variants. We observe eQTLs shared by both ancestries were strongly enriched for heritability in blood-related traits and outperformed existing functional annotations in the LDscore baseline annotation model. We calculated the mean posterior effect size for cis-variants in colocalized regions with LD-pred-funct using coloc-weighted functional priors. We trained and evaluated a Systolic Blood Pressure (SBP) PRS in the WHIMS Study with 5550 European and 6503 African cohorts. We evaluate the relative utility of ancestry-shared and ancestry-specific eQTLs as features in the PRS for each cohort. We also compare eQTL features to baseline features. Overall, we have explored the ancestry-specificity of eQTLs and the utility of prioritizing shared causal genetic signals from eQTLs to compute weighted PRS in multiple ancestries.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4148 Extending Factor Models of Pleiotropy to Incorporate Epistasis Improves Prediction Accuracy in Complex Traits

Authors:

H. Kim, A. Dahl; Univ. of Chicago, Chicago, IL

Pleiotropy is pervasive in complex traits, and biobanks provide an opportunity to jointly model pleiotropic effects across thousands of related traits. Characterizing pleiotropy is necessary for understanding shared vs specific genetic effects. Specific effects are important to understand the core biology of a trait, especially in heterogeneous traits such as major depressive disorder (MDD). Exploiting shared effects, on the other hand, improves power to detect genetic effects and polygenic prediction accuracy. However, the standard approach to understand pleiotropy-genetic correlation-is overly simplistic as it only captures genome-wide average and only applies to two traits. More recent approaches have extended genetic correlation to locus-level measures or factor models spanning many traits. Still, it remains challenging to integrate the locus-level signatures or derive biologically meaningful factors. Moreover, such models assume that pleiotropy is additive, missing potentially complex relationships between loci and factors. Here, we develop an approach to address these limitations by partitioning high-dimensional pleiotropic relationships into shared and specific interacting factors. We applied our approach to a yeast dataset with 46 traits measured on 1008 samples. First, we computed latent factors using softImpute to accommodate missing data. Then we build polygenic scores for each trait (ordinary PS) and factor (factor-PS). We found that adding the factor-PS improved prediction accuracy on top of the ordinary PS for all 46 traits (using a calibrated train-test-validate scheme). Next, we found that the epistatic interaction between the ordinary PS and factor-PS was significant for 21 traits (FDR < 10%), and that adding these terms substantially improved prediction for a subset of traits (maximum of average R2 increase across factor-PS = 17%). Notably, we found statistically significant epistatic interactions between SNPs and ordinary PS for one trait. Finally, we will present results from an application to 216 MDD-relevant traits in the UK Biobank. We previously showed how multi-trait factor analyses of this data improve prediction and specificity in MDD GWAS; here, we show how our novel approach further improves prediction and specificity using interpretable priors, advancing our understanding of MDD genetic architecture. Additionally, our factor-level PS enables powerful detection of epistatic interactions in complex human traits. We will present results evaluating the utility of factor-PS in diverse ancestries. Overall, our approach is a step toward more realistic and holistic models of phenome-wide genetic effects.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4149 † Factor analysis adjusted for cohort overlap reveals genetic components shared across GWAS traits.

Authors:

A. Omdahl[1], S. Chhetri[2], R. Keener[1], G. Qi[3], A. Battle[3]; [1]Johns Hopkins Sch. of Med., Baltimore, MD, [23]Johns Hopkins Univ., Baltimore, MD

Joint analysis of genome-wide association studies (GWAS) elucidates the contribution of pleiotropic genetic variants to correlated phenotypes. Studies performing GWAS summary statistics factorization have identified distinct genetic disease etiologies and prioritized genes relevant to correlated phenotypes. However, existing factorization methods do not account for levels of sample sharing between studies, which may inflate estimates of genetic relatedness. Though well understood in bivariate genetic correlation analyses, the confounding impact of shared participants has received limited consideration in the context of GWAS matrix factorization. To evaluate the effects and prevalence of cohort overlap in this setting, we simulated GWAS summary statistics from overlapping cohorts. Increasing sample sharing between studies inflated the correlation of summary statistics (even in the absence of genetic signal) and reduced SVD's ability to reconstruct the genetic latent space. We examined the effect of cohort overlap on estimates of trait relatedness among 4,111,707 pairs of GWAS studies from the UKBB and found non-zero cohort overlap effects in 3.8% of study pairs (Bonf. p &lt 0.05). Many such phenotype pairs (including traits like BMI and limb impedance) with confounding shared-cohort effects contribute to leading latent factors in published GWAS factorization work. To address these concerns, we present GLEANER, a method that produces **G**WAS **L**atent **E**mbeddings while **A**ccounting for **N**ois**e** and **R**egularization. This factorization method uses a regularized generalized-least-squares approach to identify genetic components from summary statistics while simultaneously accounting for estimated cohort overlap and effect size uncertainty. GLEANER is initialized to detect pleiotropic effects while enforcing component sparsity. In simulated GWAS with correlated phenotypes and cohort overlap, GLEANER outperforms SVD and FLASH in latent space reconstruction (R2). Applying GLEANER to 55 diverse UKBB GWAS (including anthropometric, ocular, behavioral, respiratory, cardiovascular, and blood-related phenotypes), we identified distinct latent components enriched for central nervous system, cardiovascular, and musculoskeletal-specific tissue markers. These components differ from those estimated without cohort-overlap correction and exclude potentially inflated relationships. We also demonstrate how our approach can evaluate GWAS from various cohorts and meta-analyses in the context of women's reproductive health phenotypes. Our work offers an interpretable workflow for jointly analyzing many GWAS, even with overlapping samples.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4150 Family history of developmental dysplasia of the hip is a risk factor for the progression of hip osteoarthritis.

Authors:

S. Yoshino[1,2], R. Yamaguchi[2], H. Tanaka[2], S. Ikegawa[1], Y. Nakashima[2], C. Terao[1]; [1]RIKEN IMS, Yokohama, Japan, [2]Dept. of Orthopaedic Surgery, Graduate Sch. of Med. Sci., Kyushu Univ., Fukuoka, Japan

Background: Developmental dysplasia of the hip (DDH) is considered to have genetic predisposition and presents many intrafamilial occurrences. However, there is no report that evaluates the effect of DDH family history on the progression after the onset of hip osteoarthritis (OA). Methods: Medical interviews about detailed clinical information including family history were conducted on 298 consecutive patients who had undergone surgery for OA due to DDH. Clinical or radiographic items that are associated with the severity of DDH (total hip arthroplasty (THA), involvement of bilateral DDH, onset age of hip pain, and three radiological indices of DDH; center-edge angle, sharp angle, and acetabular roof obliquity) were collected and evaluated in the multivariate analyses for their associations with DDH family history in a qualitative or quantitative manner. Survival time analysis for THA as the endpoint was also performed to evaluate the effects of DDH family history on the progression of OA. Results: DDH family history showed significant associations with bilateral involvement of DDH (OR=2.09 [95% CI 1.05 to 4.16]; p=0.037), early onset of hip pain (p=0.0065) and radiological severity of DDH (p=0.016). It also showed a significant association with undergoing THA (OR=2.25 [95% CI 1.09 to 4.66]; p=0.029), further supported by the Cox regression analysis (HR=1.56 [95% CI 1.15 to 2.11]; p=0.0044). Conclusions: DDH family history is a risk factor for the progression of hip OA. Stronger genetic predisposition to DDH leads to earlier onset and faster progression of hip OA.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4151 Fast and accurate heritability partitioning using association summary statistics and sparse representation of LD

Authors:

H. Li[1], R. Mazumder[2], L. O'Connor[3], X. Lin[4]; [1]Harvard Univ., Cambridge, MA, [2]Massachusetts Inst. of Technology, Cambridge, MA, [3]Broad Inst. of Harvard and MIT, Cambridge, MA, [4]Harvard T.H. Chan Sch Pub Hlth, Boston, MA

When analyzing a new genomic dataset, a common question is: are prioritized genes or regions of the genome enriched for disease heritability in GWAS? For common variant heritability partitioning, the most widely used method is stratified LD score regression (S-LDSC; Finucane et al. 2015 NG), which can jointly model a large number of overlapping functional annotations due to its computational efficiency. However, S-LDSC is inaccurate compared with slower and less versatile likelihood-based methods like GCTA (Yang et al. 2010 NG), and a particular limitation is that its results are unreliable for individual SNPs. We address these limitations with a new method, graphREML, which combines the accuracy of likelihood-based methods with the speed and versatility of S-LDSC.

graphREML utilizes linkage disequilibrium graphical models (LDGMs; Salehi, Wohns et al. bioRxiv) and GWAS summary statistics. Like S-LDSC, our method has the versatility to model numerous annotations jointly; like GCTA, it maximizes a likelihood function, leading to increased accuracy. Its use of LDGMs makes the estimation computationally efficient. It also features a flexible link function for the relationship between functional annotations and the per-SNP heritability, leading to well-calibrated heritability estimates for individual SNPs.

In simulations, we find that graphREML produces unbiased heritability enrichment estimates, with much smaller standard errors than S-LDSC (relative efficiency averages ~2.3 under realistic settings). Moreover, the estimates from graphREML remain unbiased and more precise than those from S-LDSC under model misspecification. We apply graphREML to analyze the heritability enrichments of a wide range of complex traits and diseases in the UK Biobank, using 96 functional and LD-related annotations. Our estimates are concordant with S-LDSC but have much smaller standard errors.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4152 Fast and powerful mixed-model association analysis for genome-wide association studies.

Authors:

J. Hof; Radboud Univ. Med. center, Nijmegen, Netherlands

In recent years, mixed model association analysis (MMAA) has emerged as the preferred method for performing a genome-wide association study (GWAS). MMAA can control type 1 error by accounting for population structure and familial relatedness, and can increase statistical power by conditioning on effects of loci distal to the SNP being tested. However, existing MMAA software often require long run times and substantial memory. We introduce LDAK-KVIK, a new tool for MMAA of quantitative and binary phenotypes. LDAK-KVIK first constructs a genetic prediction model, then includes this model as an offset when testing genetic variants for association with the phenotype. LDAK-KVIK has three novel features. Firstly, it includes a flexible elastic net algorithm that produces state-of-the-art genetic prediction models (e.g., more accurate than those from BayesR, glmnet and Bolt-LMM). Secondly, LDAK-KVIK never reads in more than 256 genetic variants at once, and therefore has very low computational requirements. Thirdly, we have implemented an empirical saddlepoint approximation method for robust association analysis of unbalanced binary traits, which is orders of magnitude faster than existing methods. As a result, LDAK-KVIK is both powerful and efficient. For example, LDAK-KVIK takes approximately 12 CPU hours to analyse GWAS data for 420k individuals and 10M SNPs, and requires less than 10Gb memory. By contrast, REGENIE and Bolt-LMM, two leading methods for MMAA, require 31 and 150 CPU hours, respectively, to analyse the same data. Applied to 20 traits from UK Biobank, LDAK-KVIK finds 15% and 7%, respectively, more genome-wide significant loci than Bolt-LMM and REGENIE.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4153 Fine mapping disease-causing variants through principled integration of expression quantitative trait locus results via SuSiE

Authors:

X. Zhang[1], H. Zhao[2]; [1]Yale Univ., New Haven, CT, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Over the past decades, Genome-wide association studies (GWASs) have achieved remarkable success in associating thousands of genetic variants with complex traits. However, the presence of linkage disequilibrium (LD) makes it challenging to identify the true causal variants. To address this critical gap from association to causation, many fine mapping methods have been proposed to assign well-calibrated probabilities of causality to candidate variants, taking into account the underlying LD pattern. In this study, we introduce a new framework that incorporates expression quantitative trait locus (eQTL) information to fine mapping, utilizing the sum of single-effects (SuSiE) regression model. Our new method, SuSiE^2, connects two SuSiE models, one for eQTL analysis and one for genetic fine mapping. By leveraging eQTL information, SuSiE^2 enhances both the accuracy and efficiency of association studies by prioritizing functional variants within the candidate region. This is achieved by first computing the posterior inclusion probabilities (PIPs) from an eQTL-based SuSiE model with the expression level of the candidate gene as the phenotype. These calculated PIPs are then utilized as prior inclusion probabilities for risk variants in another SuSiE model for the trait of interest. Through simulations conducted on 10,000 UKBiobank samples genotyped at 20,000 SNPs, we observed that SuSiE^2 improved the power of detecting causal SNPs by 10% while reducing false positives by 50% when utilizing the in-sample LD matrix. Moreover, when the LD matrix was calculated based on an external reference panel, SuSiE^2 achieved even better performance with a 50% increase in power and a 30% reduction in the proportion of false positives. We applied SuSiE^2 to the functional SNPs associated with Alzheimer's disease (AD) predicted from single-cell epigenomic data. Among the 23 AD risk loci studied, SuSiE successfully identified the most likely mediator for five of them, while SuSiE^2 additionally captured the mediator for four risk genes: CTSH, TSPAN14, PICALM, and BIN1. While the original SuSiE detected 27 credible sets, with an average size of 8.1, SuSiE^2 identified 31 credible sets and reduced the average size to 6.6. Evaluations of AD risk genes like CTSH and C14orf93 indicated that SuSiE^2 improved the PIPs for causal mediators and achieved superior performance in distinguishing causal SNPs from non-causal variants. In conclusion, the integration of eQTL information with fine mapping through SuSiE^2 enhances the power of detecting causal SNPs while reducing false positives and the average size of credible sets.

PB4154 Fine-mapping causal variants using summary data with heritability-induced Dirichlet decomposition prior

Authors:

X. Li[1], P. Sham[2], Y. Zhang[3]; [1]The Univ. of Hong Kong, Hong Kong, China, [2]The Univ. of Hong Kong, Pokfulam, China, [3]The Univ. of Hong Kong, Hong Kong, Hong Kong

The goal of fine-mapping is to identify the causal genetic variants responsible for complex traits or diseases. Existing Bayesian fine-mapping methods based on discrete mixture priors rely on a prespecified maximum number of causal variants, and are more likely to be trapped into suboptimal solutions. In this work, we develop h2-D2, a novel fine-mapping method based on continuous global and local shrinkage prior. We also introduce a Bayesian inference approach that can define credible set of variants in the framework of continuous priors. Simulation studies demonstrate that h2-D2 can outperform state-of-art fine-mapping methods, SuSiE and FINEMAP, both in terms of variable selection and credible sets. We applied h2-D2 to fine-map prostate cancer using summary data from meta-analysis and identified novel causal variants. Functional enrichment analysis highlighted the importance of mediation effects of gene expression on prostate cancer risk.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4155 For the case-only design how rare must a disease be to control type I and II errors

Authors:

R. Dong[1], G. Wang[1], A. Dewan[2], S. Leal[3]; [1]Columbia Univ. Med. Ctr., New York, NY, [2]Yale Sch. of Publ. Hlth., New Haven, CT, [3]Columbia Univ., New York, NY

The case-only design can be a powerful approach to identify gene-gene and gene-environment interactions for rare diseases. It has not been investigated how rare a disease must be for the case-only design to be a valid approach. Through extensive simulations studies, we investigated the rare disease assumption and show that for diseases with prevalence <0.05 the case-only design has well controlled type I error and is substantially more powerful to detect interactions than the case-control design, but for higher disease prevalence, both type I and II errors are inflated. For a case-only study (N=10,000) where the disease prevalence is 0.20, and the genetic variant has a MAF=0.20 and a main effect odds ratio (OR)=1.2 and the environmental exposure has a prevalence of 0.1 and a main effect OR=2.0, under the null of no interaction for alpha=0.05 the type I error is 0.07. For the same scenario, but where there is an interaction (OR=1.2) the power to detect an interaction is 0.49, while for the case-control design (N=10,000 cases and 10,000 controls) the power is 0.85. For a disease prevalence of 0.04 instead of 0.20 the power for the case-only design is 0.88 and for the case-control design 0.55. We also evaluated the case-only design when there are no main effects or only one main effect, and type I and II errors are well controlled even for diseases with a high prevalence. However, the increase in power for the case-only design compared to the case-control design decreases with increasing prevalence. For example, under the same settings but where the main effect ORs are 1.0 and 2.0 for the genetic and environmental factors, respectively with an interaction OR=1.2 for a disease prevalence of 0.10 the power is 0.80 for the case-only design and 0.52 for the case-control design and for a disease prevalence of 0.20 the power is 0.59 for the case-only design and 0.49 for the case-control design. In the absents of two main effects, caution should be used when implementing the case-only design for common diseases, since main effects may be present but go undetected, which could lead to an increase in type I and II errors. In conclusion, although the case-only design is a powerful method to detect interactions, in practice it might not be beneficial for most complex traits given that usually their prevalence violates the rare disease assumption.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4156 Framework for detecting oligogenic patterns in undiagnosed clinical cohorts.

Authors:

S. Pajusalu[1,2], V. Pata[1,3], M. Marandi[4], K-M. Voovere[4], K. Ounap[1,2]; [1]Dept. of Clinical Genetics, Inst. of Clinical Med., Univ. of Tartu, Tartu, Estonia, [2]Genetics and Personalized Med. Clinic, Tartu Univ. Hosp., Tartu, Estonia, [3]Anesthesiology and Intensive Care Clinic, Tartu Univ. Hosp., Tartu, Estonia, [4]Inst. of Computer Sci., Univ. of Tartu, Tartu, Estonia

We propose a framework for studying oligogenic patterns in previously sequenced clinical cohorts to test the hypothesis that the actual underlying disease mechanism for some patients with the suspected monogenic disease is the summed effect of multiple variants across different biologically relevant genes.
The workflow is meant to reanalyze variant call files and phenotypic information from referral forms. It employs Hail software as the primary data manipulation layer and is compatible with Nextflow integration for processing large datasets in parallel. Variants are reannotated with gene labels, variant impact, and maximum population allele frequency (AF) using Ensembl VEP. Low-quality variants are filtered out to reduce noise.
Our workflow compares the variant burden between phenotype positive and negative sets (e.g., the presence of breast cancer) by collating variants with unique gene labels and gene sets. We hypothesize that phenotype-positive samples without a reported single high-impact diagnostic variant would show an overrepresentation of low to moderate-effect variants in biologically relevant genes. Conversely, as a positive control, a cohort with reported pathogenic single variants would exhibit an increased burden of rare high-impact variants in relevant genes. Variants are analyzed across four impact categories (modifier, low, moderate, high) and three frequency bins ($AF<0.01$, $0.01<AF<0.05$, and $AF>0.05$). Monte-Carlo simulation for selecting random gene sets is performed within each bin to extract variant count ratios between phenotype-positive and phenotype-negative samples. The distribution of ratios is then compared to the ratio calculated for predefined biologically relevant gene sets. Randomly selected gene sets are expected to show a distribution of ratios around 1. In contrast, predefined relevant gene sets should show an increased ratio (i.e., variant burden) if an oligogenic contribution to the disease is present.
Our current but growing database from Tartu University Hospital includes 4229 samples tested with a 113-gene inherited cancer risk panel and 4469 samples with a wide 6700-gene panel associated with various monogenic diseases, grouped and tagged with phenotypic information and reported pathogenic variants if available. Preliminary analysis focusing on breast cancer confirms an increased burden of high-impact variants in already diagnosed samples, supporting the utility of this framework. Further analysis on testing the oligogenic hypothesis will be presented for the complete cohort and different phenotypes.

PB4157 From genomic blueprint to epigenetic portrait: Predicting CpG methylation from individual-level whole-genome sequencing data.

Authors:

Z. Xiao[1], Y. Gong[1], K. Su[1], A. Liu[1], C. Qiu[1], Z. Luo[1], Q. Tian[1], H. Shen[1], C. Wu[2], H-W. Deng[1]; [1]Tulane Univ., New Orleans, LA, [2]UT MD Anderson Cancer Ctr., Houston, TX

Whole-genome sequencing (WGS) offers a comprehensive view of an individual's genetic variations, while whole-genome bisulfite sequencing (WGBS) uncovers DNA methylation patterns. Genetic variations, such as single nucleotide polymorphisms (SNPs), are known to play an important role in the formation of DNA methylation marks. Generating multi-omics data from the same individual can be costly and limited. Therefore, trans-omics imputation/prediction is in critical need, as it enables us to gain deeper insights of molecular layers and uncover complex relationships and interactions within biological systems. In house, we have 310 Caucasians and 185 African Americans with paired WGS and WGBS (as training dataset), and ~7,000 individuals with only WGS (as testing dataset). As the genetic effects may be non-linear, we proposed using both linear and non-linear approach to predict individual-level WGBS data from WGS profiles at a single-nucleotide resolution. First, we developed a machine learning framework, based on elastic net regression, to integrate genetic features around individual CpG sites to build predictive models. Out of total 25,724,565 CpG sites, we obtained ~9% (2,211,322 CpGs) and ~11% (2,819,377 CpGs) well-predicted models (R^2 >= 0.01) in Caucasians and African Americans, respectively. Next, we will also build predictive models based on a non-linear approach. We will validate our approach using individuals for whom only WGS data is available. In the end, we expect our approach to have high accuracy and reliability in predicting individual-level DNA methylation patterns. Finally, we will explore the potential utility of our predictions in identifying disease-associated DNA methylation alterations and predicting disease risk based on epigenetic signatures.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4158 Genetic ancestry-based case-control matching to improve power for trait-specific association analysis.

Authors:

A. Moscati, S. Gaynor, L. Ganel, T. Joseph, GHS-RGC DiscovEHR Collaboration, Regeneron Genetics Center, Regeneron Pharmaceuticals Inc., A. Locke, E. Stahl, G. Abecasis, T. Thornton; Regeneron Pharmaceuticals, Tarrytown, NY

Studies of the genetic basis of rare diseases can often be challenging. Many such studies rely on case-only designs for efficiency - suitable for natural history studies but potentially challenging for genetic association. Large biobanks, which have revolutionized studies of common traits and diseases, can be unsuitable for analysis of rare diseases due to low prevalence. The combined analysis complementing studies that contribute predominantly cases (when enriched or ascertained for specific outcomes) with biobanks that contribute predominantly controls can achieve well-powered case-control analysis, in principle. However, these studies are challenging in practice because to avoid false positives and ensure validity of association results, the process for selecting appropriate controls for analysis with cases must account for such systematic differences between studies as heterogeneity in ancestry composition and differences in the genotyping and/or sequencing technologies used.

We present an approach for genetic association testing in case-control studies derived from the aggregation of multiple contributing studies. The pipeline optimizes the effective sample size while simultaneously controlling for bias between data sources, and benefits analyses where, in a dataset of interest, including additional controls would improve statistical power. We implement a comprehensive approach that jointly prepares array, exome, or both data types to unify a potential analytic sample and reduce noise in matching and association analyses. We then perform case-control matching based on ancestry-representative principal components using a reference panel, plus other demographic and user-specified features where relevant. The approach, implemented in a cloud-based pipeline, matches controls to cases based on a specified case-control ratio using a greedy algorithm for efficiency.

We apply the pipeline to generate a case-control cohort and evaluate genetic associations with severe obesity (BMI>40) using the Geisinger Health System DiscovEHR dataset (GHS) and UK Biobank (UKB). Using the 19K severe obesity cases and 34K controls from GHS alone results in 64% power to detect a 3% allele frequency variant with a strong genotypic relative risk of 1.20, at a P-value threshold less than 5e-8. We show that matching GHS severe obesity cases to additional UKB controls increases the effective sample size compared to using GHS alone. By matching 66K additional controls from UKB to the GHS analytic sample, power for the same variant increases to 86.3%, displaying the benefits of our approach for improved genetic association yield, while controlling type 1 error.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4159 Genetic and epigenetic insights into aging of the human retina

Authors:

T-Y. Lin[1,2], J. Advani[1], M. English[1], D. A. Ferrington[3], A. Segre[4,5], A. Swaroop[6]; [1]Natl. Eye Inst., NIH, Bethesda, MD, [2]Natl. Yang Ming Chiao Tung Univ. and Academia Sinica, Taipei, Taiwan, [3]Dept. of Ophthalmology and Visual NeuroSci.s, Univ. of Minnesota, Minneapolis, MN, [4]Ocular Genomics Inst., Dept. of Ophthalmology, Massachusetts Eye and Ear, Harvard Med. Sch., Boston, MA, [5]The Broad Inst. of MIT and Harvard, Cambridge, MA, [6]Natl. Eye Inst., NIH, Bethesda, MD

Aging is a major contributing risk factor for age-related diseases. The complex interplay of genetics, environment, and stochasticity alters local accessibility and regulation of genetic information, resulting in transcriptomic dysregulations. Aberrant gene expression patterns manifest by a gradual decline of normal physiological functions chronologically, leading to increased susceptibility to many diseases. Although genome-wide association studies (GWAS) of age-related diseases have suggested genes and pathways contributing to pathophysiology, the effects of aging in these study designs are challenging to account for and are often forgone when using age as a covariate. Quantitative trait loci (QTL) are genomic regions statistically correlated with traits (e.g., gene expression (GE)/mCpGs) and are largely non-coding regulatory sites that mediate changes in gene expression. We hypothesize that aging-associated gene expression changes are determined, at least in part, by genetic variations and epigenetic changes (especially DNA methylation) resulting from environmental factors and lifestyle. We present a novel framework to study the effect of aging in age-related diseases by longitudinally characterizing the physiologic aging of the retina by integrating diverse “omics” datasets across the lifespan. First, we modeled GE changes across age with linear and non-linear regression to identify age-related differential GE. Secondly, we will establish retinal QTLs (eQTL, mQTL) to study natural genetic variations’ impact on expression and methylation. With the QTLs, we (1) dissect genetic variation in GE/mCpGs with QTLs accounting for aging and natural variability of genetic polymorphism on GE/mCpGs; (2) explore GE/mCpGs effect on aging by analyzing the differential GE and methylated regions by comparing across the lifespan; and (3) distinguish the role of epigenetics in aging transcriptome by integrating the GE and mCpGs associated with aging with eQTM to capture the dynamics of epigenetic and indirectly environment in the aging transcriptome.

PB4160 Genetic architecture of acute COVID-19-related diarrhea in 23andMe research participants

Authors:

S. Aslibekyan[1], N. Chaudhary[2], C. H. Weldon[1], P. Nandakumar[2], J. Shelton[2], 23andMe Research Team, M. Holmes[2]; [1]23andMe, Mountain View, CA, [2]23andMe, Sunnyvale, CA

Diarrhea is a commonly reported extrapulmonary symptom during acute SARS-CoV2 infection. Understanding the genetic architecture of COVID-19-related diarrhea can provide insights into relevant biological mechanisms. Consented 23andMe, Inc adult participants were invited via email to complete an initial COVID-19 baseline and three follow-up surveys, distributed one month apart. Participants who self-reported testing positive for COVID-19 and experiencing diarrhea during their acute infection in any of these surveys were included as cases (N=59,010), and those who self-reported testing positive for COVID-19 and not experiencing diarrhea during their acute infection were included as controls (N=117,786). We conducted GWAS in the European population adjusting for age, sex, age*sex, and principal components. Genetic variants associated (P<=5*10-8) with diarrhea experienced during acute COVID-19 illness were tested for association with other COVID-related features and 1000+ phenotypes available within the 23andMe research database.

Mean age of the cohort was 45 years (SD=14). Female participants were more likely to report diarrhea during acute COVID-19 infection (72.4% vs 62.9%). Cases were more likely to be hypertensive (27.0% vs 23.3%), hypercholesterolemic (32.3% vs 31.5%), hospitalized for COVID-19 (6.3% vs 2.9%), and to subsequently experience long COVID (44% vs 23%). We identified four statistically significant index variants associated with COVID-related diarrhea. These index variants have been previously shown to be associated with severe COVID infection, electrocardiographic abnormalities and lipid metabolism. On phenome-wide analysis within the 23andMe research database, the index variant on chromosome 8 (negatively associated with COVID-related diarrhea) was linked to irritable bowel syndrome (IBS) with directionally opposite relationships for IBS subcategories: IBS-Constipation (positive association, p=1x10-13) and IBS-Diarrhea (negative association, p=1x10-133).

In summary, genetic associations of COVID-related diarrhea indicate potential relationships with IBS, cardiac electrophysiology and lipid metabolism. Future analyses will include other ancestry groups and functional characterization of top hits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4161 Genetic control of gene expression in the brain links to individual variability in neuroimaging phenotypes and disease.

Authors:

N. Hoang[1], N. Sardaripour[1], G. Ramey[2], X. Bledsoe[1], E. Liao[1], Y. Chen[1], J. Park[1], B. A. Landman[1], E. R. Gamazon[3,4], K. G. Schilling[1], M. Benton[5], J. A. Capra[2], M. Rubinov[1]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ. of California San Francisco, San Francisco, CA, [3]Vanderbilt Univ. Med. Sch., Nashville, TN, [4]Univ. of Cambridge, Cambridge, United Kingdom, [5]Baylor Univ., Waco, TX

Motivation: Neuroimaging phenotypes, such as regional volume and correlated functional activity, are heritable and linked to individual variability in human brain organization. Association studies have identified genetic variants associated with these phenotypes; however, the limited availability of neuroimaging and transcriptomic data from the same individuals has been a barrier to understanding the molecular mechanisms underlying human brain individuality.
Methods: We propose to bridge this gap by leveraging transcriptome-wide association studies (TWAS) to impute the genetically regulated component of gene expression (GREx) for hundreds of genes in eight brain regions for 39,565 individuals in the UK Biobank (UKB; 64.43 ± 7.69 mean age, 52% female) and 772 individuals in Human Connectome Project (HCP; 28.97 ± 3.58, 52% female). We applied Joint Tissue Imputation to impute GREx using models trained on *cis*-regulatory genetic variants and assayed expression from both the target brain region and other highly correlated regions. We then associated the individual-level, regional GREx to corresponding regional measures of volume in the UKB and connectivity in the HCP.
Results: Our TWAS on the UKB revealed 50 unique genes whose GREx associates with regional volume ($p \leq 0.005$, FDR). Several of these genes did not have genome-wide association study (GWAS) hits nearby, underscoring the potential for TWAS to discover new associations. Furthermore, comparing TWAS and GWAS results showed a strong correlation between the associations ($r_s = 0.67$, $p < 0.001$) but higher absolute effect sizes in the TWAS ($\bar{x}_{TWAS} = 52.63$, 95% CI [45.24, 60.03]; $\bar{x}_{GWAS} = 13.11$, 95% CI [12.91, 13.31]). We also discovered links between regional GREx and connectivity phenotypes in HCP. At nominal $p \leq 0.005$, we found 57 unique genes associated with regional homogeneity. Variation in the GREx of these genes also associated with multiple neurological and psychiatric phenotypes in BioVU, the Vanderbilt University biobank with linked electronic health records (EHRs).
Conclusions: Our analysis integrates TWAS with large-scale neuroimaging data and EHR-linked biobanks to complement traditional GWAS. Our analyses present a new avenue for studying brain-specific gene expression in neuroimaging genomics and, supporting their potential, uncover mechanisms of transcriptomic variation that contribute to individual variability in human brain organization and disease.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4162 † Genetic determinants of metabolic traits in middle-aged women predict cardiometabolic conditions across their life course.

Authors:

H. Pan[1,2], S. Ern[3,4], E. Lau[1], V. Gupta[1,2], A. Teh[1,2], P. Tan[1,2], P. Mishra[1], Y. Chen[5], R. Foo[3,4], K. Tan[1,6], J. Chan[7,8], D. Cameron-Smith[9], D. Wang[1,2,10]; [1]Singapore Inst. for Clinical Sci., Agency for Sci., Technology and Res., Singapore, Singapore, [2]Bioinformatics Inst., Agency for Sci., Technology and Res., Singapore, Singapore, [3]Yong Loo Lin Sch. of Med., Natl. Univ. of Singapore, Singapore, Singapore, [4]Cardiovascular Disease Translational Res. Program Inst., Natl. Univ. of Singapore, Singapore, Singapore, [5]Dept. of Mathematics and Computational Biology Programme, Natl. Univ. of Singapore, Singapore, Singapore, [6]Dept. of Lab. Med., Natl. Univ. Hosp., Singapore, Singapore, [7]Dept. of Reproductive Med., KK Women's and Children's Hosp., Singapore, Singapore, [8]Academic Clinical Program in Obstetrics and Gynaecology, Duke-NUS Med. Sch., Singapore, Singapore, [9]The Coll. of Hlth., Med. and Wellbeing, The Univ. of Newcastle, Newcastle, Australia, [10]Natl. Heart & Lung Inst., Imperial Coll. London, London, United Kingdom

Cardiometabolic diseases, encompassing a spectrum of disorders such as hypertension, coronary artery disease, stroke, and diabetes, are amongst the leading causes of morbidity and mortality worldwide. Mechanism studies of these cardiometabolic abnormalities reveal a complex interplay between genetic, environmental, and lifestyle factors throughout an individual's lifespan. Metabolic syndrome (MetS) is a complex cluster of traits associated with cardiometabolic diseases. The prevalence of severe MetS increases to 40% in peri-menopausal and post-menopausal women, resulting in a significant rise in heart failure and type 2 diabetes mellitus (T2DM). Despite MetS being a well-established risk factor, the impact of genetics on these traits throughout an individual's lifespan has been understudied.

To address this issue, we developed GenMetS, a polygenic model which was learned from MetS observed in middle-aged women. The model was composed of 7,850 SNPs selected from 17 GWAS studies related to the traits including waist circumference, glucose, triglycerides, HDL cholesterol and blood pressure. The relative contributions of the SNPs to MetS were learned from a multi-ethnic Asian cohort of women during pre- and post-pregnancy (N=1368, age=33.98 ± 5.72 years). Validation of GenMetS was performed on three independent cohorts: the UK Biobank (N=394,919), a Singaporean heart failure cohort (N=2310), and children from the discovery cohort at the age of 6 (N=1073).

GenMetS consistently explained 5-12% of the observed MetS in women of Asian ancestry across different age groups and nationalities. The GenMetS predicted by our genetic model was associated with the onset of six cardiometabolic diseases at different ages, including T2DM (odds ratio (OR) =1.83), hypertension (OR=1.49), and heart failure (OR=1.25). Moreover, it contributed to the prediction of multimorbidity (area under the curve = 69.3%) in conjunction with lifestyle and socioeconomic factors. The heritability of GenMetS was demonstrated by its associations with the growth trajectories of children (p-value = 1.3×10^{-7}). Our results highlight that there exists a genetic signature for metabolic traits in mid-life that persist for women, throughout their lifespan and in their offspring.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4163 Genetic determinants of the progression of Lewy body pathology

Authors:

L. Wu; Univ. Coll. London, London, United Kingdom

Parkinson's Disease (PD), PD dementia (PDD) and Dementia with Lewy bodies (DLB), which we describe here jointly as Lewy body diseases (LBD), are characterized pathologically by alpha-synuclein aggregates forming Lewy bodies and Lewy neurites. Cognitive and neuropsychiatric complications observed in LBDs correlate with the development of cortical Lewy body (LB) pathology. LB pathology can be divided into subcortical, limbic and neocortical stages. We have studied a large series of Brain Bank LBD cases to define the genetic drivers of regional LB pathology. We included 742 pathologically defined LB cases with summary pathological data together with genotyping using the Illumina Neurobooster array (NBA) and whole genome sequencing with 150 base-pair paired-end sequencing with 30x coverage generated in the Global Parkinson's Genetic Program (gp2.org). 454 (61%) cases had developed cortical LB pathology at post-mortem with a median disease duration of 12 years (interquartile range 8-20 years). We evaluated the genetic features of the most rapidly progressing cortical LB cases (n=132; disease duration <=7 years) as compared to those who did not develop cortical pathology, or developed it with a disease duration of 8 years or greater. We compared variant frequencies between cases and controls using Fisher's exact test. In common variants: 39 % of the rapid progression group carried the ApoEe4 allele compared to 32% in controls, 71 % carried the MAPT H1/H1 haplotype compared to 64% in controls (not significant) and 64 % carried the SNCA 5' PD risk allele compared to 78% in controls ($p < 0.01$). We evaluated the PD polygenic risk score and there was no difference between PD PRS between cases and controls. Cortical LB pathology in well characterized cases represents a sensitive method to define progression to advanced LB disease; and further analysis of common and rare risk variants is underway to provide new insights into the pathogenesis of these diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4164 Genetic mapping power analyses for single-cell transcriptomics.

Authors:

Z. Akras[1,2], N. Mars[1,3], R. K. Walters[1,2], B. M. Neale[1,2]; [1]Broad Inst. of MIT and Harvard, Boston, MA, [2]Analytic and Translational Genetics Unit, Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [3]Inst. for Molecular Med. Finland, FIMM, HiLIFE, Univ. of Helsinki, Helsinki, Finland

Single-cell transcriptomics paired with genetic information can elucidate mechanisms driving variability in cellular phenotypes. An important consideration in the design of these single-cell experiments is the statistical power to detect genotype-phenotype associations. Simulations of single-cell data can provide insight into the power properties of different experimental designs, but existing simulation methods focus on detecting changes in cell type composition or gene expression between sample types and do not address the genetic contribution to these differences. Furthermore, tools explicitly designed for mapping do not model the genetic effects on cell identity, nor do they consider power implications of the analysis method following data generation, such as whether to pseudobulk cells or perform a global comparison. We present a simulation framework for comprehensive power analysis of single-cell transcriptomic experiments in the context of genetic mapping. Our mixed model-based approach uses pilot data including genotype, cell state, and transcriptomic readout to estimate genetic effects on individual cell type composition and expression landscape as well as sources of variance. We then generate cells with simulated genotypes from a predetermined number of samples and assign cell states based on each cell's genotype according to the relationship learned from the pilot data. Finally, we simulate expression profiles as a function of each cell's state and genotype, with the strength of the genetic effects specified based on heritability. We examine the dependence of statistical power on parameters including number of samples, number of cells per sample, genetic and cellular heterogeneity, and analysis strategy. Our framework can inform the successful design of single-cell genetic mapping experiments to help decipher global and cell type-specific gene regulatory mechanisms.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4165 Genetic prediction of early adolescent chronotype: Effects of sex and pubertal status.

Authors:

L. Hernandez[1], M. Gandal[2], A. Fuligni[1]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Univ. of Pennsylvania, Philadelphia, PA

Adolescence is characterized by changes in sleep-wake cycles and a shift to later sleep onset and wake times, indicative of a more evening chronotype. While genome wide association studies (GWAS) in adult populations have shown that individual differences in chronotype are heritable and causally related to mental health outcomes, it remains unclear when during development genetic effects on sleep-wake cycles first emerge and whether these effects are stable during adolescence. To address these questions, here we examined the extent to which polygenic scores (PGS) derived from adult GWAS predict adolescent sleep-wake cycles and mental health. Data were obtained from 2,625 unrelated 10-13-year-old youth of European ancestry who participated in the Adolescent Brain and Cognitive Development study. Chronotype PGS were tested for associations with 1) chronotype as assessed with the Youth Munich Chronotype Questionnaire, and 2) 50 indices of youth mental health and cognitive functioning. We found that female youth were more pubertally advanced relative to male youth ($p<0.001$) and had later chronotype ($p<0.05$). As sex-differences were observed in both chronotype and pubertal status, we examined potential sex-differences in the predictive accuracy of chronotype PGS. The interaction between PGS and sex in predicting chronotype was significant ($p<0.05$), suggesting that sex moderates the relationship between PGS and sleep-wake cycles in adolescent youth. Follow-up analyses were performed in males and females separately; here, we found that PGS significantly predicted chronotype in female youth only ($p<0.001$). To determine potential biological moderators influencing the strength of the relationship between PGS and chronotype, we next performed regressions in each sex grouped by pubertal stage. Remarkably, we found that PGS was a significant predictor of chronotype only in females who were in mid- or late-pubertal stages ($p<0.05$), suggesting that puberty may be a critical transition point at which genetic variants discovered in adult populations become applicable to pediatric samples. At the behavioral level, in male youth, higher PGS was associated with lower levels of sleep-related disturbances and cognitive functioning (FDR $q<0.05$). In contrast, female youth showed a distinct association between higher PGS and lower levels of psychosis-like experiences (FDR $q<0.05$). Together, these data suggest that the predictive power of chronotype PGS emerges during puberty and emphasize the importance of sex and developmental stage as key moderators of genotype-phenotype associations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4166 Genetic relationships between BMI, height velocity and pubertal timing in an Indigenous study population

Authors:

M. Ramirez Luzuriaga, S. Kobes, W-C. Hsueh, L. Baier, R. Hanson; Phoenix Epidemiology and Clinical Res. Branch, NIDDK, Phoenix, AZ

Early pubertal maturation is often observed in boys and girls with high BMIs, and both age of puberty and BMI are heritable. In this study, we aimed to determine whether these phenotypes are associated via genetic variation that contributes to both traits. We, thus, examined the associations of a polygenic score (PS) for BMI and a PS for age of menarche (AAM) with maximum BMI and four parameters of adolescent growth in a longitudinally studied Indigenous population from the Southwestern US with high prevalence of obesity.
Pre-existing genome-wide imputed genotypes and anthropometric data were available from a longitudinal study. Adolescent growth parameters were derived from the Preece-Baines growth model, a parametric growth curve for longitudinal height data. PSs for the BMI-PS (798 markers) and the AAM-PS (275 markers) were constructed by selecting common variants (allele frequency >0.01 in the Indigenous sample) with a high imputation confidence level (score >0.5) which achieved genome-wide significance in European meta-analyses (GIANT/UK Biobank Consortium and Reprogen Consortium, respectively). Associations between PS and maximum BMI (N=6789) were adjusted for birth year, sex, and the first 5 genetic principal components (PCs). Associations with parameters of adolescent growth (N=787) were adjusted for birth year, sex, maternal diabetes and the first 5 genetic PCs. Associations were calculated using linear mixed models, accounting for familial relationships.
The BMI-PS had a modest but significant association with maximum BMI ($r=0.14$, $p=5.73\times10^{-27}$) and velocity at take-off ($r=0.10$, $p=0.003$). It also had a weak but significant inverse association with age at peak velocity ($r=-0.05$, $p=0.03$). We found no significant association of BMI-PS with age at take-off ($r=-0.04$, $p=0.06$) and age at maturation ($r=-0.03$, $p=0.14$). Genetically predicted later puberty onset (AAM-PS) had a weak but significant inverse association with maximum BMI ($r=-0.03$, $p=0.005$) and velocity at take-off ($r=-0.10$, $p=0.002$). It also had a modest but significant positive association with age at peak velocity ($r=0.13$, $p=1.8\times10^{-04}$), age at take-off ($r=0.11$, $p=0.0013$) and age at maturation ($r=0.13$, $p=1.3\times10^{-04}$). Our results suggest that many variants that associate with AAM and BMI in large European cohorts also affect these traits in this Indigenous population. They also support the notion that obesity and early puberty onset share genetic determinants.

