Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1001 3D Structure-based development of prediction model for the functional assessment of genetic variation of RAG1 and RAG2 complex

Authors:

N. Haque[1], T. Kawai[2], B. Ratnasinghe[1], R. Urrutia[1], L. Notarangelo[3], M. Zimmermann[1]; [1]Med. Coll. of Wisconsin, Milwaukee, WI, [2]Natl. Inst. of Allergy and Infectious Disease, NIH, Bethesda, Bethesda, MD, [3]Natl. Inst. of Allergy and Infectious Disease, NIH, Bethesda, Wauwatosa, MD

The current pace of genomic sequencing for patient-derived samples is unprecedented. However, the methods available for the interpretation of the effects of genetic changes on the patient's phenotype is in its early stage of development and is largely dependent of the information derived from individual sequence or their horologes. Sequence-based pathogenicity prediction performs well for some genomic variants but fails to confidently rank variants of uncertain significance (VUS). There are numerous immune deficiency syndromes that are associated with genetic variations unique to individual patients. In this study we have developed a method for genomic interpretation of variation by mathematical combination of features derived from sequence and their 3D structures. The method has been developed on one of the most vulnerable RAG1/RAG2 protein complex, central to the immune system. The variant effect prediction model was developed by leveraging enzymatic activity values of 182 clinically observed missense variants of RAG1 and RAG2. An efficient regression model was built and tested on a set of experimental data, a test set not used in model development, separately for RAG1 (R2 = 0.914 and enzyme activity RMSE = 10.34%) and RAG2 (R2 = 0.973; RMSE = 9.57%) to predict RAG activity changes from a combination of sequence- and structure-based scores. Such a model with ~10% of RMSE was further used for assessment of 711 RAG1/RAG2 variants obtained from various databases. Thus, we have demonstrated the development of advanced methods which has potential generalize the assessment of effect of genetic variation of clinically significant genetic products in rare diseases and cancers.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1002 3DVariantVision: Multimodal framework to interpret genetic variant effects based on 3D chromatin

Authors:

J. Yang, H. Wang, J. Wang; Michigan State Univ., East Lansing, MI

Deciphering the effects and mechanisms of genetic variants is essential in human genetics and precision medicine. Traditional GWAS approach suffers from low statistical power and lack of causality. Recently, deep-learning based models were developed to extract sequence information de novo to predict functional variant effects on nearby regions. However, due to the large-scale cell-type specific multi-omic data and complex chromatin folding conformation, it is extremely difficult to prioritize functional genetic variants and delineate their multi-level effects, including TF binding, epigenetics, gene expression, and long-range chromatin contacts. Here we developed 3DVariantVision, a new deep learning-based multi-modal framework to provide the comprehensive vision on genetic variant effects from genotype to phenotype by integrating diverse panels of genome-wide datasets, including ChIP-seq, Hi-C, and eQTL summary statistics. Relying on DNA sequence only, 3DVariantVision demonstrates superior performance to predict candidate functional genetic variants and their disruptive effects on specific TF bindings, histone modifications, enhancer-promoter interactions, and gene expression, leading to boosted capability of eQTL discoveries. By capturing the non-linear complex regulatory grammar across multiple levels of features and across long-range genomic distances, 3DVairantVision accurately identifies the distal target genes of non-coding variants, revealing novel mechanistic insights into trait-associated variants beyond traditional GWAS and TWAS studies.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1003 A biobank catalogue of transcriptomes and associated genetic effects based on 2,000 subjects uncovers the causal effects of Middle Eastern genetic variation and uncovers novel disease mechanisms

Authors:

Y. Mokrab[1], H. Naeem[1], I. Diboun[1], M. Ghorbani[1], R. Razali[1], E. Aliyev[1], M. Hashmi[1], R. Mathew[1], V. Mattei[1], N. James[1], L. Mathew[1], L. Silcock[1], K. Wang[1], M. K. R. Kalikiri[1], F. Vempalli[1], M. Tamanni[1], A. Khouly[1], S. Poolat[1], A. Akil[1], S. Lorenz[1], R. Ali[1], Qatar Genome Program Research Consortium, K. Fakhro[1], S. Tomei[1], D. Chaussabel[1], S. Montgomery[2]; [1]Sidra Med., Doha, Qatar, [2]Stanford Univ., Stanford, CA