Tokyo Med. Ctr., Tokyo, Japan, [18]Cross Cancer Inst., Univ. of Alberta, Edmonton, AB, Canada, [19]Univ. of Rochester, Rochester, NY

Prostate cancer (PCa) is the most frequent cancer in men, with about 1 in 8 diagnosed during his lifetime. Non-metastatic PCa is highly curable with standard care that includes radiotherapy, but long-term side effects impact survivors. The purpose of this study was to investigate the genetic basis of late bladder and bowel toxicities following radiotherapy for PCa that limit curative doses and have an adverse effect on survivors. We performed a multi-ethnic genome wide association study (GWAS) of late bladder (hematuria) and bowel (rectal bleeding) toxicities including >7,000 participants in multiple cohorts to discover new risk loci. SNP-array data from each cohort were imputed into the TOPMed reference panel and used genome build GRCh38 with standard quality control procedures. We additionally developed a polygenic risk score (PRS) for each toxicity using GWAS results from a training set and tested each PRS in the remaining participants. All analyses used Cox proportional hazards regression to model genetic association with time to onset of grade 2 or worse toxicity and were adjusted for cohort and ancestry captured by principal components. The GWAS identified six new risk loci (rs571126149 on 1p36.11, HR=2.40, $p=2.67x10^{-8}$; rs56260582 on 4p15.1, HR=1.44, $p=3.11x10^{-9}$; rs4134357 on 10q11.22, HR 1.51, $p=2.02x10^{-8}$; rs72672122 on 4q28.2, HR=2.51, $p=2.71x10^{-8}$; rs12434768 on 14q24.2, HR 2.86, $p=1.51x10^{-8}$; and chr16:31181061:C:G on 16p11.2, HR=3.05, $p=7.35x10^{-9}$). The PRSs were comprised of 4,863 and 3,705 SNPs for hematuria and rectal bleeding, respectively. Multivariable models combining the PRS and clinical factors (age at radiotherapy, prior prostatectomy, receipt of hormone therapy) show the PRS contributes independently to risk of developing late toxicity in the test set (hematuria: per-allele adjusted HR=1.02, p=0.001; rectal bleeding: per-allele adjusted HR=1.02, p=0.018). Patients in the upper 20% of the hematuria PRS had an approximately 2-fold increased risk of developing that toxicity (adjusted HR 1.98, p=0.010) and patients in the upper 20% of the rectal bleeding PRS had an approximately 1.6-fold increased risk of developing that toxicity (adjusted HR 1.63, p=0.021) compared with patients in the lower 20% of the respective PRS. PRSs could be incorporated into dosimetric models used in treatment planning for PCa to personalize treatment by prioritizing avoidance of organs at high risk and guiding selection of patients who might benefit from MR-guided radiotherapy or proton therapy.

PB4168 Genetic risk score in predicting Age-related Macular Degeneration

Authors:

X. Zhang, N. Parikshak, G. Abecasis, Regeneron Genetics Center, DiscovEHR, Mayo Clinic Project Generation, Penn Medicine Biobank, G. Coppola, E. Jorgenson; Regeneron Genetics Ctr., Tarrytown, NY

Age-related Macular Degeneration (AMD) is the leading cause of irreversible blindness worldwide and can be separated clinically into geographic atrophy (GA, dry AMD) and choroidal neovascularization (CNV, wet AMD). Current treatments are effective in preventing vision loss from CNV; however, no currently approved treatment exists to prevent vision loss from GA. Understanding the genetic risk in AMD subtypes is one of the crucial considerations in designing clinical trials. We calculated a genetic risk score (GRS) using the summary statistics of 60 loci from the Million Veteran Program, which has the largest number of AMD cases in a population-based cohort. We characterized the GRS for 4 major age groups: Age 46-55; Age 56-65; Age 66-75 and Age 76 and above, in 8 biobank cohorts for AMD (UK Biobank, Geisinger Health System, Mayo Clinic Project Generation, Colorado, UCLA, Penn Medicine Biobank, MALMO and SINAI). In addition, we characterized AMD subtypes (CNV and Late AMD) in 4 cohorts with sufficient phenotypic data. We present the distribution of AMD prevalence across GRS decile within each age category. Comparing 1^{st} to the 10^{th} GRS decile, we observed the smallest increase of AMD risk for age below 65; and the strongest increase for age 76 and above for all scenarios (All AMD, CNV and Late AMD). Specifically for age 76 and above, there is a 3x risk increase for all AMD; in late AMD, the risk is 6x. The strongest increase is in wet AMD, for which risk increased 10x between the two extreme deciles. The observed GRS trend is consistent with disease pathology - meaning that genetic risk load contributes more to the most severe AMD form - wet AMD. Meanwhile, age greater than 76 has a striking increase in disease prevalence compared to other age groups. Our results present the landscape of GRS distribution in AMD, which provides insights into the understanding of genetic risk across different age groups within AMD subtypes. These findings could also aid in the selection of participants for clinical trials of AMD treatments.

PB4169 Genetic Susceptibility of Deletions or Excess Homozygosity to Head and Neck Cancer in Whole-Genome Studies.

Authors:

C-C. Wu[1], C-H. Chen[2], R. Yu[3], S. Shete[3]; [1]Natl. Cheng Kung Univ., Tainan, Taiwan, [2]Academia Sinica, Taipei City, Taiwan, [3]The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Squamous cell cancer of the head and neck includes cancers of the oral cavity (including the gums and tongue), pharynx, and larynx and is the sixth most common malignancy worldwide. Genetic susceptibility to developing oropharyngeal and oral cancer incidence has been established as several loci, including alcohol-related genes (ADH1B and ADH7) and HLA region11, have been discovered, using whole-genome association analyses. However, the roles of deletion variants or excess homozygosity implicated in head and neck cancer susceptibility are poorly understood. Here, we performed two distinct whole-genome scans of associations between deletion variants or excess homozygosity and head and neck squamous cell carcinoma susceptibility and a meta-analysis synthesizing the association summary statistics from these two whole-genome scans. We used a logistic regression framework extension of the genome-wide statistical method we developed previously to assess the excessive homozygosity, permitting us to adjust for covariates. We used 733,202 SNPs in 2185 patients with head and neck squamous cell carcinomas from the MD Anderson Cancer Center in Houston, Texas, recruited from 1998 to 2012. The two whole-genome scans of disease-associated deletions include batch 1, with 1154 cases and 1542 controls, and batch 2, with 1031 cases and 2965 controls, respectively. We detected a 1.1-kb segment on chromosome 3p in batch 1 and 3 distinct 0.45-14kb segments on chromosome 1p, 5q, and 11q in batch 2. They were all significant at a 0.05 nominal significance level, adjusted for multiple comparison procedures. The corresponding meta-analysis identified five distinct segments on chromosome 5p, 6p, 9q, and 12q (2 segments).

PB4170 Genetic variants associated with immune cell population abundances in single-cell data.

Authors:

L. Rumker[1,2,3], S. Sakaue[1,2,3], J. B. Kang[1,2,3], Y. Reshef[1,2,3], C. Valencia[1,2,3], S. Yazar[4], J. Alquicira-Hernández[4], P. Joseph[4], S. Raychaudhuri[1,2,3]; [1]Harvard Med. Sch., Boston, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Garvan Inst. of Med. Res., Sydney, Australia

Genome-wide association studies have identified many variants that influence disease risk. To investigate the mechanisms mediating these associations, previous functional studies have primarily sought co-localizing associations of variants to univariate intermediate phenotypes, like the expression of individual genes (eQTLs) or proteins. To fully understand these disease risk mechanisms, we must also seek associations to more complex intermediate traits, like shifts in the abundance of functional cell states. However, there is limited precedent for GWAS of traits strategically defined within high-dimensional functional data, like single-cell transcriptional profiling.

In this study, we have developed a novel approach to identify fine-grained cell states in single-cell transcriptomic data that change in abundance with allelic dose of a genetic variant: cell state abundance QTLs (csa-QTLs). Our approach avoids pre-specifying candidate cell types to test so that we can more flexibly characterize genetically-associated cell states.

Applied in a genome-wide survey to a published dataset of ~1M peripheral blood cells from 969 Australians of European ancestry, our method reveals six independent loci (lead P-values less than 2e-8) associated with changes in immune cell population abundances. For example, one locus on chromosome 15 (lead SNP rs11632488, P-value 1.1e-8) is associated with increased ratio of classical to non-classical monocytes. Another locus on chromosome 12 (lead SNP rs3003, P-value 2.4e-11) is an eQTL for the NK cell lectin-like receptor gene *KLRC1*, key to innate immune destruction of malignant and virally-infected cells. We find that this SNP is associated with increased abundance of NK cells expressing TNF-alpha response genes. Interestingly, this signal co-localizes with a risk allele for psoriasis, a disease for which anti-TNF treatments have well-established efficacy. Therefore, csa-QTLs may provide disease-relevant mechanistic insight. Because we detect csa-QTLs in a population cohort without acute disease, characterizing these effects may illuminate how our genetic background can set the immunological stage for disease risk.

PB4171 Genetic variation for longitudinal change in anthropometric traits.

Authors:

K. Kemper[1], J. Sidorenko[1], H. Wang[1], B. Hayes[1], N. Wray[1], L. Yengo[1], M. Keller[2], M. Goddard[3,4], P. Visscher[1]; [1]The Univ. of Queensland, Brisbane, Australia, [2]Univ. of Colorado, Boulder, CO, [3]BioSci.s Res. Div., Bundoora, Australia, [4]The Univ. of Melbourne, Melbourne, Australia

Most genetic studies use cross-sectional data, that is a single observation on an individual at a given time. These studies cannot address questions relating to the degree of genetic control for within-person trait change without multiple measurements per person. In this study we used 50,117 European ancestry individuals from the UK Biobank with 2 repeated observations on 8 anthropometric traits (including height and weight). Individuals were 40-79 years at baseline with an average follow-up time of 7.4 years. We estimate an average loss from peak values of about 3.8 cm (females) and 3.4 cm (males) for height, about 3.7 kg (females) and 4.1 kg (males) for weight. The SNP-based heritability for rate of trait change was small but significantly greater than zero for height (0.015, s.e. 0.006), weight (0.031, s.e. 0.007) and body mass index (0.035, s.e. 0.007). We constructed polygenic scores (PGS) for the rate of trait change and found that a low PGS for height change (i.e. predicted height loss) was significantly associated with musculoskeletal disease diagnosis in an independent sample of the UK Biobank (P = 0.001). A genome-wide association study for rate of trait change found that the Alzheimer's APOE-E4 risk allele was significantly associated with weight loss (-0.047 kg per year, s.e. 0.007, $P = 2.2 \times 10^{-11}$). Further, we used an approximate random regression approach and independent cross-sectional data to show that the genetic correlation between weight measured at a young (40-50 years) or older (65-79 years) age is significantly less than unity (r_g = 0.92, s.e. 0.023, $P = 3 \times 10^{-4}$). In summary, we provide evidence at the genome and locus level for some degree of genetic control on longitudinal trait change for anthropometric traits, and show that genetic predictors of longitudinal trait change are associated with disease. Measuring large numbers of individuals over longer intervals will increase the power of future studies to investigate the genetic influence on longitudinal traits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4172 Genetic variation in the FMO and GSTO gene clusters impacts arsenic metabolism in humans

Authors:

L. Tamayo[1], L. Tong[1], T. Davydiuk[2], X. Le[2], F. Jasmine[1], M. G. Kibriya[1], J. Graziano[3], H. Ahsan[1], M. V. Gabmle[3], B. L. Pierce[1]; [1]Univ. of Chicago, Chicago, IL, [2]Univ. of Alberta, Edmonton, AB, Canada, [3]Columbia Univ., New York, NY

Background: In Bangladesh, >50 million individuals are chronically exposed to inorganic arsenic (iAs) through drinking water, increasing risk for cancer and other arsenic-related diseases. Previous studies have shown that an individuals' ability to metabolize and eliminate iAs (and their risk of toxicity) is influenced by genetic variation in the *AS3MT* and *FTCD* regions.
Methods: To identify additional loci related to arsenic metabolism, we used data from Bangladeshi individuals participating in arsenic-related research studies to conduct genome-wide association analyses of the relative abundances of arsenic species/metabolites measured in both urine (n=6,540) and blood (n=976). The arsenic species measured include inorganic arsenic (iAs), mono-methylated arsenic species (MMA) and di-methylated arsenic species (DMA), with DMA representing the "end metabolite" most rapidly excreted in urine.
Results: In analyses of urine arsenic species, we identified a novel association signal in the FMO gene cluster (1q24.3), with the lead SNP residing in *FMO3* (MMA% P=4.2x10-16). In analyses of blood arsenic species, we identify an additional signal in the FMO cluster, distinct from the signal for urine arsenic species, with the lead SNP residing in *FMO4* (DMA% P=2.26x10-22). Analyses of blood arsenic species also identified a novel signal in the *GSTO1/2* region (10q25.1) with the lead SNP residing in *GSTO1* (DMA% P=5.3x10-13). FMOs are xenobiotic metabolism enzymes, but have no known role in arsenic metabolism, while *GSTO1* has a well-known role in the reduction of arsenic species, a key step in arsenic metabolism. These newly identified SNPs did not show clear association with risk for arsenic-induced skin lesions (P>0.05), the most common sign of arsenic toxicity (based on 3,448 cases and 5,207 controls).Lead SNPs in *FMO3* region are associated with the splicing of *FMO3* (sQTL) in multiple GTEx tissue types and contain a missense variant in *FMO3*. The *GSTO1* signal is also an sQTL (for *GSTO1*) in multiple tissue types and contains a missense variant. The lead SNPs for blood DMA% in the *FMO4* gene are associated with *FMO4* expression (eQTL) in multiple tissue types.
Conclusion: We identified novel genetic associations with arsenic species/metabolites measured in both urine and blood. While previously identified regions affecting arsenic metabolism (*AS3MT* and *FTCD*) are associated with arsenic species in both blood and urine (and toxicity risk), the associations reported here appear specific to blood or urine, with no detectable impact on toxicity. These findings reveal to complexities in arsenic metabolism and its genetic contributors that require further study.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4173 Genetically regulated gene-expression associates with human functional brain-network organization

Authors:

N. Sardaripour[1], N. Hoang[1], K. Schilling[1], M. Benton[2], J. Capra[3], M. Rubinov[1]; [1]Vanderbilt Univ., Nashville, TN, [2]Baylor Univ., Waco, TX, [3]Univ. of California San Francisco, San Francisco, CA

Objective: Large-scale brain networks mediate diverse sensory-motor and cognitive functions. The structure of these networks is heritable, but the specific genes involved in their formation are still unknown. Here, we advanced our understanding of the association between regional gene expression and human brain-network organization by leveraging joint-tissue transcriptome association and local-global neuroimaging modeling to integrate information from distinct sets of data: neuroimaging, genomic, and transcriptomic.
Methods: We first inferred genetically regulated gene expression from 10 cortical and subcortical regions from the European ancestry subsets of the Human Connectome Project (772 people, mean age 28.97 ± 3.58, 52% female) dataset. Separately, we computed structural and functional phenotypes for these regions, including gray-matter volume, regional myelination, as well as inter- and intra-regional coactivity. We also computed the correlation strengths of seven major cortical networks. We then built an interpretable model to predict global network phenotypes from local regional phenotypes. Finally, we used this model to mechanistically associate individual variation in network phenotypes with individual variation in regional gene expression. We used permutation testing to compute the significance of these associations.
Results: Our local-global neuroimaging modeling revealed significant associations (nominal $p<0.01$) between putamen volume and 5/7 cortical networks associated with motor control, reward processing, and learning. Our integration of these results with data on regional gene expression identified specific genes (e.g., *SLC5A9* and *CLEC12B*) significantly associated with the default and dorsal attention networks, and a separate group of genes (e.g., *STAP1*, *PROZ*, *PKD1L1*) associated with the control and limbic networks. Separately, we found that these genes exhibited high expression levels in the corresponding brain regions of the Allen Human Brain atlas.
Conclusions: Collectively, our integrative analysis allowed us to associate regional gene expression with individual variation in human brain network organization. This approach ultimately makes it possible to advance our understanding of the transcriptomic underpinnings in healthy brains and consider how this organization varies in diseased populations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4174 GenoGAN: Synthesizing genomic data with stable deep generative networks for UK Biobank, Taiwan Biobank, and 1000 Genomes Project.

Authors:

E. Lim[1,2], A. Lim[1,3], C. Fann[1]; [1]Academia Sinica, Taipei, Taiwan, [2]Georgia Inst. of Technology, Atlanta, GA, [3]ASUS Intelligent Cloud Services (AICS), Taipei, Taiwan

Background: The limited sample size of certain rare diseases and minority populations continues to pose a significant challenge. However, instead of solely focusing on collecting more samples, an alternative approach involves generating realistic synthetic human genomic data. One method for that is through the use of Generative Adversarial Networks (GANs). These networks have shown encouraging results on specific datasets, however, often require extensive hyperparameter tuning and can struggle to converge successfully. In this regard, we introduce GenoGAN. **Methods:** GenoGAN incorporates Wasserstein generative adversarial networks with gradient penalty and Heaviside function to ensure training stability, overcoming issues like the vanishing gradient problem and mode collapse. GenoGAN takes input data with set of sequences of haplotype pairs and output user-defined n-fold of synthetic data. We evaluated GenoGAN's performance using selected sequences of phased haplotype data from chromosome 1. The dataset consisted of individuals with type 1 diabetes (T1D: n=3,698) and individuals without any reported diseases (Healthy: n=51,857) sourced from the UK Biobank. The input data included T1D associated rs6679677 and rs2476601 in *PTPN22*. We validated the results with Taiwan Biobank and the no-phenotype-info 1000 Genomes Project (1KGP). **Results:** GenoGAN generated synthetic datasets (T1D′, Healthy′) that doubled the size of the original samples, with small distance from the real data and similar minor allele frequencies (MAFs). The Jensen-Shannon divergence (JSD) between T1D and T1D′ was 0.276, and between Healthy and Healthy′ was 0.275. The cosine distances (CD) of T1D, T1D′ and Healthy, Healthy′ were 0.110 and 0.109, respectively. Notably, GenoGAN performed well even with lower frequency alleles. The minor allele frequencies (MAFs) observed at rs6679677 were T1D=0.137, T1D′=0.160, Healthy=0.101, and Healthy′=0.110. Similarly, for rs2476601, the MAFs were T1D=0.137, T1D′=0.145, Healthy=0.101, and Healthy′=0.111. However, it is worth noting that GenoGAN's performance was less favorable when the sample size was too small, e.g., with East Asian ancestry from 1KGP (n=504), resulting in higher JSD(EAS, EAS′)=0.516 and CD(EAS, EAS′)=0.385. **Conclusion:** The results demonstrate that our proposed GenoGAN can capture the complex multidimensional structure of the data distribution, thereby providing a novel method for human genomic data synthesis. We envision that by scaling up GenoGAN with a large number of GPUs, its potential for enhancing disease risk prediction for rare diseases and in minority populations can be significantly amplified.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4175 Genome wide association study (GWAS) of 110 putative fatty acids, eicosanoids, and related oxylipins in the Hispanic Community Health Study/Study of Latinos reveals shared and distinct genetic architecture

Authors:

C. Downie[1], H. M. Highland[1], A. G. Lilly[1], B. M. Welch[2], R. Kaplan[3], S. Cheng[4], B. Thyagarajan[5], M. Jain[6], C. L. Avery[1]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Univ. of Nevada, Reno, Reno, NV, [3]Albert Einstein Coll. of Med., Bronx, NY, [4]Cedars Sinai, Smidt Heart Inst., Los Angeles, CA, [5]Univ. of Minnesota, Minneapolis, MN, [6]Sapient, San Diego, CA

Introduction: Chronic low-grade inflammation is a pathological feature of multiple cardiometabolic traits, including obesity and type 2 diabetes. Bioactive polyunsaturated fatty acid (PUFA)-derived eicosanoids and related oxylipin compounds are involved in the modulation of inflammation. To-date, no large-scale GWAS of eicosanoids has been conducted. **Methods:** Analyses were performed in n=11,584 participants with measured genetic and oxylipin data from the baseline study visit of the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), a multi-center community-based cohort of Hispanic/Latinos recruited from four US communities between 2008-2011. Putative oxylipin spectral peaks were quantified from plasma samples via directed non-targeted liquid chromatography-mass spectrometry. HCHS/SOL participants were genotyped on the MEGA array and imputed to the TOPMed imputation panel. We performed GWAS of 110 putative fatty acid and oxylipin peaks using SUGEN, adjusting for age, age^2, sex, recruitment site, background group, and 10 ancestral principal components.**Results:** The spectral peaks were grouped into three broad classes: putative free fatty acids, very long chain dicarboxylic acids, and eicosanoids and related oxylipins. 61 (55.5%) of the 110 spectral peaks had at least one genome-wide significant locus (Bonferroni-adjusted $p < 5.15E-11$), and most peaks were associated with only one or two significant loci. Putative fatty acid peaks displayed primarily shared loci (e.g., *FADS*, *FUT2*); several of these loci were also associated with putative eicosanoid peaks. The *SLCO1B1* locus, which encodes the OATP1B1 uptake transporter protein, was associated with multiple eicosanoid peaks, including putative prostaglandins, leukotrienes, and putatively novel oxylipins. Other loci were only associated with one eicosanoid peak; for example, *UGT2B7,* which encodes a protein involved in the conjugation and elimination of xenobiotics and endogenous compounds, was associated with a putative diHOME peak.**Conclusions:** Our results suggest that putative fatty acids and related oxylipins have an oligogenic genetic architecture. Although some genetic loci are highly shared across similar classes of compounds, there are also some distinct genetic effects. These insights on the genetic architecture of oxylipin compounds may help inform the development of eicosanoid-targeted therapeutics.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4176 Genome-wide association identifies novel etiological insights associated with Parkinson's Disease in African and African admixed populations.

Authors:

M. Makarious[1], M. Rizig[2], S. Bandres-Ciga[1], O. Ojo[3], P. Wild Crea[1], O. Okunoye[2], Nigeria Parkinson Disease Research Network, nternational Parkinson's Disease Genomics Consortium - Africa (IPDGC Africa), Black and African American Connections to Parkinson's Disease (BLAAC PD) Study Group, the 23andMe Research Team, M. Nalls[4], C. Blauwendraat[1], H. Houlden[5], A. Singleton[6], N. Okubadejo[3], Global Parkinson's Genetics Program; [1]NIH, Bethesda, MD, [2]UCL, London, United Kingdom, [3]Univ. of Lagos, Idi Araba, Lagos State, Nigeria, [4]Natl. Inst Aging, Bethesda, MD, [5]Inst Neurology, London, United Kingdom, [6]NIA, Bethesda, MD

Aim: The central objective of this study is to perform a comprehensive genome-wide assessment of Parkinson's disease (PD) in populations of African and African admixed descent. The goal is to characterize ancestry-specific risk, genetic variations, and to identify novel mechanisms of disease etiology.Background: Understanding genetic mechanisms across diverse populations can provide unique insights into complex traits like PD. Historically, our understanding of the genetics of PD has been disproportionately based on European, Asian, and Latin American populations. This has led to a significant gap in our knowledge about the disease's genetics and clinical characteristics in underrepresented populations, particularly individuals of African and African admixed ancestries.Materials & Methods: We performed an extensive genome-wide assessment of PD in a large cohort comprising 197,918 individuals. The cohort included 1,488 PD cases and 196,430 controls, all of African and African admixed ancestry. The study analyzed a range of factors, including ancestry-specific risk, differential haplotype structure, coding and structural genetic variation, and polygenic risk profiling.Results: The analysis identified a novel common risk factor for PD at the GBA1 locus, specifically the rs3115534-G variant. This risk factor also appeared to influence the age at onset. Interestingly, this factor was found to be rare in non-African/African admixed populations. Unlike previously identified GBA1 associated disease risk variants, this newly discovered signal potentially mediates PD risk through expression quantitative trait locus (eQTL) mechanisms, suggesting a novel functional mechanism.Discussion: Our study identifies a novel African-ancestry genetic risk factor in GBA1 as a risk factor of PD in the African and African admixed populations. This discovery is in stark contrast to previous work focused on Northern European populations. It underscores the importance of understanding ancestry-specific genetic risk in complex diseases, and the need for equitable inclusion of diverse groups in PD clinical trials. Given the genetics of these underrepresented populations, their inclusion in such studies opens new avenues towards RNA-based and other therapeutic strategies aimed at reducing lifetime risk of PD. This is particularly important as the field moves towards precision medicine in PD clinical trials.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4177 Genome-wide association studies in a large Korean cohort identifies novel quantitative trait loci for 36 traits and sheds light on the genetic architecture of complex traits

Authors:

Y. Jee[1], A. Martin[2,3,4], P. Kraft[5]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, Cambridge, MA, [4]Dept. of Med., Harvard Med. Sch., Boston, MA, [5]Transdivisional Res. Program, Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Bethesda, MD

Genome-wide association studies (GWAS) have identified many loci associated with complex traits. However, most of these studies were conducted in populations of European ancestry, which has limited opportunities for biological discovery.

We conducted GWAS of 36 human quantitative traits in the Korean Cancer Prevention Study-II (KCPS2) Biobank (n=153,354). Our analysis discovered 2,453 associated loci (range 2-312 loci, median 45), including 922 novel loci (range 0-192 loci, median 12) that were not reported in previous GWAS related to the corresponding trait. We also identified widespread pleiotropy in which 4,506 gene regions contained variants associated with one or more traits (range 1-25 traits, median 2.3). For example, variants near *ALDH2* were associated with 25 traits, including blood pressure and alcohol-related traits. Following meta-analysis of 20 traits across KCPS2, Biobank Japan (BBJ), and Korean Genome and Epidemiology Study, we further identified 1,109 novel loci (range 1-171 loci, median 33).

We investigated the genetic architecture of 12 traits in KCPS2 and compared with previously published BBJ and UK Biobank (UKB). While the S parameters linking minor allele frequency and effect sizes were similar across the biobanks (median -0.5), the polygenicity and heritability parameters estimated in UKB were mostly higher than those in KCPS2 and BBJ. Compared to BBJ, KCPS2 showed higher heritability parameters for body mass index, height, and blood pressure but lower heritability for most of the hematological traits such as white blood cell and hemoglobin.

To identify potential causal variants, we performed fine-mapping using SuSiE. For example, we fine-mapped 25 traits associated with the region spanning *ALDH2* on chromosome 12 (± 500kb from rs671, which is known to be functionally related to alcohol metabolism). 1,476 variants in this region were fine-mapped to a total of 48 credible sets, among which 14 contain exactly one variant (range 1-568 variants, mean 43.9). The posterior inclusion probability of rs671 was greater than 90% for 7 traits including alcohol intake, gamma-glutamyl transferase, and blood pressure.

Our findings highlight how broadening the population diversity of GWAS samples can aid discovery (e.g., the minor allele of rs671 is common in East Asian but quite rare in European ancestry populations). Our results also provide insights into the genetic architecture of complex traits in East Asian populations. By increasing the sample size and ancestral diversity of GWAS samples, our analysis may help identify novel targets for prevention and treatment, thus offering equitable access to precision medicine to diverse populations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4178 † Genome-wide association studies with Japanese National Health Insurance System.

Authors:

Y. Yamasaki[1], N. Nishiya[1], Y. Sutoh[1], S. Komaki[1], S. Minabe[1], H. Ohmomo[1], K. Tanno[1], K. Asahi[1], Y. Ishigaki[1], M. Sasaki[1], A. Shimizu[2]; [1]Iwate Tohoku Med. Megabank Organization, Iwate Med. Univ., Yahaba, Japan, [2]Iwate Tohoku Med. Megabank Organization, Iwate Med. Univ., Iwate, Japan

Large-scale genome-wide association analyses (GWAS) have contributed to the development of precise polygenic models for accurately estimating disease risks. Community cohort studies are used to estimate the effect size of a variant in the general population while minimizing bias. However, accurately defining case subjects based on the diagnosis can be challenging in these studies. To overcome these limitations, a medical data source that covers most of the target population is promising. Here, we present the results of a feasibility study of GWAS using health insurance claim data retrieved from the Japanese National Health Insurance System, which covers a broad segment of the general population.Health insurance claim data for approximately 14,000 residents of the Iwate prefecture, Japan, participating in the Tohoku Medical Megabank Project was retrieved from the Japanese National Health Insurance System. A case-control GWAS was performed using SAIGE, with age, sex, and the top 10 principal components of genotypes as covariates. Different case definitions were compared, “including”/“excluding” health insurance claim data in the same samples. The analysis focused on hypertension, diabetes, dyslipidemia, Alzheimer's disease (AD), and Parkinson's disease (PD), for which health insurance claim data is substantial.When health insurance claim data was not included in the definition, the percentages of patients with hypertension, diabetes, dyslipidemia, AD, and PD were 46.6%, 11.2%, 53.6%, 0.2%, and 0.2%, respectively. In contrast, when health insurance claim data was included in the definition, the percentages were 50.6%, 12.2%, 59.9%, 1.3%, and 0.7%, respectively. In GWAS results of hypertension, diabetes and PD, the samples including and excluding health insurance claim data showed no significant differences. However, for dyslipidemia, genes around 5p13-14 were detected as seen in previous GWAS studies of serum low-density lipoprotein cholesterol but only in the definition including health insurance claim data. Additionally, the apolipoprotein E (APOE) gene, which has been repeatedly associated with AD in previous case-control AD-GWAS studies, was only detected when using the definition with health insurance claim data for AD. APOE has never been detected in previous AD-GWAS studies based on a community cohort, even in recent large studies using UK Biobank data. Therefore, this study could also be the first replication of the association between APOE and AD in a community-based cohort of the general population. These findings indicate the validity of using health insurance claim data in GWAS on community-based cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4179 Genome-Wide Association Study (GWAS) by proxy (GWAX) of risk for Alzheimer's disease and related disorders (AD/ADRD) with optical coherence tomography (OCT) retinal thickness endophenotype in the Tohoku Medical Megabank Organization (ToMMo) Eye Study, a large Japanese cohort

Authors:

M. Taira[1,2], A. J. Saykin[3,4], N. Fuse[1,5]; [1]Dept. of Integrative Genomics, Tohoku Med. Megabank Organization, Tohoku Univ., Sendai, Japan, [2]Div. of Neurology, Dept. of NeuroSci. & Sensory Organs, Graduate of Med., Tohoku Univ., Sendai, Japan, [3]Indiana Univ. Sch. of Med., Indianapolis, IN, [4]Indiana Alzheimer's Disease Res. Ctr., Indiana Univ., Indianapolis, IN, [5]Tohoku Univ. Advanced Res. Ctr. for Innovations in Next-Generation Med., Sendai, Japan

Background: AD/ADRD is age-related and highly heritable. GWAX is an efficient research strategy for population-based studies of complex diseases, in which first-degree relatives of cases serve as surrogate phenotypes. However, recent GWAX have indicated low heritability in AD/ADRD. Retinal imaging by OCT is noninvasive, repeatable, and can detect structural changes of the retina that thin out with progressive neurodegeneration. The ToMMo Eye Study is an ophthalmology cohort consisting of 95K individuals included in the TMM Project, a prospective cohort study of 120K adults. Combining retinal thickness and genetics may highly be informative for AD/ADRD pathophysiology, but so far GWAX combined with retinal thickness has not been performed. Method: Retinal nerve fiber layer and ganglion cell layer thickness calculated on subjects' SD-OCT (Topcon OCT-2000) scans. 5,250 pseudo-cases and 42,305 pseudo-controls as discovery, and 916 pseudo-cases and 12,483 pseudo-controls as replication, were analyzed in GWAX of AD/ADRD excluding close relatives. Imputation was performed using beagle5.4. GWAX using plink2 included 65 million variants that satisfied RSQR > 0.3. 10 principal components of the population structure were used as covariates. AD/ADRD GWAX with retinal thickness for 3,071 pseudo-cases and 20,308 pseudo-controls performed as meta-analysis. Results: On hg37, in AD/ADRD GWAX, the strongest association was *APOE* (chr19: Base Position (BP) 45411941, p < 3.0e-36) as expected. This gene effect stood out via mother's dementia (p < 1.13e-30) but had no correlation via father's dementia. Six loci (1:91939115, 10:134466627, 12:6538149, 18:59219633, 11:33590240, 4:54422066) were also statistically significant (p < 5e-8) and 61 loci (p < 1e-6) were suggestive. In AD/ADRD GWAX with OCT, the strongest association was the same locus on *APOE* (p < 2.4e-21). *INPP5A* (10:134388125, p <3.3e-9) and *CDH20* (18:59219633, p < 7.5e-9) remained. *APOE* showed the strongest risk heritability. *INPP5A* may dysregulate of phosphoinositide (PI) and PI- 5-phosphatase in AD. The CDH (cadherin superfamily) genes code vascular/cell adhesion, the regulation of tissue organization, and morphogenesis. *CDH13* was already reported on AD/ADRD GWAS in a Caucasian population. Some other genes are reportedly associated with psychiatric disorders relevant to ADRD. Conclusion: We report the first AD/ADRD risk gene investigation by GWAX with retinal thickness worldwide and highlight possible roles and pathways for susceptibility loci with high odds ratio and *ApoE* effects in Japanese ethnicity, that correlated with retinal thickness in a Japanese population.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4180 Genome-wide association study of emphysema- and airway-predominant deep learning subtypes.

Authors:

D. Hill[1], K. Kim[2], M. Moll[2], M. Torop[1], A. Masoomi[1], S. Bodduluri[3], P. J. Castaldi[2], B. D. Hobbs[2], J. Dy[1], S. P. Bhatt[3], M. H. Cho[2]; [1]Northeastern Univ., Boston, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Univ. of Alabama at Birmingham, Birmingham, AL

Background: Chronic obstructive pulmonary disease (COPD) is characterized by a combination of two different structural diseases: emphysema and airway disease. The relative contribution from these two diseases can be used to categorize patients into emphysema-predominant and airway-predominant phenotypes, which is established with CT measures of emphysema and airway remodeling. While CT can differentiate between these two phenotypes, CT results are often unavailable due to expense and entail radiation exposure. In previous work, a neural network model (SpiroNet) trained on spirometry volume-time curves was effective in differentiating emphysema-predominant and airway-predominant subtypes on CT scans. Whether these phenotypes have specific genetic susceptibility, differing from summative measures of lung function and COPD, is unknown.
Methods: We used SpiroNet, a fully convolutional neural network, to predict emphysema-predominant and airway-predominant phenotypes from volume-time exhalation curves from the UK Biobank (N=352,684) and performed GWAS on each phenotype as a binary indicator (Emphysema: case 30,677, control 322,007; Airway: case 101,849, control 250,835), adjusting for age, sex, pack-years, ever smoking status, batch, and ancestry principal components using plink with Firth fallback. We considered $< 1x10^{-10}$ as genome-wide significant ($5x10^{-9}$, two traits), and loci as associations > 500kb apart. We compared results to previously published GWAS using COPD and measures of lung function (forced expiratory volume in one second, forced vital capacity, and the ratio of these two measures).
Results: We identified 83 loci between the two phenotypes (3 for emphysema and 80 for airway) at genome-wide significance. Seventy-nine of these loci were within 500kb of previously described regions associated with lung function or COPD, with the exception of 4 airway-associated variants in the HLA region (spanning HLAA and ZKSCAN4), and one airway-associated variant > 500kb away from the lead variant near HHIP). The top loci for emphysema were near EFEMP1 and CCDC91, and for airway, HHIP and NPNT.
Conclusions: Emphysema-predominant and airway-predominant phenotypes can be established in the UK Biobank by using a neural network model applied to spirometry, and are associated with different genetic loci. Deep learning models can be used to infer disease subtypes in large population-based cohorts and identify subtype-specific genetic risk variants.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4181 Genome-wide association study of fibrotic disease across organs and systems.

Authors:

E. Joof[1], G. M. Massen[2], O. C. Leavy[1], G. Parcesepe[1], I. D. Stewart[2], R. G. Jenkins[2], J. K. Quint[2], G. Aithal[3], C. J. Scotton[4], D. P. Auer[3], S. Francis[3], L. V. Wain[1], R. J. Allen[1], DEMISTFI Consortium; [1]Univ. of Leicester, Leicester, United Kingdom, [2]Imperial Coll. London, London, United Kingdom, [3]Univ. of Nottingham, Nottingham, United Kingdom, [4]Univ. of Exeter, Exeter, United Kingdom

Rationale: Fibrosis is a major factor in global mortality and can affect virtually every organ system. The incidence of fibrotic conditions in many different organ systems hinders the development of targeted therapies. A potential strategy to overcome this challenge is to target common genetic mechanisms and pathways shared across organs.
Objectives: We sought to identify shared genetic signals across different fibrotic organs and systems, and for fibrotic multimorbidity.
Methods: The study utilised samples of people with European ancestry from the UK Biobank. Fibrotic diseases, as defined by a published consensus list, were combined across 13 organs or systems (Respiratory, Liver, Bile, Cardiomyopathy, Intestinal-Pancreatic, Integumentary, Skeletal, Systemic, Reproductive, Urinary, Blood-vessel, Atherosclerosis and Diabetes). Individuals that had a fibrotic condition recorded in their hospital or mortality records were defined as cases (and all others defined as controls). For the fibrotic multimorbidity analysis, individuals with a fibrotic disease(s) in more than one organ/system were defined as cases and the rest as controls. Genome-wide association analyses were conducted assuming an additive genetic effect and conditioning on the first ten genetic principal components. LD score regression was used to estimate global genetic correlation and colocalisation analysis was used to test for shared causal genetic variants between organs and systems.
Results: We detected multiple genome-wide significant signals including 11 signals of association for fibrotic multimorbidity. Colocalisation analyses revealed at least six shared common genetic causal variants. A signal at *PTPN22* (a gene known to be associated with conditions such as Systemic Lupus Erythematosus and Rheumatoid Arthritis) overlapped between two single fibrotic organ/system GWAS and the fibrotic multimorbidity GWAS.
Conclusions: Functional follow-up of these shared signals may reveal potential causal pathways of general fibrosis and provide new insight into signalling responses shared by different fibrotic diseases which can be leveraged in the development of new therapies. We are currently expanding the analyses to other ancestry groups to identify more genetic signals that overlap between different fibrotic diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4182 Genome-wide Implementation of Multi-population Joint Analysis Marginal Summary Statistics (mJAM) and its Applications in Polygenic Risk Score Models

Authors:

J. Shen[1], J. Baurley[2], J. He[1], G. King[1], C. A. Haiman[1], D. V. Conti[1]; [1]Univ. of Southern California, Los Angeles, CA, [2]BioRealm LLC, Mammoth Lakes, CA

Previously we proposed a multi-population fine-mapping approach called "mJAM" to jointly analyze marginal GWAS summary statistics. mJAM effectively fits a multi-SNP model within each population with population-specific reference LD and then performs a fixed-effect meta-analysis of the joint model while incorporating a Bayesian 'g-prior' for robust estimation. The resulting model provides the flexibility to identify noteworthy SNPs using existing feature selection approaches. We propose a scalable version of the previous region-wise mJAM implementation that can be applied to genome-wide data ("GW-mJAM"). We illustrated GW-mJAM with forward selection as the main approach for selecting index SNPs, applied GW-mJAM on the latest prostate cancer summary statistics with 4 populations, and constructed PRS using the index SNPs selected by GW-mJAM. Since mJAM model estimates the joint SNP effects at a multi-population level and does not assume population-specific weighting, resultant PRS built from GW-mJAM can be applied to individuals of any ancestry without estimating ancestry or using self-identifying population information. We evaluated GW-mJAM's PRS using incident data from the MultiEthnic Cohort Study (5 populations, 2,885 cases, 25,904 controls; Kolonel et al., 2000). GW-mJAM selected 471 index SNPs that are conditionally genome-wide significant. Among men of African ancestry in the MEC (592 cases and 1,957 controls), the AUC of GW-mJAM PRS is 0.800 (0.782 - 0.818) and the OR of 1-standard-deviation increase in PRS is 1.96 (1.76 - 2.18). Among men of European ancestry (530 cases and 5,571 controls), the AUC of GW-mJAM PRS is 0.823 (0.807 - 0.840) and the OR of 1sd PRS model is 2.25 (2.03 - 2.50). By lowering the significance threshold for index SNP selection, GW-mJAM includes additional regions and SNPs across the genome. However, evaluation performance in the MEC did not improve with more variants being included in the PRS model. For example, using a p-value threshold of 10^{-6}, GW-mJAM selected 601 index SNPs but AUC and 1sd OR showed similar decrement among all populations in MEC (AUC = 0.795 (0.778 - 0.813); 1sd OR = 1.93 (1.73 - 2.15) among men of African ancestry). In addition to GW-mJAM with forward selection, we incorporate GW-mJAM with other feature selection approaches as well as apply GW-mJAM to three other cancer types (breast, colorectal, and lung) with available multi-population summary statistics. PRS models built from GW-mJAM's results are evaluated and compared with other GW PRS approaches such as PRS-CSx (Ruan et al., 2022) to investigate the impact of trait characteristics, quality of reference panel, and methodology on test performance.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4183 Graph Attention Networks-based Predictive Model for Healthcare using EHR

Authors:

X. Huang[1], Z. Wang[1], J. De Jong[2]; [1]Yale Univ., New Haven, CT, [2]Boehringer Ingelheim Pharma GmbH & Co.KG, Biberach, Germany

The widespread digitalization of patient data via electronic health records (EHRs) has brought unprecedented opportunities for risk modeling. While numerous risk models have been developed for a wide spectrum of diseases, they often overlook the inclusion of family relationships and histories. Additionally, deep learning predictive models, although effective, suffer from a lack of interpretability. Moreover, there are limited interpretable models that utilize the prior medical ontology. To leverage these available information, we developed a Graph Attention neTworks-based predictive model for EHR (GATEHR) to simultaneously predict future disease risks for thousands of diagnosis codes using patients' EHRs, family health history and knowledge graph of medical ontology. This model incorporates family health history, which has been well accepted as a major predictor for a range of diseases, through electronically constructed family pedigrees (e-pedigrees), and knowledge graph of medical ontology, via graph attention networks (GAT). Furthermore, it is able to enhance the model interpretability by assessing the impact of disease risk factors using attention-based feature importance. We compared predictive performance of GATEHR and other existing methods, assessed the interpretability of our model. Precision, recall, F1 score, and area under the curve (AUC) were selected to measure the performance. The results showed that our graph-based neural network model outperforms the other baselines in disease risk prediction tasks. Besides, our model demonstrated the impact of family health history among patients with Nonalcoholic Fatty Liver Disease (NAFLD) and Nonalcoholic Steatohepatitis (NASH). The results emphasized the significant potential and value of integrating family health history and medical ontology into GAT for disease risk prediction. This study offers improved predictive accuracy and interpretable insights into disease risk models.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4184 graphPred: multi-ancestry polygenic risk prediction with millions of SNPs in minutes

Authors:

P. Salehi Nowbandegani[1], G. Genovese[2], L. O'Connor[1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Broad Inst, Cambridge, MA

State-of-the-art polygenic risk score (PRS) methods employ computationally intensive Bayesian algorithms, leading to compromises that affect their prediction accuracy. Most rely on HapMap3 SNPs, representing <20% of common SNPs in European populations, and they typically analyze data from a single ancestry group, causing non-transferability. These limitations apply both to individual-level methods and to those that operate on GWAS summary association statistics.

For summary statistic-based methods, the computational bottleneck is their use of slow and memory intensive LD matrix operations. We recently introduced linkage disequilibrium graphical models (LDGMs), which accelerate LD matrix operations dramatically with no loss in accuracy. We developed a new PRS method, graphPred, which leverages LDGMs to perform exceptionally fast Bayesian inference without the computational compromises of existing methods. graphPred is a Gibbs sampler for a generalized SuSiE model (Wang et al. 2020). It uses a novel sampling scheme that greatly accelerates convergence. graphPred incorporates data from multiple ancestry groups, it jointly models almost every SNP at >1% frequency in 1000 Genomes, it learns a flexible effect-size distribution during sampling, and it can incorporate functional annotations into the prior distribution.