Mapping genetic variation to transcriptome activity at a population level is a robust approach to linking regulatory mechanisms to traits and diseases, allowing both association and causality to be inferred. Here, we present a large study of predominantly healthy individuals from Qatar Biobank, combining whole genome sequencing (WGS) (30x coverage; n=6,216) and whole blood RNA-Seq (20-100 M reads; n=2,127) data to build a comprehensive catalogue of genetic variants regulating various transcription traits. Investigating the effects of single nucleotide polymorphisms (SNPs), insertions/deletions (Indels), and structural variants (SVs) on gene expression, splicing (isoform-level and intron-level), and allelic expression (variant-level and gene-level) in cis, identifying ~12 million novel associations of eQTLs, isoQTLs, sQTLs, and aseQTLs. We co-localized the QTL signals with a GWAS on 6,218 subjects from the same QBB cohort, featuring 45 clinically relevant traits. With this analysis, we colocalized 40 causal SNPs in 30 genes and validating 8 which were previously linked to the GWAS traits, while establishing novel trait relationship between 22 genes. Our colocalization analysis also led to finetuning the associations for 9 SNPs where the identified QTL gene was other than the most proximal gene to the GWAS SNP, an example is our identified QTL rs11234557 for SUGP1 with an established role in lipid homeostasis. Allele frequency analysis of our fine-mapped QTL SNPs revealed significant differences between the Arab major sub ancestries and the East Asian (EAS) ancestry from the 1KG. IPA enrichment analysis for the corresponding genes revealed a signature for viral infection, cancer, endocrine disorders, immunological and inflammatory disease for the causal variants with varying frequencies with respect to EAS as opposed to respiratory, hematological, cardiovascular, and hepatic disease for South Asians (SAS). This study produced the largest whole blood multi-QTL resource available to date based on non-imputed data and samples, uniformly generated and processed in a single center. By revealing novel loci in a Middle Eastern population, this resource illustrates the need for greater diversity in public reference datasets in order to gain more complete understanding of functional impact of genetic variation in the global human population.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1004 A common flanking variant is associated with enhanced meiotic stability of the *FGF14*-SCA27B locus

Authors:

M. Danzi[1], D. Pellerin[2], G. Del Gobbo[3], M. Couse[4], E. Dolzhenko[5], M-J. Dicaire[2], A. Rebelo[1], V. Roth[6], M. Wandzel[6], C. Bonnet[6], C. Ashton[2], P. Lamont[7], N. Laing[8], M. Renaud[6], G. Ravenscroft[8], H. Houlden[9], M. Synofzik[10], M. Eberle[5], K. Boycott[3], T. Pastinen[11], All of Us Long Reads Working Group, B. Brais[2], S. Zuchner[1]; [1]Univ. of Miami, Miami, FL, [2]McGill Univ., Montreal, QC, Canada, [3]CHEO Res. Inst., Ottawa, ON, Canada, [4]BC Children and Women's Hosp., Vancouver, BC, Canada, [5]Pacific BioSci.s, Oceanside, CA, [6]Univ. Hosp. of Nancy, Nancy, France, [7]Royal Perth Hosp., Perth, Australia, [8]Harry Perkins Inst. of Med. Res., Perth, Australia, [9]Univ. Coll. London, London, United Kingdom, [10]Hertie Inst. for Clinical Brain Res., Tuebingen, Germany, [11]Children's Mercy Hosp. and Clinics, Kansas City, MO

The factors driving initiation of pathological expansion of tandem repeats remain largely unknown. Late-onset spinocerebellar ataxia type 27B caused by intronic GAA repeat expansions in *FGF14* has recently been discovered as one of the most common genetic causes of adult-onset ataxia worldwide. Initial observations suggested that intermediate and expanded *FGF14* alleles are highly unstable in the germline. Leveraging long-read PacBio HiFi sequencing on 2,191 individuals and Sanger sequencing on 339 individuals, we here investigated if sequence variants in or near the *FGF14* repeat locus affect the meiotic stability of the locus. We identified a 5'-flanking 17-bp deletion-insertion in 70.34% of alleles (3,463/4,923) which is uniquely associated with alleles containing fewer than 30 GAA repeat units (odds ratio: 44,158, 95% confidence interval: 13,981 - 139,474). Furthermore, this common flanking variant also predicted meiotic stability of the repeat locus (odds ratio: 47.04, 95% confidence interval: 25.24 - 85.15) based on a total of 470 meiosis events measured by PacBio sequencing (403 events) and Sanger sequencing (67 events). To our knowledge, this is the first evidence of a stabilizing variant flanking the *FGF14*-SCA27B locus and the first description of a genomic element that so strongly predicts the stability of a short tandem repeat in humans. This finding may yield further insight into the mechanisms underlying tandem repeat expansions and facilitate the identification of similar sequence variants at other known pathogenic repeat loci.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1005 A compendium of HLA allelic associations with plasma protein levels in the UK Biobank