We evaluated the performance of graphPred in analyses of real and simulated data. In a wide range of realistic simulations, with different sample sizes and genetic architectures, it outperforms the widely used PRS-CS (Ge et al. 2019) by 16% in a realistic simulation with N=100k, and by over 20% in well-powered simulations with high sample size (N=1M) or low polygenicity; moreover, it ran ten times faster. The difference in performance was mostly eliminated when artificially restricting graphPred to HapMap3 SNPs, indicating that its ability to model a larger number of SNPs confers a significant advantage. In a preliminary analysis of three real phenotypes (height, BMI and T2D), the improvement was even larger, including in individuals of non-European ancestry. graphPred is implemented in C as a plugin for bcftools, and it runs in under 10 minutes. Our results illustrate how linkage disequilibrium graphical models enable the development of powerful new methods.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4185 Group-penalized exponential tilt model for identification of differentially methylated genes in epigenetic association studies

Authors:

H. Sun; Pusan Natl. Univ., Busan, Korea, Republic of

DNA methylation is a representative epigenetic change that occurs in our body and plays an essential role in regulating gene expression as well as in cancer progressing. Identification of differentially methylated genes between two biological conditions has been popularly conducted in epigenetic association studies. However, most of statistical methods aim to detect differences in mean methylation levels between two conditions. So, they are limited to identify differences in methylation variances which have been recently observed in cancer research. We propose a new statistical method based on a group-penalized exponential tilt model that essentially combines an exponential tilt model and group lasso. The proposed method can identify differentially methylated genes when two biological conditions are different in methylation mean only, methylation variance only, or both. It can be extended to genes with overlapping CpG sties when group lasso is replaced by overlapping group lasso. The proposed method is able to prioritize differentially methylated genes based on their selection probability, which is computed by bootstrap resampling. In our extensive simulation study, we demonstrated that the proposed method has superior selection performance, compared with the existing statistical methods developed for detection of differentially methylated genes. We also applied it to 450K DNA methylation data of The Cancer Genome Atlas Breast Invasive Carcinoma Collection (TCGA-BRCA). We were able to identify potentially cancer-related genes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4186 † GUIDE learns interpretable latent factors from genetic association studies

Authors:

D. Lazarev[1,2,3], A. Bloemendal[1,3], G. Chau[1,3], C. Churchhouse[1,3], B. Neale[3,1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Inst. of Technology, Dept. of Mathematics, Cambridge, MA, [3]Massachusetts Gen. Hosp., Boston, MA

Learning a set of modules, or latent factors, mediating the effects of a large set of SNPs on some set of complex traits can help inform disease classification and elucidate complex disease mechanisms, otherwise muddled by polygenic and pleiotropic effects. We propose a method, Genetic Unmixing by Independent DEcomposition (GUIDE), to estimate a set of statistically independent latent factors that best extract the information encoded in the underlying genetic architecture by picking a basis to express these factors that is simultaneously informed by the SNPs and traits corresponding to a set of summary statistics. In particular, GUIDE builds a three-layer network consisting of SNPs, traits, and latent factors that mediate their interactions, and picks a basis for the latent factors that maximizes the sparsity of interlayer weights, resulting in factors that are more enriched for particular traits and load onto sets of genetic variants that are more significantly associated with given diseases and disease pathways. For example, we built a GUIDE model using UK Biobank data and focused on Alzheimer's disease (AD), peripheral vascular disease, and high cholesterol, finding that a common latent factor that explains a large part of the genetic variance for all three traits specifically and significantly implicates genes in the cholesterol metabolism pathway. Moreover, the top GUIDE factor for AD—explaining 87.5% of the genetic variance of the disease—is highly enriched for the *APOE* genes, with 49 of the top 54 loci in the 19:45386467-45445517 region near *APOE* contributing 50.9% of the variance of this latent factor. By contrast, the top factor for the state-of-the-art method based on principal component analysis explains only 10.2% of the genetic variance of AD, mostly picking up a host of related genes such as *APOC*, *APOB*, *LDLR*, among others, without significant enrichment for *APOE*, and with the top 50 loci—spanning most of the chromosomes—contributing only 12.7% of this factor's variance. Moreover, GUIDE prioritizes genes, such as *RBFOX1* (chr. 16), *CSMD1* (chr. 8), and *PCSK9* (chr. 1), which have only recently been implicated in AD. GUIDE thus allows using summary statistics for the construction of parsimonious and interpretable network models that deconvolve the shared and specific effects of SNPs on complex traits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4187 GWAS conditioned by SNP-specific shape effects identifies 11 loci underlying shape covariation of the cerebral cortex and cranial vault

Authors:

S. Goovaerts[1], M. Yuan[1], H. Hoskens[2], N. Herrick[3], M. D. Shriver[4], J. R. Shaffer[5], S. M. Weinberg[5], S. Walsh[3], P. Claes[1]; [1]KU Leuven, Leuven, Belgium, [2]Univ. of Calgary, Calgary, AB, Canada, [3]Indiana Univ. - Purdue Univ. Indianapolis, Indianapolis, IN, [4]Penn State Univ, University Park, PA, [5]Univ. of Pittsburgh, Pittsburgh, PA

Covariation in brain and cranial vault shape inevitably arises from their structural relationship and proximity during development, where close coordination between both tissues is required for “normal” craniofacial development. Several studies have suggested cell-to-cell signaling as an important driver for their integrated co-development, with the FGF, BMP, Wnt, and Hedgehog signaling pathways playing essential roles in both brain and cranial vault development. Functional studies have supported this hypothesis but are limited to candidate genes and pathways. GWAS provides an unbiased framework and could potentially implicate novel genes and mechanisms underlying brain-vault covariation. A recent study scanned the mouse genome and identified a single locus associated with global axes of shape covariation between the brain and cranial vault. Here, we propose a novel approach that differs in that it extracts a SNP-specific latent phenotypic axis for one multivariate trait that is used for conditioning on another multivariate trait under coinvestigation. Specifically, we assessed the dependency of genome-wide associations for multivariate 3D cortical and cranial vault shape derived from MRIs of 4,148 participants of recent European ancestry from the ABCD study cohort. We demonstrate an improved discovery rate over previous methods and identify genes involved in signal transduction (*BMP2*, *PTHLH*, *ABR*, and *TIAM2*) and regulation of ossification and osteoblast differentiation (*RUNX2*, *BMP2*, *PTHLH*, and *DLX5*). Among the 11 identified loci, 4 could not be identified in separate GWASs on brain and cranial vault shape using the same data and were hence a product of our novel approach. Altogether, we demonstrate a new, powerful method for identifying the genetics underlying brain-vault covariation, thereby identifying genes that support the current hypothesis that close regulation of calvarial ossification is crucial for their integrated co-development and morphological covariation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4188 GWAS of 5,811 hepatitis B virus infection cases and 152,913 controls of Koreans with replication analysis of 171,822 of Japanese

Authors:

S-H. Jee, K. Jung, H. Kimm; Graduate Sch. of Publ. Hlth., Yonsei Univ., Seoul, Korea, Republic of

Hepatitis B virus (HBV) infection is a major causal factor in the development of liver cancer. So far, genetic epidemiological studies on HBV have been small in scale. The objective of this study was to perform genome wide association study (GWAS) analysis to identify new genetic factors related to HBV in Koreans and Japanese. Korean Cancer Research and Prevention (KCPS-II) data of 158,724 people and summary statistic of Biobank of Japan (BBJ) data of 171,822 people were obtained. Novel SNPs were found through GCTA-COJO analysis. Related genes were mapped through FUMA GWAS analysis in KCPS-II data. BBJ data were used for replication analysis. In KCPS-II data, 24,346 SNPs with $P < 10^{-8}$ were identified from GWAS analysis. Of these, 5,521 ($P < 10^{-8}$)/19,218 SNPs were replicated/identified in BBJ. Finally, 23 SNPs were identified as Novel SNPs independent of previously reported SNPs. Of these, 14 ($P < 10^{-8}$)/20 SNPs were replicated/identified in BBJ. In addition, the first 232 genes were mapped. Among them, 54 genes with a CADD score of 20 or more were identified. This is the largest HBV GWAS study conducted in Asian countries. It replicated previously reported results and found new genetic factors. Results of this study could be used as a basis for further research on prevention and treatment of HBV infection and liver cancer.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4189 GXwasR: A tool for conducting sex-aware quality control, association analysis, and testing various models of sex-dependent genetic effects in complex traits.

Authors:

B. Bose[1], L. L. Pesce[1], E. Khramtsova[2], B. Stranger[1]; [1]Northwestern Univ., Chicago, IL, [2]Janssen Pharmaceuticals, Spring House, PA

Motivation: Many human complex traits and diseases exhibit sex-differentiated characteristics, yet the causes of these differences are largely unexplored. To understand the processes underlying these differences, sex-aware genomic analyses are crucial and so is a need for computational tools that implement currently accepted state-of-the-art best practices for performing sex-aware quality control (QC) and genetic analysis.
Our Tool: We present a new software tool, GXwasR, that in addition to enabling a standard genome-wide association study (GWAS), can perform a sex-aware GWAS. Standard QC and association functions are provided, together with sex-aware QC of genotype data. It performs sex-combined and sex-stratified GWAS and X-Chromosome Wide Association Studies (XWAS). Importantly this tool has functionality for testing genetic associations between phenotype and variants on the X-chromosome (chrX). ChrX requires different statistical association models than autosomes because of, e.g., chrX inactivation (XCI), unique patterns of recombination.
Functionalities: GXwasR includes several functions grouped in six different categories (A-E) enabling a comprehensive pipeline for sex-aware genetic analysis: (A) sex-aware pre-imputation and post-imputation QC of genotype data, such as filtering variants considering differential missingness between cases and controls, handling of pseudo-autosomal regions, X-transposed regions and ampliconic regions of chrX, sex-specific filtering of variants based-on Hardy-Weinberg Equilibrium and Minor Allele Frequency etc., (B) sex-combined and sex-stratified GWAS with XWAS implementing different statistical models to consider XCI patterns for dosage compensation while controlling for multiple covariates and the interactions with those covariates, (C) sex-differential tests to evaluate the difference in effect size, trait heritability etc., (D) high level analysis enabling sex-specific gene-based tests, GWAS and XWAS meta-analyses, and generation of both standard and sex-aware polygenic risk scores and (E) several utility functions for the application of the best practices for additional quality control of genetic data necessary for the sex-aware tests.
Implementation: GXwasR is written in R, and is fully open-source with a comprehensive tutorial with simulated data and several use-case scenarios using real genotype datasets.
Impact: With this work, our goal is to make sex-aware genomic analysis more accessible to researchers by providing a theoretical background and a practical framework to perform sex-aware analysis of genotype and phenotype.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4190 Haptoglobin genotype calling and allele specific expression in AD

Authors:

E. Vazquez-Hidalgo, H. Bai, W. Bush; Case Western Reserve Univ., Cleveland, OH

Alzheimer's disease (AD) is a complex neurodegenerative disorder with multifactorial etiology. We explore the combined effects of apolipoprotein E (*APOE*) and haptoglobin (*HP*) in AD. In most cases, the greatest genetic risk factor for AD is *APOE*. *APOE* has three alleles: *APOEε2*, *APOEε3*, and *APOEε4*. Relative to *APOEε3*, *APOEε2* protects against AD but *APOEε4* increases AD risk. AD susceptibility is further modulated by dosage effect. Homozygous individuals for *APOEε4* are at higher risk for AD but those that are homozygous for *APOEε2* have greater protection against AD. The *APOE* protein, apolipoprotein E (APOE), potentially plays a role in amyloid-β (Aβ) protein removal. Increased Aβ plaques and *APOEε4* allele dosage are associated with AD. APOE's ability to clear Aβ depends on APOE's oxidation state. Oxidized APOE decreases its ability to remove Aβ. Recently, we have shown that *APOE* is modulated by haptoglobin (HP) encoded by *HP*. HP is a glycoprotein that possesses antioxidant properties. Experiments revealed that HP binds to APOE, likely protecting APOE from oxidation. Furthermore, HP promotes APOE mediated Aβ clearing. Yet, the impact of *HP* genotype on AD remains unknown. *HP* has two alleles, *HP1* and *HP2*, and consists of five or seven exons, respectively. As a result, *HP* has three common genotypes: *HP1-1*, *HP1-2*, and *HP2-2*. In European ancestry populations, *HP1-2* is the largest genotype class and exhibits considerable impact on AD risk. Expression of *HP* copy number variation (CNV) adds an additional layer of complexity to HP-APOE interaction. Therefore, expression imbalance potentially contributes to AD phenotypic variation and disease pathophysiology. Understanding the interplay between *HP* CNV and *HP* allele specific expression (ASE) in AD could provide some insight into the underlying genetic interactions that regulate AD.

Here we evaluate the impact of *HP* CNV and measure ASE to identify allelic imbalance. To determine the copy number of the *HP* CNV and other structural polymorphisms, we aligned WGS reads to custom *HP* references for deletion states that reflect *HP1* and *HP2* states, allowing identification of reads spanning intron junctions that uniquely identify *HP2* carriers. Allelic copy numbers were determined based on bi-allelic copy number for each sequence boundary. ASE was measured using RNA-seq to evaluate allele-specific read counts to exploit differential expression of *HP* isoforms in heterozygotes. We show that risk of developing AD is not only linked to *APOE* genotype, but may also be influenced by level and type of *HP*. Knowing transcriptional expression of specific alleles can help us better understand how genetic variants affect phenotypes

PB4191 Haptools: a toolkit for admixture and haplotype analysis.

Authors:

A. Massarat[1], M. Lamkin[1], C. Reeve[1], A. Williams[2], M. D'Antonio[1], M. Gymrek[1]; [1]Univ. of California San Diego, La Jolla, CA, [2]23andMe, Inc., Sunnyvale, CA

Genome-wide association studies (GWAS) have promised to revolutionize our understanding of the genetic components of many diseases and facilitate personalized medical care. Yet researchers still struggle to compute disease risk equitably. GWAS predictions are often limited to the study population and perform poorly when applied to individuals of mixed descent.

In addition to variant-level analyses, phenotypic effects may also be mediated by haplotypes (combinations of variants that are inherited together) or by the local ancestry background on which a variant falls. Thus, leveraging local ancestry and haplotype information in GWAS and downstream analyses may improve the utility of genomics for individuals from diverse and recently admixed ancestries. We and others have begun to develop methods to improve risk prediction in admixed individuals by inferring haplotypes and local ancestry, but an absence of ground truth data makes it difficult to benchmark these tools. Most existing simulation, visualization and variant analysis frameworks are based on variant-level analysis and do not automatically handle these features.

We present haptools, an open-source toolkit for performing local ancestry aware and haplotype-based analysis of complex traits. Haptools supports fast simulation of admixed genomes, visualization of admixture tracks, and simulation of haplotype- and local ancestry-specific phenotype effects. Since its original publication, haptools has been expanded to simulate traits deriving from complex variants such as tandem repeats. The haptools python library powers its ability to quickly load an exceptionally wide variety of file formats into standardized data structures, including genotypes from the new PLINK2 PGEN format or from VCFs generated by five different tandem repeat callers. We also developed a new file format for haplotypes (.hap) which, compared to other formats, is more flexible but also easier to parse and faster to query.

We demonstrate the utility of our toolkit by benchmarking it against others in our field, such as admix-simu and GCTA. Using haptools, we can illustrate the decrease in power that we expect for detecting haplotype and ancestry-dependent causal effects via a GWAS. Since the release of our publication, we've also demonstrated this phenomenon in fine-mapping methods.

Overall, haptools provides a valuable set of utilities for developing and benchmarking methods for ancestry-aware analysis of complex traits by simulating genotypes and phenotypes for GWAS and polygenic risk scores. We intend for it to help improve our ability to predict disease risk for individual patients based on their genotypes.

PB4192 Hardy-Weinberg equilibrium test accounting for population structure and genetic relatedness in large-scale whole genome sequencing studies.

Authors:

D. Shyr, R. Dey, X. Lin; Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Large-scale cohort studies such as the Center for Common Disease Genomics have integrated deep whole-genome sequencing and other omics data with clinical data. Assessing the Hardy-Weinberg Equilibrium (HWE) assumption appropriately for these datasets is integral to quality control procedures; however, this is challenging due to ancestral heterogeneity and genetic relatedness of the samples. Currently, there are no existing methods that incorporate both population structure and genetic relatedness when testing for HWE. We propose a novel HWE test using the generalized estimating equation that accounts for population structure with principal components and the relationship among samples with a family-specific genotype correlation matrix. Our results demonstrate that ignoring population structure and relatedness when evaluating HWE inflates the false positive rates drastically. Compared to other methods, our approach controls for type-I error the best while maintaining high power. Our implementation is scalable and practical such that HWE tests can be performed efficiently across millions of markers and over a hundred thousand samples.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4193 † Harnessing the AI revolution: Application of Large Language Models (LLMs) for genotype refinement and imputation

Authors:

D. Pandey[1], R. Dhar[2], V. Narasimhan[1]; [1]The Univ. of Texas at Austin, Austin, TX, [2]Indian Inst. of Technology Kharagpur, Kharagpur, India

A critical technical step in the processing of next-generation sequencing data for medical or population genetics is genotype refinement or imputation, which is the process of predicting unobserved genotypes or correcting spurious genotypes in a newly sequenced individual using a reference panel of haplotypes to get the most accurate genetic sequence information for each person. Existing imputation methods are based on Hidden Markov Models (HMMs) which are a slow statistical process that must evaluate how a new sequence matches each one of the millions of references and suffers from limitations related to accuracy, computational resources, and scalability. In the field of natural language processing, the introduction of LLMs trained on extremely large datasets for similar problems of word auto correction or sentence completion have rendered HMMs largely obsolete.

Here we examined the use of LLMs in genotype refinement/imputation by training two transformer-based language models from scratch for a similar task of predicting the 101st variant given 100 preceding variants as input. We built a benchmarking dataset comprised of genotype data from chromosome 20 of the 1000 Genomes Project Phase3, and the UKBiobank whole genome sequencing dataset and evaluated the performance of our models by examining the accuracy of our model at predicting variants at different minor allele frequencies (MAF) bins. The first model, a bigram language model, had 0.205 million trainable parameters. It was trained for 500 epochs, resulting in a decrease in cross entropy loss from 0.482 to 0.071 on the validation set. The second model, GPT2, was trained from scratch along with the GPT2 Tokenizer on the same data. It had 124.4 million trainable parameters and was trained for 160,000 steps, resulting in a decrease in cross entropy loss from 2.3066 to 0.995 on the validation set. We observed that the predictive performance of both models improved as the predicted variant transitioned from rare to common within the MAF bins. Using our benchmarking data, we also examined the impact of different tokenization schemes, training dataset size, and model architecture on the model accuracy.

This study serves as a proof of principle for the application of LLMs in various population genetic tasks and will lay the foundation to develop architectures designed not for language but specifically for genomic sequence information.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4194 Harnessing transcriptomic signals for amyotrophic lateral sclerosis to identify novel drugs and enhance risk prediction

Authors:

O. Pain[1], A. Jones[1], A. Al Khleifat[1], D. Agarwal[2], D. Hramyka[3], H. Karoui[4], J. Kubica[5], D. J. Llewellyn[6], J. M. Ranson[6], A. Iacoangeli[7], A. Al-Chalabi[7]; [1]King's Coll. London, London, United Kingdom, [2]Wellcome Ctr. for Human Genetics, Oxford, United Kingdom, [3]Charité – Univ.smedizin Berlin, Berlin, Germany, [4]Imperial Coll. London, London, United Kingdom, [5]Univ. of Warsaw, Warsaw, Poland, [6]Univ. of Exeter Med. Sch., Exeter, United Kingdom, [7]King's Coll. London, London, United Kingdom

Introduction: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease. This study integrates the latest ALS genome-wide association study (GWAS) summary statistics with functional genomic annotations with the aim of providing mechanistic insights into ALS risk loci, inferring drug repurposing opportunities, and enhancing prediction of ALS risk and clinical characteristics.
Methods: Genes associated with ALS were identified using GWAS summary statistic methodology including SuSiE SNP-based fine-mapping, and transcriptome- and proteome-wide association study (TWAS/PWAS) analyses. Using several approaches, gene associations were integrated with the DrugTargetor drug-gene interaction database to identify drugs that could be repurposed for the treatment of ALS. Furthermore, ALS gene associations from TWAS were combined with observed blood expression in two external ALS case-control datasets to calculate polytranscriptomic scores and evaluate their utility for prediction of ALS risk and clinical characteristics, including site of onset, age at onset, and survival.
Results: SNP-based fine-mapping, TWAS and PWAS identified 117 genes associated with ALS, with TWAS and PWAS providing novel mechanistic insights. Drug repurposing analyses identified five drugs significantly enriched for interactions with ALS associated genes, with directional analyses highlighting α-glucosidase inhibitors may exacerbate ALS pathology. Additionally, drug class enrichment analysis showed calcium channel blockers may reduce ALS risk. Across the two observed expression target samples, ALS polytranscriptomic scores significantly predicted ALS risk (R^2 = 4%; p-value = 2.1×10^{-21}).
Conclusions: Functionally-informed analyses of ALS GWAS summary statistics identified novel mechanistic insights into ALS aetiology, highlighted several therapeutic research avenues, and enabled statistically significant prediction of ALS risk.

PB4195 High-dimensional causal inference from GWAS summary statistic data

Authors:

N. Machnik, S. Mahmoudi, M. R. Robinson; Inst. of Sci. and Technology Austria, Klosterneuburg, Austria

Inferring causal relationships using high-dimensional observational data is a crucial first step for understanding the ethology of common complex disease. Mendelian Randomization (MR) is currently the most commonly used approach to investigate causal relationships in data where genomic information is linked to electronic health records, but relies upon strong assumptions that are often not fulfilled. In this study, we introduce Casual Inference GWAS (CI-GWAS), a novel approach that leverages graphical models to perform causal inference using GWAS summary statistic data. CI-GWAS consists of three main steps: (i) a GPU-based algorithm for variable selection, called cuda-skeleton, to learn a sparse graph representing all causal SNP-trait and trait-trait relationships within a single-step; (ii) a modified sRFCI algorithm to infer causal directions in the inferred sparse graph, accounting for potential hidden variables and confounders; and (iii) a data-driven sDAVS algorithm to estimate the magnitude of causal effects across the learnt graph structure. CI-GWAS estimates causal SNP-trait and trait-trait relationships for 17 phenotypes and 2.2 million SNP markers in less than a day in over 400,000 UK Biobank individuals. By inferring causal relationship among 17 traits jointly we find, contrary to MR, that almost all phenotypic dependencies can be attributed to a common underlying latent cause, with no evidence for a causal relationship. The exception is a clear causal relationship between higher alcohol consumption and cardiovascular disease. Our model also provides a likely causal set of fine-mapped SNP-trait associations and reveals a lack of direct pleiotropy among all traits. Thus, we demonstrate the unique biological insight that can be obtained from high-dimensional graphical inference in large-scale summary statistic data.

PB4196 *HORNET* identifies a complex gene network underlying Alzheimer's disease risk in diverse populations

Authors:

N. Lorincz-Comi[1], Y. Yang[1], X. Zhu[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ., Shaker Heights, OH

Background
The ABCA7 gene is highly associated with both early- and late-onset Alzheimer's disease (AD) in diverse populations. In vivo models suggest that ABCA7 is involved in the clearance of amyloid beta plaques, a hallmark feature of AD pathology, suggesting it has a causal role in modifying AD risk. However, the 500Kb window around ABCA7 contains 25 other genes, making evaluation of its causal role challenging because of complex regulatory mechanisms. Here, we searched the 1Mb region around ABCA7 to identify genes with direct causal effects on AD risk after adjusting for inter-relationships between expression patterns of surrounding genes.
Methods
We developed the HORNET software to estimate direct causal effects of gene expression using multivariable Mendelian Randomization (MR) and GWAS summary statistics. We applied HORNET to gene expression data in blood from European (EUR; n=31k) and African American (AA; n=757) populations separately. AD GWAS data were from Jansen et al. (n=455k). Population-specific regulatory networks were constructed using graphical lasso.
Results
25 genes in a 1Mb window around ABCA7 had cis-eQTLs (P<5E-8) in EUR and 23 in AA. The regulatory network of gene expressions was marginally denser in AA than EUR (P=0.051). For example, each gene on average either regulates or is regulated by 10 other genes in EUR and 16 in AA. The expression of these genes explained 95.7% of the local heritability of AD in EUR and 73.5% in AA, suggesting well-specified causal models and the appropriate tissue.
The local genetic correlation between AD risk and ABCA7 expression was 0.93 in EUR and 0.90 in AA and its total unmediated causal effect on AD was large (AA odds ratio=1.33, EUR odds ratio=2.40; both P<1E-100). However, after considering neighboring genes, ABCA7 had no direct causal effect on AD risk in EUR (P=0.24) or AA (P=1.00). Our regulatory network suggests that ABCA7 expression indirectly confers AD risk by regulating nearby genes such as KISS1R and ARID3A (both P<0.05 in EUR and AA). Genetic correlations between ABCA7 and these two genes ranged in absolute value from 0.71-0.76 in EUR and 0.48-0.96 AA, suggesting strong regulatory dependencies.
Conclusions
This was the first application of HORNET, which has statistical and computational advantages over existing alternatives that will be discussed. Using ABCA7, we demonstrated that evaluation of a gene for causality must consider surrounding genes in the target gene's network. We could only identify genes with direct causal effects on AD risk by considering the broader regulatory context. We plan to validate these findings using data from African, Asian, and European individuals in the UK Biobank.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4197 Human age- and sex-specific molecular phenomena inferred by leveraging public transcriptome data with machine learning.

Authors:

K. Johnson, A. Krishnan; Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Age and sex are historically understudied factors in biomedical studies even though many complex traits and diseases vary by these factors in their incidence and presentation. As a result, there are massive gaps in our understanding of genes and molecular mechanisms that underlie sex- and age-associated physiology and disease. Hundreds of thousands of publicly-available human transcriptomes capturing gene expression profiles of tissues across the body and subject to various biomedical and clinical factors present an invaluable, yet untapped, opportunity for bridging these gaps. Here, we present a computational framework that leverages these data to infer genome-wide molecular signatures specific to sex and age groups. As the vast majority of these expression profiles lack age and sex labels, the core idea of our framework is to use the measured expression data to predict missing age/sex metadata and derive the signatures from the predictive models. We first manually curated ~30,000 primary samples associated with age and sex information and profiled using microarray and RNA-seq. To the best of our knowledge, this dataset is the largest collection of expression data labeled with age and sex. We used this dataset to infer sex-biased genes within each of eleven age groups along the human lifespan. We also trained machine learning (ML) models to predict these age groups from gene expression values separately within females and males. Dataset-level cross validation shows that these ML classifiers are able to discriminate between age groups in a biologically meaningful way in each sex across technologies. Further, these predictive models capture sex-stratified age-group ‘gene signatures’, i.e., the strength and the direction of importance of over 18,000 genes across the genome, specific to each age group in each sex. Enrichment analysis of these gene signatures with prior gene annotations helped in identifying relevant age- and sex-associated multi-tissue and pan-body molecular phenomena (e.g., general immune response, inflammation, metabolism, hormone response). We have made our results — thousands of gene, pathway, trait, and disease signatures — and curated expression data, the largest public dataset of its kind, available for reanalysis or application to a broad range of disorders with age or sex biases. A Shiny app we developed makes these results and data easy to query and visualize for the community to use for hypothesis generation and novel biological discovery. Overall, we have presented a path for effectively leveraging massive public omics data collections to broadly investigate the genomic basis of age- and sex-differences in physiology and disease.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4198 IBDMap: leveraging IBD mapping for validating and uncovering binary trait associations at biobank scale

Authors:

G. Evans[1], J. Baker[1], A. Petty[2], L. Petty[1], H-H. Chen[1], R. Bohlender[3], C. Huff[3], J. Below[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ Med Ctr., Nashville, TN, [3]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

The recent increase in available biobank genetic datasets has created numerous opportunities for novel disease gene discovery. Identity by descent (IBD) mapping is an established approach for gene discovery that evaluates segment sharing among cases and controls to identify genomic regions harboring rare, disease-causing variation undetectable through traditional genome wide association studies. However, IBD mapping in biobank scale data is a substantial computational challenge. To this end, we developed IBDMap, a multithreaded, scalable C++ tool which employs a map/reduce parallelized permutation strategy to determine IBD sharing enrichment by comparing genome wide sharing rates among cases and controls. To demonstrate feasibility and viability for end users employing data inputs of all sizes, we developed a robust, phenome-wide analytical pipeline that (1) extracts biobank scale phenotype data, (2) executes IBDMap in reasonable runtime with a highly parallelized approach, and (3) maps known associations from both OMIM and the NHGRI-EBI GWAS Catalog to genome-wide significant breakpoint regions in the IBDMap results. We used iLASH to identify consensus IBD segments for 67,128 individuals of European descent present in Vanderbilt University's biobank, BioVU who had been previously genotyped on the Multi-Ethnic Genotyping Array (MEGAEX).
We then applied IBDMap and IBDReduce across 1,641 unique categorical phenotypes (delineated by PheWAS Catalog phecodes) across our entire cohort. Our phenome-wide analysis identified genome-wide significance in over 100 unique signal locations spanning over 50 unique phenotypes. As an example, we highlight three associations related to phenotypes affecting height, including (1) congenital spine deformities (phecode 754), overlapping the gene POLR3GL where locus 1q21.1 has been previously connected to short stature, (2) malnutrition (phecode 260.3), overlapping gene FAM110C and variant rs300695 implicated in affecting height, and (3) spinal enthesopathy (phecode 715.3), matching multiple genes also implicated in affecting height. We demonstrate the utility of applying established IBD mapping statistical method(s) at scale in a computationally tractable infrastructure and timeframe. We are continuing to refine our analytical pipeline and aim to uncover more detailed associations - both novel and previously validated - across all significant signals from our phenome-wide analysis.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4199 Identification of genetic effects on seasonal variation in disease risk based on temporal patterns from 1,952 diseases in over 7 million individuals.

Authors:

S. Rognvaldsson[1], P. Vartiainen[1,2], E. Viippola[1], M. Pirinen[1,3,4], S. Jones[1], H. M. Ollila[1,5,6,7], A. Ganna[1,8]; [1]Inst. for Molecular Med. Finland (FIMM), Helsinki Inst. of Life Sci., Univ. of Helsinki, Helsinki, Finland, [2]Pediatric Res. Ctr., Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland, [3]Dept. of Publ. Hlth., Faculty of Med., Univ. of Helsinki, Helsinki, Finland, [4]Dept. of Mathematics and Statistics, Univ. of Helsinki, Helsinki, Finland, [5]Broad Inst. of MIT and Harvard, Cambridge, MA, [6]Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [7]Anesthesia, Critical Care, and Pain Med., Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [8]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA

Seasonal variation has affected human societies throughout history, shaping various aspects of life including agriculture, migration patterns and culture. This influence is observed in the occurrences of diseases such as viral and bacterial infections, cardiovascular disease and mental disorders. While there are a multitude of factors influencing the timing of disease diagnoses, genetic factors have not been extensively explored. The aim of this project was to elucidate genetic variation that contributes to seasonal disease risk. First, we derived a statistical approach to study seasonality patterns for 1,952 disease endpoints in the entire Finnish population (n=7,166,416), which is subjected to marked seasonal changes due to Finland's location in the northern hemisphere. A significant seasonality pattern was observed in 54% of the diseases with infectious, mental health and respiratory disease categories showing the most extreme seasonality. A total of 69 diseases with significant seasonal disease patterns were selected for genetic analyses in the FinnGen study population (n=473,897). For each disease we tested both a dichotomous phenotype representing whether a person was diagnosed in a period of high/low disease prevalence based on the nationwide seasonality pattern and a continuous phenotype representing the magnitude of the seasonality pattern at the diagnosis time. While we discovered that the majority of variants that associate with diseases do not show seasonal association, we identified 14 genome-wide significant loci associating with seasonality, including a top-sQTL, rs41273830[T], in *ITGB8* for major depression and a stop-gain variant, rs601338[A], in *FUT2* for intestinal infections. Both the *ITGB8* and *FUT2* variants were associated with increased disease risk in periods of low prevalence. Further replication studies are on-going in collaboration with other nordic countries to assess how robust seasonality affecting variants are across populations. Our approach introduces a new aspect to genetic research and enables identifying new disease variants whose effects are currently obscured by seasonal variation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4200 Identification of optimal values, or sweet spots, for 69 blood metabolites, and genetic loci associated with deviation from optima.

Authors:

O. Vishnyakova[1,2], J. Min[2], X. Song[3,2], K. Rockwood[4], L. Elliott[2], A. Brooks-Wilson[1,2]; [1]Genome Sci. Ctr., BC Cancer, Vancouver, BC, Canada, [2]Simon Fraser Univ., Burnaby, BC, Canada, [3]Surrey Mem. Hosp., Fraser Hlth.Authority, Surrey, BC, Canada, [4]Div. of Geriatric Med., Dalhousie Univ., Halifax, NS, Canada

Homeostasis allows the maintenance of stable physiological conditions and body chemistry. Previous observations on a group of exceptionally healthy 'Super Seniors' show a lower variance of multiple physiological measures, including telomere length and hematology measures, compared to a less healthy group matched for age, indicating that healthier individuals have values closer to an optimal 'sweet spot'. We tested the hypothesis that lower variance in healthier people is an indicator of health-relevant phenotypes using metabolomics data from a larger community sample, the Canadian Longitudinal Study on Aging (CLSA) Comprehensive Cohort. The findings validated the proposed approach. We restricted analysis to the largest ethnic group (European). After sample and data quality control, data used included measures of 989 metabolites measured in a subset of 8,764 CLSA participants aged 45 to 85 years. Health deficit was defined through five instruments, including a deficit accumulation frailty index (FI), a count of major diseases, a count of all disorders, physical and cognitive functioning.

Our two-step sweet spot discovery pipeline revealed heteroskedasticity with lower variance for the healthiest adults for 151 (15%) metabolites. We identified optimal values for 69 of them by testing for the changes of the effect on the health deficit using segmented regression.

We examined the sweet spots in two ways. First, we constructed a per-participant representation of homeostatic dysregulation by summing the absolute difference of each metabolite from its corresponding sweet spot, across 69 metabolites. This cumulative deviation from sweet spot (CDSS) biomarker was strongly associated with FI on a test set (p-value=$3.9x10^{-21}$). Survival analysis using Cox regression model with age, sex and CDSS as predictors revealed that CDSS is associated with increased risk of mortality (HR=1.48; 95%CI [1.38;1.59]).

Second, we conducted genome-wide association analyses on the absolute difference of the metabolite measures to their corresponding sweet spots, for each of the 69 metabolites with sweet spots. We identified 20 distinct {metabolite, sex, genetic variant} combinations that were not present in a GWAS of metabolite concentrations in CLSA. Findings of biological interest include {1-oleoyl-GPC (18:1), male, rs148368178 (associated with *CERK*, which is involved in calcium homeostasis)} and {lithocholate sulfate, female, rs4149056 (*SLCO1B1*, associated with statin-induced myopathy)}. This work identifies a new paradigm for identification of biomarkers relevant to health, using analysis of variation between healthier and less healthy groups.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4201 Identification of potential novel genes associated with clonal hematopoiesis using exome sequencing data

Authors:

Y. Han, G. McInnes, M. Luth, D. Jakubosky, B. Cajes, S. Bruse, O. Gottesman; Empirico Inc., San Diego, CA

Clonal hematopoiesis of indeterminate potential (CHIP) is a state characterized by the presence of somatic mutations in blood cells and has been associated with the pathogenesis of hematological malignancies as well as risk for several non-malignant diseases. Large-scale biobanks comprising sequencing data linked to rich phenotypic information, such as the UK Biobank, have enabled a greater understanding of the role of CHIP in disease. A greater understanding of the driver genes associated with the development of CHIP could enable targeted screening and early intervention strategies to manage potential risks, and may lead to the discovery of potential novel therapeutic targets for CHIP-associated diseases. While several driver genes such as DNMT3A, TET2, ASXL1, JAK2, and SRSF2 have been well-studied, much remains to be discovered. In this study, we conducted a comprehensive investigation of the phenotypic associations of genetic variants in known CHIP driver genes and sought to identify novel CHIP driver genes. We first performed phenome-wide association studies for burdens of genetic variants in known CHIP driver genes using exome sequencing and phenotypic data from the UK Biobank. We then employed a novel genome-wide clustering method to discern patterns of associations across these genes, and identified consistent clusters of associations across a range of phenotypes including hematological phenotypes, inflammation, and cancer, in particular hematological malignancies. Building upon these findings, we employed our clustering method to identify new CHIP driver genes that exhibit similar patterns of associations to known CHIP driver genes. We identified several novel genes with clusters of associations that match those observed in known driver genes and with plausible biological mechanisms for influencing CHIP. This study demonstrates the utility of large-scale biobanks with exome sequencing data paired with phenotypic information for both the identification of CHIP and expanding our understanding of the role of CHIP in disease. Further, this study highlights the potential of our pattern-matching approach for discovering potential new CHIP driver genes that may contribute to early risk detection and the development of intervention strategies for hematological malignancies and other CHIP-associated diseases. This research has been conducted using the UK Biobank Resource under Application Number 34229.

PB4202 Identifying associations of rare noncoding variants with autism through integration of gene expression, sequence and sex information

Authors:

R. Li, J. Ernst; Univ. of California, Los Angeles, Los Angeles, CA

The growth of whole-genome sequencing (WGS) data has facilitated genome-wide identification of rare noncoding variants. However, elucidating these variants' associations with complex diseases remains challenging.
To better understand these associations we first revisit a previous report of significant brain-related noncoding association signals of autism spectrum disorder (ASD) detected from *de novo* variants in the Simons Simplex Collection (SSC) WGS data when using a deep-learning-based pathogenicity score. We first demonstrate that local GC content is sufficient to capture association signals in variants near brain-expressed genes similar to those previously reported based on deep learning. Additionally, we show that this local GC content signal is specific to male probands with a female sibling (minimum p-value in brain tissue=$1.3x10^{-4}$) compared to male probands with a male sibling (minimum p-value in brain tissue=0.31). We further show among male probands and female siblings the signal is specific to variants upstream of their assigned TSS (minimum p-value in brain tissue=$3.3x10^{-6}$ for upstream variants vs. 0.057 for downstream variants).
Based on these findings, we developed an approach, k-mer-based gene expression neighborhood test (KGNT), to more systematically consider gene expression and sequence information for testing for association signals. KGNT first organizes variants into "neighborhoods" based on their assigned genes and pairwise gene expression correlations determined based on a large compendium of expression data. Then for each neighborhood KGNT tests for associations between the variants' k-mer distributions and phenotype. Applying KGNT to the SSC *de novo* variants upstream of TSS in male proband-female sibling families, we identified ASD association signals with 6-mers ($p=1.7x10^{-9}$ for the top neighborhood), surpassing the association using GC content ($p=1.2x10^{-7}$ for the top neighborhood). From the top neighborhoods, we extracted specific 6-mers driving the proband-sibling difference beyond GC content. Genes associated with top neighborhoods showed the strongest enrichment for synapse and some other brain-related gene ontology terms. In addition, we examined the chromatin state assignments of the variants in the top neighborhoods and observed sibling variants preferentially in quiescent states.
In summary, we identified using local GC content an ASD association signal from *de novo* noncoding variants in male probands with female siblings upstream of brain-expressed genes, which we were able to further refine and enhance with KGNT.

PB4203 Identifying common genetic susceptibility underlying co-morbid phenotypes using binomial regression.

Authors:

P. Panja[1,2], S. Bhattacharjee[2]; [1]Regional Ctr. for Biotechnology, Faridabad, India, [2]Natl. Inst. of BioMed. Genomics, Kalyani, India

The models suggested in multiphen and bamp provide an alternative to study population based genetic association with multivariate phenotypes by exploring the dependence of genotype on phenotype instead of the naturally arising dependence of phenotype on genotype. However, these approaches test the null hypothesis of no association with any of the constituent traits versus the alternative hypothesis of association with at least one of the constituent traits of the multivariate phenotype vector. Thus, such tests do not provide evidence of pleiotropy or common genetic factors underlying all the traits constituting the multivariate phenotype, which might be correlated. With respect to a pair of co-morbid phenotypes (both binary, a combination of binary and quantitative or both quantitative), we aim to modify the proposed bamp (binomial regression based association of multivariate phenotypes) approach to test the null hypothesis of no association with at least one of the phenotypes versus the alternative hypothesis with both the phenotypes. Identifying the pleiotropy of two diseases is important to decipher the underlying molecular events of two correlated phenotypes. Likelihood ratio test (lrt) will be used for this purpose. Proposed method can also differentiate between mediated pleiotropy and horizontal pleiotropy. Extensive simulations would be done for different values of correlation coefficients between the two comorbid traits to identify the power of the test and to compare the power of the same model which has used multiple testing correction instead of considering a multivariate phenotype vector. p { line-height: 115%; margin-bottom: 0.25cm; background: transparent }p { line-height: 115%; margin-bottom: 0.25cm; background: transparent }

PB4204 Identifying demographic, socioeconomic, behavioral, and environmental factors contributing to disparities in the prevalence of sepsis

Authors:

A. Biji[1,2], M. Stapylton[2], S. Cullina[1,2], G. M. Belbin[3], E. E. Kenny[2,4,5], S. Asgari[5,2,4]; [1]Graduate Sch. of BioMed. Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Inst. for Genomic Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Gencove Inc., New York, NY, [4]Dept. of Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Dept. of Genetics and Genomics, Icahn Sch. of Med. at Mount Sinai, New York, NY

Background: Sepsis is the body's extreme reaction to an infection. It is the second cause of in-hospital deaths and the most expensive inpatient medical condition in the US, with the highest incidence among African American/Africans (AA) and Hispanic/Latin Americans (HL). Thus, identifying potential factors that cause racial/ethnic disparities in sepsis prevalence is a public health priority. **Methods**: We investigated the incidence of sepsis in the *BioMe* biobank (N = 50292, ages: 18-105, median (m) = 52.32). Sepsis cases (N = 871 including 245 AA and 353 HL) were assigned any of the following ICD10 codes: A40, A41, R65.20, and R65.21, and controls (N = 49421) did not have any of these codes. We used a logistic model with sepsis as the outcome and sociodemographic covariates as predictors after accounting for age, sex, and 10 genotyping principal components. **Results**: Compared to self-reported European Americans (EA), we found a significantly higher sepsis burden in self-reported AA (odds ratio (OR) = 2.45 [95% CI 2.02-2.98], p-value (p) = 4.9e-19) and HL (1.98 [1.65-2.38], p = 2.7e-13). Self-reported ancestry groups are too broad and do not capture differences in sub-populations. So, we assigned population groups based on recent, shared genetic ancestry (identity-by-decent (IBD), Belbin G et al, Cell 2019) and observed a similar trend of significantly higher sepsis burden in AA (1.98 [1.58-2.49]) and HL (1.9 [1.53-2.36]) IBD communities than in Europeans. Puerto Ricans (OR 2.13) and Dominicans (OR 1.63) showed different sepsis burdens, a distinction that is missed when only using self-reported ancestry. We tested 55 sociodemographic factors, 24 of which were significantly ($p < 9.1e-4$) associated with sepsis, with kidney disease, age, and diabetes being the top three risk factors. We observed that the median age of sepsis diagnosis was significantly lower in AA (m = 58.6, p = 1.4e-05) and HL (m = 57.8, p = 1.4e-4) compared to EA (m = 64). Within age groups, sepsis risk was significantly higher in younger (< 50) AA (2.95 [1.92-4.53]) and HL (3.04 [2.04-4.54]) compared to same-age EA. This is notable because while sepsis in older adults may not be preventable due to age-related comorbidities, it can be preventable in younger patients. We are currently exploring the relative contribution of all significantly associated sociodemographic factors to racial/ethnic disparities in sepsis risk. **Conclusion**: By leveraging biobanks we can replicate known epidemiological trends of racial/ethnic disparities in sepsis and explore sociodemographic risk factors in diverse populations, enabling the development of targeted preventive measures for sepsis.

PB4205 Identifying risk genes from copy number variations by statistical fine mapping

Authors:

B. Jiang[1], M. Qiao[1], P. Carbonetto[1], K. Tayeb[1], W-P. Lee[2], X. He[1], G. Wang[3]; [1]Univ. of Chicago, Chicago, IL, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Columbia Univ., Fort Lee, NJ

Copy number variations (CNVs) are important sources of genetic variations. Many CNVs have been associated with a number of human diseases and phenotypes. CNVs, however, often span multiple genes, making it difficult to identify causal genes underlying the associations. Existing gene association analysis methods cannot distinguish between casual genes and nearby non-causal genes that are similarly disrupted by CNVs. In this study, we developed a statistical method, borrowing ideas from statistical fine-mapping in genome-wide association analysis (GWAS), to identify causal genes from CNVs. Our method, CNV-Mapper, is based on a regression model that jointly analyzes all genes in a region and infer the effects of CNV disruption of these genes on the phenotype. By using a sparse prior, CNV-Mapper encourages the selection of one or few causal genes that drive the CNV association, and reports Posterior Inclusion Probabilities (PIPs), which are probabilities that any genes are causal given the data. Thus CNV-Mapper not only reports potential causal genes, but quantifies the uncertainty of these predictions. CNV-Mapper is able to handle both quantitative traits, and case-control data. To evaluate the performance of CNV-Mapper, we conducted realistic simulations by using parameters learned from real data and real breakpoints of CNVs. Our findings demonstrate that PIPs from CNV-Mapper are calibrated, meaning it effectively controls the False Positive rates at the specified levels. Compared with existing methods, CNV-Mapper is significantly better at classifying risk genes and non-risk genes. We are applying CNV-Mapper to data obtained from the Alzheimer's Disease Sequencing Project (ADSP), and will release CNV-Mapper as an R package. In summary, CNV-Mapper provides a much-needed statistical tool that translates CNV associations into knowledge of putative risk genes underlying human diseases.

PB4207 Impact of GWAS meta-analysis heterogeneity on polygenic prediction accuracy.

Authors:

Y. Wang, C-T. Liu; Boston Univ. Sch. of Publ. Hlth., Boston, MA

Introduction. A polygenic risk score (PRS) represents an individual's genetic predisposition for a particular trait or disease based on the cumulative effects of multiple genetic variants. Various PRS methods have leveraged genome-wide association study (GWAS) summary statistics that often derived from GWAS meta-analyses in a large-scale consortium to maximize statistical power. However, the impact of heterogeneity in effect sizes among cohorts on PRS predictive accuracy remains unclear. **Methods.** We conducted simulations to investigate the implication of heterogeneity on PRS performance. We simulated 20 independent cohorts (N=10,000 each) for each ancestry (AFR, EUR), using haplotypes from the 1000 Genomes Project Phase 3 reference panel. Heterogeneity was introduced for true causal effect size by varying genetic correlation levels across cohorts (rg = 1, 0.9, 0.6, 0.3). We performed GWAS for each cohort and meta-analyzed ten distinct cohorts with various proportions of AFR cohorts. We applied clumping and thresholding (C+T) to the meta-GWAS summary statistics and evaluated the predictive performance with the remaining AFR samples. We next re-constructed the PRS by excluding heterogeneous ($I^2 > 75$) variants. **Results.** The simulation study illustrated that the number of heterogeneous variants increased as genetic correlation decreased across cohorts. Generally, the PRS was more predictive with higher proportions of target ancestry-matched cohorts and larger cross-cohort genetic correlations. When rg=1, excluding heterogeneous variants substantially improved prediction accuracy for PRS built from multi-ancestry meta-GWAS, but not for single-ancestry meta-GWAS. However, when rg < 1, removing the heterogeneous variants reduced prediction accuracy for both single and multi-ancestry meta-GWAS. We will conduct real data analysis with the UK Biobank data and the summary statistics (without_UKB) from the Global Lipids Genetic Consortium (GLGC) meta-GWAS results. **Summary.** In conclusion, our study provides insights into the impact of between-study heterogeneity on polygenic prediction and highlights the potential to enhance prediction accuracy by incorporating heterogeneity measurements. This underlies the importance of sharing heterogeneity measurements with GWAS meta-analysis summary statistics for large-scale consortia.

PB4208 Improved Estimation of Functional Enrichment in SNP Heritability Using Feasible Generalized Least Squares

Authors:

Z. Xiong, T-Q. Thach, D. Zhang, P. Sham; The Univ. of Hong Kong, Hong Kong, China

Functional enrichment results typically implicate tissue or cell-type specific signaling or biological pathways in disease pathogenesis and as therapeutic targets. We propose generalized Linkage disequilibrium score regression (g-LDSC), a novel method that requires only genome-wide association studies (GWAS) summary level data to estimate functional enrichment. The method adopts the same assumptions and regression model formulation as stratified Linkage disequilibrium score regression (s-LDSC). While s-LDSC only partially utilizes LD information, our method utilizes the whole LD matrix which accounts for possible correlated error structure via a feasible generalized least squares estimation. We demonstrate through simulation studies under various scenarios, that g-LDSC provide less biased and more precise estimates of functional enrichment than s-LDSC, regardless of model misspecification. In an application to GWAS summary statistics of 15 traits from the UK Biobank, estimates of functional enrichment using g-LDSC were lower, and more realistic, than those obtained from s-LDSC. In addition, g-LDSC detected more significantly enriched functional annotations among 24 functional annotations for the 15 traits than s-LDSC (118 versus 51).

PB4209 Improvements in Disease Risk Predictions Resulting from a Novel System of Local Ancestry Informed Polygenic Risk Scores

Authors:

S. Kulm[1], G. Busby[1], A. Bolli[1], J. Kintzle[2], G. Botta[1]; [1]Allelica, New York, NY, [2]Allelica, New York City, NY

Polygenic risk scores (PRSs) can identify individuals of high risk for disease who may benefit from targeted medical care. Nearly all PRSs are evaluated upon the same ancestry group of which the original variant effect sizes were estimated. This procedure fails individuals of admixed ancestry as they are not of a single, clear ancestry group. We hypothesizes that by inferring the local ancestry of an individual we could improve the risk predictions of admixed individuals.

To test this hypothesis we first used the FLARE tool, with the 1000 Genomes as reference, to infer the ancestry at single variant resolution for 8,294 individuals of admixed ancestry from the UK Biobank. To each continental ancestry specific segment we applied 150 difference panels of variants effect sizes designed to predict the risk of coronary artery disease. Under ten fold cross validation we created a ensemble PRS for each ancestry segment using the training fold and compared its performance in the testing fold to the single panel that was found to work best across the entire region of the genome.

Logistic regression models that adjusted for age and the top four genetic principal components, containing the sum of the ancestry-specific PRSs generated a lower brier score (0.05730 SE = 0.00256) than the PRS created from a global ancestry approach (0.05744 SE = 0.00252). Furthermore, the PRSs generated from just the majority specific ancestry segment, led to lower brier scores than the single global PRS when applied to groups whose ancestry were over 80% African, European or South Asian.

While improvements can be made that limit the use of discrete ancestry groups, this procedure provides one of the first large-scale examples of how local ancestry information can be practically combined with the traditional PRS creation process. Ongoing work shows that the improvement identified for coronary artery disease also extends to breast and prostate cancer. As a result, the predictive benefits of PRSs may now be more equitably applied to a wider share of individuals.

PB4210 Improving Diagnostic Specificity of Polygenic Risk Scores: A Methodological Approach Combining Large Biobank-Scale Data and Target Phenotype Cohorts with Limited Sample Sizes.

Authors:

Y-C. Lin[1], D. Pal[2], L. Strug[1]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]King S Coll. London, London, United Kingdom

Polygenic risk scores (PRS) are increasingly being developed on large biobank-scale data to improve the prediction of genetic susceptibility to complex traits, which relies on large sample sizes. However, biobank-scale data can lack phenotypic specificity, leading to PRS being defined in cohorts with increased phenotypic heterogeneity and suffering from biased effect size estimates. The resulting PRS are thus not specific for the clinical samples where their application might be the most beneficial. For instance, cohorts with Idiopathic Generalized Epilepsy (IGE) have been used to construct PRS for Juvenile Myoclonic Epilepsy (JME), a sub-type which would benefit from the availability of specific biomarkers. IGE-PRS is correlated with many epilepsy subtypes (e.g., AUC; Rolandic Epilepsy (RE): 0.75; Electrical Status Epilepticus in Sleep (ESES): 0.63) including JME (AUC: 0.69), and therefore cannot offer diagnostic specificity which would be helpful in the clinic. Here we ask whether one can refine a PRS such as the IGE-PRS to improve specificity for sub-types such as JME, particularly when we only have access to (significantly smaller) genomic data from the JME clinical samples? We propose a framework that incorporates both the effect sizes from biobank scale GWAS of related phenotypes and the statistical evidence (e.g., p-values) obtained from GWAS on the specific phenotype of interest (e.g., JME) as penalized weights. We apply the methodology to (1) the IGE-JME example and (2) a second example that uses a large-scale attention deficit hyperactivity disorder (ADHD) GWAS to improve a smaller PRS of impulsivity (a component trait of ADHD) in JME measured by the Barratt Impulsivity Scale (BIS). We show that the derived JME-specific PRS is no longer correlated with the epilepsy subtypes (AUC; RE: 0.56; ESES: 0.53) but remains strongly correlated with JME (AUC: 0.75). We further show that for the BIS-PRS there is a three-fold improvement in predictive capacity compared to using the ADHD cohort alone (R^2; ADHD-PRS: 2.2%; BIS-PRS: 7.8%). Our framework represents a holistic approach to combine and learn from limited sample sized clinical cohorts and GWAS summary statistics derived from large biobank-scale data, to improve PRS predictive capacity for the phenotype of interest. We propose one such methodological approach to combine these data for improved predictive capacity. Although large biobank-scale data has provided unique opportunities to generate replicable PRS, improved applicability in the clinic can still be derived from the incorporation of clinically refined samples to improve external validity.

PB4211 Improving genetic analyses of cardiovascular traits via Multimodal REpresentation learning for Genetic Discovery on Low-dimensional Embeddings (M-REGLE)

Authors:

Y. Zhou[1], J. Cosentino[2], C. McLean[1], F. Hormozdiari[1], B. Behsaz[1]; [1]Google, Cambridge, MA, [2]Google, San Francisco, CA

EHR systems containing multiple high-dimensional clinical data (HDCD) modalities (e.g., ECG, PPG, MRI) for each individual provide a unique opportunity in clinical diagnosis and genetic studies of complex traits as multiple modalities relevant to a single organ system (e.g., circulatory system) may encode complementary information. We propose a novel deep learning method (M-REGLE) to discover genetic associations on multiple complementary HDCD and showcase its effectiveness for cardiovascular modalities. In M-REGLE, we jointly learn a lower representation (i.e., latent factors) of multimodal HDCD using a convolutional autoencoder (CAE) and then perform GWAS on each latent factor to study the genetics of the underlying system. To validate the advantage of M-REGLE's multimodal learning, we compare it to single modal learning where representations are learnt on each data modality separately and downstream analyses are performed on the summation of all representations.
We demonstrate the utility of M-REGLE on cardiovascular traits in UK Biobank by jointly modeling 12 leads of ECG and PPG waveforms. We trained multiple CAEs: i) trained on each ECG lead individually (SCAE-12E), ii) trained jointly on 12 leads (MCAE-12E), iii) trained individually on lead I ECG and PPG (SCAE-EP), and iv) trained jointly on lead I ECG and PPG (MCAE-EP). As baselines for comparison, we compute PCA on the same four input data settings. Multimodal learning produced better latent representations than single modal (MCAE-12E reconstruction MSE = 7.3e-5 vs SCAE-12E = 2.62e-4, MCAE-EP = 2.1e-4 vs SCAE-EP = 2.4e-4) and CAE outperformed PCA (MPCA-12E = 7.7e-5, MPCA-EP = 3.7e-4).
To show that M-REGLE improves statistical power, we performed GWAS on uncorrelated latent factors and then combined their GWAS. MCAE-12E detected 275 genome-wide significant (GWS) hits (20 more than SCAE-12E), 243 of which have been reported for ECG-related traits in the GWAS catalog. We then calculated the $E[X^2]$ statistics on all GWAS catalog variants for ECG-related phenotypes. We observed a significant power increase for MCAE-12E compared to the second best method (SCAE-12E) ($E[X^2]$= 130.6±2.4 vs 89.2±1.8; P<5.0e-38). GWAS performed on MCAE-EP showed a similar pattern: MCAE-EP detected the largest number of GWS hits, rediscovered the most known ECG-related hits, and improved GWAS power (46.2±1.0 vs 39.7±0.8 for SCAE-EP). CAE GWAS show significant cardiovascular functional enrichments (56-66 unique terms) and improve enrichment power over PCA (SCAE-12E over SPCA-12E, P=1e-10). We believe M-REGLE will become a standard method for using multimodal HDCD for GWAS and downstream analyses.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4212 Improving the understanding of psychiatric disorders using multivariate analysis of brain phenotypes

Authors:

A. Auvergne[1], N. Traut[1], L. Troubat[1], L. Henches[1], H. Julienne[1], A. Frouin[1], C. Boetto[1], S. Kazem[2], R. Toro[1], H. Aschard[1]; [1]Inst. Pasteur, Paris, France, [2]CHU Sainte-Justine, Montreal, QC, Canada

There are increasing evidences of genetic correlations between psychiatric disorders and brain magnetic resonance imaging (MRI) phenotypes. However, deciphering the joint genetic architecture of these outcomes has proven challenging, and new approaches are needed for inferring potential genetic structure underlying those phenotypes. Here, we demonstrate how multivariate analysis can reveal links between brain phenotypes and psychiatric disorders missed by univariate approaches.

We first conducted univariate and multivariate genome-wide association studies (GWAS) for eight MRI-derived brain volume phenotypes in 20K UK Biobank participants, using JASS, a robust multitrait analysis pipeline we recently developed. We then clustered these variants based on their multitrait association with MRI phenotypes using an optimized k-medoids approach along an innovative data-driven algorithm for selecting the number of clusters. We conducted enrichment analysis to assess whether and how these various (univariate, multitrait, and cluster) can distinguish disease-associated and non-disease-associated variants from six psychiatric disorders: bipolarity, attention-deficit/hyperactivity disorder (ADHD), autisms, schizophrenia, obsessive-compulsive disorder and major depressive disorder.

Univariate GWAS display only negligible genetic correlation with psychiatric disorders and top variants did not show any enrichment for association with psychiatric disorders. Conversely, the multitrait GWAS, which identified 49 significant loci including 27 not detected by the univariate analysis, show significant enrichment at top variants with both ADHD and schizophrenia ($P<10^{-7}$). The cluster-based analysis also detected two clusters of variants with enrichment for association with ADHD (P = 3.04e-9) and schizophrenia (P = 6.3e-10) and also a concordant direction of signals. By construction, those associated clusters correspond to linear combination of the volumetric phenotypes studied, and we argue that they can be interpreted as latent brain phenotypes. Altogether, this approach can demonstrate how multitrait analysis can be used to infer genetically driven neuroanatomical latent structure associated with psychiatric disorders.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4213 ImputeTrans: a transformer-based deep-learning tool for genotype imputation

Authors:

J. Fu[1], U. An[1], J. Choi[1], A. Ament[1], E. Eskin[2], S. Sankararaman[3]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Univ. of California Los Angeles, Los Angeles, CA, [3]UCLA, Los Angeles, CA

Genotype imputation is a computational strategy that predicts unobserved or missing genotype values to approximate whole-genome sequencing data. It is a foundational tool for fine mapping and identification of causal variants, which further facilitates meta-analysis that combines results from multiple studies, and increases the power of genome-wide association studies. Genotype imputation reduces expense and efforts for large-scale studies such as genome-wide association studies (GWAS) without losing much accuracy.
Currently, most state-of-the-art methods in this area employ a Hidden Markov Models (HMM) framework, while some others apply positional Burrows-Wheeler-Transform (pBWT). However, standard statistical methods may suffer in performance when working with regions involving complex linkage disequilibrium regions. In recent years, deep learning methods has proved its capability and suitability in imputation, and it has been widely-used in many areas such as imputation tasks including image imputation, as well as natural language processing such as sequence translation tasks. Recently, deep learning methods that incorporate autoencoders and transformer have also been developed for genotype imputation, which prove a relatively fast and accurate performance compared to some standard statistical methods, and requires no further access to a reference panel. However, these methods has not gone thorough comparison with other state-of-the-art methods.
Therefore, we present a fast and scalable method, ImputeTrans, which adapts a transformer-based deep learning method as a framework to impute genotypes. We evaluate this method comprehensively against current state-of-the-art methods in different scenarios. We show that our method achieves a robust and accurate performance and scalability, and gain improvements in certain aspects compared to standard methods.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4214 † Incorporating annotation stratified genetic covariance across complex traits to improve polygenic risk prediction

Authors:

C. Zhang[1], H. Zhao[2], G. Zhou[3]; [1]Yale Univ., new haven, CT, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT, [3]Yale Univ., New Haven, CT

In recent years, the rapid development of novel polygenic risk score (PRS) methods have led to the widespread utilization of PRS in disease prevention, monitoring, and treatment. However, the accuracy of genetic risk prediction remains moderate. Currently, most PRS were built based on the summary statistics from the target trait, while many traits exhibit some degree of shared genetic architecture or pleiotropy dependent on the functional annotation. Appropriate leverage of pleiotropy and functional annotation can potentially improve the performance of PRS. In this study, we present PleioSDPR, a novel statistical method designed to leverage pleiotropy by integrating genome-wide association study summary statistics from various complex traits. PleioSDPR characterizes the joint distribution of effect sizes across different traits to be null for all traits, only causal in one trait, and causal in multiple traits with different functional and non-functional genetic covariance. Through extensive simulations and real trait applications, we demonstrate that PleioSDPR significantly improves prediction performance compared with PRScsx, SDPRx, and also weighted combinations of PRSs derived from LDpred2 and PRScs. For example, by incorporating information from schizophrenia (N = 130,644) or Neuroticism (N = 63,661), PleioSDPR effectively improves the prediction accuracy of bipolar disease(N = 353,899) and major depressive disorder (N = 142,646), respectively. Moreover, our findings demonstrate that traits exhibiting high genetic correlations and low overlapping sample sizes help more to the improvement of prediction accuracy of the target disease. Overall, our study highlights the potential of PleioSDPR to enhance the accuracy of genetic risk prediction by leveraging pleiotropy and considering a broader spectrum of traits and diseases. These findings contribute to the understanding of polygenic risk prediction and underscore the importance of incorporating pleiotropic information for improved utilization in disease prevention and treatment strategies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4215 Incorporating external risk information with the Cox model under population heterogeneity: Applications to trans-ancestry polygenic hazard scores.

Authors:

D. Wang[1], W. Ye[1], J. Zhu[1], G. Xu[1], W. Tang[2], M. Zawistowski[1], L. Fritsche[1], K. He[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Harvard Univ., Boston, MA

Background: Polygenic hazard scores (PHS) offer valuable insights for survival risk discrimination, yet these models, predominantly developed for European ancestry (EUR) individuals, encounter substantial limitations when applied to non-EUR populations. The inherent heterogeneity between external EUR-based PHS and internal non-EUR individual-level data can introduce substantial bias. To address this challenge, we propose a novel method designed to effectively integrate survival risk information across diverse populations, thereby enhancing the prediction accuracy of PHS models for non-EUR cohorts. **Methods:** Here, we develop a Kullback-Leibler (KL)-based Cox model (CoxKL) to incorporate external risk scores derived from published EUR-based PHS models with internal non-EUR genotype data with time-to-event outcomes. To adjust for population heterogeneity, partial-likelihood-based KL information is utilized to measure the discrepancy between the external risk information and the internal data. We also establish the asymptotic properties of the CoxKL estimator. **Results:** Simulation studies show that the proposed CoxKL method drastically improves both estimation efficiency and prediction accuracy. We applied the Cox method to develop trans-ancestry PHS models for prostate cancer and breast cancer in African ancestry (AFR) individuals. By integrating EUR-based PHS with internal AFR genotype data, the trans-ancestry PHS models by CoxKL method yielded considerable improvements on the risk discrimination of prostate cancer (C-Index: 0.68 [CoxKL PHS]; 0.54 [EUR-based PHS]; 0.49 [AFR-based PHS]) and breast cancer (C-Index: 0.83 [CoxKL PHS]; 0.53 [EUR-based PHS]; 0.50 [AFR-based PHS]). **Conclusion:** Our proposed CoxKL method serves as an accurate, efficient, and stable data integration tool, with an important application in developing trans-ancestry PHS models and enhancing survival risk discrimination in non-EUR populations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4216 Incorporating information from relevant endophenotypes improves polygenic risk score prediction for asthma.

Authors:

E. Kharitonova[1], F. Ockerman[1], Q. Sun[1], L. Zhou[1], H. Cao[2], L. Raffield[1], A. P. Reiner[3,4], N. Cox[5], S. Kelada[1], R. Tao[5], Y. Li[1]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Florida State Univ., Tallahassee, FL, [3]Univ. of Washington, Seattle, WA, [4]Fred Hutchinson Cancer Res., Seattle, WA, [5]Vanderbilt Univ Med Ctr., Nashville, TN

Current polygenic risk scores (PRS) for complex traits suffer from poor predictive performance. This is partially caused by the inability of studies to identify all genetic variants associated with a disease due to the limited number of cases in study populations. Since inflammation and immune response are known to contribute to a variety of health conditions, we hypothesized that endophenotypes could be used to improve PRS models. We focused on asthma as a test case as it is a common, chronic lung disease that is characterized in part by inflammation that typically features eosinophil and lymphocyte recruitment to the airways. As such, we reasoned that incorporating genetic variants into the asthma PRS model that have been identified to be associated with well-powered quantitative blood cell traits, i.e., endophenotypes, even if they have not yet been shown to be associated with asthma should improve the prediction power of the PRS model.

Here, we developed a novel PRS method which incorporates genetic information from endophenotypes. First, genetic variants associated with the clinical endpoint of interest and those associated with relevant endophenotypes are identified. Next, the selected variants are used to create a polygenic risk score through penalized regression, by weighting the variants based on whether they are associated with the clinical endpoint, the endophenotypes, or both. Unlike previous studies that developed polygenic risk scores based on the PRSs of many associated traits, our method integrates genetic variants from the endophenotype summary statistics directly into the PRS for the clinical endpoint without generating separate risk scores for each endophenotype.

We applied the novel polygenic risk score method to European individuals in UK Biobank to generate a PRS for asthma that incorporates genetic information from selected relevant blood cell traits (eosinophil count and lymphocyte percentage). We found that the proposed method significantly improves the prediction of asthma compared to most current PRS methods, including those designed for multiple traits (such as PRSice2, LDpred2, penalized regression, multi-PRS elastic net, and wMT-SBLUP) in a held-out test set of European individuals from UK Biobank.

In conclusion, we found that relevant endophenotypes can be used to improve polygenic risk score performance for asthma. However, due to the heterogeneity of asthma phenotypes, it is expected that this method's improvement in risk score prediction of asthma will vary in different cohorts based on the distribution of asthma subtypes in the populations of interest.

PB4217 Incorporating local ancestry information to predict genetically driven CpG methylation from SNP genotype data

Authors:

Y. Cheng, H. Li, A. Justice, K. Xu, H. Zhao; Yale Univ., New Haven, CT

To integrate results from genome-wide association studies (GWAS) with gene expression data from eQTL studies, transcriptome-wide association study (TWAS) has been developed, which aims to impute gene expression from SNP genotype data, and investigate its association with phenotypes. This framework has been widely used to identify the role of gene expressions in complex traits and to illustrate the path from genotype to expression, and then to phenotypes. It is also of interest to investigate this path with gene expression replaced by DNA methylation (DNAm), which plays an important regulatory role in complex phenotypes. Fryett et al. has extended the TWAS framework and proposed a methylome-wide association study (MWAS) model to impute DNAm from genotypes. However, their training and testing DNAm data are measured using array-based platforms, which profile only a small proportion of CpG sites in the human methylome. Also, the datasets used in their imputation model are based on a British ancestry population, which has limited utility to be applied to non-European populations. To address these gaps, we utilized Methylation Capture Sequencing (MC-seq) data in an admixed cohort (African Americans) to establish an MWAS framework. Our model was fitted by elastic-net regularized linear model, in which we incorporated the ancestral heterogeneity across genomic regions (local ancestry (LA)) to improve the DNAm prediction. Incorporating LA in our model enabled us to detect and control different genetic effects of each SNP by ancestry groups and allowed the model to be applied to cohorts with African, European, or admixed African and European ancestral backgrounds. Our MWAS framework was established using genomic data from the Veterans Aging Cohort Study (VACS) with a total of 2,244 participants. Among them, 377 samples self-reported as African Americans had DNAm data profiled by MC-seq, and this subset was used to train models. The remaining samples without MC-seq data were used as an application set to test the association between imputed methylation and phenotypes of interest. Using the tenfold cross-validation R^2 (the square of the correlation between predicted and observed methylation) in the training set, and R^2 in an independent testing set, we compared our model with the conventional model without LA information and demonstrated that our model improved the prediction R^2 (paired t-test p-value = 1.77E-139 in the training set, 5.69E-14 in the testing set). These findings highlight the importance of incorporating LA in MWAS frameworks for an admixed population.

PB4218 Incorporating short tandem repeats (STRs) improves genetic predictions of gene expression.

Authors:

M. Lamkin[1], Y. Li[1], H. Ziaei-jam[1], M. Gymrek[2]; [1]Univ. of California, San Diego, San Diego, CA, [2]Univ California San Diego, La Jolla, CA

Transcriptome wide association scan (TWAS) utilizes the imputation of gene expression from genotype datasets in order to identify expression-trait associations, which can help identify potential causal genes and cell types underlying complex traits. Multiple methods for predicting gene expression from genotypes exist, but all limit feature selection to common single nucleotide polymorphisms (SNPs) and thus may not capture variation in expression driven by other variant classes. Short tandem repeats (STRs), which consist of consecutively repeated units of 1-6bp are among the most polymorphic regions of the human genome. Recent studies have identified thousands of STRs for which variation in repeat length across individuals is associated with complex traits including gene expression. Here, we extend TWAS models to incorporate both linear and non-linear effects of STRs.
To train and test our linear models, we focused on 359 European individuals from the 1000Genomes Project, for which we have previously generated genome-wide STR genotypes and for which expression data for lymphoblastoid cell lines has been generated by the Geuvadis Project. Prior to training, we filtered and quantile normalized expression data and regressed out PEER factors, top 3 ancestry principal components, and sex. We used 5-fold cross validation to train and evaluate four different linear models, linear regression, Lasso regression, Ridge regression, and ElasticNet regression. For each linear model tested, we generated three feature sets: only SNPs, SNPs + linear STR effects, and SNPs + both linear and non-linear (quadratic) STR effects. These models were evaluated with an R squared score and compared to the prior state of the art models generated by TWAS / FUSION. Overall, when tested on twenty genes we saw that the STR models outperformed SNP models in six of the twenty. When testing on genes with current known eSTRs such as TIMM10 and CSTB, we saw an increase in R squared from the SNP Lasso model to the SNPs + linear STRs Lasso model by 0.028 and 0.038 respectively. We also saw an increase in the R squared of 0.038 and 0.054 when compared to the SNPs + both linear and nonlinear STRs Lasso model. Given these results, we've seen that incorporating STRs into the gene expression imputation models has increased predictive power of these models. Overall, our results suggest STRs explain additional heritability of gene expression and result in improved genetic predictors of gene expression.

PB4219 Increasing the Power of the Sequence Kernel Association Tests (SKAT) with Common Variant eQTLs

Authors:

Y. Yang[1], W. Bush[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ, Cleveland, OH

Rare alleles arise from mutations on an existing haplotype background. However, current gene-based tests for rare-variants generally consider the impact of low-frequency coding variants as an independent effect from the more commonly occurring regulatory variants that surround them. In this work, we propose to increase the statistical power of kernel-based rare-variant association tests by accounting for the surrounding cis-regulatory variant's effects on gene expression. This method incorporates common variant cis-eQTLs around the gene or SNP-set of interest as a fixed effect by estimating their impact on gene expression. We estimate gene expression changes using PrediXcan association models as a covariate. SKAT is then used to test for the residual random effect of coding rare-variants. We perform comprehensive simulation studies that demonstrate the biological conditions under which our method can substantially increase power, while maintaining the type I error in the absence of association. SKAT is known to perform best when a high proportion of test variants have a causal effect, and when these effects are in the same direction. Our proposed method improves the power of SKAT where a low proportion(<10%) of tested variants have small mixed effect sizes (OR<1.0), more closely resembling real world variant effects. We also simulate a range of effect sizes for gene expression, to provide insight into the relationship between eQTLs and rare variants. Power analyses were performed with both exact p-values computed via the Davies method and with p-values derived empirically through permutation tests.We applied our approach to real data from the Alzheimer's Disease Sequencing Project for the amyloid precursor protein (APP) gene as a proof of principle. Our general approach can be extended to all current set-based rare variant association tests whose performances are also likely dependent on the impact of surrounding regulatory variation. This approach can then be extended to jointly consider multiple contributing genes in the same pathway, providing further information to detect rare variant effects.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4220 Inferring susceptibility of multiple populations to TCDD using estimates of its interaction with aryl hydrocarbon receptor (*AHR*) variants.

Authors:

U. Chimeh, M. C. Rogers, D. L. Aylor; North Carolina State Univ., Raleigh, NC

Current genetic literature mostly represents people of European ancestry and, consequently, does not adequately account for variants that are uncommon in European populations. Despite this deficit, we propose that information about trait variation in understudied populations can be gleaned from the variants that they share with studied populations. Here, we use the frequencies of single nucleotide polymorphisms (SNPs) in a well-studied nuclear receptor, aryl hydrocarbon receptor (AhR), to predict population risk. AhR is essential in the metabolism, and thus, the toxicity of compounds such as 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD) and polycyclic aromatic hydrocarbons (PAHs). The highest recorded TCDD exposure happened in 1976 in Seveso, Italy, from an industrial plant explosion. TCCD exposure from this accident differentially decreased offspring birthweight in individuals with different variants of 6 *AHR* SNPs.

We predict birthweight in multiple populations if they were similarly exposed to TCDD. To do this, we integrate the Seveso estimates of *AHR*-TCDD interaction with *AHR* variant frequencies in these populations. AHR variant frequencies were obtained from a public repository of human variation established by The 1000 Genomes Project. We identified haplotypes from the 6 *AHR* SNPs and used the European haplotypes as a proxy for those in Seveso. Most haplotypes (96%) in the 1000 Genomes pool were shared between Europe and at least one other population. Based on the distribution of risk variants, we predicted that average birthweight would decrease the most in the admixed American population and the least in Europe after TCDD exposure. The same was true for the increase in the proportion of underweight births (birthweights below 2500g). These interactions between *AHR* and TCDD have yet to be replicated in other populations; however, the risk allele of one SNP, rrs2282885, has been associated with increased susceptibility to PAHs in coke-oven workers from China. Our results suggest that toxicant exposure will have disparate effects on populations with different risk variant frequencies. This sets a precedent for predicting population susceptibility to toxicants and other adverse exposures using the frequencies of functional risk variants.

PB4221 † Integrating EHR-based biobanks and GWAS summary statistics to predict the progression of autoimmune diseases from pre-clinical outcomes.

Authors:

C. Wang, H. Markus, L. Carrel, G. Foulke, N. Olsen, B. Jiang, D. Liu; Penn State Coll. of Med., Hershey, PA

Many autoimmune diseases have a preclinical stage where early symptoms start to appear, but full-blown disease has not developed. Developing biomarkers to inform disease progression from pre-clinical stage will be critical for slowing down progression and mitigating symptoms. With electronic health record (EHR)-based biobanks, it has become feasible to identify individuals with pre-clinical disease status by lab tests and calculate polygenic risk scores (PRS) for disease progressions. Compared to case control (CC) studies, EHR-based biobanks have much fewer number of cases. To combine the large sample sizes of CC and detailed phenotypes in biobanks, we propose a novel method called Genetic Prediction Score (GPS) to predict disease progressions from pre-clinical stage. GPS incorporates PRS weights for CC as prior via a penalty term that penalizes deviations of the parameter estimates from the prior. Using data-driven validations, GPS forces parameter estimates to be similar to the CC weights when the prior information helps improve prediction accuracy and trains the model using the biobank data alone if prior does not help. We conducted extensive simulations considering different sample sizes of patient cohorts, genetic correlations between progression and CC phenotypes, and trait polygenicity. We compared GPS with different PRS construction strategies including applying PRS methods (LDpred2, Lassosum, and PRS-CS) to biobank data only, stacking CC and biobank only risk scores, using MTAG to analyze CC and progression traits and generate PRS using MTAG results, and TL-PRS, a transfer learning-based method incorporating pre-trained CC weights. In all scenarios, GPS consistently achieved the highest or comparable prediction accuracy. The improvement was particularly significant leading to 2x to 4x improvements in R^2 when genetic correlation between CC and progression trait was low and when the biobank had a limited sample size. For applications, we analyze progression phenotypes of systemic lupus erythematosus (SLE) from antinuclear antibody positive and rheumatoid arthritis (RA) from rheumatoid factor positive individuals in the BioVU biobank, and then validate progression prediction in All of US biobank. GPS demonstrates the strongest agreement between PRS deciles and observed progression prevalence among individuals within each respective decile. Compared to the second-best method TL-PRS, the estimates are 0.749 vs 0.370 for RA and 0.508 vs 0.466 for SLE. In summary, GPS is a useful tool to predict disease progression from pre-clinical outcomes and will play a key role in extending utility of PRS in the era of precision medicine.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4222 † Integrating genetic data in Trial Emulation: Exploring the potential of Polygenic Risk Scores.

Authors:

J. German[1,2], A. Ganna[1], A. Philippakis[2]; [1]Inst. for Molecular Med. Finland, Helsinki, Finland, [2]Eric and Wendy Schmidt Ctr., Broad Inst. of MIT and Harvard, Cambridge, MA

Using genetic information to identify individuals that would most benefit from pharmacological intervention is a central goal of pharmacogenomic and precision medicine. However, naively approaches in large-scale biobank data is subjected to confounding, which limits interpretability. Trial emulation approaches are the state-of-the art methodology to ask causal questions using real world data, and they thus represent a promising venue to test the impact of genetics on differential treatment response, when randomized control trials (RCTs) are not available or too small. In this study, we aim to investigate the utilization of polygenic risk scores (PRS) in trial emulation designs using 429,191 individuals from FinnGen, a biobank-based study with comprehensively longitudinal drug purchases information from national registers. We selected and emulated four trials using the same methodology as the RCT Duplicate project, which is the largest RCT replication initiative. Two RCTs (EMPAREG, TECOS) focused on T2D patients and two on atrial fibrillation (ARISTOTELE, ROCKET). We achieved estimate agreement in 3 out of 4 trials when considering the overlap of confidence intervals (95% CI) between the original RCT and our trial emulation. First, we assessed how genetics can help understanding confounding effects present in observational data. In the EMPAREG trial we show that using a trial emulation approach (including propensity score matching) results in reduced differences in a PRS for T2D between the treatment and control cohorts compared to a naïve approach (standardized difference = 0.0042, P-value = 0.9089 and standardized difference = 0.0875, P-value = 8.75e-10 for trial emulation and naïve approach, respectively). Second, within the successfully emulated trials, we investigated the potential interaction between PRS for the trial outcome and the drug, aiming to identify subgroups with differential treatment response. No significant interaction was observed, indicating that PRS did not identify individuals with better treatment response. In conclusion, our work highlights the importance of trial emulation when studying genetic impact on differential treatment response in biobank studies, as genetic studies are not immune to traditional epidemiological bias. While the idea of integrating genetics into trial emulation is promising, overcoming the challenges of statistical power, even at the scale of half a million individuals remains a critical area of improvement.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4223 Integration of polygenic risk scores with clinical factors improves 10-year risk prediction of coronary artery disease

Authors:

P. Tshiaba, D. Ratman, J. Sun, T. Tunstall, R. Maier, P. Shah, M. Rabinowitz, A. Kumar, K. Im; MyOme, Inc, Menlo Park, CA

Background: Polygenic scores (PRS) have the potential to improve the accuracy of clinical risk tools and identify individuals at elevated risk of coronary artery disease (CAD) not captured by risk models based on traditional risk factors. However, generalizability across cohorts and populations remains a major challenge for PRS models.
Methods: We trained ancestry-specific ensemble models by combining internally developed with publicly available PRS models for CAD and type 2 diabetes. The cross-ancestry PRS (caPRS) is a weighted sum of ancestry-specific ensembles. Then, we combined the caPRS with the Atherosclerotic Cardiovascular Disease - Pooled Cohort Equation (ASCVD-PCE) to derive the integrated risk score (IRS), an absolute 10-year risk of developing CAD. We compared the performance of IRS against ASCVD-PCE overall and for each self-reported ethnicity in the 3 validation cohorts. Hazard ratios (HRs) were estimated with Cox proportional hazards models adjusted for age and sex to examine the association between an SD change in each predictor (caPRS, IRS or ASCVD-PCE) and 10-year CAD incidence. Model performance includes discrimination assessed with the Harell's C index, calibration comparing observed vs expected event probabilities, and net reclassification index using a 20% high risk threshold.
Results: The caPRS was significantly associated with 10-year CAD incidence across all validation cohorts, including non-European ethnicities, with HRs ranging from 1.35 (95% CI: 1.16-1-56) in Africans up to 1.82 (95% CI: 1.43-2.32) in South Asians. The IRS showed improved discrimination compared to the ASCVD-PCE in all validation cohorts and ethnicities tested. The largest gain in performance was observed in South Asian individuals with a 6% increase in C-index. The IRS was better calibrated than the ASCVD-PCE across all validation cohorts. For individuals classified as borderline/intermediate ASCVD-PCE risk (5-20%), the IRS reclassified between 6% and 10% of individuals into high-risk category with the relative risk of 10-year CAD incidence ranging from 3.22 (95% CI: 2.90-3.58, UK Biobank) to 3.67 (95% CI: 2.93-4.59, Atherosclerosis Risk in Communities). Identifying up to 16.3 additional CAD cases per 1K individuals in the borderline/intermediate ASCVD-PCE group.
Conclusions: Adding a PRS to a commonly used clinical risk tool more accurately identified people at high risk of developing CAD across diverse populations. The integrated risk score efficiently reclassified individuals at borderline/intermediate clinical risk to high-risk demonstrating potential utility to guide preventive interventions, such as statin therapy initiation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4224 † Integrative analysis of genetic studies and gene co-expression patterns highlights shared and distinct transcriptional mechanisms associated with asthma, COPD and asthma-COPD overlap (ACO) syndrome.