Authors:

C. Adams, C. Benner, R. K. Pendergrass, M. I. McCarthy, A. Mahajan, C. Hammer; Genentech, South San Francisco, CA

Human leukocyte antigen (HLA) alleles are established risk factors for many immune-related diseases. They can also affect protein expression, in particular through the initiation of signaling cascades in response to immune activation upon antigen presentation and recognition. For example, cytokine expression, which is important in immunity and inflammation, is partially determined by MHC peptide recognition by CD4 T-cells. The systematic measurement of plasma protein levels (PPLs) in a subset of participants from the UK Biobank (UKB) has previously been used to identify more than 10,000 non-MHC quantitative trait loci (pQTL). Here, we present an HLA allele-wide association study of PPLs in UKB participants. We estimated associations between 2,940 PPLs and imputed HLA alleles in 35,571 UKB participants of European ancestry. PPLs were measured using the Olink Explore 3072 platform and inverse rank normalized. Statistically independent HLA allele associations were identified with stepwise conditional testing. We also estimated associations for HLA class I alleles grouped according to their interactions with killer cell immunoglobulin-like receptors (KIR) (Bw4 vs. Bw6, C1 vs. C2). Regression analyses were adjusted for age, sex, batch, UKB center, array, time between blood sampling and measurement, and 20 principal components. We also examined interaction between PPLs associated with disease-relevant HLA alleles, making use of genetically predicted protein levels (GPPLs) composed of non-MHC pQTLs. We identified 4,408 statistically independent associations between 1,809 PPLs and 97 HLA alleles. Of these, 4,035 were trans associations with 1,775 proteins outside the extended MHC region. To demonstrate the complex relationship between HLA status, protein expression and disease risk, we investigated the interaction between a GPPL for CCL19 and HLA-DRB1*03:01 or HLA-DRB1*04:01 in type 1 diabetes, finding significant interaction terms ($CCL19_{GPPL}$×$DRB1*03:01_{DOM}$: OR_{IXN}=2.26, p=0.001; $CCL19_{GPPL}$×$DRB1*04:01_{DOM}$: OR_{IXN}=1.95, p=0.03). Both alleles were associated with CCL19 PPLs, as well as the disease phenotype. Furthermore, 109 PPLs were significantly associated with at least one KIR ligand group after Bonferroni correction, including proteins encoded by genes located in the leukocyte receptor complex on chromosome 19, which harbors all KIR and other immune-relevant genes. Our results demonstrate and build on the important contribution of HLA alleles to protein levels and disease risk. This resource will be useful to improve our understanding of the relationship between complex traits, immunogenetics, and disease-relevant protein networks.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1006 A DNA repair-reporter deep mutational scan to comprehensively map missense effects in *MUTYH*

Authors:

S. Hemker, A. Bashir, B. Burugula, G. Clark, S. Jayakody, E. Kirk, J. Kitzman; Univ. of Michigan, Ann Arbor, MI

For the vast majority of genetic variants, the impacts upon gene function and organismal phenotype are unknown. This remains the case even at deeply studied genetic disease loci such as *MUTYH*, which underlies a recessive cancer predisposition syndrome for which up to ~1% of individuals worldwide are carriers. Of the ~800 *MUTYH* missense variants reported in ClinVar, 95% remain as variants of uncertain significance (VUS). This reflects the difficulty of classifying rare missense variants, which can range from having no effects to complete functional impairment. Traditional experimental and bioinformatic methods lack the scale and accuracy to resolve these and as-yet unseen *MUTYH* VUSs. Therefore, we established a multiplexed assay of variant effects (MAVE) to profile every *MUTYH* missense variant. Because MAVEs typically rely upon cell survival to measure variant function, non-cell-essential disease genes have mostly been off-limits to this powerful approach. We overcome this limitation using a high-throughput DNA damage reporter. In this assay, the repair event catalyzed by MUTYH - excision at a 8oxoG:A mispair lesion, the major post-replication byproduct of oxidative damage - results in GFP expression. We generated CRISPR-induced *MUTYH* knockout human cell lines, into which we stably integrate libraries of *MUTYH* missense variants. Variants that restore MUTYH function, and therefore GFP expression, can be sorted *en masse* via flow cytometry. Following deep sequencing, a function score is calculated based upon each variant's enrichment/depletion between the starting and the sorted, repair-positive cell populations. In pilot studies, we have profiled all 969 missense variants in a 51-codon region overlapping a key catalytic domain. Nonsense and synonymous variants are well separated in this assay, and we observed loss of function effects at known pathogenic variants such as the p.Tyr151Cys founder allele. Function scores are being generated for the remainder of the protein, and are being calibrated using clinical variants with standing interpretation. These results will inform mechanistic studies of *MUTYH* and related DNA glycosylases and allow for resolution of clinically reported VUS.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1007 A high-resolution view of human gene expression and splicing diversity with long-read sequencing

Authors:

S. Yan, H. Eden, M. Li, A. Battle, W. Timp, R. C. McCoy; Johns Hopkins Univ., Baltimore, MD

Differences in gene expression are the primary source of phenotypic diversity within and between species. Variation in both RNA transcript abundance and splicing can have dramatic consequences for the function of proteins and non-coding transcripts, in turn driving phenotypes and disease. Short-read sequencing, which still dominates functional genomic datasets, requires computational reconstruction of RNA isoforms. In contrast, long-read sequencing enables the direct identification of complete RNA isoforms, allowing for accurate resolution of splicing and exon structure across full transcripts. Recently published long-read studies have demonstrated that more than half of all RNA isoforms observed in a single long-read sequenced sample are absent from existing annotations based on short reads. However, these studies—as well as many other RNA sequencing datasets—predominantly include individuals of European ancestry, thus limiting our view of global gene expression diversity and evolutionTo address these limitations, we generated Nanopore long-read RNA sequencing data from five lymphoblastoid cell lines, derived from globally diverse individuals in the 1000 Genomes Project (representing populations from Africa, the Americas, Europe, East Asia, and South Asia). By aligning this sequencing data to the complete T2T-CHM13 reference genome, we observe improved resolution of transcripts within repetitive genomic regions, such as the HLA and immunoglobulin loci, when compared to short-read RNA-sequencing of the same samples. We additionally discover 158,735 novel isoforms unannotated in GENCODE, underscoring the power of long reads for transcript discovery. Finally, we intersect these novel transcripts with rare splice-altering variation in the respective genomes, establishing mechanisms that explain the observed isoform diversity. Together, our results demonstrate how long-read sequencing of diverse individuals improves understanding of human gene expression and splicing diversity and evolution.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1008 A high-throughput screen to nominate phenotypically relevant asthma genes from genome-wide association studies.

Authors:

I. Salamone, E. Zhong, C. Ober, X. He, M. Nobrega; Univ. of Chicago, Chicago, IL

Genome-wide association studies (GWAS) often implicate non-coding variants in disease risk, suggesting that common variants modulate disease risk through transcriptional regulation of downstream genes. Although advances in functionally informed fine-mapping methods have led to increasingly confident identification of causal variants, it is still difficult to pinpoint the gene or genes that are regulatory targets of these variants. The difficulty of this task, which is commonly described as the variant-to-function problem, is further compounded in complex diseases such as asthma, where phenotypes arise as a result of perturbations of transcriptional programs in many cell types and causal variants may have phenotypic impact on multiple genes and across multiple tissues or cell types. In fact, asthma is considered a group of diseases with shared symptoms that result from many distinct mechanisms including airway inflammation, mucus overproduction, and epithelial barrier dysfunction. To improve nomination of target genes associated with asthma, we have developed a high-throughput CRISPR/Cas9-based screen. This screen allows us to test the role of all putative target genes at a GWAS locus and select candidates that modulate disease-relevant cellular phenotypes. As proof of principle, we have nominated a pool of putative target genes using functionally informed fine-mapping of adult- and childhood-onset GWAS loci. By performing our screen in bronchial epithelial cells, which play a primary role in the etiology of asthma, we are able to evaluate how candidate genes influence barrier maintenance. Overall, this screen will identify both candidate genes at asthma risk-associated loci that may play a role in complex disease pathogenesis as well as the cell type in which they are acting. These results will not only allow us to address the variant-to-function problem, but also elucidate the genetic architecture of this group of diseases called asthma that affect hundreds of millions of people worldwide.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1009 A hyperVNTR is located in intron 8 of the human dopamine transporter gene (SLC6A3).