Authors:

M. Pividori[1], J. Joo[2], B. E. Himes[2]; [1]Univ. of Colorado, Aurora, CO, [2]Univ. of Pennsylvania, Philadelphia, PA

Asthma, chronic obstructive pulmonary disease (COPD), and asthma-COPD overlap (ACO) syndrome are complex respiratory disorders with some overlapping clinical features. Among the many genetic loci associated with asthma and COPD, some were shared with ACO, and a few potential ACO-specific loci have been observed. However, most of these studies have focused on individual variants and ignored context-specific gene-gene interactions.We performed GWAS using the UK Biobank (UKB), where we determined asthma-only status (n = 19,217) using ICD codes and self-reported doctor diagnosis, COPD-only status (n = 13,055) using spirometric evidence of moderate-to-severe airflow limitation by the modified GOLD criteria, and ACO status (n = 7,035) as those with asthma and COPD. Controls (n = 162,645) had none of these conditions. We then performed transcription-wide association studies (TWAS) for asthma-only, COPD-only, and ACO, and integrated them with gene co-expression modules learned from recount2, a large expression compendium. We used MultiXcan for TWAS to compute gene-trait associations. We defined 987 gene modules extracted with the Pathway-level Information Extractor matrix factorization approach on recount2, where a module represents a group of genes with similar expression profiles across the same contexts (such as tissues or cell types). We then computed gene module associations with asthma-only, COPD-only, and ACO by testing whether genes that were part of a module were more strongly associated than genes that were not. For associated modules, we conducted a phenome-wide analysis using additional gene module associations for more than 4,000 traits computed in UKB, and 309 phecodes in the Electronic Medical Records and Genomics (eMERGE) network phase III.We identified 24 significantly associated gene modules: 13 associations with asthma-only, 11 with COPD-only, and 6 with ACO. One of these modules, which was expressed in lung adenocarcinoma samples and was associated with smoking, neutrophils and rheumatoid arthritis in UKB and emphysema in eMERGE, was specifically associated with asthma-only and COPD-only. Four modules, which were expressed in different populations of tonsil innate lymphoid cells (ILCs) and associated with atopy, eosinophils and Crohn's disease in UKB, were specifically associated with asthma-only and ACO. Another module, which was expressed in lung and tonsil ILCs and associated with smoking in the UKB and atherosclerosis in eMERGE, was specifically associated with COPD and ACO.Our study highlights shared and distinct, context-specific gene modules that can help elucidate the genetic underpinnings of asthma, COPD, and ACO.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4225 Integrative multi-omics approach for improving causal gene identification

Authors:

C. Wu[1], A. King[2]; [1]UT MD Anderson Cancer Ctr., Houston, TX, [2]Florida State Univ., Tallahassee, FL

Transcriptome-wide association studies (TWAS) have become popular methods in exploring gene-trait associations, integrating gene expression datasets and genome-wide association studies (GWAS) to identify likely causal genes, thereby enhancing interpretability. Nonetheless, traditional TWAS approaches primarily focus on gene expression, making it challenging to prioritize causal genes due to linkage disequilibrium and correlations among gene expressions. Several other regulatory mechanisms, such as DNA methylation and splicing, substantially influence gene expression, contributing to the genetic underpinnings of complex traits and diseases. These mechanisms potentially provide orthogonal information useful for prioritizing causal genes. Here, we introduce a novel integrative omics model that aggregates gene expression, DNA methylation and splicing data to identify associated genes for our traits of interest. Specifically, we rely on gene expression, methylation and splicing prediction models in blood tissue based on data obtained from the eQTLGen Consortium, BIOS Consortium, and PredictDB group, respectively. These omics prediction models are then combined using an aggregated Cauchy combination test. By analyzing genome-wide association study (GWAS) summary statistics for 24 complex traits, we show that our integrated method, which leverages these complementary omics biomarkers, achieves higher statistical power, and improves the accuracy of likely causal gene identification in blood tissues than individual omics methods. Under Bonferroni correction, our innovative method identified 7,432 significant gene-trait pairs, outperforming TWAS (SUMMIT), MWAS, and splicing TWAS, which identified 3,478, 4,816, and 1,383 pairs, respectively. Moreover, our method demonstrated an AUC of 0.796 in identifying likely causal genes, reflecting a significant improvement over SUMMIT ($\Delta = 0.043$, p-value = 5.9x10-4) and MWAS ($\Delta = 0.024$, p-value = 9.3x10-4). Finally, we apply our integrated model to a lung cancer GWAS dataset, demonstrating the integrated models improved identification of prioritized genes for lung cancer risk.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4226 Intergenerational Socioeconomic Status and Genotype-by-Environment Interaction Impacting Metabolic Syndrome Traits: A Feasibility Study

Authors:

X. Mao[1], E. MANUSOV[2], V. Diego[1], E. Abrego[1], M. Almeida[1], J. Blangero[3], S. Williams-Blangero[1]; [1]Univ. of Texas Rio Grande Valley, Brownsville, TX, [2]Univ. of Texas Rio Grande Valley Rio Grande Valley, Brownsville, TX, [3]Univ. of Texas Rio Grande Valley Sch. of Med., Brownsville, TX

Background: Understanding the impact of intergenerational socioeconomic status (SES) and genotype interactions on metabolic syndrome severity among Mexican Americans is crucial. While previous studies have examined gene-environment interactions (GXE) in relation to health outcomes, limited research has explored the role of intergenerational SES, specifically parental education, in this context.
Objective: This feasibility study aims to elucidate the mechanisms underlying GXE interactions with respect to intergenerational SES factors. We hypothesize that parental education directly influences variations in offspring phenotypes, including BMI, lipids, and blood pressure (metabolic syndrome).
Methods: We employed Mendelian Randomization analysis to examine the causal effect of education on metabolic syndrome. The genetic instrumental variable effect (GIV-Wald ratio) was given by the ratio of the regression coefficient of the child's outcome on the GIV to the regression coefficient of the parent's exposure variable on the GIV. We calculated the Wald Ratio (W) using the Mahalanobis distance of gene expression variables related to adaptive immunity, innate immunity, and hemostasis systems, along with three parental exposure variables (education, income, and socioeconomic index), for waist circumference, blood pressure (SBP/DBP), triglycerides (TG), high-density lipoprotein (HDL), fasting glucose (FG), and fasting insulin (FI).
Results: The results of the Mendelian Randomization analysis and Mahalanobis distance calculations will provide insights into the causal relationship between parental education and offspring metabolic syndrome phenotypes.
Discussion: Parental SES has a direct impact on offspring outcomes through socioeconomic effects, and GXE effects of SES on metabolic syndrome phenotypes have been established. Investigating the intergenerational effects of SES through genetic variation is a novel approach. Utilizing the Wald-ratio from Mahalanobis distance as an instrument in the Mendelian Randomization as a quasi-randomized trial to investigate GXE effects represents another innovative aspect of this study.
Conclusion: This feasibility study utilizes a novel approach to analyze the interaction of genetic variation and phenotypes, employing a causal relationship model. The findings from this study will contribute to our understanding of intergenerational socioeconomic status effects on metabolic syndrome and inform future research in this area.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4227 Interplay between *EIF2AK4* and *HLA-DRA* genes is associated with human survival to the oldest old age: New findings from the UK Biobank data

Authors:

A. Yashin, D. Wu, H. Duan, R. Holmes, O. Bagley, A. Yashkin, I. Akushevich, K. Arbeev, S. Ukraintseva; Duke Univ., Durham, NC

Introduction: Experimental studies show that the *GCN2/EIF2AK4* gene, which is a major sensor of amino acid deprivation in the integrated stress response pathway, is involved in the regulation of aging and survival. The *HLA-DRA* gene belongs to the human leukocyte antigen gene family (class II region) which encodes molecules involved in response of adaptive immunity to infections which play important role in organism's survival. It remains unclear whether interplay of these genes is associated with human survival. The objective of this study is to test the presence of such connection using human data. **Method.** We estimated associations of interactions between SNPs in *EIF2AK4* and *HLA-DRA* genes in UK Biobank participants, with survival of their mothers (114,573-cases and 213,618-controls) and fathers (66,206-cases and 288,281-controls) using a logistic regression model with interaction. Education, sex, smoking status, and the first five genetic principal components were included as observed covariates. The primary outcome was the parent survival to age 85. Linkage Disequilibrium (LD) testing and the SNP-clumping procedure were used to reduce the number of tests in SNPxSNP interaction analysis of survival. **Results.** We found three statistically significant associations of interacting SNPxSNP pairs with mothers' survival (one SNP, rs35602605, in *EIF2AK4*, and three -- rs3129887, rs2239805, rs115317719 -- in *HLA-DRA*) with β coefficients ranging from 0.0508 to 0.0523, with p-values ranging from 2.37E-04 to 2.78E-04, and with the Bonferroni correction threshold 4.13E-04. The associations of interactions between SNP-pairs with fathers' survival were nominally significant and consistent with the results for mothers' survival. They involve the same three *HLA-DRA* SNPs interacting with rs2412463 and rs11635537 SNPs in *EIF2AK4*. The LD between these SNPs and rs35602605 is characterized by D'=1.0, R^2=0.10 for rs11635537, and D'=1.0, R^2=0.09 for rs2412463 SNPs, respectively. **Conclusion.** The observed associations between SNPxSNP interactions within the *EIF2AK4* and *HLA-DRA* genes and survival beyond age 85+ show consistency of mechanisms across biologic sex indicating that genetic machinery regulating survival in the part dealing with nutritional stress and immunity have overlapping components in males and females. These results also show that hypotheses about the role of genetic interactions in complex traits derived from experimental data can be tested using human data. More analyses will allow for a better understanding of the role of interplay between multiple genes in multifactorial regulation of human aging, health, and lifespan related traits

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4228 Interpretable machine learning models for pre-screening cardiomyopathies.

Authors:

M. Kasapi, K. McGurk, T. M. D. Ebbels, J. M. Posma, J. Ware; Imperial Coll. London, London, United Kingdom

Cardiomyopathies (CM) intervene with the normal function of the heart muscle and are the most common cause of sudden death in young adults. The two most common inherited CMs are Hypertrophic Cardiomyopathy (HCM) and Dilated Cardiomyopathy (DCM). Rare variants account for less than 50% of cases and recent GWAS have shown that SNP heritability has a strong polygenic influence on the phenotype which can account for the rest of the cases. As we move towards an era where genome sequencing becomes part of routine care, it is imperative to use these personalized data types to streamline patient care and contribute to the better diagnosis of these diseases. We used the UK Biobank, alongside an internal HCM cohort, to train models that can pre-screen for HCM and DCM via prediction-classification modelling. Models are trained on basic clinical and demographic features with HCM/DCM-specific genomic information. This includes rare variants in genes associated with HCM and DCM, which are curated based on evidence for disease, protein consequence, and minor allele frequencies, among other filters. We compared 4 distinct machine learning methods: Support Vector Classifiers (SVC) with both linear and non-linear kernels, and 2 ensemble methods, Random Forests (RF) and Gradient-Boosting Trees (GBT). The classifiers were trained 100 distinct times, where each time random training and test splits (80:20 ratio) were done ab initio (total sample sizes: HCM: 1040, DCM: 921, Controls: 7944). Splits of sets were tracked to ensure that the same train-test split was assigned across different models, to allow for robust modelling. Data samples were kept moderately imbalanced to reflect the prevalence of HCM and DCM in the general population, while ensuring good sample size for training. Performance was assessed by precision and recall. For HCM, the SVCs showed the highest recall, 0.79±0.026 and 0.77±0.025 for linear and non-linear kernels, respectively. The ensemble methods showed the highest precision with 0.94±0.017 for RF and 0.93±0.019 for GBT, whereas the SVCs showed slightly lower values (linear: 0.78±0.028, non-linear: 0.85±0.02). In most cases we observed that non-HCM controls are correctly classified. For DCM, the highest recall is also with SVCs (linear 0.73±0.03, non-linear:0.71±0.03), however the precision in these models is below 0.5. We observe the opposite trend in ensemble methods with high precision (RF: 0.85±0.01, GBT: 0.84±0.01) and recalls below 0.5. Our findings indicate that integrating an SVC with an ensemble method yields the best performance, representing a promising step in the development of an interpretable ML pipeline for pre-screening cardiomyopathies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4229 Interrogating MR instruments for biological plausibility.

Authors:

C. Fawcett, C. P. Nelson, V. Codd; Univ. of Leicester, Leicester, United Kingdom

Mendelian Randomisation (MR) is a method of investigating the causal relationship between an exposure and outcome, using genetic variants as unconfounded instruments and proxies to examine this relationship. However, many instruments are generated using all SNPs previously identified to be of statistical significance in a GWAS. This means that these instruments fail to examine the important nuance which may be revealed by further biological consideration of which SNPs are included in an instrument. A 130 SNP telomere length instrument was generated by Codd et al. (2021) using genome-wide data. By examining these 130 SNPs and identifying their potential roles, we can categorise these by established and predicted biological relevance. These categories allow for new biologically-relevant instruments to be constructed, with varying levels of strength and evidence of involvement in telomere biology. This allowed for the creation of five tiers of MR instrument, with differing levels of biological relevance in telomere length. Using this five-tiered system, we reinvestigate over 100 diseases in UK Biobank to investigate the role of telomere biology on previously established causal associations. Re-examining previous MR findings with this tiered system can provide new insights into the mechanisms underlying the relationship between telomere length and disease. By categorising a genome-wide instrument into biologically relevant tiers, it is possible to uncover more information about important factors linking exposures to outcomes. This is of particular importance as MR is used routinely to establish causal relationships with genome-wide instruments which do not consider the role of included SNPs.

PB4230 Introducing an optimized, automated pipeline for phasing, local ancestry inference, and Tractor GWAS on admixed cohorts

Authors:

N. Shah[1], A. X. Maihofer[2], T. Tan[1], J. Mauer[1,3], C. Zai[4], M. Santoro[5], C. Nievergelt[6], E. Atkinson[1]; [1]Baylor Coll. of Med., Houston, TX, [2]UCSD, La Jolla, CA, [3]Univ.e Federal de São Paulo, São Paulo, Brazil, [4]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, [5]Federal Univ. of Sao Paulo, Sao Paulo, Brazil, [6]Univ California San Diego, La Jolla, CA

Admixed individuals have been traditionally excluded from association analyses, contributing to disparities and Eurocentric biases in post-association analyses such as polygenic risk scores (PRS) and fine-mapping efforts. While recent efforts to sequence admixed individuals globally have shown promise in addressing this issue, limited methods exist to fully overcome it. A key challenge is the presence of randomly distributed stretches with variable lengths from different ancestral backgrounds, with individuals having 0, 1, or 2 copies of specific ancestral segments. This variability can lead to false positive and false negative results, particularly for ancestry-specific risk loci. Admixed populations may also exhibit different patterns of linkage disequilibrium (LD), complicating LD-based methods and compromising association analysis accuracy. To overcome false-positive results and produce ancestry-specific summary statistics, we propose the *Tractor* GWAS method, leveraging local ancestry for association analysis in admixed cohorts. Unlike traditional GWAS, the *Tractor* GWAS method involves multiple steps: phasing, local ancestry inference, and subsequent regression analysis with local ancestries. These steps require some preprocessing and nuance which may pose a barrier to adoption. To overcome this barrier, we have developed a scalable and user-friendly pipeline for conducting *Tractor* GWAS in collaboration with the PGC-PTSD Ancestry Working group. We have identified appropriate tools/methods for each step, curated tailored reference panels for 2-way and 3-way admixed individuals based on the recently released TGP/HGDP joint-call dataset, and containerized the workflow in Docker for easy accessibility to users. Our pipeline uses QC'd PLINK data files as input for statistical phasing, which are then processed for local ancestry inference. These local ancestry calls are subsequently employed for association analyses using the *Tractor* method. By adopting our approach, researchers can achieve harmonized analysis and facilitate cross-cohort comparisons, thereby identifying ancestry-specific loci beyond well studied homogeneous populations. We aim to promote wider adoption of the *Tractor* GWAS method by offering a more user-friendly approach, particularly benefiting groups with limited bioinformatics expertise. Through our efforts, we strive to overcome challenges associated with admixed individual analyses, eliminate biases, and emphasize the significance of the *Tractor* GWAS method in advancing genetic research.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4231 Investigating the Genetic Association between Type 2 Diabetes and Dementia.

Authors:

Y. Jobbi[1], N. ElHouda Barhoumi[2], E. Ahmed Fouad ElHady[3], A. Olaitan I.[4]; [1]Aminu Kano Teaching Hosp., Kano, nigeria, Kano, Nigeria, [2]Univ. of Med., Tunis, Tunisia, Tunis, Tunisia, [3]Faculty of Med., Ain Shams Univ., Cairo, Egypt, Cairo, Egypt, [4]Dept. of Computer Sci., Univ. of Ibadan, Ibadan, Oyo State, Nigeria, Ibadan, Nigeria

Dementia is a chronic, progressively degenerative brain syndrome. It is one of the major causes of disability in older populations. Type 2 diabetes mellitus (T2D) is a well-known risk factor associated with dementia. Older patients with T2D have a higher risk of about 60% of dementia when compared to those individuals without the disease. This study aims to identify novel genetic biomarkers that link dementia with type 2 diabetes in humans using Insilco analysis. NCBI, GEO2R, NIH Microarray expression dataset GSE161355 (Affymetrix GPL570 platform, the Affymetrix Human Genome U133 Plus 2.0 Array) from the brain temporal cortex neurovascular units of T2D and matched control samples. The findings from this study were downloaded, and further filtrations were performed using R- language, and limma to remove probe sets without corresponding gene symbols. Genes with multiple probes were filtered to retain features with maximum variance using the WGCNA collapseRows function, and significant Differentially Expressed Genes (DEGs) were identified using an unadjusted p-value < 0.05 and |log fold change (logFC)| > 1. The upregulated and downregulated genes were determined by the positive and negative values of the logFC values, and the data visualization of differential analysis (cases vs controls) was designed by EnhancedVolcano package for volcano plots using R- language. The Gene Ontology (GO) analysis indicated that genes from diabetes were mainly concerned with macromolecule biosynthesis, oxidation of organic compounds etc. The results of the cellular component were significantly mentioned in mitochondria, and respiration chain system, while the results of KEGG analysis were significantly enriched in tumor necrotic factor (TNF) signaling pathway, cell cycle, and inflammatory pathways. The understanding of this study revealed that cytochrome oxidase subunits 5A, 6C, and 7C are the potential biomarkers in T2D and dementia in the mitochondrial electron transport chain, and their upregulations lead to oxidative phosphorylation. In the present study, we performed bioinformatics analysis to investigate the link between dementia and T2D. We found out the shared relationship is based on mitochondrial dysfunction and altered metabolism in the related body cells. Cytochrome oxidase was identified as a potential biomarker of these diseases. Our findings provided new insights and directions to the understanding of dementia and T2D and can be used to understand better the pathology of these diseases and develop better treatment options. Nevertheless, these findings need further validation using animal models and related clinical investigations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4232 Investigating the impact of different copy number variant region definitions on copy number variation association analysis with whole genome sequencing data: Lessons learned from the Alzheimer's Disease Sequencing Project (ADSP).

Authors:

A. Tucci[1], H. Wang[2], Y. Si[1], Y. Cheng[1], L-S. Wang[2], G. Schellenberger[2], J-Y. Tzeng[3], W-P. Lee[2]; [1]North Carolina State Univ., Raleigh, NC, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]North Carolina State Univ, Raleigh, NC

Background: The heritability of Alzheimer's disease conferred through single nucleotide variants (SNVs) identified through genome wide association studies accounts for less than half of the total estimated heritability. Copy number variations (CNVs) within the genome are an alternative form of genetic variation that could explain some of the remainder of these AD heritability estimates. A critical early step in CNV association analysis is to define a "CNV region" (CNVR) to use as the locus unit. Selecting a specific definition for CNVRs is a non-trivial task that affects the analysis and result interpretation. In addition, misaligned CNV breakpoints that arise in whole genome sequencing (WGS) datasets with large samples can further complicate the impact of these CNVR definitions. We focus on elucidating how different CNVR definitions can influence a CNV association analysis of AD.
Methods: Using WGS data from the Alzheimer's Disease Sequencing Project (ADSP) R3 dataset of 16,905 samples, we called CNVs with Manta and Smoove and consolidated using the joint-genotyping algorithm GraphTyper2 to generate a CNV callset. Three different approaches (as defined by CNVRuler) were used to define CNVRs: density trimming, reciprocal overlap, and fragment-based. For the density trimming-based approach, two sets of CNVRs were created using density thresholds of 0.1 and 0.5. Each CNVR set was then used to perform an AD association analysis via logistic regression. The abundance of CNVRs defined and the regions identified as statistically significant were used to compare CNVR definitions to help construct guidelines for future such analyses.
Results and Discussion: Focusing on regions of genes previously identified as associated with AD status through variation in copy number, we observe significant differences between the three definitions of CNVRs. For CNVRs defined using density trimming, adjustment of the density threshold from 0.1 to 0.5 did not substantially impact the number of CNVRs defined, and neither identified a significantly associated region. In contrast, reciprocal overlap and fragment-based approaches defined more granular regions, resulting in improved sensitivity for identifying regions potentially associated with AD. The fragment-based method can provide the most detailed resolution, but is sensitive to misaligned breakpoints and may be better coupled with joint-genotyping methods that attempt to resolve this, like GraphTyper2. Ultimately, reciprocal overlap remained more sensitive than density trimming without being as susceptible to generating spurious CNVRs that represent sequencing noise rather than true genetic events.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4233 Investigating the role of rare microRNA-associated germline variants in the epileptic encephalopathies

Authors:

I. Fashina[1,2], Genomics England Research Consortium, S. J. Furney[1], G. L. Cavalleri[1]; [1]RCSI, Dublin, Ireland, [2]SFI Ctr. for Res. Training in Genomics Data Sci., Galway, Ireland

The epileptic encephalopathies (EE) represent rare and devastating forms of epilepsy with a largely monogenic genetic architecture. Although a genetic cause is identifiable in around 40% of cases, the majority screen negative on genomic testing. Rare damaging variants have been shown to be overrepresented in EE cohorts compared to controls. However, these studies have largely been limited to coding variants from whole exome sequencing (WES) data. Therefore, the role of rare variants within non-coding elements of the genome is understudied in these epilepsies. MicroRNAs are small ~22nt non-coding RNAs which act as master gene regulators, by binding to the 3'UTR of their mRNA targets. microRNAs have been observed to be dysregulated in studies of epilepsy patient samples, animal models as well as through in-vitro experiments. Using whole genome sequencing (WGS) data, we set out to test the hypothesis that rare microRNA-associated variation are contributing to genetic risk for the EEs.
We analysed whole genome sequencing data (WGS) in 1836 individuals (348 EE cases and 1,488 chronic kidney disease controls) accessed through the rare disease programme of the Genomics England 100,000 Genomes Project. Using SAIGE-GENE v0.44 in the Aggregate Variant Testing (AVT v3.1) pipeline of the Genomics England Research Environment (GEL RE), we assessed the enrichment of rare damaging variants across 4 functional domains. These domains are within coding sequences (CDS), conserved 3'UTRs and predicted microRNA-binding 3'UTRs of 540 confirmed epilepsy genes from the GEL panel application. We also tested enrichment of rare variants in microRNA-encoding genes.
We will present results of enrichment for rare damaging variants across functional domains, in coding sequences, predicted 3'UTR microRNA-binding sites and microRNA-encoding genes.
Ours is the first study to use WGS data to test the enrichment of rare damaging variants outside of coding sequences, particularly with regards to microRNA regulation in the epilepsies. We will extend this analysis to larger epilepsy cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4234 *Is inherited muscle strength a proxy for intrinsic capacity to resist age related pathologies and mortality?*

Authors:

E. Sillanpää[1], P. Herranen[1], K. Koivunen[1], T. Rantanen[1], K. Tiainen[1], U. Kujala[1], S. Ripatti[2], T. Palviainen[3], J. Kaprio[3], FinnGen, K. Waller[1], L. Joensuu[1]; [1]Univ. of Jyväskylä, Jyväskylä, Finland, [2]Inst. for Molecular Med. Finland FIMM, Helsinki, Finland, [3]Inst. for Molecular Med. Finland, Helsinki, Finland

Background: Low muscle strength has been associated with lower risk for diseases and premature mortality. We hypothesize that muscle strength genotype may reflect individual's intrinsic capacity to resist age-related pathologies, as well as predict better survival after acute diseases and longer lifespan. These hypotheses, and whether the potential association of muscle strength genotype and mortality can be modified with long-term adherence to physical activity (PA), were tested in Finnish population-based datasets.Methods: A polygenic score for hand grip strength (PRS HGS, ~1M SNPs) was constructed using Pan-UK Biobank (N=418,776) as a base data and SBayesR methodology. Association tests were conducted in the FinnGen cohort (n=342,443, age 40-108-y). For PRS HGS validation (n=429) and to test if physically active lifestyle can modify the association of PRS HGS and mortality (n=5,275) we used the Finnish Twin Cohort (FTC). Disease diagnosis, death dates and causes (all-cause and cardiovascular [CVD]) were obtained from the national digital registers. PA was assessed three times during years 1975-1990 using validated questionnaires. Linear and Cox regression models were utilized.Results: PRS HGS explained 6.1% of the variation HGS and 5.4% in knee extension strength in FTC. In FinnGen, a higher PRS HGS predicted a lower body mass index (β=−0.112 kg/m^2, P=1.69x10^{-11}) in women but not in men (β=0.004 kg/m^2, P=0.768). A higher PRS HGS associated with reduced risk for selected cardiometabolic diseases 3-6%, chronic pulmonary diseases 6%, musculoskeletal and connective tissue diseases 2-10%, depression 5%, and vascular dementia 7%. Only in women a higher PRS HGS associated with decreased risk for any dementia 6%, and for Alzheimer's disease 4%. Participants with a higher PRS HGS had 4 % decreased risk for cardiovascular and 3% for all-cause mortality. PRS HGS was not associated with better survival after adverse acute health events. In FTC a total of 1,330 deaths occurred (433 CVD related) during the mean 17.5-y follow-up. We found a significant sex*PRS HGS interaction (p=0.024, p=0.032) in all-cause and CVD mortality prediction, respectively, with higher PRS HGS associated with decreased mortality risk in men (HR 0.93 and HR 0.88) Associations persisted after adjusting for PA. No PA*PRS HGS interactions were found. In FTC PRS HGS did not predict mortality in women. Conclusion: The genotype that supports higher muscle strength protects against future health adversities but might not reflect the recovery potential after severe adversity. Low inherited muscle strength may be a predictor of CVD mortality in men regardless of their adulthood physical activity.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4235 Is linearity too strong of an assumption?

Authors:

R. Devito[1], D. Gulati[1], M. Gymrek[2]; [1]Univ. of California San Diego, San Diego, CA, [2]Univ California San Diego, La Jolla, CA

State of the art polygenic scores (PGS) assume additive and linear models of how variants and covariates influence a phenotype. While this has benefits in terms of ease of implementation and interpretability, it can lead to model-mismatch effects when the assumption is broken. Linear models' inability to capture these nonlinear interactions negatively impacts their performance both in predicting the phenotype and interpreting which variants are causal. Evaluating the extent of this mismatch is difficult, as we lack both ground truth understanding of the genetic architectures that lead to different phenotypes and genomics tools for fitting nonlinear models to biobank scale WES data.

To address the first point, we introduce a new open source phenotype simulation tool, CITRUS, where complex phenotypes are defined from genotypes using a user-defined graphical model. These networks allow modeling of arbitrary cis- and trans-acting epistatic interactions, haplotype effects, and other linear and nonlinear dynamics numerically. CITRUS provides a ground truth measure of importance for individual variants and pathways (interactions between individual variants) using approximated Shapley values, which can be used to benchmark model interpretation methods. We use these simulations to demonstrate that model-mismatch leads to worse predictive and variant identification performance as the nonlinearity of the phenotype increases for linear models when compared with nonlinear models.

To address the second challenge, we introduce a new PGS using tree-based methods which have demonstrated superior performance in traditional machine learning tasks. Prior studies applying nonlinear models to polygenic scores and causal variant identification have made sacrifices in either the types of nonlinearity they could capture or requiring a feature selection step that removed real signal from the model input, as they could not scale to the input feature size (number of variants) in traditional PGS. We address these shortcomings with an autoML pipeline for fitting tree-based nonlinear models (random forests, XGBoost, and LightGBM) for PGS. The pipeline is designed for scaling to biobank sized data in cloud and HPC settings and provides feature importance and feature interaction scores using Tree SHAP. We include additional libraries for preprocessing genotype, phenotype, and covariate data at scale. We compare phenotype prediction performance on UK Biobank data between hyperparameter optimized linear and nonlinear models, compare variants identified as associated, and for the tree-based models look for examples of pairwise nonlinear variant-variant interactions.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4236 isGWAS: ultra-high-throughput, scalable and equitable inference of genetic associations

Authors:

Z. Kuncheva[1,2], C. N. Foley[1,2], R. Marioni[3], H. Runz[4], B. Sun[4]; [1]Optima Partners Ltd, Edinburgh, United Kingdom, [2]Bayes Ctr., Edinburgh, United Kingdom, [3]Univ. of Edinburgh, Edinburgh, United Kingdom, [4]Biogen Inc, Cambridge, MA

The accelerating accumulation of genetic data and samples in large-scale deeply phenotyped cohorts poses significant computational, financial and data privacy bottlenecks for massive-scale genome-wide association analyses (GWAS). These limitations hinder collaboration and accessibility, particularly to less financially flexible research groups. Here, we present in-silico GWAS (isGWAS), a new algorithm and tool which can bypass the need to access or hold individual-level genetic data, requiring instead sample-level sufficient statistics to rapidly estimate regression parameters in case-control GWAS. Our approach offers several key advances over current gold-standard approaches: (1) massively improved computational efficiency and unique scalability for sequencing scale data across any sample size (e.g., GWA analyses of ~11m variants is completed in 4 minutes achieving ~1000-fold improvement relative to current approaches); (2) a new re-sampling approach extrapolating locus-level GWA results to larger sample sizes, facilitating future cohort and scenario planning; (3) the method requires only four input features per genetic variant: the allele frequencies in cases and controls and the number of cases and controls. These sufficient statistics satisfy wide-ranging data privacy concerns facilitating integration of case and/or control data from distinct studies. isGWAS makes feasible routine testing of alternative definitions of case status with no significant additional financial cost or carbon footprint. We showcase concordance with existing methods and the impact of isGWAS using biobank and disease consortium cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4237 Joint analysis of multiple phenotypes for extremely unbalanced case-control association studies using multi-layer network

Authors:

H. Xie[1,2], X. Cao[1], S. Zhang[1], Q. Sha[1]; [1]Michigan Technological Univ., HOUGHTON, MI, [2]Medpace Inc., Cincinnati, OH

Genome-wide association studies (GWAS) are an essential tool for analyzing associations between phenotypes and single nucleotide polymorphisms (SNPs). Most of the binary phenotypes in large biobanks are extremely unbalanced, which leads to inflated type I error rates for many widely used association tests for joint analysis of multiple phenotypes. In this article, we first propose a novel method to construct a Multi-Layer Network (MLN) using individuals with at least one case status among all phenotypes. Then, we introduce a computationally efficient community detection method to group phenotypes into disjoint clusters based on the MLN. Finally, we propose a novel approach, MLN with Omnibus (MLN-O), to jointly analyze the association between phenotypes and an SNP. MLN-O uses the score test to test the association of each merged phenotype in a cluster and an SNP, then uses the Omnibus test to obtain an overall test statistic to test the association between all phenotypes and an SNP. We conduct extensive simulation studies to reveal that the proposed approach can control type I error rates and is more powerful than some existing methods. Meanwhile, we apply the proposed method to a real data set in the UK Biobank. Using phenotypes in Chapter XIII (Diseases of the musculoskeletal system and connective tissue) in the UK Biobank, we find that MLN-O identifies more significant SNPs than other methods we compare with.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4238 Joint fine-mapping of single variants and gene-based tests from exome sequencing and genotype imputation

Authors:

Y. Zou, J. Mbatchou, L. Gurski, M. Suciu, Mayo Clinic Project Generation, M. Ferreira, J. Marchini; Regeneron Genetics Ctr., Tarrytown, NY

Fine-mapping analysis has traditionally focused on imputed common variants due to the low imputation accuracy for the rare variants. The identified causal variants are therefore usually non-coding variants, which can be difficult to map to nearby potential causal genes. To identify the nearby causal coding rare variants or genes, one common strategy is to analyze sequenced rare variants or gene-based burden tests conditional upon nearby common variant associations. One disadvantage of this approach is that it does not fully explore the space of causal models, so may lose power to detect the true causal variants when the Linkage Disequilibrium (LD) structure between single variants and gene-burden masks is complex.

To overcome the issue, we present a novel pipeline that enables joint fine-mapping of imputed common variants, sequenced rare variants, and gene-based burden masks. The pipeline takes summary statistics (z scores), genotype files with single variants (imputed and sequenced variants), and gene masks definition files. We incorporated functionality to REGENIE to compute the LD between single variants and gene masks, where the gene masks are dynamically generated according to mask definitions and annotations. We use SuSiE-RSS to identify putative causal variants or genes. In simulation studies using genotype data from an RGC cohort (Project Generation), our joint fine-mapping approach identifies the coding or gene causal signals, without losing power in identifying non-coding causal variants using 95% credible sets (CSs). To further illustrate the efficacy of the approach, we test the pipeline on empirical data using a quantitative trait, eosinophil count data from the same RGC cohort Project Generation. We identified 121 independent causal signals (95% CSs), out of which 114 contain single variants only (90 CSs with imputed common variants only, 8 CSs with sequenced rare variants only). In addition to the single variant signals, we are able to identify 7 putative causal genes (eg, IL33, SH2B3, SRSF2, S1PR4), some of which have been functionally validated to play a role in lymphocyte and eosinophil development or allergic traits. Overall, our joint fine-mapping pipeline thoroughly explores the entire range of potential causal variants, allowing for comprehensive identification of rare variants and genes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4239 † Joint modeling of genomic and exposomic data for variance decomposition analysis to improve heritability estimation of complex human phenotypes

Authors:

F. Akhtari[1], X. Tong[2], A. Burkholder[1], J. S. House[1], D. C. Fargo[1], C. S. Schmitt[1], J. E. Hall[1], A. A. Motsinger-Reif[1]; [1]NIEHS, Durham, NC, [2]Univ. of Kentucky, Lexington, KY

The etiologies of common complex diseases involve both genetic and environmental factors and their interactions. According to the World Health Organization, approximately 23% of all deaths and 26% of deaths among children under five years of age are due to modifiable environmental factors. These include factors such as air pollution, water and sanitation, hazardous chemicals, and occupational exposures. Calculating heritability is vital for understanding disease etiology and helps anchor expectations in gene mapping. While SNP-based heritability estimation for common complex human phenotypes using genotype or whole genome sequencing data is common, few studies have estimated the environmental component of phenotypic variance for complex diseases due to insufficient exposure data to evaluate the contribution of environmental factors. Comprehensive data collection on various environmental exposures is needed to better understand the environmental component in disease etiology. The Personalized Environment and Genes Study (PEGS) study is a diverse North Carolina-based cohort with extensive health and exposure data and whole genome sequencing (WGS) data from individuals of varying age, race, education, and socioeconomic status. To improve heritability estimation, and to better explain the phenotypic variance in complex traits, we integrated genomic and exposomic data from PEGS and modeled the phenotypic variance as explained by the genome (G), exposome (E) and their interaction (GxE). We used genome-wide complex trait analysis (GCTA) to partition the complex trait variation for type 2 diabetes, height and body mass index (BMI) in PEGS to estimate the trait variance explained by variance in the genome, exposome and their interaction. Analogous to genomic relationship matrices (GRMs), we computed environmental kinship matrices using the extensive exposure data from the PEGS surveys. We show that the exposome explains and contributes to a significant amount of the phenotypic variation through its additive and interaction effects for both BMI and type 2 diabetes, while the phenotypic variation in height is mostly explained by variation in the genome. For type 2 diabetes, 50.9% of the phenotypic variance is explained by the genome, 2.8% by the exposome and 18.3% by their interaction. For BMI, the genome, exposome and their interaction explain 18.9%, 22.2% and 11.4% of the phenotypic variation respectively. These results show the importance of the exposome in dissecting phenotypic variance to understand the etiology of complex human traits. For future work, we will expand this variance decomposition analysis for additional phenotypes in PEGS.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4241 Killer cell immunoglobulin-like receptor (KIR) genetic variation in the natural history of type 1 diabetes

Authors:

A. Romero[1], L. Leaton[1], S. Onengut-Gumuscu[2], K. Waugh[3], S. D. Slack[1], N. R. Pollock[1], M. Rewers[3], J. Norris[4], P. Norman[1], R. K. Johnson[1]; [1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [2]Univ. of Virginia, Charlottesville, VA, [3]Barbara Davis Ctr. for Diabetes, Aurora, CO, [4]Colorado Sch. of Publ. Hlth., Aurora, CO

HLA genetic variation confers the strongest risk for type 1 diabetes (T1D); however, this risk differs by stage of disease (initiation of preclinical islet autoimmunity, IA, versus progression to T1D) and the underlying causal mechanisms remain unclear. KIR physically interacts with HLA molecules to modulate innate and adaptive immune responses. Studies investigating *KIR* in T1D risk have been restricted to the T1D endpoint. We investigated the association of *KIR* genetic variation and the combination of *KIR-HLA* variation in the risk of T1D, IA, and the progression from IA to T1D in the prospective Diabetes Autoimmunity Study in the Young (DAISY) cohort. DAISY follows 2,547 high-risk children for the development of IA and T1D. Genome-wide SNP data were generated using a customized Illumina exome array for subjects selected in 2015 for multi-omics nested case-control study, including 89 T1D cases and 88 T1D controls, and 207 IA cases and 203 IA controls. By 2023, 234 IA cases had developed, of which 112 (48%) progressed to T1D at an average of 5.5 years post-IA. We imputed *KIR* with KIR*IMP and *HLA* with the Michigan HLA multiethnic reference panel. Genes were categorized into present vs. absent for analysis. We tested *KIR* genes and *KIR-HLA* combinations for association with IA and T1D risk using logistic regression adjusted for the high-risk HLA-DR3/4 haplogenotype and genetic PC1. Associations for T1D progression were tested using Cox regression with additional adjustment for age at IA seroconversion. KIR imputation accuracy ranged from 88% to 99%. No *KIR* genes or *KIR-HLA* combinations were associated with IA or T1D risk. After Bonferroni correction, six *KIR* genes were protective for T1D progression (P<0.00192), including *KIR2DS5* (OR=0.49, 95%CI: 0.31-0.76), *KIR2DS1* (OR=0.56, 95%CI: 0.39-0.81), *KIR3DS1* (OR=0.56, 95%CI: 0.39-0.81), *KIR2DP1* (OR=0.58, 95%CI: 0.44-0.76), *KIR2DL5* (OR=0.59, 95%CI: 0.43-0.79), and *KIR2DL1* (OR=0.60, 95%CI: 0.45-0.79). Two *KIR* genes increased risk of T1D progression, including *KIR2DS4* (OR=1.78, 95%CI: 1.24-2.53), and *KIR3DL1* (OR=1.78, 95%CI: 1.24-2.53). The effect of *KIR2DL1* on T1D progression differed by its *HLA-C2* ligand (interaction P=0.031). In the absence of *HLA-C2*, *KIR2DL1* was protective for the progression to T1D (OR=0.43, 95%CI: 0. 28-0.64), but was not associated with T1D progression in the presence of *HLA-C2*. Genetic variation of both inhibiting and activating *KIR* genes affect the risk of progressing from IA to T1D among children at high genetic risk. These effects differ by presence of HLA ligands and by stage of disease progression. Further elucidation of *KIR-HLA* allelic variation in T1D risk is warranted.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4242 Laipy: artificial intelligence for next-generation robust local ancestry inference.

Authors:

A. Jaras[1], D. Mas Montserrat[1], C. Lopez[1], B. Oriol Sabat[2], A. Ioannidis[1]; [1]Stanford Univ., Stanford, CA, [2]Univ. of California, Los Angeles, CA

The decreasing cost of sequencing technologies is leading to the growth of biobanks composed of numerous high-resolution whole genome sequences, which combined with new algorithmic techniques, are enabling personalized data-driven precision medicine. However, this new paradigm is benefiting mostly European-descent individuals, due to a large imbalance of available data, which includes mostly European populations, and due to the difficulty of processing genomic data from individuals of admixed populations with current predictive models. Local ancestry inference (LAI) methods, also referred to as ancestry deconvolution, provide high-resolution ancestry classification predictions, assigning an ancestry label to every genomic position or at windowed regions of the genome. These techniques are used in admixture mapping studies, historical and migration studies, genome-wide association studies, polygenic risk scores, and other predictive methods. Recent LAI methods including G-Nomix, LAI-Net and SALAI-Net, provide fast and accurate predictions, however, they are not built for easy use in clinical genetics by non-specialists. In this work, we introduce “laipy” a python framework that combines, extends, and unifies all 3 methods, while providing algorithmic and architecture improvements, better input/output and visualization capabilities, an easy-to-use phasing error correction system, and quality control methods based on uncertainty quantification techniques. The framework is easy to install, allows to interchange the updated versions of G-Nomix, LAI-Net and SALAI-Net seamlessly, and provides state-of-the-art speeds and accuracies. We run our framework within the whole UK Biobank and include a detailed benchmark with different number of populations, admixture times, and genome sequence resolution demonstrating the accuracy and effectiveness of the introduced framework.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4243 Large gene prioritization benchmark enables supervised learning of effector genes from GWAS loci

Authors:

C. Cole[1], P. Mohammadi-Shemirani[2], T. Lau[1], D. Merico[3], T. Masud[1]; [1]Deep Genomics, Toronto, ON, Canada, [2]Deep Genomics Inc., Toronto, ON, Canada, [3]Vevo Therapeutics, San Francisco, CA

Correctly prioritizing causal genes which mediate the effect of genome-wide association (GWA) loci on a phenotype remains a bottleneck for efficient target identification from complex trait association studies. Biases in the selection of genes used to benchmark existing approaches limit their generalizability between traits with different genetic architectures. In addition, many new methods have been proposed which claim superior accuracy over and above the nearest gene but their relative strengths have not been compared or combined systematically. In this study, we harmonize three large locus-to-gene (L2G) datasets and compare seven existing methods for gene prioritization before creating a supervised learning model to combine functional annotations with existing gene prioritization strategies. First, we create a high quality set of fine-mapped variants linked to effector genes following three different methods from Weeks et al 2021 (n = 715 pairs), Mountjoy et al 2021 (n = 433 pairs), and Forgetta et al 2022 (n = 415 pairs) using imputed UK Biobank summary statistics to perform functional fine-mapping through PolyFun with the BaselineLF-v.2.2 to estimate priors and SuSIE+FINEMAP to estimate credible sets. Crucially, by balancing the biases implied with these three different methods, we create a more representative set of L2G pairs with respect to complex trait architectures than any dataset alone. We used this set of 1564 L2G pairs to compare the precision and recall of seven individual gene prioritization strategies (distance by three metrics, polygenic priority scores (PoPS), robustness estimates for PoPS, combined SNP to Gene (cS2G), transcriptome-wide association studies, eQTL colocalization, and summary-based Mendelian randomization through HEIDI) and find that no method individually exceeds the performance of genomic distance. Using our harmonized benchmark, we create a supervised combination of genomic features, functional annotations, and existing gene prioritization approaches that outperforms any strategy individually on a held-out test set (AUROC = 0.7446 versus 0.6686 for best performing strategy of distance by any genic feature) or simple combination of features (PoPS + distance AUROC = 0.7192). These results demonstrate that combining strategies lends significant power over any individual approach for identifying effector genes. Moreover, as the community develops additional strategies, it will be critical to build representative datasets that serve to systematically compare gene prioritization strategies and better capture their generalizability to complex trait biology.

PB4244 Large-scale admixture mapping unravels novel genetic insights into human disease.

Authors:

M-C. López Cano[1], S. Moreno Grau[1,2], D. Mas Montserrat[1], J. Abante[1,3,4], G. Venkataraman[1], M. Rivas[1], A. Ioannidis[1,5]; [1]Dept. of BioMed. Data Sci., Stanford Univ. Sch. of Med., Stanford, CA, [2]Galatea Bio, Inc., Hialeah, FL, [3]Dept. of BioMed. Sci., Facultat de Med. i Ciències de la Salut, Barcelona, Spain, [4]Dept. of Mathematics and Computer Sci., Univ.t de Barcelona, Barcelona, Spain, [5]Inst. for Computational and Mathematical Engineering, Stanford, CA

The vast majority of genetic studies are conducted in samples from European-descent populations, missing out on the full diversity of genetic variation and disease risk explainability. Admixture mapping - an association analysis between local ancestry inference (LAI) results and phenotypes of interest - proves to be a powerful alternative to common methodologies like Genome Wide Association Studies (GWAS) in diverse and admixed populations with smaller sample sizes. In this work we provide a novel software package that allows researchers to easily conduct admixture mapping analysis and present a large-scale admixture mapping study on a set of unrelated individuals from the UK Biobank, revealing new population-specific associations.

Local and global ancestry inference is estimated using RFMix with African, African Hunter Gatherer, East Asian, South Asian, Oceanian (Australo-Papuan), European, West Asian, and Indigenous American population groups. We focus on 109 phecodes of medical interest, ICD10, algorithmically defined outcomes, cancer registry and family history. The association analysis is carried out per ancestry and condition, and multiple hypothesis testing correction is applied.

We detect multiple genetic loci significantly associated with numerous human diseases among various populations. While some of these regions have already been reported (i.e., well-known regions for seborrhoeic keratosis and lipidemias), many include new findings pertaining to breast cancer (BC), menopausal disorders, skin disease, and heart attack. We specifically highlight a protective association between Indigenous American ancestry and BC in chromosomal region 8p22. Our finding is in agreement with the low incidence of BC in Latinas with respect to others, and supports the rationale of protective variants acting in Latinas. Overall, our approach identifies novel genomic regions associated with clinically relevant phenotypes, and deepens the understanding of previously identified associations.

PB4245 Large-scale GWAS of strabismus identifies several novel risk loci and provides support for a link between maternal smoking and childhood eye disease

Authors:

S. MacGregor[1], W. He[1], P. van der Most[2], J. Ong[3], L-D. Hwang[4], L. Mauring[5], K. ÕUnap[6], B. Barry[7], E. Abner[6], N. Martin[8], D. Plotnikov[9], Y. Wu[1], P. Gharahkhani[1], H. Snieder[2], T. Palumaa[6], J. Guggenheim[10], D. Mackey[11], E. Engle[12], H. Choquet[13]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Univ. of Groningen, Groningen, Netherlands, [3]QIMR Berghofer Med. Res. Inst., Herston, Australia, [4]The Univ. of Queensland, St Lucia, Australia, [5]Univ. of Tartu, Tarty, Estonia, [6]Univ. of Tartu, Tartu, Estonia, [7]Boston Children's Hosp., Boston, MA, [8]Queensland Inst Med Res, Brisbane, Australia, [9]Kazan State Med. Univ., Kazan, Russian Federation, [10]Cardiff Univ., Cardiff, United Kingdom, [11]Lions Eye Inst., Nedlands, Australia, [12]Boston Children s Hosp., Boston, MA, [13]Kaiser Permanente - Div. of Res., Oakland, CA

Strabismus (misalignment of the eyes) is a common pediatric ophthalmic condition with genetic and non-genetic risk factors contributing to its etiology. There are many manifestations of strabismus, including esotropia (exotropia) where there is an inward (outward) turn of one or both eyes. Due to the heterogeneity of strabismus and sample size limitations, previous genome-wide association studies encountered difficulties in identifying strabismus risk variants. Here, we conducted large-scale meta-analyses using 11 strabismus GWAS of European ancestry from 7 cohorts to discover new genetic variants for strabismus and its sub-types. We identified 4 genome-wide significant independent loci (*NPLOC4-TSPAN10-PDE6G-FAAP100*, *COL6A1*, *ZNF701* and *CHRNA3*) in the meta-analysis of broadly defined strabismus (20,464 cases and 954,921 controls). We also identified 5 (*UTS2*, *CHRNA3*, *DYNLRB2*, *NPLOC4-TSPAN10-PDE6G-FAAP100* and *MAD1L1*) independent loci by narrowing down the strabismus definition to esotropia (5,963 cases and 588,794 controls) and exotropia (3,998 cases and 583,468 controls). Some of these have been previously associated with ocular traits such as refractive error (e.g. *TSPAN10*, *MAD1L1*) and myopia (e.g. *COL6A1*) or cigarette smoking behaviour (*CHRNA3*). We also performed a cross-tissue transcriptome-wide association study, implicating 7 genes for esotropia (*ADAMTS7*, *C17orf70*, *CACNA2D2*, *COL6A2*, *PDE6G*, *PURG*, *SLC16A3*). In summary, we successfully replicated the previously reported strabismus locus near *NPLOC4-TSPAN10-PDE6G-FAAP100* and found a further 6 novel loci, providing new insights into strabismus biology. Finally, since previous observational studies have reported an association between maternal smoking during pregnancy and strabismus in offspring, here we conducted Mendelian randomization to help assess if there is a causal relationship; our genetic data provided evidence supportive of causality.

PB4246 LDPredx is a scalable, theoretically-justified method for cross-ancestry polygenic risk prediction

Authors:

M. Tudball[1], T. Lu[1], S. Bhatnagar[1], V. Forgetta[1], B. Richards[2]; [1]5 Prime Sci., Montreal, QC, Canada, [2]McGill Univ., Montreal, QC, Canada

Current polygenic risk scores (PRS) do not perform well in non-European ancestries, greatly limiting their clinical utility. This has spurred the development of new cross-ancestry methods which estimate PRS in one ancestry using data from multiple ancestries. However, many of these sophisticated methods perform similarly to, or even underperform, a simple linear combination of single-ancestry PRS (a "meta-score").
We make two contributions to this problem. Firstly, we propose a new method based on GWAS summary statistics called LDPredx, which is a strict generalisation of single-ancestry LDPred-inf to multiple ancestries. LDPredx is based on the cross-ancestry infinitesimal model. We show that this established population genetics model gives the LDPredx posterior an exact closed form, which provides computational tractability and generalisability to many ancestries, and sidesteps the need for external training data. We show in UK Biobank that LDPredx exhibits favourable performance and dramatically reduced computation time against other cross-ancestry methods. Our software is compatible with Hail 0.2, thereby facilitating scalable computing and improved access to data resources.
Secondly, we utilise LDPredx's foundation in population genetics theory to provide the first formal, mathematical description of the factors driving cross-ancestry portability. We first derive a formula for the LDPredx posterior, showing that it depends on the number of markers in the PRS, cross-ancestry genetic correlation and ancestry-specific trait heritabilities, sample sizes and linkage disequilibrium structure. We use this formula to probe the conditions under which cross-ancestry PRS will be the most effective. Furthermore, we shed light on the meta-score's surprising effectiveness by proving that it is the best linear approximation to LDPredx. When there is no linkage disequilibrium among markers in the PRS, we prove that LDPredx and the meta-score are, in fact, equivalent. Together, these results prove that LDPredx will outperform the meta-score whenever the markers in the PRS are linked. We verify all of our mathematical results using simulations and real data in UK Biobank.
LDPredx is a powerful tool both for polygenic risk prediction and illuminating the theoretical underpinnings of cross-ancestry portability.

PB4247 Learning portable polygenic risk score models with mixtures of pre-trained experts to improve accuracy across the continuum of ancestry

Authors:

S. Zabad, S. Gravel, Y. Li; McGill Univ., Montreal, QC, Canada

Polygenic risk scores (PRS) provide an estimate of the additive genetic component of complex traits and diseases. In recent years, there has been growing interest in incorporating polygenic scores into clinical practice, drug development pipelines, and personalized medicine. A large and fast-growing number of PRS estimates have been generated from diverse cohorts and made publicly available. One challenge for realizing the potential of current PRS models, however, is their poor portability to out-of-sample individuals and well-documented disparity in prediction accuracy across ancestries. To address this problem, recent PRS methods devised approaches to infer ancestry-specific variant effect size estimates, coupled with joint priors that encourage concordance. While this class of methods have been shown to significantly improve prediction accuracy for underrepresented populations, they do not completely bridge the gap. Moreover, cross-ancestry PRS methods operate on the assumption of discrete and uniform populations, which tends to work poorly for small or admixed subpopulations and does not capture the full continuum of ancestry. This problem is further compounded by the fact that recent analyses have shown limited PRS portability across other cohort variables, such as age, sex, and socioeconomic status.

To mitigate the PRS portability problem, we propose a Mixture-of-Experts (MoE) modeling framework, which can accommodate heterogeneity of effect sizes and automatically specialize individual experts on various partitions of the data. Specifically, MoEs consist of an ensemble of K PRS models whose outputs are combined on a per-sample basis using a flexible “gating” model. The gating model takes as input a list of covariates for each sample, such as Principal Components, age, and sex, and outputs probabilistic weights for combining the predictions of the PRS models in the ensemble.

To showcase the utility of this framework, we illustrate how it can be used to efficiently combine predictions from pre-trained PRS models from the PGS Catalog. In a 5-fold cross-validation analysis in the UK Biobank and CARTaGENE datasets, we show that MoEs significantly improve prediction accuracy over the best individual model, with mean improvements of up to 12% in underrepresented populations and admixed samples. It also produces scores that perform more consistently across a wide range of sociodemographic profiles. These benefits are achieved without imposing any assumptions or arbitrary subdivisions on the data at training time, which allows the model to automatically detect sources of heterogeneity and deploy the right model for each individual.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4248 Learning the environmental architecture of cardiometabolic disease at biobank scale.

Authors:

S. Tangirala, C. Patel; Harvard Med. Sch., Boston, MA

A key challenge in capturing the architecture of complex traits involves decoupling genetic from nongenetic variation. In nongenetic or environmental research, the scale in identifying and reproducing associations and predictions has not been achieved relative to genetic investigations. Biobank-scale analyses used to produce robust genetic findings can be repurposed to discover exposure-disease connections. We conducted a Exposure-Wide Association Study (ExWAS) to systematically identify associations across 362 nongenetic and behavioral factors for each of the 3 binary disease phenotypes (e.g., type 2 diabetes, hypertension, coronary artery disease [CAD]) using a sample of 472,240 White European (WE) participants from the UK Biobank (UKB). Furthermore, we highlight different ways of triangulating the identified associations. Genetics can help identify factors at scale. Thus, we computed causal estimates between each non-genetic factor-disease phenotype pair bi-directionally to also account for potential reverse causality (utilizing bi-directional Two-Sample Mendelian Randomization [MR] in FinnGen and UKB cohorts). We also perform ExWAS on biological mediators of complex traits such as BMI, HbA1c, Glucose, and 249 cardiometabolic biomarkers (e.g., lipoprotein lipids, amino acids, glycolysis metabolites, etc.). Among the FDR < 0.05 significant associations (341 unique exposures) identified for biological mediators, we find that the interquartile range of the absolute value of beta estimates is [0.0237, 0.074] with a mean of 0.0587. For CAD, we identified 172 FDR < 0.05 significant non-genetic factors (IQR of odds ratios (OR): [0.71,1.51], mean OR: 1.11), for hypertension we identified 248 ([0.71, 1.34], 1.07), and for type 2 diabetes we identified 224 ([0.85,1.27], 1.12). Overall, among the FDR-significant non-genetic factor associations, we observed concordance in direction between associations computed from the observational analysis and MR analysis, however only for a subset of the significant factors did we find evidence for potential causal relationship(s). For example, we found having a college or university degree with hypertension (observational OR = 0.75, observational beta-estimate = -0.287, observational FDR = 7.61×10^{-121}, MR beta estimate = -1, MR p-value = 1.71×10^{-18}) to have a more significant protective effect than mainstays such as never smoking (observational OR = 0.81, observational beta-estimate = -0.21, observational FDR = 4.19×10^{-90}, MR beta estimate = -0.42, MR p-value = 0.016). We present an integrative ExWAS and MR approach for systematically prioritizing nongenetic associations at biobank scale.

PB4249 Leveraging AI to improve variant prioritization algorithms and scale whole genome analysis

Authors:

S. White[1], T. Bowers[2], S. Hofherr[1], E. Frise[1], M. Reese[1]; [1]Fabric Genomics, Oakland, CA, [2]Broad Inst., Boston, MA

Over the past eighteen months, the genomics industry introduced genome sequencing with interpretation as low as USD $1,000. As genome prices continue to decline, the healthcare and insurance industry will incorporate sequencing into their standard practices of care. Labs are increasingly moving towards genome backbone sequencing and a “sequence once, interpret many times” paradigm. While sequencing costs have declined, the interpretation costs remain high due to the need for individuals highly skilled in clinical genetics to manually interpret and review each case. The expert interpretation component is more costly and takes longer than the sequencing itself. It can take a highly trained clinical genetics professional 20 minutes to 4 hours to review evidence and classify a single variant. In order to scale clinical diagnostics, labs must utilize automation and AI software as an adjunct to their clinical interpretation services. Fabric Genomics has pioneered AI-driven scalable genomic interpretation with a suite of ground-breaking proprietary and patented algorithms. Fabric’s newest software release, FE3, leverages state of the art AI including variant prioritization algorithms and automated ACMG variant classification, resulting in fewer variants to manually review and faster curation and reporting of those variants. The platform enables multiple concurrent or sequential independent analyses be performed on a genome backbone. The latest software supports build 38, MANE transcript, and additional annotations. New workflows and interfaces include auto approval for negative panel cases, upfront display of the number of classified variants for panel cases, automated ACMG classification for WES/WGS, and mitochondrial analysis. These advancements in AI algorithms will provide genomics labs better options for scalability and the opportunity to fully realize the possibilities and benefits of whole genome sequencing as a backbone.

PB4250 Leveraging and Partitioning of Polygenic Risk Scores Identifies Proteomic Networks Underlying Cancer Risks

Authors:

D. Dutta[1], J. Zhang[2], J. Coresh[3], A. Battle[4], E. Platz[4], N. Chatterjee[4]; [1]Natl. Cancer Inst., Rockville, MD, [2]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [3]Johns Hopkins Univ, Baltimore, MD, [4]Johns Hopkins Univ., Baltimore, MD

Background: Genome-wide association studies (GWAS) have identified numerous common susceptibility variants across various cancers. Understanding the impact of these variants on intermediate molecular phenotypes, such as gene expression and protein levels, can help prioritize disease-relevant target genes and proteins, and facilitate partitioning of polygenic scores (PGS) according to distinct networks reflecting converging effects of underlying SNPs. **Methods**: We investigated the associations of plasma protein levels with cancer-related SNPs for 21 cancers, curated from the PGScatalog, with levels of 4,955 plasma measured by SomaScan, for 9,083 participants (7,213 European Americans and 1,871 African Americans) at visit 2 in the Atherosclerosis Risk in Communities (ARIC) study. We adopt two complementary strategies to detect convergence of multiple association signals of cancer-related variants with plasma protein levels: (A) pQTS: association of the PGS for a particular cancer with plasma protein levels (B) ARCHIE: a sparse canonical correlation-based method to identify subsets or partitions of cancer related variants, constituting the PRS, associated to selected set(s) of proteins. **Results**: Across all cancers, we identified 90 associated proteins using pQTS of which 53 were guided purely by trans-associations between cancer-related SNPs and proteins. By partitioning the cancer-related SNPs, ARCHIE identified 19 significantly associated protein networks encompassing a broader set of 245 proteins and replicating a substantial fraction of trans-associations identified by pQTS (71.7%). We found that the proteins identified by pQTS and/or ARCHIE are enriched for relevant biological processes and cell types as well as cancer drivers and have concurrent somatic evidence of being associated with the respective cancers. For example, using the SNPs associated to cervical carcinoma, we identify a set of 80 proteins, primarily enriched in various immune response pathways and inflammatory responses. Additionally, we identify proteins that are associated with multiple related cancers indicating potential pleiotropic activity. **Conclusion**: Our analysis leverages known GWAS associations for cancers to identify protein networks underlying cancer risks and accordingly partition or subset polygenic scores into mechanistic components. As detailed molecular data of relevant tissues, cell-types and developmental stage becomes increasingly available, similar approaches will prove to be important tools for identifying downstream molecular targets for GWAS variants and improving interpretation and research application of PGS.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4251 Leveraging functional annotations to identify interactions between rare-variant gene sets and environmental factors

Authors:

S. McCabe[1], Z. Li[1], X. Li[2], H. Zhou[3], D. Christiani[4], X. Lin[5]; [1]Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Harvard TH Chan Sch. of Publ. Hlth., Boston, MA, [3]Harvard, Boston, MA, [4]Harvard Med. Sch., Boston, MA, [5]Harvard T.H. Chan Sch Pub Hlth, Boston, MA

Analyses of gene environment interactions can provide insights into how the association of environmental risk factors, such as smoking or the concentration of air pollutants, on health-related outcomes can vary based on the genetic profiles in an individual. While analyses of common variants in this setting have been studied extensively, rare variants have been shown to explain a larger proportion of heritability and are often more deleterious. However, identification of interactions between rare-variant gene sets and environmental factors is more challenging. Though the development of large biobank datasets can provide hundreds of thousands of samples which can help in the detection of rare-variant effects and improve statistical power, these analyses are often still underpowered due to the rarity of the variants. We propose STAAR-GEI, a method that incorporates multi-faceted variant functional annotations to improve the statistical power of testing interactions between rare-variant gene sets and environmental factors. STAAR-GEI constructs an omnibus test that combines a SKAT, Burden, and ACAT framework using dynamic multiple variant functional annotation weights. STAAR-GEI also uses functional annotations to define the rare-variant sets to be tested and can efficiently handle population structure and sample relatedness through a generalized linear mixed model (GLMM) framework. In simulations, we found incorporating functional annotations with STAAR-GEI improved statistical power of testing rare-variant gene set by environment interactions compared to the existing variant-environment interaction tests. We apply this method to an analysis of the UK Biobank dataset to identify rare-variant gene sets which are interacting with several environmental factors on diseases and traits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4252 † Leveraging genetic correlation and multiple population datasets to improve genetic prediction across populations

Authors:

L. Xu, G. Zhou, G. Leying, H. Zhao; Yale Univ., New Haven, CT

The disparity in genetic risk prediction accuracy between European and non-European populations poses a critical challenge of health disparity. Previous studies have highlighted the necessity to include datasets from multiple populations, account for genetic correlations across different populations, and consider suitable shrinkage distribution for polygenic risk prediction models. However, no previous study has comprehensively integrated all these elements into a single predictive model. To bridge this gap, we introduce a new method, JointPRS, which simultaneously models multiple populations. JointPRS improves over the existing methods by leveraging datasets from diverse populations, instead of solely relying on auxiliary European groups. Moreover, our model incorporates an automated estimation of chromosome-wise cross-population genetic correlation, outperforming methods that do not use such information. To validate our method, we chose a commonly used method, PRS-CSx, for comparison. We first assessed the prediction performance of JointPRS through simulations. We employed the spike and slab distribution for three populations (European, EUR; East Asian, EAS; and African, AFR) with specific correlation as the true model, and then varied the percentage of causal SNPs (p) from small to large (p=0.005, p=0.05, p=0.5). The average relative improvement of JointPRS over PRS-CSx measured in R-squared percentage across different correlation strengths was 0.21% for EAS and 0.33% for AFR when p=0.005; 7.75% for EAS and 3.6% for AFR when p=0.05; and 17.9% for EAS and 7.76% for AFR when p=0.5, implying the effectiveness of our prediction model. We then applied JointPRS to predict six complex traits - height (HGT), body max index (BMI), HDL cholesterol, LDL cholesterol, total cholesterol (TC), and triglycerides (TG) - in the UK Biobank dataset. Compared to PRS-CSx, JointPRS significantly improved the prediction accuracy for the EAS and AFR populations. The average relative improvement of JointPRS over PRS-CSx measured in R-squared percentage is 10.7% in EAS and 16.9% in AFR for HGT; 23.1% in EAS and 23.8% in AFR for BMI; 9.65% in EAS and 5.18% in AFR for HDL; 14.8% in EAS and no improvement in AFR for LDL; 21.4% in EAS and 7.16% in AFR for TC; and 7.45% in EAS and 3.57% in AFR for TG. These results demonstrate that JointPRS can enhance genetic risk prediction results in non-European populations over PRS-CSx.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4253 Leveraging heritability and genetic correlation to maximize GWAS power in EHR-connected biobanks

Authors:

N. Tatonetti[1], M. Zietz[2]; [1]Cedars-Sinai Med. Ctr., Los Angeles, CA, [2]Columbia Univ., New York, NY

Complex diseases are a significant global health challenge, necessitating rigorous and expansive study into their genetics. Observational data, such as Electronic Health Records (EHR), offer numerous advantages in the study of complex disease genetics. These include their large scale, cost-effectiveness, information on many different conditions, and future scalability with the widespread adoption of EHRs. Observational data, however, are challenging for research due to noise and confounding. EHR data reflect factors including the healthcare process, and access to care, as well as broader societal effects like systemic biases. In this study, we introduce a novel phenotyping method designed to strengthen and purify the genetic signal in EHR-based genetics research. Our approach quickly refines a linear phenotype by optimizing its heritability and genetic correlation, iteratively becoming closer and closer to the genetic component of the complex trait of interest. We validate the effectiveness of this approach by demonstrating its ability to predict polygenic scores, to enhance the power of genome-wide association studies (GWAS), and to improve heritability estimates in data from the UK Biobank. Our phenotyping does not rely on individual-level data, requiring as inputs only population-matched estimates of heritability, genetic correlation, and phenotypic correlation. Once the phenotype has been trained, our approach can be used to estimate the individual-level genetic component of the trait of interest. This purified genetic signal can then be used for EHR studies concerning complex traits and diseases. We demonstrate the utility by showing systematic improvement in GWAS data when using noisy and biased EHR-based phenotypes. This advancement helps to bolster the adoption and utility of observational and EHR data in genetic studies, accelerating our understanding of complex diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4254 Leveraging local ancestry and cross-ancestry genetic architecture to improve the genetic prediction of complex traits in admixed populations

Authors:

G. Zhou[1], I. Yolou[1], H. Zhao[2]; [1]Yale Univ., New Haven, CT, [2]Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Polygenic risk score (PRS) has been increasingly popular due to its ability to identify individuals with high disease risk for more effective population screening, diagnosis, and monitoring. However, the broader application of PRS is hindered by the limited transferability of PRS developed in Europeans to non-European populations. While many statistical methods have been developed to improve the performance of PRS in non-EUR population, most of them focused on the discrete genetic ancestry clusters and did not consider the admixed individuals. Admixed individuals pose a unique challenge for calculation of PRS due to the complexity of local ancestry and cross-ancestry effect sizes. Here we present a statistical method called SDPRX_admix for calculating PRS in admixed individuals. SDPR_admix characterizes the joint distribution of the effect sizes of a variant with two ancestries to be both zero, ancestry specific or correlated. We compared the performance of SDPR_admix with the conventional method BSLMM which assumes no heterogeneity of effect sizes by local ancestry. Extensive simulation revealed that SDPR_admix outperformed BSLMM in scenarios assuming heterogeneity of effect sizes based on local ancestry, while achieving similar performance to BSLMM in the scenario assuming no such heterogeneity. We analyzed 5 complex traits in individuals of African and European admixed ancestries where we trained the PRS model from the PAGE study (N = 13K) and tested the performance in UK Biobank (N = 4K). SDPR_admix outperformed BSLMM in all 5 traits as measured by Pearson R2 (Height: 0.015 vs 0.006; BMI: 0.0021 vs 0.0015; White blood cell counts: 0.02 vs 0.0018; Platelet counts: 0.0026 vs 0.0012; Hemoglobin concentration 0.001 vs 0.0006), though the predictive performance was low due to the small sample size of the training data. Our results suggested the benefits of incorporating local ancestry and modeling cross-ancestry genetic architecture to calculate PRS for admixed individuals.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4255 Leveraging multimodal neuroimaging data to identify novel genetic pathways to Alzheimer's disease

Authors:

Y. Tian, J. Park; Univ. of Toronto, Toronto, ON, Canada

Although genome-wide association studies (GWASs) have identified a number of genetic risk factors for Alzheimer's disease (AD), GWASs do not provide a comprehensive understanding of how the genetically-regulated structural and functional brain pathways drive AD progression, which is essential for characterizing the genetic mechanism of the disease and the development of AD targeted therapeutics. There is substantial evidence in the study of brain disorders that brain magnetic resonance imaging (MRI) measures, including multiple MRI modalities, such as structural, functional, and diffusion MRI, are useful biomarkers for AD and are modulated by genetic factors. However, due to both the high dimensionality and complexity of multi-modal MRI data, e.g., correlations of Imaging Derived Phenotypes (IDP) within modalities, current methods are unable to fully utilize brain imaging data. We propose a three-step mediation method for analyzing pathways of gene-AD effects by incorporating high-dimensional and multimodal brain MRI measures as mediators in GWAS. First, to reduce high dimensionality of MRI we apply principal component analysis (PCA) to reduce MRI dimensionality. Next, we estimate the genetic effects on reduced-dimensional MRI features using regressions. Lastly, we test for the existence of causal genetically regulated effects of genes on AD with an adaptive association test. This method has been extended to rely exclusively on publicly available GWAS summary statistics accommodating data from diverse studies, and external reference panels. Simulation results validated the robust control of type I error rates for the proposed method, pertaining to both continuous and binary traits. We applied the proposed method to UK Biobank (UKB) and International Genomics of Alzheimer's Project (IGAP) data and identified 12 genes affecting AD through structural MRI, 33 genes via diffusion MRI, and 1 gene from functional MRI. The driving motivation behind this study was the vast amount of MRI data in the UK Biobank and the power loss accompanying the analysis of numerous individual IDPs with current methods. Consequently, we devised an association test to evaluate the genetically regulated effects of specific MRI modalities on AD progression. This approach facilitates the identification of novel genetic pathways to AD, offering considerable potential for disease understanding and therapeutic development.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4256 Linkreg: Inferring cis-regulatory element to gene links using diverse epigenomic annotations across cell types.

Authors:

Q. Zeng[1], G. Xiang[2], R. Hardison[1], X. Zhu[1], Q. Li[1]; [1]Pennsylvania State Univ., University Park, PA, [2]Camp4 Therapeutics, Boston, MA

Cis-regulatory elements (CREs) are crucial in regulating gene expression, but understanding the intricate links between CREs and their target genes on a genome-wide scale remains challenging. Current methods for linking candidate CREs (cCREs) to genes often rely on simple distance thresholds or consider only a limited set of histone marks (e.g., H3K27ac), overlooking the broad impact of diverse functional marks on gene regulation. Although the epigenetic regulatory potential (eRP) score integrates epigenomic annotations that are derived from a comprehensive set of epigenomic features in multiple cell types by a computational model (e.g., ChromHMM), it lacks statistical rigor and interpretation. To address these limitations, we introduce Linkreg, a novel Bayesian model that infers cCRE-gene links by leveraging gene expression levels across cell types and epigenomic annotations in a principled statistical framework. Linkreg is built upon the scientific foundations established in eRP score, which proposes that the regulatory effects of a cCRE on gene expression are determined solely by the cCRE's epigenomic state profile, and that the effects of multiple cCREs on a gene are additive. By simultaneously selecting relevant cCREs and estimating the regulatory effects associated with different epigenomic states, Linkreg provides a more accurate and interpretable characterization of the gene regulatory network. Linkreg takes gene expression levels, cCREs, and their corresponding epigenomic annotations in various cell types as input. By using a multinomial latent formulation, it generates a posterior probability to assess if a specific cCRE regulates a particular gene. A scalable variational EM algorithm has been developed for efficient estimation in large-scale genomic analyses. Through comprehensive simulation studies based on real data, we have demonstrated the superior performance of Linkreg compared to distance and eRP score methods, achieving substantially higher precision-recall AUC values (≥ 0.2 higher) and better control over the false discovery rate. When applied to the mouse VISION dataset comprising 12 cell types in hematopoiesis, including 13418 genes and more than 200000 cCREs, Linkreg effectively identifies experimentally validated cCREs. Moreover, in the human EpiMap dataset comprising 304 cell types in diverse tissue samples, including 18306 genes and more than 1 million cCREs, Linkreg successfully identifies thousands of cCRE-gene links validated by chromatin conformation experiments or CRISPR screening. A user-friendly Python package for Linkreg has been developed.

PB4257 Localized Multi-Trait Model: Predicting Disease Risks, Identifying Variant Associations, and Mapping Trait Networks

Authors:

C. Lee[1], A. Khan[1], S. Ma[2], I. Ionita-Laza[1]; [1]Columbia Univ., New York, NY, [2]Jiao Tong Univ., Shanghai, China

Despite the impactful success of traditional genomic analyses such as Genome-Wide Association Studies (GWAS) and Polygenic Scores (PGS), they present certain limitations. Notably, binary trait overlooks phenotypic heterogeneity, causing information loss and obstructing advances in personalized medicine. Additionally, the case-control imbalance hampers GWAS's efficacy. While logistic regression enhances the power of selection-biased samples, it could be better for risk prediction due to the potential misinterpretation of effect sizes. We suggest the Liability Threshold-based Phenotypic Integration (LTPI). Leveraging the liability threshold model and multi-trait phenotypes from Electronic Health Records (EHR), the LTPI aims to circumvent the challenges above. It could unveil shared genetic factors between seemingly unrelated diseases, opening avenues for universal treatment strategies. We focus on utilizing comprehensive disease histories in EHR, highly available data. We conducted an LTPI analysis using UK Biobank and eMERGE, leveraging global and regional genetic covariance estimates among traits. Initially, we assumed a homogeneous genetic structure at each locus and gathered disease risk estimates for chronic kidney disease (CKD) and coronary artery disease (CAD). The LTPI scores ($LTPI_{Global}$), aggregating EHR phenotypes, showed enhanced prediction accuracy compared to binary PheCode phenotypes. However, subsequent GWAS using $LTPI_{Global}$ exposed an increased False Positive Rate (FPR), suggesting potential bias in our initial assumption. Our GWAS analysis yielded three association patterns: 1) True Positives (TP) influenced by both target and non-targets. 2) TP, guided solely by the target. 3) False Positives (FP) steered only by non-targets. The model's robustness against FPR was noteworthy when no associations were present to any included traits. However, we discovered that all TPs could face bias when local genetic covariance is current within a subgroup. Our findings led to a new hypothesis that each locus has a distinct genetic structure, which can be explored using recent techniques providing local genetic covariance estimates. To validate our model, we conducted simulations assuming local covariance. The results demonstrated that LTPI could generate locus-specific risk ($LTPI_{Local}$) suitable for GWAS, with superior predictive power than $LTPI_{Global}$, and maintains robustness even in FP scenarios (3). By the time of the meeting, we aim to present GWAS results on kidney disease and anxiety disorder traits using $LTPI_{Local}$, underscoring the model's applicability and potential in pleiotropic association mapping.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4258 LOCATER: Enhancing GWAS with genealogical relationship inference

Authors:

X. Wang[1], R. Christ[1], L. Aslett[2], D. Steinsaltz[3], I. Hall[1]; [1]Yale Univ., New Haven, CT, [2]Durham Univ., Durham, United Kingdom, [3]Oxford Univ., Oxford, United Kingdom

Genome-wide association studies (GWASs) have advanced our understanding of the genetic basis of phenotypes, yet a significant portion of phenotypic variance remains unexplained by identified genetic variants. Recently there has been renewed interest in ancestry-based methods to help address this gap by capturing loci with associations driven by allelic heterogeneity and difficult-to-tag structural variants. To complement this class of methods, we have developed LOCATER, an association testing workflow for inferred ancestral structures. While LOCATER can be adapted to work with any ancestry inference engine, in our current work we run LOCATER on top of probabilistic ancestral structures inferred using the R package kalis, a highly optimized implementation of the Li and Stephens model. LOCATER combines quadratic form and sequential testing approaches aimed at combining signals across weak-effect variants.

In experiments with simulated multiethnic datasets, we demonstrate that LOCATER can rescue signals driven by multiple causal variants that are missed by single-marker tests. On real sequencing data from Finnish individuals, LOCATER successfully replicates known loci associated with multiple lipid traits. All genome-wide significant signals identified by single-marker tests were also detected by LOCATER. In this pilot analysis, LOCATER demonstrated a stronger association signal in cases involving multiple unlinked causal variants. We further present work from ongoing analyses of a new multi-ancestry cohort, aiming to identify novel signals related to lipid traits and early-onset coronary artery disease.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4259 Longitudinal dynamics of lysophosphatidylcholines in relation to mortality, aging and *APOE*: Findings from Long Life Family Study.

Authors:

K. Arbeev[1], O. Bagley[1], A. Kulminski[1], E. Stallard[1], S. Cosentino[2], A. Yashin[1], S. Ukraintseva[1]; [1]Duke Univ., Durham, NC, [2]Columbia Univ. Med. Ctr., New York, NY

Recent studies found associations of lower levels of lysophosphatidylcholines (LPC) with adverse health outcomes and increased mortality risk. However, longitudinal dynamics of LPC in relation to mortality and aging-related outcomes as well as genetic underpinnings of such relationships remain understudied. Such analyses require specific methodologies for joint analyses of longitudinal and time-to-event outcomes that could also allow embedding different aging-related characteristics in the analytic framework. We applied such approaches, joint models (JM) and stochastic process models (SPM), to study longitudinal dynamics of LPC in relation to mortality and aging-related outcomes and the known genetic risk factor for those outcomes (*APOE4*) in the Long Life Family Study (LLFS). In total, we analyzed 23 LPC variants, with 3,614 measurements of each in 2,464 LLFS participants, and 1,330 deaths among the participants. JM analyses confirmed associations of lower levels of 18 LPC variants with increased mortality risk in the model adjusted for baseline age, sex, country, education, smoking and four genetic principal components (PCs), with the largest effect size observed for LPC 15:0/0:0 (hazard ratio for one-unit decrease=1.346, 95% CI (1.214, 1.493)). In the model adjusted for the *APOE* e4 status (carrier/non-carrier), we revealed association of the e4 allele with lower values of LPC 15:0/0:0 (regression coefficient: -0.114, p=0.015). SPM applications decomposed the observed associations of LPC 15:0/0:0 with mortality into several components representing different aging-related characteristics such as: 1) declines in robustness (p=2.1e-12) and resilience (p=0.003), related to deviations of the metabolite from optimal levels (those minimizing mortality risk at respective ages), 2) age-related decline in mean allostatic ("equilibrium") trajectories of the metabolite (p<1e-16), and 3) the persistent gap between the optimal and equilibrium trajectories that widens with age (p<1e-16). We also found that such characteristics are different in carriers and non-carriers of *APOE* e4 allele (p<1e-16). Various sensitivity analyses confirmed robustness of results to different aspects of computational procedures (e.g., analysis of a randomly selected person from a family; inclusion of additional covariates such as medication use and different numbers of PCs; additional quality control procedures). Results of our study support LPC as a major biomarker of human aging and related decline in robustness/resilience, and call for further exploration of genetic and other factors underlying age-dynamics of LPC in relation to mortality and diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4260 Low Coverage Meta-Imputation Improves Imputation Accuracy for Ancient DNA.

Authors:

K. Kumar[1], S. Zollner[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ Michigan, Ann Arbor, MI

Imputation is an essential, cost effective tool that increases power for downstream analyses such as GWAS or fine mapping. Traditionally, imputation has been developed for SNP array data. Low coverage sequencing is a growing alternative to SNP arrays that is both cost effective and unbiased for ancestry, which makes it better at detecting rare variants for non-European populations. New imputation algorithms such as GLIMPSE have been developed to impute low coverage samples. However, the imputation accuracy of GLIMPSE, like other algorithms, depends on the ancestry and sample size of the reference panel. For non-European ancestry populations, where we have fewer samples, low coverage imputation may benefit from a “meta” approach of combining results from smaller ancestry specific panels and larger European ancestry panels. Currently, methods for such meta imputation are designed for SNP arrays, and, therefore, do not take into account genotype uncertainty that is characteristic of low coverage samples or the difficulty in pre-phasing such samples.We design a new meta-imputation method that combines estimates from multiple reference panels using dynamically estimated weights tailored for each individual and genomic region. We use a diploid Li and Stephens Hidden Markov Model (HMM) to account for the difficulty of pre-phasing. Our method, unlike existing meta-imputation methods, accounts for genotype uncertainty by integrating over all possible genotypes in the emission probability of our HMM, weighted by genotype likelihoods. Our method outputs allelic dosages along with meta-imputed genotype dosages for each individual and marker.We meta-impute ancient DNA samples that are first imputed by GLIMPSE 2.0.1 using both African ancestry and European ancestry reference panels from 1000 Genomes. Our meta-imputed ancient African samples yield a higher R2 than imputing with either reference panel alone and performs comparably to “mega” imputation with a single combined African and European ancestry reference panel. Increasing the accuracy of imputation through meta imputation allows for better performance in downstream analyses, increasing the power for genomic discoveries, which will benefit non European populations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4261 Low-coverage sequencing imputation with 150,119 UK Biobank reference samples

Authors:

O. Delaneau[1], S. Rubinacci[2], R. Hofmeister[3], B. Mota[1]; [1]Univ. of Lausanne, Lausanne-Dorigny, Switzerland, [2]Brigham and Women's Hosp., Boston, MA, [3]Univ. of Lausanne, Ecublens, Switzerland

Low-coverage whole genome sequencing (lc-WGS) followed by genotype imputation is a cost-effective technology that can enhance genome-wide analysis and access to personalized medicine. Recent advances show that a shift from SNP arrays to lc-WGS is beneficial, although with prohibitive computational costs for large reference panels. Therefore, sequencing projects like the recent UK Biobank (UKB) WGS, bring new possibilities, such as improved reference panels, but also new computational challenges.

We present a new lc-WGS imputation method, GLIMPSE2, designed to handle millions of reference samples with an accuracy inaccessible to other methods at sustainable costs. Using 150,119 UKB samples as a reference panel, we obtain a reduction of running time of 100-1000 times compared to existing methods, achieving imputation of a genome for less than 0.10$.

Lc-WGS greatly benefits from the UKB reference panel, mainly for very low-coverage data (0.1-0.5x) and at rare variants (<0.1% MAF). For 0.25x and 0.5x, our method imputes variants at 0.01% MAF with r2=0.8 and r2=0.89 respectively. As a comparison, imputation using the UKB Axiom array reaches an accuracy of r2=0.71. By looking at non-homozygous reference calls, we show that the process of imputation increases “in-silico” the coverage of lc-WGS samples by an order of 10x, resulting in a striking reduction of sequencing costs.

We evaluated the performance of the UKB reference panel against 1000 Genomes by imputing 276 genomes from the Simons Genome Diversity Project. As expected, the UKB reference panel substantially improves the imputation of European individuals, especially those with Northern European ancestry. As a proof of concept, we imputed four ancient Viking samples and show that UKB reference panel brings a significant boost of accuracy (for 0.1x, 1000G r2=0.83; UKB r2=0.92), implying that Viking ancestry is recovered remarkably well from the UK Biobank.

Furthermore, in order to quantify the impact of these results for disease association, we performed GWAS analyses using 10,000 UKB individuals across 100 quantitative traits, comparing lc-WGS and SNP array to high coverage data. We found that the UKB Axiom array is quantitatively similar to 0.25x data (beta r2=0.9, p val r2=0.87), and inferior to 1x data (beta r2=0.97, p val r2=0.95). Looking at precision and recall of the hits, 0.5x captures high coverage GWAS signals better than the UKB Axiom array, suggesting it is better suited for fine mapping.

Overall, we present the remarkable performance of lc-WGS imputation from the UKB reference panel with a competitive financial cost, that could lead to a boost of sample size and signal of future genomic studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4262 Machine learning based integration of large-scale priors for genetic fine-mapping, colocalization and in-silico functionalization

Authors:

K. Bhattacharyya[1,2], S. Bhattacharjee[2]; [1]Univ. of Calcutta, Kolkata, India, [2]Natl. Inst. of BioMed. Genomics, Kalyani, India

Identification of causal genetic variants together with their potential regulatory mechanism can offer the most critical insights into the proper understanding of the complex genetic etiology of complex traits. So far, genome wide association studies have been remarkably successful in identifying genetic variants associated with various complex traits. However, the interpretation of these GWAS variants in terms of causality and the perception regarding the role played by these variants in the genetic etiology of complex traits have remained significantly ambiguous due to three major reasons- A. complex LD structure among the associated variants making it almost impossible to separate false positives from true causal variants, B. majority of the associated variants are in noncoding region, C. nonavailability of large gold standard sets of regulatory variants for training and validation through Machine Learning models. Knowledge from annotations can help to overcome the low power of fine-mapping due to strong LD. This highlights the requirement of novel methods that can dynamically incorporate large-sets of priors based on available knowledge. Here, we propose a statistical method combining Machine Learning with existing Bayesian techniques to efficiently integrate large-scale functional annotations and epigenomic landscape in a tissue/cell-type specific manner. A unique feature of our method is its ability to not only infer causal variants, but also potential gene(s) through which their action is mediated along with potential regulatory mechanisms. The proposed systematic prioritization method focuses on utilization of Bayesian statistical methods for Colocalization (e.g. Coloc), fine-mapping (e.g., Sum of Single Effects Regression Model or SuSiE) and Machine Learning technique XGBoost. We apply the proposed method for integrative analysis of GWAS summary data, GTEx v8 data, LD structure, Functional Annotations for quantitative lipid traits in relevant tissues. The main utility of such prioritization is to facilitate interpretation of these quantitative lipid traits associated loci to draw inference regarding genetic causality of CVD. Systematic and efficient prioritization of causal variants in complex trait associated loci along with identification of regulated cis-Genes is a critical step in guiding wet-lab validation experiments and reducing the resource burden. Further, improved gene-prioritization will enhance our understanding of biological processes driving complex diseases and help to pinpoint potential drug targets.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4263 Machine learning-derived risk of atherosclerosis progression reveals novel genetic associations and empowers drug target discovery

Authors:

L. Leal[1], L. Chen[2], S. Hu[2], H. Climente-González[2], R. Nielsen[1], R. Gupta[1], R. R. Kitchen[1], J. M. M. Howson[2]; [1]Novo Nordisk Res. Ctr. Oxford, Oxford, United Kingdom, [2]Novo Nordisk Res. Ctr. Oxford, Human Genetics CoE, Oxford, United Kingdom

Atherosclerosis (ASCVD) progresses with age yet, typically, ASCVD diagnoses appear in electronic medical records (EHR) as discrete events such as presence/absence of coronary artery disease (CAD). Binary phenotypes such as these have lower statistical power than continuous phenotypes and do not reflect the underlying incremental biology of atherosclerosis progression. EHR provide an opportunity to model phenotypes longitudinally and identify novel genetic associations in GWAS, however there remain challenges that reduce performance of GWAS, specifically regarding underdiagnosis and missing data. We hypothesised re-encoding individuals on an atherosclerosis continuum would be beneficial to understand atherosclerotic biology and identify potential drug targets for atherosclerosis.

We introduce a reproducible pipeline for phenotype re-definition and present its implementation with ASCVD in UK-Biobank. Taking 51,056 cases and 325,949 controls, it trains a Machine Learning (ML) classification model integrating Polygenic risk scores (PRS) with clinical and life-style variables and computes a continuous progression phenotype of ASCVD. We generated interpretable ML models and found the CAD PRS was amongst the top-10 high impact features, and that a high number of individuals were predicted to have advanced ASCVD but had not yet had a CVD event. We then performed GWAS of the progression phenotypes, identifying 74 associated genetic regions, 33 of which were not in the binary GWAS. We replicated 35 (of 74) associations in the CAD GWAS by Aragam et al 2022 (181,522 CAD cases, 1,165,690 controls), despite our smaller cohort size. Taking ASCVD progression as an outcome, we implemented systematic Mendelian randomisation (MR) and genetic colocalisation using tissue-specific eQTLs and plasma pQTLs and identified 285 potential causal genes for ASCVD, which do not map to previously known CAD loci. Thirty-nine of these did not implicate major lipids. 12 genes were differentially expressed in aortas of atherosclerotic individuals with consistent effect direction to that from MR. One of these novel targets is ZNF197, a regulatory protein for which increased gene expression was found associated with reduced atherosclerosis.

By moving from a binary to a continuous phenotype using ML, we leveraged association signals in GWAS and identified potential causal genes for ASCVD. Comprehensive genetic analysis together with molecular data annotations allowed us to characterise non-lipid related genes with potential for novel mechanisms of action. Following the use case for ASCVD, this pipeline can now be implemented to other disease areas.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4264 Mapping sleep's phenotypic and genetic links to multiple organs: a systematic analysis of multi-organ images in the UK Biobank

Authors:

Z. Fan[1], Y. Li[2], J. Shu[2], X. Yang[2], B. Li[2], J. Lin[3], Q. Wang[4], P. Paschou[2], T. Li[5], H. Zhu[5], B. Zhao[6]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Purdue Univ., West Lafayette, IN, [3]Yale Univ., New Haven, CT, [45]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [6]Univ. of Pennsylvania, Dept. of Statistics and Data Sci., Philadelphia, PA

Sleep is essential for human health, but a systematic analysis of the relationship between sleep and various organs, along with their genetic underpinnings, is lacking. Using imaging features of organ (brain, heart, and abdomen) structures and functions as clinical endophenotypes, we present a systematic genetic investigation of sleep and muti-organ connections from over 40,000 subjects in the UK Biobank. We identified novel phenotypic and genetic links between sleep and a wide range of imaging traits, such as brain structures, white matter integrity, brain activities, cardiac structures and functions, as well as abdominal compositions. We prioritized imaging modalities and traits for specific sleep conditions, such as the resting brain function measures in the somatomotor network with narcolepsy. Overlapping genetic influences were detected between sleep and multiple organs, some of which showed evidence of shared causal genetic variants. In conclusion, large-scale imaging genetic data illuminate the implications of sleep on whole-body health and their genetic links. An interactive web browser (www.ig4sleep.org) has been developed to facilitate exploring our results.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4265 Mendelian Randomization analysis of metabolites associated with severe obesity in the Hispanic Community Health Study/ Study of Latinos (HCHS/SOL)

Authors:

K. Young[1], V. Buchanan[2], M. Graff[1], M. Krishnan[3], H. Highland[4], B. Yu[5], C. Avery[1], S. Buyske[6], J. Cai[3], M. Daviglus[7], A. Howard[3], C. Isasi[8], R. Kaplan[8], R. Loos[9], Q. Qi[8], R. Rohde[3], J. Rotter[10], L. Van Horn[11], P. Gordon-Larsen[3], E. Boerwinkle[5], K. North[3]; [1]Univ North Carolina, Chapel Hill, NC, [2]Univ. of North Carolina - Chapel Hill, Westfield, IN, [3]Univ. of North Carolina, Chapel Hill, NC, [4]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [5]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [6]Rutgers Univ, Piscataway, NJ, [7]Univ. of Illinois, Chicago, IL, [8]Albert Einstein Coll. of Med., Bronx, NY, [9]Univ. of Copenhagen, Copenhagen, Denmark, [10]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [11]Northwestern Univ., Chicago, IL

Severe obesity (SevO: body mass index (BMI)≥40) is a major risk factor for heart disease and Type 2 Diabetes. Both disproportionately impact Hispanic/Latinos, 24.5% of whom are projected to have SevO by 2030. However, the underlying metabolic dysfunction characteristic of SevO remains unknown.

To assess if metabolomic associations with SevO are causal or consequential, we first identified metabolites associated with SevO in the Hispanic Community Health Study/Study of Latinos (HCHS/SOL). For the top 20 SevO associated metabolites, we extracted HCHS/SOL metabolite GWAS (mGWAS) summary statistics to derive metaboQTLs, and summary statistics from 1) a multi-population meta-analysis of SevO (N>70,000), and 2) UK Biobank (UKBB) to implement bidirectional Mendelian Randomization (MR).

Anthropometry and data for 640 metabolites were available for 551 females (27% SevO) and 371 males (15% SevO). In the meta-analysis, 224 metabolites were associated with SevO ($p<0.05/640$). Of the top 20 SevO metabolites, we excluded 8 with no mGWAS signals. For the remaining 12, we included independent SNPs ($p<5E-8$) as instrumental variables (IVs) in the forward MR. For the 59 independent SNPs in the SevO GWAS, we extracted summary statistics from the pan-ancestry UKBB for both measured BMI (BMI_m) and BMI calculated from bioimpedance (BMI_B) (35 SNPs) as IVs in the reverse MR.

In the forward MR, no metabolites were causally associated with SevO, though N-Acetylasparagine was significantly causally associated with both BMI phenotypes (ß (SE) =0.004 (0.001), BMI_m p =9.50E-6; BMI_B p=2.39E-4). The strongest genetic signal for this metabolite was rs10189885 (ß (SE): 0.981 (0.026), p=7.30E-308), an intronic variant in *ALMS1P1*, a pseudogene associated with Alström syndrome, a recessive condition whose phenotype includes hyperinsulinemia-associated childhood obesity.

In the reverse MR, BMI_m showed causal associations with four metabolites, including phenylalanine (Robust IVW ß (SE): 0.357 (0.115), p=1.9E-4) and 2-methylbutyrylcarnitine (Robust IVW ß (SE): 0.432 (0.0.118), p=2.62E-4). Causal estimates for both metabolites were robust to horizontal pleiotropy. Phenylalanine is an essential amino acid found in most protein food sources and has been positively associated with obesity as well as 2-year risk of hypertriglyceridemia in Hispanic/Latino children. 2-methylbutyrylcarnitine is a product of branched chain amino acid catabolism and a biomarker of meat and fish consumption that has been previously positively associated with obesity in Hispanic/Latino children. Our work is a first step towards disentangling the metabolic causes and consequences of SevO.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4266 Mendelian randomization approach suggests the potential of repurposing anti-diabetic drugs for the prevention of Parkinson's disease.

Authors:

J-Y. Lee[1], D. Park[2], J. Park[3], J. Sung[1]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Ajou Univ. Hosp., Suwon, Korea, Republic of, [3]Seoul Natl. Univ. Sch. of Publ. Hlth., Seoul, Korea, Republic of

Anti-diabetic drugs have shown some evidence suggesting a protective role in the prevention of Parkinson's disease (PD), however, the results were controversial. Mendelian randomization (MR) analysis using genetic instrumental variables associated with target genes of drugs has the potential to simulate the effect of the drug. Therefore, the objective of this study is to evaluate the potential repurposing of anti-diabetic medications for the prevention of PD. We identified the target genes of oral hypoglycemic drugs from Drugbank. Subsequently, we identified the SNPs associated with the expression of these genes using the expression quantitative trait loci (eQTL) data obtained from whole blood samples in the GTEx project. Utilizing these SNPs as instrumental variables, we performed an MR analysis to investigate the impact of drug target genes on the occurrence of PD. We obtained the GWAS data from the Diabetes Meta-Analysis of Trans-Ethnic association studies (DIAMANTE) Consortium for type 2 diabetes and from the International Parkinson's Disease Genomics Consortium for PD.
From the MR analysis, we revealed associations between several genes targeted by the anti-diabetic drugs and the incidence of PD. Notably, *GPD1*, inhibited by metformin, exhibited a significant increase in the risk of PD (p-value from MR analysis using Wald ratio method = 0.006). Additionally, *CPT1A* and *CFTR*, both inhibited by glyburide, showed tendencies towards a protective and harmful effect on PD, respectively, although these associations were not statistically significant (p-value from Wald ratio methods = 0.06 and 0.09).
Our findings suggest a potential role for anti-diabetic drugs in the prevention of PD. Inhibiting target gene expression with metformin or glyburide was associated with an increased risk of PD, which raises important considerations for using these drugs in individuals at higher risk of PD. Conversely, the potential protective effect of inhibiting *CPT1A* by glyburide, although not significant, indicates the possibility of exploring this drug as a potential medication option. In conclusion, this study highlights the potential involvement of specific target genes of anti-diabetic medications in the development of PD, providing enhanced opportunities for optimizing medication selection in diabetic patients at higher risk of developing PD.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4267 Mendelian randomization shows no causal effect of serum vitamin D levels on thyroid function.

Authors:

T. Zemunik, N. Pleic, I. Gunjača, M. Babić Leko; Univ. of Split, Sch. of Med., Split, Croatia

Background: Vitamin D plays an essential role in the normal functioning of many organs, including the thyroid gland. As a result, it is not surprising that insufficient levels of vitamin D are seen as a potential factor contributing to the emergence of several thyroid disorders, such as autoimmune thyroid disease and thyroid cancer. Nevertheless, the exact relationship between serum vitamin D levels and thyroid function remains incompletely understood. Here we use a Mendelian randomization approach (MR) to investigate the causal effect of serum vitamin D levels on the indicators of thyroid function; thyroid-stimulating hormone (TSH), free thyroxine (fT4), and thyroid peroxidase antibodies (TPOAb). **Methods:** We performed a two-sample MR study using summary statistics from the most comprehensive genome-wide association studies (GWAS) of serum vitamin D levels (25 hydroxyvitamin D (25(OH)D), n= 443,734), TSH (n=119,715), fT4 (n=49,269) and TPOAb (n=18,297). The multiplicative random-effects inverse variance weighted (IVW) method was chosen as the main analysis. Sensitivity analysis was performed using the weighted median and mode analysis, as well as MR-Egger, MR-PRESSO and Causal Analysis Using Summary Effect estimates (CAUSE). **Results:** Our analysis suggests that serum vitamin D levels are not causally associated with the determinants of thyroid function. Genetically predicted vitamin D levels were not causally associated with TSH (β=-0.02, P=0.512), nor with fT4 (β=0.05, P=0.229). The direction of the association between vitamin D and fT4 levels was consistent across different MR analyses, while this was not the case in the TSH analysis. The insignificant relationships were further confirmed by the CAUSE analysis for both TSH and fT4. Vitamin D levels showed a negative association with both TPOAb levels (β=-0.02, P=0.712), and TPOAb positivity (OR=0.57, P=0.141), however, these associations were not significant. **Conclusions:** This MR study does not support a causal association between genetically predicted serum vitamin D levels and the determinants of thyroid function. Further studies, particularly randomized controlled trials, are necessary to evaluate the therapeutic advantages of using vitamin D supplementation for the treatment of thyroid dysfunction.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4268 Meta-analysis of Alzheimer's disease GWAS identifies novel loci and implicates regulation of a hypoxic-responsive gene as a disease mechanism

Authors:

A. Diwadkar[1], J. Regan[1], X. Wang[2], H. Markus[2], L. Carrel[1], D. Liu[3]; [1]Penn State Univ., Hershey, PA, [2]Penn State Coll. of Med., Hershey, PA, [3]Penn State Univ., Hershey, PA

Alzheimer's disease (AD) is the most common form of dementia and is characterized by formation of amyloid-beta (Aβ) plaques and neurofibrillary tau tangles in the brain. AD is known for its phenotypic heterogeneity and sex differences where females tend to have an earlier age of onset, faster disease progression, and more severe disease outcomes. AD is strongly influenced by genetic risk factors, with an estimated heritability of 60 to 80%. To date, over 95 loci have been associated with AD risk. Yet, much of the disease heritability remains unexplained. There is a need to enlarge sample sizes, improve sample diversity, and better accommodate phenotype heterogeneity to improve power. To enhance the analyses of AD GWAS, we propose a novel meta-analysis approach IMAC (Integrated Meta-Analysis for Cross-trait GWAS) a mixed effect meta-regression model that uses factors of genetic correlation matrix as covariates to adjust for heterogeneity of AD phenotypes while accounting for sample overlaps. IMAC includes fixed effect, random effect analysis, and meta-regression as special cases. Unlike other cross-trait methods such as MTAG which assumes that genetic effects between phenotypes follow a multivariate normal distribution, our method is more flexible and can accommodate cross-trait genetic effect differences. For example, variants with similar effects between different AD subphenotypes would be most powerfully analyzed by a fixed effect method. Alternately, variants that differentially affect AD subphenotypes would benefit from models that incorporate factors as covariates to characterize genetic effect heterogeneity. We applied this method to perform a meta-analysis on 4 large publicly available AD and AD proxy GWAS summary statistics namely, Bellenguez et al. (2022), Wightman et al. (2021), de Rojas et al. (2021) and Jansen et al. (2019). We performed imputation on the meta-analysis results using FIZI to identify 30 known and 9 novel AD loci. Further, we applied statistical fine-mapping using susieR and utilized eQTL, transcriptomic, and epigenomic datasets in brain-related cell types to identify functional regulatory variants for experimental validation using a massively parallel reporter assay. The novel risk loci identified include a locus near the gene HIF-1α (hypoxia-inducible factor-1α), which is produced in both acute and chronic hypoxia. Hypoxia is a strong risk factor for AD. In AD models, HIF-1α can mediate hypoxic effects leading to neuronal apoptosis, increased levels of Aβ, and aberrant phosphorylation of tau proteins. Overall, our method provides novel risk loci for follow-up studies that may further elucidate the pathophysiology of AD.

PB4269 Meta-analysis of cardiac eQTLs improves identifying heart failure mechanisms

Authors:

S. Figarska[1], L. Zhang[1], S. B. Montgomery[2], J. R. Priest[1]; [1]Tenaya Therapeutics, South San Francisco, CA, [2]Stanford Univ., Stanford, CA

There are limited sources of eQTLs in the heart, more specifically the left ventricle (LV), impeding the study of the genetic and molecular mechanism of heart failure. One of the sources is GTEx that offers data from 386 LV samples. These samples were collected postmortem from mainly healthy individuals aged 20-71 yrs, 33% females, mostly European ancestry. A separate source is data from Myocardial Applied Genomics Network (MAGNet) which includes 313 LV freewall tissue samples harvested at the time of cardiac surgery from subjects with heart failure (HF) undergoing transplantation and from unused donor hearts. To expand insight into LV eQTLs and inform the mechanisms of heart failure risk loci, we reprocessed MAGNet data to make it more comparable with GTEx. Specifically, we imputed MAGNet genetic data using TOPMed, we calculated latent factors and re-called eQTLs with a MAF>0.01 threshold. For each set of eQTLs we subsequently tested colocalization with GWAS on HF in individuals of European descent, obtained from GBMI (Global Biobank Meta-Analysis Initiative). Colocalization was performed with coloc for each locus where there was a GWAS SNP p<1e-7 and within 250kb there was an eQTL SNP in either MAGNET or GTEx with a p<1e-4. We found colocalizations between ABO and SPATS2L eQTLs and HF GWAS, for both GTEx and MAGNet. Notably, colocalization between PTPN11, known as a mendelian cause of Noonan syndrome which includes cardiac manifestations, colocalized with HF only for GTEx data. On the other hand, colocalization between NPC1, a gene previously shown to be associated with risk of coronary heart disease, and HF, was observed only in MAGNet data sets. We have meta-analyzed both eQTL datasets to create the largest available set of eQTL data in left ventricle and report 10,706 genes with an eQTL (FDR 0.05). We expect these data to increase statistical power for finemapping and colocalization and shed more light on molecular mechanisms of genetic risk for heart failure.

PB4270 Meta-analysis of set-based multiple phenotype association test based on GWAS summary statistics from different cohorts

Authors:

L. Zhu; Michigan Technological Univ., Houghton, MI

Genome-wide association studies (GWAS) have emerged as popular tools for identifying SNPs that are associated with complex diseases. Standard analysis of a GWAS involves assessing the association between each individual SNP and a disease. However, this approach suffers from limited reproducibility and difficulties in detecting multi-SNP and pleiotropic effects. Although joint analysis of multiple correlated phenotypes for GWAS can identify and interpret pleiotropic loci which are essential to understand pleiotropy in diseases and complex traits, most of the multiple phenotype association tests are designed for a single SNP, resulting in much lower power when the number of SNPs increases and SNPs are correlated, especially when their effect sizes are small and only their cumulative effect is associated with multiple phenotypes. To overcome these limitations, set-based multiple phenotype association tests have been developed to enhances statistical power and facilitates the identification and interpretation of pleiotropic regions. Nevertheless, most existing methodologies fail to consider the impact of varying sample sizes and sample overlapping when combining GWAS summary statistics from different studies. In this research, we propose a new method, named Meta-TOW-S, which conducts joint association tests between multiple phenotypes and a set of SNPs (such as SNPs in a gene) utilizing GWAS summary statistics from different cohorts. Our approach applies set-based tests using the Optimal Weighted Combination of SNPs and accounts for sample size differences across studies by employing the Cauchy combination method. Meta-TOW-S combines the advantages of set-based tests and multi-phenotype modeling, exhibiting computational efficiency and enabling analysis across multiple correlated phenotypes, while accommodating overlapping samples from different GWAS cohorts. To assess the performance of Meta-TOW-S, we developed a phenotype simulator package that encompasses a comprehensive simulation scheme capable of modeling multiple phenotypes with multiple SNPs, including noise structures and diverse correlation patterns among phenotypes. Simulation studies validate that Meta-TOW-S maintains a desirable type-1 error rate and enhances power across various simulation scenarios. Furthermore, we demonstrate that Meta-TOW-S outperforms single phenotype-based methods by detecting a larger number of significant genes using real GWAS summary statistics obtained from multiple consortia.

PB4271 Metabolite prediction models in UK Biobank: A metabolome-wide association study (MWAS)

Authors:

L. Huang[1], A. L. Tapia[2], J. Chen[3], B. Rowland[3], J. D. Rosen[3], J. Wen[4], Y. Li[3,5,6], L. Raffield[5]; [1]Curriculum in Bioinformatics and Computational Biology, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Dept. of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA, [3]Dept. of Biostatistics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [4]Dept. of Genetics, Univ. of North Carolina at Chapel Hill, Chapel Hill, Chapel Hill, NC, [5]Dept. of Genetics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [6]Dept. of Computer Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

As potential disease risk factors, multi-omics readouts including transcripts, proteins, and metabolites are all of the interest. However, due to cost and tissue availability, sample sizes for omics data have severely lagged behind genetic data. To fill this gap, we use genetic and metabolomic data from UK Biobank (UKBB) to perform a metabolome-wide association study (MWAS). Our analyses included 101,349 European ancestry participants (EUR) (defined based on genetic similarity to 1000G) with 161 QC+ metabolites measured using the Nightingale platform. We identified metabolite quantitative trait loci (mQTL, p < 1e-6) with a subset of 45,581 individuals, built metabolite prediction elastic net models with these mQTLs in an independent subset of 45,466 individuals, and assessed the performance of the prediction models in the remaining 9,812 individuals. Our results showed that a number of metabolites can be reasonably predicted: median testing R^2 0.095, and 74 metabolites with testing R^2 > 0.1. We also applied our pre-trained prediction models to non-EUR ancestry UKB participants. Models show worse performance than in EUR participants (median testing R^2 0.053, 0.047, and 0.038, respectively for African, East Asian, and South Asian ancestry participants), similar to the transferability issue reported in TWAS or polygenic risk score studies. We proceeded with the 74 metabolites with testing R^2 > 0.1 and tested associations with 29 blood cell traits in the 333,501 EUR UKB samples without measured metabolites. We also tested the associations between measured metabolites and blood cell traits, using the 96,494 unrelated samples with both phenotypes. At a Bonferroni threshold of 2.4e-5, we had a median of 68 (range: 34-73) significant associations per blood cell trait using measured metabolites; and a median of 44 (range: 1-61) using predicted metabolites. The findings are largely expected because most of the Nightingale metabolites are lipid-related, and lipid traits have well-established relationships with blood cell indices. Association results are reasonably consistent between measured and predicted metabolites. We also performed MWAS between metabolites and ICD-10 disease case/control status. We identified numerous significant associations; for example, higher leucine is significantly associated with a higher risk of gout (M10), essential hypertension (I10), and disorders of lipoprotein metabolism and other lipidaemias (E78). In summary, MWAS in biobank samples can be a powerful approach to reveal molecular mechanisms and potentially discover novel therapeutic targets.

PB4272 Metabolome-wide Mendelian randomization for youth type 2 diabetes

Authors:

K. FAGBEMI[1], R. Avocegamou[1], M. Yazdanpanah[1], N. Yazdanpanah[1], D. MANOUSAKI[2]; [1]CHU Sainte-Justine, Univ. of Montreal, Montreal, QC, Canada, [2]Dept. of Pediatrics, Faculty of Med., Univ. of Montreal,, Montreal, QC, Canada

BACKGROUNDPreviously a rare disease in children, type 2 diabetes (T2D) has an increasing prevalence in youth, and is closely related to the pediatric obesity epidemic. Given the role of metabolism in diabetes, we aimed to identify circulating metabolites having a causal link with youth T2D as early disease biomarkers, using two-sample Mendelian randomization (MR).**METHODS AND RESULTS**
For our MR study, we tested causal effects on youth T2D of metabolites with available SNP-instruments in four GWAS. Effects of these SNPs on pediatric T2D were derived from the multi-ethnic ProDiGY GWAS (3,006 cases/6,061controls) or its European subset (664 cases/1434 controls). In multi-instrument MR analyses, steiger testing evaluated the directionality of the MR associations, and reverse two-sample MR analyses were performed for metabolites with evidence of reverse causation in our forward MRs. Multivariable MR (MVMR) tested effects of the metabolites on youth T2D conditioning on childhood BMI. Genetic colocalization was applied to identify shared causal variants between the MR-prioritized metabolites and youth T2D. Among 586 unique metabolites tested in the multiethnic MR, 25[DM1] metabolites demonstrated a causal effect on youth T2D (FDR P-values < 0.1), most of which clustered in the glycerophospholipid class. Among these, PC aa C32:2 and PC ae C36:2 had a protective effect (OR = 0.83, 95% CI: 0.77-0.89; OR = 0.89, 95% CI: 0.82-0.96). Steiger testing provided evidence for reverse causality for 4 metabolites (HDL diameter, caproate (6:0), alanine, serum cholesterol). However, the findings of the reverse MR analyses for the 4 metabolites did not support a causal effect of youth T2D on these metabolites. MVMR analyses showed that, conditioning on childhood BMI, the MR associations of HDL.D, serum cholesterol and PC aa C34:3 with youth T2D disappeared, while those of PC aa C32:2 and PC ae C36:2 remained. Among the candidate metabolites, only the glycerophosphocholine PC ae C36:2, colocalized with youth T2D (H4=0,804).In the European MR analysis, 8 of the 586 tested metabolites showed a causal effect on youth T2D (FDR P-value< 0.1), 6 of which are glycerophospholipids. 1-stearoyl-2-linoleoyl-GPE (18:0/18:2) had a protective effect on youth T2D (OR=0.90; 95% CI: 0.85-0.95), whereas the other 7 metabolites increased T2D risk, with 1-Docosahexaenoyl-GPE(22:6) associating with the highest risk (OR = 1.22; 95% CI: 1.08-1.37). Steiger testing supported the expected direction of the causal association for all 8 metabolites.We have identified causal effects of several glycophospholipids on youth T2D in our MR studies, including the PC ae C36:2, which colocalized with youth T2D.

PB4273 Meta-learning for instant genetic classification with neural networks.

Authors:

D. Bonet Sole[1,2], D. Mas Montserrat[1], X. Giro-i-Nieto[2], A. Ioannidis[1]; [1]Stanford Univ., Stanford, CA, [2]Univ.t Politècnica de Catalunya, Barcelona, Spain

Large-scale biomedical research databases provide the opportunity to adopt machine learning and deep learning approaches for genetic studies and precision medicine. However, training deep learning models and adjusting hyperparameter configurations for new tasks and datasets is computationally demanding and time-consuming. Traditional statistical and machine learning methods remain the preferred choice for most genomic studies, while neural network alternatives require extensive hyperparameter tuning or work only under very specific limitations. We present a meta-learning framework designed to perform instant classification on genetic classification tasks. A pre-trained hypernetwork receives a labeled SNP dataset and generates the weights of a task-specific neural model tailored to the provided dataset that can be directly used for inference, removing the need for training a new model. We effectively decouple the complexity of specialized genetic prediction models that perform individual tasks from a general meta-model. In other words, we train a high-capacity meta-model to encode task-specific variations in the parameters of a smaller model. We report extensive experiments on the UK Biobank and HapMap3 datasets for phenotype prediction tasks along with ancestry inference from genotype data, showing that our method outperforms competing neural networks approaches, traditional methods, and boosting machines, while being significantly faster. We provide invariance to permutations of input samples with scalability with respect to the dataset size, as well as feature-permutation invariance. Additionally, our approach demonstrates robust adaptability across a variety of tasks with little to no fine-tuning, positioning our approach as a strong solution for numerous applications and rapid model deployment. Our approach introduces a promising paradigm for obtaining instant predictions, with the potential to substantially decrease the computational burden of deep learning.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4274 Methods for multi-phenotype colocalization analysis in a single cohort

Authors:

S. Hanks[1], X. Yin[2], M. Laakso[3], X. Wen[4]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Nanjing Med. Univ., Nanjing, China, [3]Inst. of Clinical Med., Kuopio, Finland, [4]Univ. of Michigan, Ann Arbor, MI

Genetic colocalization is the process of identifying genetic variants that are causal for multiple association signals at a single locus. Most existing methods explicitly assume that the traits are measured in independent, non-overlapping samples. However, there are increasing numbers of cohorts with multiple phenotypes collected on the same samples, such as the METSIM study measuring ~1.4K metabolites in ~6K individuals. The consequences of using these existing methods with a single cohort design are currently unknown. To investigate the consequences of violating the independent cohort assumption, we used genetic data from the METSIM study to simulate two continuous traits, varying the proportion of the error variance that is attributed to individual-level confounding. We used fastENLOC to perform colocalization on the simulated data and found that Type I error rates are well-controlled (FDR less than 5%) when treating a single cohort as independent samples. We also propose a new method to perform colocalization in a single cohort by explicitly estimating the shared unobserved confounding across the two traits with probabilistic principal component analysis (PPCA). We then control this estimate as a covariate in the fine-mapping stage of the colocalization analysis. With this new method, Type I error remains well-controlled, and power increases up to 22%. In the future, we will use this method to perform colocalization analysis with metabolite data in the METSIM study.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4275 Methyl-TWAS: A powerful method for precise pseudo-transcriptome-wide association studies (TWAS) using long-range DNA methylation.

Authors:

S. Kim[1], Y. Qin[1], H. Park[1], M. Yue[1], Z. Xu[1], E. Forno[1], W. Chen[1], J. Celedon[2]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Children's Hosp of Pittsburgh of UPMC, Univ. of Pittsburgh, Pittsburgh, PA

While transcriptome-wide association studies (TWAS) using genotype data have gained much popularity, these show low prediction accuracy of imputed gene expression. This can be because SNPs are neither tissue specific nor disease-specific and are not affected by environmental factors while gene expressions are tissue- and disease-specific and largely affected by environmental factors. Also, majority of GWAS SNPs indirectly regulate gene expression by regulating DNA methylation.We previously developed geneEXPLORE that incorporates long-range methylation CpGs to maximize prediction accuracy, outperforming other methods in pan-cancer. However, this study did not apply the method for TWAS. Owing to the good prediction accuracy of gene expression using long-range DNA methylation, here we propose to conduct TWAS using long-range DNA methylation rather than genotype data. To this end, we developed Methyl-TWAS, the first TWAS method that incorporates DNA methylation instead of genotype data. Using nasal epithelium, we found that the predictive power of DNA methylation on gene expression is much higher than that of SNPs. The genes better predicted by Methyl-TWAS are in immune pathways whereas the genes better predicted by PrediXcan are in metabolic and biosynthetic pathways. Further, Methyl-TWAS predicts immune genes and differentially expressed genes significantly better than randomly selected genes while PrediXcan does not. Owing to the accurately predicted expressions of genes, Methyl-TWAS outperforms PrediXcan in identifying DEGs of atopic asthma. Also, in an external test data set, Methyl-TWAS identified differentially expressed genes of atopic asthma accurately as much as using observed expression data. Methyl-TWAS would give opportunities for researchers to accurately conduct TWAS using increasing numbers of publicly available DNA methylation data to study various immune diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4276 MiXeR-TAG: A new method for classification of overlapping and trait specific variants.

Authors:

N. Parker[1], O. Frei[1], A. Shadrin[1], G. Hindley[1], O. Smeland[1], O. Andreassen[2], A. Dale[3]; [1]Univ. of Oslo, Oslo, Norway, [2]Univ. of Oslo, Oslo, Oslo, Norway, [3]Univ. of California San Diego, San Diego, CA

Previous studies have identified a need for assessment of genetic overlap between pairs of traits beyond genetic correlation. Bivariate MiXeR uses a Gaussian mixture model to estimate the number of shared and trait-specific genetic variants between two complex traits. However, identification of which genetic variants are shared or trait-specific was not previously available.

Here we present a novel extension to bivariate MiXeR to assign genetic variants to one of 3 categories: specific to trait 1, specific to trait 2, or shared by both traits. In addition, we report trait-specific variants located in the same independent genomic block. We also use this novel MiXeR based trait annotation of genetic variants (MiXeR-TAG) to perform gene enrichment analyses for each category. P-values from the original GWAS were used to threshold variants to be significantly associated with at least 1 trait. For each variant likelihood estimates are derived for the 4 categories and variants were assigned the category with the highest value. For gene enrichment analyses, we selected the nearest gene assigned to independent significant SNPs (independent at R^2<0.1 and distance 250kb) and used hypergeometric tests to assess significant overlap. We used GWAS summary statistics for four trait comparisons to test this method: (1) cerebral cortical thickness (TH) and height, (2) cerebral cortical surface area (SA) and height, (3) Crohn's disease (CD) and body mass index (BMI), and (4) CD and rheumatoid arthritis (RA). Enrichment analyses showed that TH genes were upregulated in the brain (p_{fdr}=2.7e-10). The same was true for SA genes (p_{fdr}=2.2e-2). Gene ontology enrichment analyses implicated neuron development and the post-synapse cellular component for both TH and SA genes. Enrichment among GWAS catalog genes showed TH genes were enriched for genes linked to cognitive ability and several psychiatric disorders (p_{fdr}<0.05). Also, height genes were enriched for the height GWAS genes (p_{fdr}=2.7e-122). Genes shared by CD and BMI were upregulated in adipose tissue (p_{fdr}=1.93e-6) while RA genes were upregulated in blood vessels (p_{fdr}=3.7e-3). Genes shared by both CD and BMI as well as CD and RA were enriched for cytokine and immune system processes based on gene ontology groups and KEGG pathways (p_{fdr}<0.05). Also, BMI specific genes were enriched for BMI GWAS genes (p_{fdr}=1.8e-120).

Overall, genes mapped to variants assigned to trait specific or shared categories by MiXeR-TAG exhibited gene enrichment for biologically viable and relevant gene sets. The MiXeR-TAG approach provides a novel method for understanding the shared and unique genetic architecture of complex traits.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4277 Modelling genotype-phenotype dose-response dynamics to prioritise novel drug targets: a statistical workflow for common and rare variants

Authors:

L. Stefanucci[1], Z. Ke[1], C. Jones[1], D. Ochoa[2], S. Jeremy[1], E. Holzinger[3], J. Maranville[3], E. McDonagh[4], K. Alasoo[5], I. Dunham[6], M. Ghoussaini[7], G. Trynka[8]; [1]Wellcome Trust Sanger Inst., Cambridge, United Kingdom, [2]European Molecular Biology Lab., European Bioinformatics Inst. (EMBL-EBI), Hinxton, United Kingdom, [3]BMS, Cambridge, MA, [4]Stanford Univ., PharmGKB, Palo Alto, CA, [5]Univ. of Tartu, Tartu, Estonia, [6]Wellcome Sanger Inst., Wellcome Genome Campus, Cambridge, United Kingdom, Saffron Walden, United Kingdom, [7]Wellcome Trust Sanger Inst, Cambridge, United Kingdom, [8]Wellcome Sanger Inst., Hinxton, United Kingdom

Unexpected toxicity and erroneous drug target selection are the primary culprits behind the high attrition rates encountered during drug development. Human genetics holds great promise to mitigate these challenges: drugs supported by genetic evidence exhibit a higher success rate than those lacking such support. When multiple independent variants are identified for the same gene-trait association (i.e. allelic series), they can be used to construct dose-response curves and titrate the relationship between protein function and phenotypes. The construction of these relationships can provide crucial information to the drug development process. For instance, a positive relationship indicates that mimicking the loss of protein function (e.g. by targeting with an inhibitor) becomes the key mechanism for disease prevention. Mendelian randomisation (MR) leverages GWAS and QTL to construct these dose-response relations. However, the number of instrument variants available limits the power to estimate these relations. Yet, including additional rare variants, beyond QTL and GWAS, could further validate MR observations. Furthermore, rare variants provide insights at the dose-response curve extremes, which are more relevant for drug development.We developed a framework that can use Open Targets data (2,959,742 genetic variants and 22,274 common traits) to correlate genetic variants with disease risk, focusing in particular on rare variants. To estimate the coding-variant effect on protein function, when experimental data were not available, we trained a gradient-boosted decision tree model (Specificity=0.98; Sensitivity=0.81). To infer the latent dose-response relation, we used a Bayesian hierarchical framework, independently modelling the different classes of variants. Extensive simulations show an accurate predictive capacity (MAPE=2.01%). Summary statistics modelling confirmed the biological mechanism and the expected dose-response correlation for a well-characterised genotype-phenotype association, such as PCSK9 and hypercholesterolemia. By factoring in rare variants, our approach unveiled a stronger correlation (β=0.24; CI=[0.12-0.29]) compared to MR (β=0.074, sd=0.004) between PCSK9 concentration and high cholesterol. This promising method can be expanded to virtually all available genes and phenotypes.To conclude, our workflow models dose-response relationships between genes and diseases, combining the effect of common and rare variants. This approach can systematically reveal gene roles in disease aetiology and, notably, provides insight into the directionality of the effect and, thus, drug modulation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4278 MR-link 2: Improved *cis* Mendelian randomization validated through three independent validation datasets.

Authors:

A. van der Graaf[1], R. Warmerdam[2,3], U. Võsa[4], L. Franke[5,3], Z. Kutalik[1]; [1]Univ. of Lausanne, Lausanne, Switzerland, [2]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [3]Oncode Inst., Utrecht, Netherlands, [4]Univ. of Tartu, Tartu, Estonia, [5]Univ. Med. Ctr. Groningen, Groningen, Netherlands

Background: Causality shapes human biology, but it is difficult to prove as it usually requires randomized trials. Mendelian randomization (MR) can identify causal relationships from observational data but has increased false positive rates (FPRs) when genetic instruments are scarce. This typically occurs when molecular traits are considered: often only a single *cis* associated region may be available for analysis.
Methods: We present a new, summary statistics *cis* MR method: MR-link 2. MR-link 2 models all SNPs in a region to estimate the causal effect while accounting for pleiotropy. We compare MR-link 2 to three *cis* MR methods: MR-IVW, MR-IVW-R and MR-PCA and two colocalization approaches: coloc and SuSiE-coloc. We test each method in three independent validation datasets of causal relationships: i) simulations, ii) gold standard metabolite networks and iii) canonical causal relationships between complex traits.
Results: In simulations that include pleiotropy, MR-link 2 has well-calibrated FPR and high power, resulting in area under the receiver operator characteristic curves (AUC) superior to other methods. In some cases, more than 0.2 units better than the best competing method, MR-PCA. Our simulations show that when MR-link 2 assumptions of infinitesimal genetic architecture are violated, FPR increases slightly, still it outperforms competing methods in 75% of simulated scenarios.
Using 921 metabolite pairs as true causal relationships derived from 3 metabolic pathway databases (KEGG, MetaCyc and Wikipathways) and metabolites from 4 metabolite QTL (mQTL) studies, MR-link 2 achieves an AUC of 0.696, outperforming all tested competing methods (max AUC: 0.664). MR-link 2 also has lower bias in causal effect estimation (0.036) than the best competing approach, MR-IVW (0.040) when testing the causal effect of metabolites on themselves using mQTLs coming from different studies.
Applied to 9 canonical causal relationships in complex traits (e.g., smoking causes cancer), and 5 true negatives (e.g., adult blood pressure causes child onset asthma), all MR methods correctly distinguish causal from non-causal pairs. When comparing individual locus-based causal effect estimates, MR-link 2 has the lowest heterogeneity across loci (median Cochran's Q: 686, lowest competing: MR-IVW, 1438) and best calibrated FPR (0.09) for the true negative pairs at ($P<0.05$) compared to other methods (lowest FPR: MR-IVW, 0.15).
Conclusion: MR-link 2 is a MR method for *cis* causal inference. In three validation datasets, MR-link 2 outperforms competing approaches. MR-link 2 has lower FPR while still retaining high power, due to being more robust to MR assumption violations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4279 MTClass: Identification and annotation of multi-phenotype cis-eQTLs using machine learning.

Authors:

R. Li[1], S. Qin[2]; [1]Emory Univ., Atlanta, GA, [2]Emory Univ, Atlanta, GA

Dysregulation of gene expression contributes to the pathophysiology of many human diseases. Mapping genetic variants that affect the expression of one or more genes, termed expression quantitative trait loci (eQTLs), is a growing area of interest. Multi-phenotype eQTL mapping identifies variants that affect the expression of the same gene across multiple phenotypes (e.g., tissues, exons), thereby potentially recognizing variants with stronger and broader functional impacts that are more likely to lead to phenotypic consequences. However, measuring the effect of a variant on gene expression across many phenotypes is a challenge. To solve this problem, we propose a model-free strategy named MTClass. Instead of calculating a p-value under a statistical testing framework, we attempt to classify vectors of multi-phenotype expression values in terms of donor genotype for the variant of interest. We then rank variant-gene pairs based on classification performance. Using data from the GTEx Consortium, we utilized our strategy in an example with 13 brain tissues, 317 donors, and 47% missing data. To accommodate missing expression measures in donor-tissue combinations, we used multiple imputation with predictive mean matching. MTClass was able to identify variants and genes with stronger functional impacts than competing methods such as multi-phenotype association tests. Our method consistently outperformed two other methods in terms of neighboring GWAS SNP hits calculated for the top 5,000 variants. Using gene-set enrichment analysis, we observed more significant enrichment from our method's top 100 genes than from those of other methods. We extended the same framework to classify variants that affect the expression of multiple exons in brain tissues. In relevant brain regions, we found greater overlap with known disease-related genes among our top 100 genes compared to single-tissue approaches and other multivariate methods. Finally, we constructed a "2D case" in which we used an artificial neural network to classify genotypes across multiple exons and 9 tissues with no missing data. We found that other methods were not able to do this and that MTClass can uncover variants that are both eQTLs and sQTLs across multiple tissues. Together, these results emphasize that multi-phenotype eQTLs from our method likely have functional consequences, and they suggest the value of further pursuing such variants.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4280 mtPGS: Leverage Multiple Correlated Traits for Accurate Polygenic Score Construction

Authors:

C. Xu, S. Ganesh, X. Zhou; Univ. of Michigan, Ann Arbor, MI

Background: Accurate polygenic scores (PGS) facilitate the genetic prediction of complex traits and aid in the development of personalized medicine. Multivariate PGS methods leverage traits that are correlated or relevant to the target complex trait of interest to facilitate its prediction. However, existing multivariate PGS methods often make relatively simple modeling assumptions on the shared genetic architecture between the target trait and the relevant traits, and these methods have largely ignored the environmental correlation between traits due to sample overlap. Further efforts are needed for the development of multivariate PGS method that relies on flexible modeling assumption and incorporates environmental correlations for PGS construction. **Methods:** We develop a statistical method called multi-trait assisted PGS (mtPGS), which can construct accurate PGS for a target trait of interest through leveraging multiple traits relevant to the target trait. Specifically, mtPGS borrows SNP effect size similarity information between the target trait and its relevant traits to improve the effect size estimation on the target trait, thus achieving accurate PGS. In the process, mtPGS flexibly models the shared genetic architecture between the target and the relevant traits to achieve robust performance, while explicitly accounting for the environmental covariance among them to accommodate different study designs with various sample overlap patterns. In addition, mtPGS uses only summary statistics as input and relies on a deterministic algorithm with several algebraic techniques for scalable computation. **Results:** The predictive performances of mtPGS were evaluated through comprehensive simulations and applications to 25 traits in the UK Biobank (UKB). In the simulation settings with distinct genetic architectures and various combinations of SNP heritability and genetic/environmental correlation, mtPGS achieved an average of 7.05%-504% accuracy gain compared to the seven other state-of-the-art PGS methods. mtPGS also achieved robust predictive performances in the simulations with different scenarios of sample overlap and different number of relevant traits. For the prediction of 25 traits in the UKB, mtPGS achieved an average of 2.17%-51.12% accuracy gain over competing PGS methods. mtPGS compares favorably to the other PGS methods with relatively low computing time and memory cost. **Conclusion:** Our proposed PGS method, multi-trait assisted PGS (mtPGS), represents an accurate and scalable method for PGS construction in the large-scale biobank datasets.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4281 Muesli intake protects against coronary artery disease: A Mendelian randomization study on 13 dietary traits.

Authors:

J. Park[1], B. Petrazzini[1], S. Bafna[1], A. Duffy[1], I. Forrest[1], H. M. Vy[1], C. Marquez-Luna[1], M. Verbanck[2], J. Narula[1], R. S. Rosenson[1], D. M. Jordan[1], G. Rocheleau[1], R. Do[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Université Paris Cité, Paris, France

Background: Diet is a key modifiable risk factor of coronary artery disease (CAD). However, the causal effects of specific dietary behaviors on CAD risk remain unclear, as observational studies are potentially biased by confounding and reverse causation. Given the genetic heritability of lifestyle traits and the advancement of dietary data in population biobanks, genetic epidemiology could help infer causality between specific dietary traits and CAD risk.
Methods: We performed two-sample MR using inverse variance weighted (IVW) regression to estimate the causal effects of 13 common dietary traits on CAD risk, using cross-sectional genetic and dietary data on up to 420,531 UK Biobank participants and 184,305 CARDIoGRAMplusC4D participants of European ancestry. To examine the underlying mechanisms mediating any detected associations, we then conducted follow-up MR analyses involving 171 plasma metabolite levels from UK Biobank. Finally, we performed sensitivity analyses using weighted median estimation, MR-Egger regression, and MR-PRESSO.
Results: Genetically-proxied muesli intake was negatively associated with CAD risk (OR 0.74, 95% CI 0.65-0.84, $P = 5.39 \times 10^{-4}$). Sensitivity analyses using weighted median estimation demonstrated a nominally-significant association in the same direction. Additionally, we identified acetate (OR 0.037, 95% CI 0.01-0.12, $P = 1.15 \times 10^{-4}$) as the plasma metabolite potentially mediating this association.
Conclusions: Consuming muesli, a mixture of oats, seeds, nuts, and dried fruit, may causally reduce CAD risk. Circulating levels of acetate, a gut microbiota-derived short-chain fatty acid, may causally mediate this cardioprotective effect. These findings could prioritize clinical trials for dietary interventions, provide mechanistic insights into a gut-heart axis, and inform dietary policy for population health.

PB4282 Multi ancestry multi trait meta analysis of autoimmune diseases.

Authors:

K. Anderson Fears, D. Liu, B. Jiang, X. Wang; Pennsylvania State Univ., State College, PA

Genetic association signals are often shared between traits or ancestries, and jointly analyzing datasets via meta-analysis across different traits and ancestries will likely improve power. To take advantage of the wealth of GWAS data available for including multiple traits or multiple ancestries, we propose a new method for a combined multi-trait and cross ancestry meta-analysis. The new method uses a variable number of principal components from a genetic correlation matrix as covariates in a meta-regression model to account for phenotype heterogeneity and adjusts for sample overlaps using residual correlation from LD score regression. To test the effectiveness of our new method, we compiled the largest multi-ancestry SLE dataset consisting of GWAS summary statistics for 740,000 individuals in six different ancestries for 14 autoimmune diseases. For many of these diseases both genetic and environmental risk factors are shared with many precursors to the diseases only becoming highly specific immediately prior to development of final stages. These similarities in triggers have made specification in testing arduous and gives the perfect testing grounds for our method. To test our method with those available we compare our method with the multi-trait analysis of genome-wide association (MTAG) method, using Popcorn for genetic correlation, as well as a standard fixed effect meta-analysis. Our results show that IMAC outperforms MTAG in simulation, with controlled type 1 error compared to MTAGs conservative type 1 error, and higher statistical power across all scenarios of heritability (0-1) and sample sizes (20,000, 50,000 and 100,000). On real world data, IMAC, using a single principal component with a p-value cutoff of 0.2, identifies 57, 81, 105, 127 and 134 novel loci compared to MTAGs 61, 61, 30, 28, and 29 across five correlation sets. Our findings highlight the importance of including multi-ancestry and multi-trait information together, which along with increasing sample sizes, increases power for rare variant detection and has the potential to reduce health disparities.

PB4283 Multi-ancestry transcriptome predictions with functionally informed variants improve transcriptome-wide association studies in TOPMed MESA

Authors:

X. Hu[1], D. Araujo[2], S. Rich[1], J. Rotter[3], M. Cho[4], L. Raffield[5], Y. Li[5], D. Liu[6], H. Wheeler[2], H. Im[7], A. Manichaikul[1], TOPMed Multi-Omics Working Group; [1]Univ. of Virginia, Charlottesville, VA, [2]Loyola Univ. Chicago, Chicago, IL, [3]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [4]Brigham and Women's Hosp., Boston, MA, [5]UNC - Chapel Hill, Chapel Hill, NC, [6]Pennsylvania State Univ., Hershey, PA, [7]Univ. of Chicago, Chicago, IL

Reliable prediction of genetically regulated gene expression is key to accurate transcriptome-wide association studies (TWAS). Reference transcriptome prediction models for TWAS have been constructed primarily based on individuals of European ancestry. With the emergence of multi-ancestry GWAS, there is a need for reliable multi-ancestry transcriptome prediction models for downstream TWAS efforts. Furthermore, the genomic variants overlapping with key annotations (e.g., fine-mapping, 3D genomics informed regions, and epigenetic processes) are more likely to be functionally relevant to influence gene expression. We developed multi-ancestry transcriptome prediction models with functionally informed variants (FIVs) by leveraging PBMC RNA-seq from 1,287 TOPMed MESA multi-ancestry samples and corresponding whole-genome sequencing data. Then we examined the performance of models on both prediction accuracy and TWAS. We built four prediction models including one benchmark model (Elastic Net, EN), and three models with FIVs, i.e., EN with fine-mapped variants; Prediction Using Models Informed by Chromatin conformations and Epigenomics, PUMICE; and PUMICE with fine-mapped variants. The prediction accuracy of four models was then assessed in Geuvadis cohort using 449 multi-ancestry samples with LCL RNA-seq. To examine model's performance on TWAS, we leveraged summary statistics from two recent multi-ancestry GWAS, the Global Lipids Genetics Consortium (GLGC) GWAS (N~1.65 million), and lung function GWAS (N=580,869). We then examined TWAS precision by overlapping Bonferroni-significant TWAS genes with previously identified GWAS trait-related putative causal genes (i.e., Mendelian and Mouse knockout genes, genes with coding variants, genes with rare exonic association, nearest genes). While the gene expression prediction accuracy was similar across the four models in both discovery and validation analyses, the TWAS from models with FIVs outperformed. The TWAS from models with FIVs identified more putative causal genes than the TWAS from EN model for three out five lipid traits and for three out of four lung function traits respectively. For example, the TWAS from PUMICE and EN identified 87 and 80 putative causal genes respectively for total cholesterol. Similarly, the TWAS from PUMICE identified 13 putative causal genes for peak expiratory flow rate, while the TWAS from EN only identified 6 genes. Our study demonstrates the value of including FIVs in multi-ancestry transcriptome prediction models for improving TWAS precision.

PB4284 Multi-class Modeling Identifies Shared Genetic Risk for Late-onset Epilepsy and Alzheimer's Disease

Authors:

M. Fu, T. Tran, UCLA Precision Health Data Discovery Repository Working Group, UCLA Precision Health ATLAS Working Group, K. Vossel, T. Chang; Univ. of California, Los Angeles, Los Angeles, CA

Introduction: Previous studies show a strong link between late-onset epilepsy (LOE) and Alzheimer's disease (AD). Individuals with AD have a higher risk of developing LOE, while LOE can be a subtype and risk factor for AD. However, their shared genetic risk beyond the *APOE* gene remains unclear. Our study aims to identify the shared genetic factors of AD and LOE, interpret the biological pathways involved, and determine the effect of shared genetic risk on AD through LOE. **Methods:** We used electronic health records (EHRs) from UCLA Health for discovery analyses and validated our findings in the All of Us database. We defined phenotypes using phecodes with patients' records aged 60-90. A two-step Least Absolute Shrinkage and Selection Operator (LASSO) workflow was used to identify shared and disease-specific genetic variants between AD and LOE based on prior functional genomic data. Shared risk variants were mapped to genes for biological interpretations. We calculated an AD-LOE shared risk score and used it as a proxy in a causal mediation analysis. **Results:** In the UCLA European genetic inferred ancestry (GIA) sample (N=17,031), the two-step LASSO method identified 34 shared genetic loci between AD and LOE, located at *19q13* (the *APOE* region), *8p21*, *6p12*, and *11q12*. These loci were further mapped to 65 genes, which showed enrichment in molecular functions and pathways such as tau protein binding and plasma lipoprotein metabolism. Disease-specific risk genes, such as *CR1* (AD-specific) and *PTK2B* (LOE-specific), were also identified. Individuals with high predicted shared risk scores have a higher risk of developing AD, LOE, or both in their later life compared to those with low-risk scores. LOE partially mediates (20%) the effect of AD-LOE shared genetic risk on AD. Validation results from All of Us were consistent with findings from the UCLA sample. **Conclusion:** Our study used machine learning to identify shared genetic risks of AD and LOE in the European GIA population. In addition to providing substantial evidence for the significant contribution of the *APOE-TOMM40-APOC1* gene cluster to shared risk, we uncovered novel genes that may contribute to shared or disease-specific risk. We developed models using the UCLA sample and validated them on the All of Us database to ensure our findings are reliable and generalizable. Our study is one of the first to use All of Us genetic data to investigate AD. It provides insights into the mechanisms underlying AD and LOE and could lead to disease prevention, targeted treatment strategies, and innovative drugs for the co-occurrence of these two diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4285 Multidimensional analysis of pedigree, epidemiologic, and molecular data identify risk and perceived causative factors for ME/CFS.

Authors:

R. Moslehi[1], A. Kumar[1], A. Bhanushali[1], M. Tracy[1], A. Dzutsev[2]; [1]Univ. at Albany, State Univ. of New York, Albany, NY, [2]NCI, NIH, Bethesda, MD

Background: Myalgic encephalomyelitis (ME)/chronic fatigue syndrome (CFS) is a complex disabling disorder with no known etiology or approved treatment. Estimates of the prevalence suggest that up to 3.4 million Americans may be afflicted. It has been suggested that ME/CFS may be triggered by an infectious illness including COVID-19, hence the prediction that 10 million new cases of ME/CFS may be diagnosed globally due to the pandemic. We conducted a molecular epidemiologic study to identify risk factors and biologic mechanisms for ME/CFS. Methods: Our clinic-based case-control study involved 59 carefully selected ME/CFS patients and 54 appropriately matched healthy controls. We compared cases and controls with respect to the following: 1. prevalence of autoimmune disease (AID) and cancer among their first-degree relatives, 2. prevalence of epidemiologic factors, and 3. serum levels of 48 cytokines. Statistical methods used were logistic regression and cumulative incidence analysis to calculate odds ratios (OR), relative risks (RR), 95% confidence intervals (CI) and p-values. We used machine learning approaches to identify a cytokine profile of ME/CFS. Results: Our analysis revealed that ME/CFS cases were five times more likely than controls to have a family history of AID (OR=5.30, p=0.002). The life-time risk of AID among first-degree relatives of cases was significantly higher compared to the relatives of controls (RR=3.72, p=0.0006). First-degree relatives of cases also had a significantly higher risk of early-onset (diagnosed <60 years of age) cancer compared to the relatives of controls (RR=2.81, p=0.03). Comparison of epidemiologic factors identified history of allergies requiring medication (OR=6.00, p<0.0001), exposure to contaminants (OR=4.35, p=0.0002), history of illness requiring hospitalization (OR=4.33, p=0.0004), ≥4 episodes of significant illness requiring hospitalization (OR=24.36, p<0.0001) and ≥2 episodes of significant stress (OR=3.07, p=0.03) as risk factors for ME/CFS. The most common self-identified perceived *causes* of ME/CFS reported by cases in response to an open-ended question were Infectious Illness (27.3%), Infectious Agents (15.9%), and Stress (15.9%). Our analysis identified a cytokine profile of ME/CFS, which classified patients with 84% accuracy (kappa=0.68, p=0.025, sensitivity=0.75, specificity=1.00) in a separate test set in random forest models. Conclusions: Findings from our multidimensional analysis of pedigree, epidemiologic and molecular data suggest certain risk factors for ME/CFS and links with AID and cancer, providing etiologic clues and druggable targets for treatment of ME/CFS.

PB4286 Multi-omics Integration Identifies Genes Influencing Traits Associated with Cardiovascular Risks

Authors:

S. Acharya[1], L. Liao[1], W. Jung[1], E. Kang[1], V. A. Moghaddam[1], M. Feitosa[2], M. Wojczynski[3], S. Jin[1], J. Anema[4], K. Schwander[5], J. O. Connel[6], M. Province[1], M. Brent[1]; [1]Washington Univ. in St Louis, St Louis, MO, [2]Washington Univ Sch Med., Saint Louis, MO, [3]Washington Univ Schl Med, St Louis, MO, [4]Washington Univ. Sch. of Med., St. Louis, MO, [5]Washington Univ. Sch. of Med., St Louis, MO, [6]Univ. of Maryland, Bethesa, MD

The Long Life Family Study (LLFS) comprises 4,953 participants aged 24-110 years in 539 pedigrees displaying exceptional longevity. We aim to identify genetic mechanisms that protect LLFS participants against age-related cardiovascular risks. We hypothesized that (1) among genes that lie near non-coding genomic variants associated with a trait, genes whose RNA level is also associated with the trait are more likely to be causal, and (2) genes with low P-values that interact with each other in a molecular system and participate in the same biological process are more likely to be causal. Based on these hypotheses, we developed a freely available multi-omics integration pipeline that identified candidate causal genes for 11 cardiovascular risk traits. Using our pipeline, we aggregated gene-level statistics from rare-variant analysis, GWAS, and gene expression-trait association by Correlated Meta-Analysis (CMA). It then identifies Protein-Protein Interaction (PPI) network modules enriched for both genes with low CMA P-values and genes annotated to biological process terms overrepresented in these modules. Each input to CMA is generated by a linear mixed model. All 11 traits were adjusted for family relatedness, age, sex, field center, and 10 genetic PCs. Pulmonary traits were further adjusted for height and smoking, low-density lipoprotein and total cholesterol for statin use, and waist and pulse pressure for BMI. Across all traits, CMA identified 51 significant genes after Bonferroni correction ($P \leq 2.8 \times 10^{-7}$). *CETP*, *NLRC5*, *SLC45A3*, and *TOMM40* lie within 50 Kb of a known trait-associated variant (*previously associated genes*). Module analysis identified 65 genes (2 CMA-significant) that (1) have CMA P-value $\leq 5 \times 10^{-3}$, (2) lie in a PPI module enriched for genes with low P-values, and (3) are annotated with a biological process that is enriched among module genes, 10 of which were previously associated with the same traits. Permutation analysis showed that these criteria yield a false positive rate of 1 in 14876. For high-density lipoprotein levels, *ENPP2* (P < 1×10-4), *ABCG1* ($P < 6 \times 10^{-4}$), *APOC3* ($P < 2 \times 10^{-5}$), and *CETP* ($P < 2 \times 10^{-15}$) interact in a PPI module whose genes have P-values that are significantly lower than expected and are significantly enriched for lipid-related biological processes. *ABCG1*, *APOC3*, and *CETP* are previously associated genes participating in cholesterol transport. *ENPP2* has been implicated in adipose tissue expansion in obesity and participates with *APOC3* in the glycerolipid catabolic process. Overall, module analysis identified highly plausible candidate causal genes whose P-values after CMA alone were merely suggestive.

Cancer Res. Inst., Tokyo, Japan

Background Lung cancer among never-smokers is a significant global health burden, with the highest incidence rates found in East Asian (EAS) women. Polygenic risk scores (PRSs), representing cumulative genetic susceptibility, can stratify women by lung cancer risk. However, PRS development has focused on European (EUR) individuals who are active smokers. We developed and validated single-and multi-ancestry PRSs for lung adenocarcinoma (LUAD) in EAS never-smokers, using the largest available genome-wide association study (GWAS) dataset. *Methods* Several PRS methods were evaluated to assess LUAD risk in EAS women using summary statistics from 3,564 never-smoking cases and 16,238 controls of EAS ancestry, and from 2,058 never-smoking cases and 5,575 controls of EUR ancestry. Single-ancestry PRS methods that used GWAS data from only EAS women included a PRS incorporating 25 variants that have previously reached genome-wide significance, PRS-25, as well as a Bayesian-based PRS, LDpred2. PRS tuning and validation was conducted in the Female Lung Cancer Consortium in Asia, an independent dataset of 4,438 never-smoking EAS cases and 4,544 controls, by estimating the area under the receiver operating characteristics curve (AUC). The AUC of LDpred2 PRS was then projected at different sample sizes using estimates of effect-size distribution and heritability derived from EAS populations using GENESIS. Next, we developed a multi-ancestry PRS using CT-SLEB, an approach incorporating genetic data from EAS and EUR individuals that models the genetic correlations across ancestries. We also estimated the lifetime absolute risk of LUAD based on age-specific lung cancer incidence and overall mortality rates. *Results* The single ancestry methods PRS-25 and LDpred2 PRS had AUCs of 0.62 and 0.63, respectively. Using LDpred2 PRS, we projected that a future study with a 1:1, 1:4 or 1:10 case-control ratio would need 105,000, 65,000 or 55,000 EAS never-smoking LUAD cases, respectively, to attain an AUC of 0.70. We found that the multi-ancestry PRS method CT-SLEB had an AUC of 0.64. Compared to women in the middle quintile, those in the lowest and highest 5% of the CT-SLEB PRS had 0.42 and 4.40-fold risk of developing LUAD, respectively. Further, the lifetime risk (age 30-80) of LUAD in women in the lowest and highest 5% of the PRS were 0.78% and 6.69%, respectively. *Conclusions* Improved methods of using GWAS data to generate a PRS could result in increasing AUC estimates and guide sample size calculations for new studies aiming to further characterize the genetic architecture of LUAD in never-smokers. This approach could inform primary and secondary prevention efforts in the future.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4288 Multi-Trait Analyses Reveal Novel Genetic Etiology for Congenital Heart Disease and Congenital Diaphragmatic Hernia

Authors:

Y. Xie[1], R. Wu[1], K. Ng[2], W. Dong[2], H. Li[1], M. Lek[2], M. Brueckner[2], H. Zhao[1]; [1]Yale Univ. Sch. of Publ. Hlth., New Haven, CT, [2]Yale Univ. Sch. of Med., New Haven, CT

Compared with common diseases, genetic factors are likely to play a more critical role in the etiologies of birth defects in contrast to non-genetic factors (i.e., environment). With its low occurrence in the population, rare de novo variants (DNVs) have been shown to be a major contributor to birth defects. Meanwhile, the development of transcriptomic technologies enables researchers to understand genomic function at the single-cell resolution and may help reveal the pathogenesis of birth defects. Currently, the integration of DNVs and single-cell expression data has not been thoroughly explored. To bridge this gap, we developed an analytical pipeline to discover the shared genetic mechanisms between birth defects by incorporating DNV data from multiple congenital traits and single-cell data from developing tissues. For DNVs, we curated publicly available data from 2,645 congenital heart disease (CHD) trios, 827 congenital diaphragmatic hernia (CDH) trios, and 1,789 autism-unaffected trios as healthy controls. For single-cell expression, we utilized published mouse embryonic data between 9.5 and 13.5 days of gestation and human fetal data from 72 to 129 days. We applied the EncoreDNM method to test genetic correlation across traits both globally and by partitioning genes using highly expressed and uniquely expressed gene information from single cells. Specifically, we found an overall significant correlation enrichment between CHD and CDH (ρ=0.5, p=8.1e-5). In the partitioned analysis, we found significant correlations between CHD and CDH in intermediate mesoderm over 50 times of replication (mean ρ=0.81, mean p=3.4e-4) and foregut (mean ρ=0.80, mean p=4.3e-4), and correlation enrichment in the stomach (mean ρ=0.81, mean p=3.3e-4) and Liver (mean ρ=0.70, mean p=6.0e-6). To identify specific genetic factors, we applied M-DATA to conduct multi-trait analyses among the curated cohorts. By jointly analyzing CHD and CDH, we identified three additional genes for CHD (*MYRF*, *BRAF*, *PPL*), and five additional genes for CDH (*PTPN11*, *POGZ*, *RAF1*, *GATA6*, *KDM5B*). Among these genes, *BRAF*, *KDM5B*, *RAF1*, and *POGZ* were highly expressed across all tissues, and *PTPN11*, *GATA6*, and *MYRF* were highly expressed in intermediate mesoderm and foregut. *PPL* was uniquely expressed exclusively in the intermediate mesoderm, and *MYRF* displayed both high and unique expression in the stomach. These results may shed light on the common etiology of birth defects and motivate the development of statistical methods that can integrate DNVs and single-cell expression data from developing tissues.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4289 Multi-trait GWAS for diverse ancestries : Mapping the knowledge gap

Authors:

H. Julienne[1], L. Troubat[2], H. Aschard[1]; [1]Inst. Pasteur, Paris, France, [2]AP-HP, Assistance Publique - Hôpitaux de Paris, Paris, France

Approximately 95% of samples analyzed in univariate genome-wide association study (GWAS) are of European ancestry. As genetic hindsights gained on European ancestry generalize only partially to other ancestries, this bias could result in increased health disparities. While the genetic community increasingly recommends including more individuals from non-European ancestries in GWAS studies, bias in method development has received less attention. The majority of methods in statistical genetics are developed on European ancestry only (65% of recent publications we surveyed). This European by default mode creates a snowballing effect where secondary analysis increases further the genetic knowledge gap between European and non-European ancestries. Yet, existing data in non-European populations, often of modest sample size, could benefit from innovative approaches maximizing statistical power.

In this context, we tested if the properties of our pipeline for conducting multi-trait GWAS (JASS, Joint Analysis of Summary Statistics) - that is the ability to detect biologically relevant associations missed by univariate GWAS without increasing inflation(1) - would generalize to non-European ancestries. To this end, we conducted the joint GWAS of 19 hematological traits and glycemic traits accross five ancestries (European (EUR), admixed American (AMR), African (AFR), East Asian (EAS), South-East Asian (SAS)).Results:

We detected 367 new genome-wide significant associations in non-European populations (15 in AMR, 72 in AFR and 280 in EAS), which represents respectively 7%, 25% and 21% of all associations in the AFR, AMR and EAS populations.

Overall, multi-trait testing increases the replication of European associated loci in non-European ancestry by 15%. Pleiotropic effects were highly similar at significant loci across ancestries (e.g. the median correlation between multi-trait genetic effect of EUR and EAS was 0.88). For hematological traits, strong discrepancies in pleiotropic effects are tied to known evolutionary divergences: the ARKC1 loci which is adaptive to overcome the p.vivax induced malaria.

Altogether these analyses suggest that multi-trait GWAS methods can be a valuable tool to narrow the genetic knowledge gap between European and non-European populations. (Funding: ANR-20-CE36-0009)

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4290 † Multivariable Mendelian Randomization adjusting for heritable confounding suggests that C-reactive protein is a biomarker but not causal for multiple complex diseases

Authors:

R. Shi, J. Morrison; Univ. of Michigan, Ann Arbor, MI

C-reactive protein (CRP) is a marker of inflammation found to be associated with immune response, cardiovascular disease, and neuropsychiatric disorders in observational studies. However, it is unknown whether CRP causally affects these traits, or is correlated due to reverse causation or unobserved confounding. Mendelian randomization (MR) is a method for estimating causal effects using genetic variants as instrumental variables, thereby avoiding the biases of observational studies. However, MR may produce biased results if factors that confound the exposure and outcome are heritable, leading to horizontal pleiotropy. This is a major concern for studies of CRP, because CRP increases in response to inflammation due to many heritable conditions.Multivariable mendelian randomization (MVMR) can be used to eliminate bias due to heritable confounding when GWAS summary data are available for confounders. Prior univariable MR studies of CRP have suggested causal effects of CRP on several traits such as schizophrenia, bipolar disorders and colorectal cancer. In this study, we used MVMR to estimate the causal effect of CRP on 14 outcomes, including cardiovascular and neuropsychiatric diseases, previously linked with CRP in literature. One major challenge of using MVMR to adjust for heritable confounding, is that heritable confounders may be unknown in advance. We combined literature derived confounders with data driven confounder selection, initially considering thousands of traits present in the MRC-IEU GWAS database and finally selecting a small number of candidate confounders. In initial univariable MR analyses, we found evidence for a causal protective effect of increased plasma CRP level on the risk of schizophrenia, Alzheimer's disease, coronary artery disease, and colorectal cancer, consistent with previous MR results and opposite of observational associations. However, after adjusting for heritable confounders, we found no evidence of causal effects of CRP on any of the 14 traits examined. We found that BMI may be a source of heritable confounding for several relationships, with other confounders including triglycerides, smoking, and diabetes. These results suggested that previous univariable MR analyses of CRP may be biased by heritable confounding and that CRP may have fewer causal effects on human diseases than previously suggested. We have also demonstrated a novel approach of confounder selection using public GWAS databases which may increase the number of traits that can be effectively analyzed using MVMR.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4291 Multivariable Mendelian Randomization identifies LDL cholesterol-independent proteins putatively causal for coronary artery disease

Authors:

D. Shungin[1], A. Hartley[2], A. Carter[2], J. Howson[2], J. Bowden[3]; [1]Human Genetics Ctr. of Excellence, Novo Nordisk, Måløv, Denmark, [2]Human Genetics Ctr. of Excellence, Novo Nordisk, Oxford, United Kingdom, [3]Human Genetics Ctr. of Excellence, Novo Nordisk & Univ. of Exeter, Oxford/Exeter, United Kingdom

Coronary artery disease (CAD) remains a significant global health burden and identifying modifiable risk factors beyond low-density lipoprotein-cholesterol (LDL) is critical for improving prevention and treatment strategies. To identify proteins with LDL-independent effects on CAD, we performed a multivariable Mendelian Randomization analysis (MVMR) across GWAS results for 2,932 plasma proteins in up to 48,645 participants from the UK Biobank Pharma Proteomics Project.

We created genetic instruments for 2,019 proteins with cis-protein quantitative trait loci (pQTL) within a +/-500kb region ($P<5x10^{-8}$); for LDL we derived instruments from GWAS in the UK Biobank (N=400,223; European ancestry) while CAD estimates were extracted from the largest published meta-analysis (Aragam et al, 2022, Ncontrols/cases= 984,168/181,522; European ancestry). We applied a recent MVMR method (Batool et al, 2022) that derives principal component instruments from a set of highly correlated SNPs to increase statistical power of analyses in cis-region. We modelled two exposures at a time, a protein and LDL, and repeated this pair-wise analysis for all proteins to derive causal effects for these genetically predicted traits.

We identified multiple proteins with putative causal effects on CAD independent of LDL, i.e. their causal effects are not attenuated after inclusion of LDL in MVMR. Amongst the prioritized proteins we detected IL1RN that is implicated in CAD in addition to LDL, via a non-LDL (inflammatory) mechanism i.e. both IL1RN (odds ratio [OR]=1.06 per 1 standard deviation [SD] increase of IL1RN, 95%CI:1.03-1.11) and LDL are causally related with CAD in MVMR (OR=1.39 per 1SD increase of LDL, 95%CI:1.30-1.47). Furthermore, we validated the known effects of drug targeting APOBR on CAD which are driven primarily by LDL (OR=1.39 per 1 SD increase of LDL, 95% CI:1.30-1.48), rather than protein levels (OR=1.00 ,95% CI:0.99-1.01 for 1-standard deviation increase of APOBR). Follow-up sensitivity univariable MR analyses for prioritized and non-prioritized proteins further estimated the putative causal effects of each protein on CAD when not accounting for LDL, underscoring the utility of MVMR in estimating effects of related exposures with shared genetic predictors.

Overall, these findings shed light on alternative pathways involved in CAD pathogenesis and provide valuable insights for development of targeted therapies. Further validation of these causal relationships and identification of underlying mechanisms will pave the way for interventions aimed at reducing CAD risk in the population.

PB4292 † Multivariable Mendelian randomization reveals potential causal genes that contribute to blood pressure traits in diverse populations

Authors:

Y. Yang[1], N. Lorincz-Comi[1], X. Zhu[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ., Shaker Heights, OH

High blood pressure (BP) is a major risk factor for cardiovascular disease. Identifying genes that cause BP variation is crucial for uncovering molecular mechanisms and discovering drug targets. Popular non-experimental methods to investigate causality - such as colocalization, TWAS, and univariable Mendelian randomization (UVMR) - leverage summary-level gene expression data but are not robust because of high correlations among gene expressions in a locus. It is also unclear whether causal genes discovered in European (EUR) populations are transferrable to non-EUR populations. To address these issues, we performed multivariable Mendelian randomization (MVMR) to robustly identify causal genes influencing systolic and diastolic BP (S/DBP) across diverse populations. We implemented MVMR using MR Joint Outliers-aNd-Exposures Selection (Mr.Jones), which was recently developed by our group to prioritize causal genes and identify horizontal pleiotropy with variable selection penalties. We used summary-level GWAS data for eQTLs in blood tissue from the eQTLGen consortium (n=30K) and for BP traits from Surendran et al. (n=800K), BioBank Japan (n=150K), and Liang et al. (n=30K) for EUR, East Asian (EAS), and African (AFR) populations, respectively. We targeted the top 10 most significant loci in the European SBP GWAS and searched for causal genes in these loci across populations. Each locus was defined as a 2Mb window centered around the lead SNP. In EUR, we examined 295 genes and identified 28 and 27 genes with P<5E-8 for SBP and DBP, respectively. In EAS and AFR, we analyzed 279 and 232 genes, respectively, resulting in the discovery of 6 and 3 genes for SBP, and 6 and 2 genes for DBP. Gene expressions in the top 10 loci explained 0.63 and 0.68 of local heritabilities for SBP and DBP in EUR. In EAS and AFR, the fractions were 0.30, 0.22, 0.20, and 0.17, respectively. Our analysis also resolved many inconsistencies in the literature, particularly with regard to TRAFD. Despite historically inconsistent effect directions found in the TWAS hub across six studies, our analysis observed TRAFD as a significant risk gene for SBP with Z-scores > 20. By leveraging eQTL and GWAS data, our MVMR analysis holds promise for discovering novel genes causally associated with BP traits. In subsequent analyses, we plan to scan the whole genome in search of causal BP genes and examine their functional enrichments.

PB4293 Native Hawaiians and Pacific Islanders: Is APOE a Biomarker of Disease?

Authors:

J. Tavana[1], R. J. Hansen[1], B. J. Vaitohi[1], C. S. Pakalani[1], A. T. Perez[1], F. Matthes[2], S. Polaapau[2], S. F. Funaki[2], T. D. Packard[1], J. S. Kauwe[1], P. G. Ridge[1]; [1]Brigham Young Univ., Provo, UT, [2]Brigham Young Univ. Hawaii, Laie, HI

Native Hawaiians and Pacific Islanders (NHPI) are among the least represented racial groups in Alzheimer's disease (AD) research (for example, there are only 36 samples in the NACC). The prevalence of AD is unknown in NHPIs. Likewise, no large studies have reported disease biomarkers, including assessing APOE genotypes for correlation with AD. In one small study in Guam natives, APOE e4 was not correlated with AD. We have enrolled 648 NHPIs in our cohort with AD8, CDR scores, or NACC cognitive tests. We have collected APOE genotypes for 234 individuals.

Study participants were recruited during brain health educational workshops that utilize visual and interactive learning. During these workshops, participants are invited to provide a blood or saliva sample after signing an IRB approved consent form. Samples are then processed in our lab and APOE genotypes are collected.

Table 1 summarizes the cognitive assessments and APOE genotypes for 234 individuals. APOE allele frequencies vary widely based on race. However, in our dataset, the e4 frequency in NHPI females and males is the same and higher than reported in other races.

We are underpowered to detect significant trends in subjects with and without dementia (Table 2). Our preliminary data reveal e4 allele frequencies in subjects with and without dementia. No trend towards e4 differences in impaired versus normal subjects.

We are augmenting and refining the existing cohort. We are genotyping APOE in 414 additional NHPIs and formally diagnosing each subject. We will have sufficient samples to determine whether or not APOE correlates with AD status. If APOE is not a biomarker of AD in NHPIs, this suggests that the genetic architecture of AD in NHPIs is unique and demonstrates the importance of prioritizing NHPIs in future AD research.

PB4294 Network diffusion-based risk scoring models for coronary artery diseases in UK biobank individuals: Fusing polygenic impact of intermediate clinical factors on complex disease

Authors:

Y. Nam[1], S-H. JUNG[1], K. Jaeyoung[2], J-S. Yun[3], D. Kim[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Sungkyunkwan Univ., Seoul, Korea, Republic of, [3]The Catholic Univ. of Korea, Seoul, Korea, Republic of

Background: Intermediate clinical risk factors, such as biomarkers derived from urine- or blood-based laboratory results, have been studied for their genetic or clinical interactions with complex diseases. While composite polygenic risk scores (PRSs) have demonstrated the increased accuracy in risk prediction for common diseases by aggregating the genetic predisposition of multiple intermediate risk factors, there are limitation in leveraging extensive genetic relationships in scoring. Genetic correlation networks can help elucidate the complex relationships between phenotype and clinical factors. A combined model, incorporating extensive relationships from correlation networks, is likely to enhance the ability to stratify high-risk individuals compared to standard PRS or linear combinations of independent scores. **Methods:** We developed a network-based composite risk scoring model (net-cPRS) that aggregates the propagated polygenic impact of intermediate phenotypes on complex disease from networks. Initially, we built a genetic correlation network using linkage disequilibrium score (LD scores) with GWAS summary statistics across the phenotype of interest (binary trait) and intermediate phenotypes. Subsequently, label propagations were applied to estimate the polygenic impact on the phenotype by diffusing the query on the binary trait to clinical factors. The estimated impacts depict the direction and magnitude of genetic impacts at the summary level and allow for the combination of multiple risk scores for intermediate clinical factors using pre-defined coefficients in regression models. A fine-tuning process was performed to estimate individual risk scores using individual genetic profiles. **Results:** As a proof-of-concept study, we developed net-cPRS for coronary artery diseases (CAD) using data from 370K European individuals in UK Biobank. Genetic correlation networks were built using LD scores between independent GWAS summary of CAD and 12 intermediate factors, including BMI, HDL/LDL-C, TG, BP, FG, HbA1C and eGFR. Network-diffused genetic impacts for CAD were obtained for 12 intermediate factors and applied as weights in a logistic model. The scoring model was fine-tuned using individual genetic profiles with 5-fold cross-validations. In terms of prediction accuracy, the average AUC of net-cPRS was 0.747, demonstrating improved prediction ability compared to standard PRS (0.65) and composite PRS (0.721). **Conclusion:** Proposed net-cPRS, which incorporates genetic relationships, can improve the prediction ability of PRS models. However, further experiments are needed to apply net-cPRS to additional phenotypes.

PB4295 Network-based approach to gene prioritization at GWAS loci.

Authors:

L. Martini[1], B. Hobbs[2], A. Fazzone[3], L. Becchetti[4], M. Gentili[1], M. Cho[5]; [1]Harvard, Boston, MA, [2]Brigham and Women s Hosp., Needham Heights, MA, [3]Centai, Turin, Italy, [4]Sapienza, Roma, Italy, [5]Brigham Women's Hosp., Boston, MA

Translation of risk loci identified by genome-wide association studies to disease-causing genes and biologic pathways is challenging. Often, researchers attempt to identify a causal gene at each locus using a series of bioinformatics methods. However, the genetic risk to most diseases is likely distributed across a large number of biologic processes with a network of molecular interactions contributing to disease biology. Considering each locus in isolation does not leverage the relationship between genes associated across loci.
In this work, we propose the Relations-Maximization Method (RMM-GWAS), a new network-based approach to identify effector genes from a GWAS. Our method builds on the hypothesis that disease-relevant genes across GWAS loci share biological processes, pathways, and correlated gene expression levels. It integrates network topology and gene biological information to prioritize a set of genes, one per disease locus, such that the overall number of shared interactions is maximized.
We assessed the performance of our framework, comparing it with well-established baselines: dmGWAS, SigMod, LEAN, DEPICT and DOMINO. We compared them along three different axes: i) prediction of FDA-approved drug targets, ii) prediction of genes that have been previously identified to be involved in murine disease-related phenotypes, and iii) functional analysis of the set of statistically significant Reactome pathways associated with the prioritized gene sets. We compared them on the COPD GWAS and we found RMM-GWAS to be the only heuristic to prioritize genes that are targets of FDA approved drugs. Furthermore, genes prioritized by RMM-GWAS are enriched in pathways and biological processes previously linked to COPD including inflammation and immune response, WNT/beta-Catenin/TCF/FZD4 interactions, and C-type lectin receptor signaling.

PB4296 Neuroimaging PheWAS of Essential Tremor Genes: Matching Genes to Neuromorphology

Authors:

X. Bledsoe[1], E. Gamazon[2]; [1]Vanderbilt Univ., Nashville, TN, [2]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN

Essential tremor (ET) is a progressive and debilitating condition characterized by motor tremor in the hands and arms that can eventually spread to impair head motion, mastication, and speech. Significant progress has been made in assessing the joint molecular and neurophysiologic causes of ET. At a neural level, current data suggest that ET results from a dysfunctional "tremor pacemaker" in the olivary nucleus operating in concert with cerebellothalamocortical circuits. At a molecular level, GWAS data and expression analyses have highlighted variation in DNA and RNA transcripts that correlate with disease status. While these data are meaningful contributions, it is difficult to discriminate between brain measures that drive the disease from those which result from it.

We address this gap by first performing a transcriptome-wide association study (TWAS) of ET by applying the JTI-PrediXcan methodology to summary statistics from the largest GWAS of the condition to date. I performed a transcriptome based, tissue-specific neuroimaging phenome wide association study (PheWAS) to identify brain measures that are putatively impacted by the gene expression profile associated with ET. For each gene that was significantly associated with ET (Bonferroni threshold of 0.05), I identified the associated cortical and subcortical neuroimaging measures, matching on tissue context (study-wide false discovery rate ≤ 0.05).

The TWAS identified 90 different gene products for which genetically regulated gene expression is associated with ET. These include top loci from the initial publication as well as novel genes. From the neuroimaging PheWAS, 14 of the top 15 neuroimaging measures reflect structural connectivity measures. The three most impacted measures are the left and right inferior cerebellar peduncles and the middle cerebellar peduncle. These findings were driven by altered expression of *BACE2* and *LINC00323.* Additionally, the bilateral corticospinal tract and posterior limbs of the internal capsule are each represented in the top 15 associations.

Our TWAS data replicate and extend the set of transcript-level associations reported by Liao et al. Findings from the neuroimaging PheWAS replicate prior work highlighting the cerebellar peduncles as regions involved in ET pathophysiology and then show that expression of BACE2 and LINC00323 are associated with these structures. Additionally we capture associations between ET gene transcripts and 4 neuroimaging measures of the descending motor tract. These measures indicate that gene expression alterations that occur secondary to ET SNPs are associated with motor neuroanatomy in patients without overt disease.

Trace elements are important for human health but may exert toxic or adverse effects. Mechanisms of uptake, distribution, metabolism, and excretion are partly under genetic control but have not yet been extensively mapped. Here we report a comprehensive multi-element genome-wide association study (GWAS) of 57 essential and non-essential trace elements. We performed GWA meta-analyses of 14 trace elements in up to 6564 Scandinavian whole-blood samples, and GWASs of 43 trace elements in up to 2819 samples measured only in the Trøndelag Health Study (HUNT). We identified 11 novel genetic loci associated with blood concentrations of arsenic, cadmium, manganese, selenium, and zinc in genome-wide meta-analyses. In HUNT, several genome-wide significant loci were also indicated for other trace elements. Using two-sample Mendelian randomization, we found several indications of weak to moderate effects on health outcomes, the most precise being a weak harmful effect of increased zinc on prostate cancer. However, independent validation is needed. Our new understanding of trace element-associated genetic variants may help establish consequences of trace elements on human health.

PB4298 New insights into thyroid hormone regulation: a transcriptome and proteome-wide association study.

Authors:

S. Monteiro-Martins[1], R. Sterenborg[2,3], M. Medici[2,3], A. Köttgen[1,4], A. Teumer[5,6], on behalf of the ThyroidOmics Consortium; [1]Univ. of Freiburg, Freiburg, Germany, [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [3]Erasmus Med. Ctr., Rotterdam, Netherlands, [4]Johns Hopkins Univ., Baltimore, MD, [5]Univ. Med. Greifswald, Greifswald, Germany, [6]DZHK (German Ctr. for Cardiovascular Res.), Partner Site Greifswald, Greifswald, Germany

Thyroid hormones, including thyrotropin (TSH) and free thyroxine (FT4), are regulated via the hypothalamic-pituitary-thyroid (HPT) axis and play a crucial role in regulating metabolic processes in humans. We aimed to better understand molecular mechanisms underlying TSH and FT4 levels through tissue-specific transcriptome-wide association studies (TWAS) and plasma protein-wide association studies (PWAS). TWAS was performed based on HPT-relevant tissues from GTEx v8, and PWAS on plasma protein levels measured by the Somalogic v4.0 assay, using GWAS-summary statistics for TSH and FT4 levels from up to 271,040 European ancestry individuals in the ThyroidOmics Consortium. Statistical significance was set at $p<1.74\times10^{-06}$ (TWAS) and $p<3.78\times10^{-05}$ (PWAS). The relationship between eQTLs, pQTLs, and trait GWAS summary statistics was analyzed through conditional colocalization analysis. TWAS identified 297 and 113 transcripts associated with TSH and FT4, respectively, with 25 associated to both. Of these, 24 for TSH and 14 for FT4 were not in loci revealed by the underlying GWAS, demonstrating the increased power of our approach. Colocalization revealed a shared genetic basis between mRNA levels ($PPH_4>0.8$) with TSH for 158 genes and with FT4 for 45 genes. Interestingly, there were tissue-specific colocalizations between CAPZB expression and TSH levels related to independent genetic variants in different tissues, including a putative regulatory variant in the thyroid.PWAS identified 18 and 7 proteins associated with TSH and FT4, respectively, with 2 shared proteins, HEXIM1 and QSOX2. Of these, 5 TSH and 7 FT4-associated proteins were not encoded within significant GWAS loci. Colocalization was observed for 5 plasma protein levels with TSH and 5 with FT4. Comparing results from PWAS and TWAS, 10 TSH genes and 1 FT4 gene were significant in both. Of these, ANXA5 expression was inversely associated with TSH in all studied tissues and plasma protein levels (TWAS-$p=7.61\times10^{-12}$ [whole blood], $p=6.40\times10^{-13}$ [hypothalamus], $p=1.57\times10^{-15}$ [pituitary], $p=4.27\times10^{-15}$ [thyroid], PWAS-$p=1.18\times10^{-13}$), supported by colocalization. Our analyses revealed new thyroid function-associated genes and prioritized candidates in known GWAS loci, contributing to a better understanding of transcriptional regulation and protein levels relevant to thyroid function.

PB4299 Next-generation map of constrained coding regions from hundreds of thousands of humans

Authors:

S. Lulla, P. McHale, B. Pedersen, A. Quinlan; Univ. of Utah, Salt Lake City, UT

A longstanding interest in human genetics has been to identify the subset of the human genome that is critical to normal human development. In pursuit of this question, we previously created a map of constrained coding regions (CCRs) [1], or regions where the absence of genetic variation implies negative selection due to critical function or disease pathology. We defined a region as the coding distance between protein-changing variants, and we weighted region lengths by sequencing coverage. We then quantified the degree of constraint of each region, where regions with the greatest distance between protein-changing variants have the highest predicted constraint. This map provided a more fine-scale metric of intraspecies constraint than other previously established gene-wide measures and nominated new protein-coding regions that are essential to human development.

We will present progress on a more rigorous approach to modeling constraint that calculates a ratio of observed to expected constraint in small sliding windows across protein-coding exons. Such an approach allows us to relax the original requirement of the complete absence of protein-changing variants in a CCR to capture cases where genetic variation in a region is present but extremely sparse, which will occur more often as cohort sizes increase. The gnomAD v2 and forthcoming population-scale datasets provide unprecedented deep samples of human coding variation, allowing us to construct a higher-resolution map of constraint and assess which CCRs from the previous dataset survive given the expanded dataset. We anticipate that our efforts will yield a much higher resolution map of constrained coding regions in the human genome, providing a valuable resource for rare disease interpretation and identifying coding sequence that is essential to human development.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4300 *NODAL* variants are associated with a continuum of laterality defects from simple D-transposition of the great arteries to heterotaxy.

Authors:

Z. Dardas[1], J. Fatih[1], A. Jolly[1], M. Dawood[1], H. Du[1], C. Grochowski[1], E. G. Jones[2], S. Jhangiani[3], X. Wehrens[1], P. Liu[1], W. Bi[1], E. Boerwinkle[4], J. Posey[1], D. Muzny[3], R. Gibbs[3], J. Lupski[1], Z. Coban Akdemir[5], S. Morris[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Texas Children's Hosp., Houston, TX, [3]Baylor Coll. Med., Houston, TX, [4]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [5]UTHlth.Sch. of Publ. Hlth., Houston, TX

Background: NODAL signaling plays a critical role in embryonic patterning and heart development in vertebrates. Genetic variants resulting in perturbations of the TGF-β/NODAL signaling pathway have reproducibly been shown to cause laterality defects in humans. To further explore this association and improve genetic diagnosis, the study aims to identify and characterize a broader range of *NODAL* variants in a large number of individuals with laterality defects. **Methods and Results:** We re-analyzed a cohort of 307 proband-only exomes of individuals with clinically diagnosed laterality congenital heart disease (CHD) using family-based, rare variant genomic analyses. For those with candidate contributory variants, variant allele confirmation and segregation analysis were studied by Sanger sequencing in available family members. To this cohort, we added 12 affected subjects with known *NODAL* variants and CHD from institutional research and clinical cohorts to investigate an allelic series. Missense, nonsense, splice site, indels, and/or structural variants of *NODAL* were identified as potential causes of heterotaxy and other laterality defects in 33 CHD cases. We describe a recurrent complex indel variant for which the nucleic acid secondary structure predictions suggest secondary structure mutagenesis as a possible mechanism for formation. We identified two copy number variant (CNV) deletion alleles spanning *NODAL* in two unrelated CHD cases. Furthermore, 17 CHD individuals were found (16/17 with known Hispanic ancestry) to have the c.778G>A:p.G260R *NODAL* missense variant which we propose reclassification from a variant of uncertain significance (VUS) to likely pathogenic. Quantitative human phenotype ontology-based analyses of the observed clinical phenotype for all cases with p.G260R variation, including heterozygous, homozygous, and compound heterozygous cases, reveal clustering of individuals with biallelic variations. This finding provides evidence for a genotypic-phenotypic correlation and an allele-specific gene dosage model. **Conclusion**: Our data further support a role for rare deleterious variants in *NODAL* as a cause for sporadic human laterality defects, expand the repertoire of observed anatomical complexity of potential cardiovascular anomalies, and provide evidence that the population specificity of *NODAL* variants should be taken into consideration in genetic counseling and clinical genomic testing for this condition.