Authors:

D. Vandenbergh[1], A. Apsley[2], M. Verbiest[3], E. Domico[4], M. Anisimova[3]; [1]Penn State Univ, University Park, PA, [2]The Pennsylvania State Univ., University Park, PA, [3]Zürich Univ. of Applied Sci., Wädenswil, Switzerland, [4]Johns Hopkins Univ., Baltimore, MD

Multiple genetic analyses of SLC6A3 have generated conflicting results for dopamine-related phenotypes, which might result from an inability to test relevant loci in the gene. We identified 5 Tandem Repeats that vary in copy number (VNTR) in SLC6A3 using Tandem Repeat Annotation Library (TRAL), and characterized 3 that have not been studied. Copy number and sequence similarity of each repeat unit of the five VNTRs is reported, along with the correlations of SNP-SNP, SNP-VNTR and VNTR-VNTR alleles across the gene. One VNTR in intron 8 is hyper-variable (hyVNTR) with a range of 3.4-133.4 repeat copies and 46 alleles in the 64 long-read haplotype-phased chromosomes analyzed (93% heterozygosity). The consensus sequence of the repeat unit is 38 bp with 82% G+C content. The repeat is predicted to form G-quadruplexes (G4s, G-tetrads) in silico, which was confirmed by circular dichroism spectroscopy. Multiple putative PRDM9 binding sites (recruiter of recombination promoting proteins) are present in the repeat, and it is in low linkage disequilibrium (LD) with flanking genetic markers (r2=0.016 and 0.001), suggesting it is a hotspot for recombination. Studies of other sites in SLC6A3 could not estimate genetic effects of this hyVNTR due to lack of LD.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1010 A likely pathogenic variant in *RYR2* causing Catecholaminergic polymorphic ventricular tachycardia in an Iranian family.

Authors:

N. Naderi, M. Maleki, S. Kalayinia; Rajaie Cardiovascular Med. and Res. Ctr., Tehran, Iran, Islamic Republic of

Background: Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an arrhythmia disorder from stress or physical activity. CPVT is often associated with syncope or sudden cardiac death, especially in childhood, and accounts for about 50-60% of cases. Genetic changes also have a significant role in CPVT etiology. Next-generation sequencing (NGS) technology can be helpful in the identification of heterogenic disease causes such as CPVT. **Method:** After confirming the CPVT in the patient by a cardiologist, blood samples of the patient and her family members were received. DNA extraction and whole-exome sequencing (WES) were performed to identify the causative variants. Finally, PCR and Sanger-sequencing were done for confirmation and segregation of the candidate variant. **Result:** A likely pathogenic heterozygous missense variant, c.A12280G:p.I4094V, was detected in the *RYR2* gene. The *in silico* analysis of rs1573933519 indicated the pathogenicity of this variant. The c.A12280G was confirmed in the patient and segregated in the pedigree available members. **Conclusion:** The *RYR2* mutations are involved in Arrhytmogenic right ventricular dyspasia, ventricular arrhythmias and Catecholaminergic polymorphic ventricular tachycardia. Considering that the CPVT leads to syncope and cardiac arrest in 30% of cases, genetic evaluation of these patients using the WES technique is important approach.**Keywords:** Catecholaminergic polymorphic ventricular tachycardia (CPVT), *RYR2* gene, whole exome sequencing (WES)

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1011 A multi-omics approach to characterize genetic architecture of plasma lipidome in Hispanics/Latinos

Authors:

W. Zhu[1], H-H. Chen[2], A. Petty[3], H. Highland[4], L. Petty[1], M. Yaser[5], K. Young[6], P. Meikle[7], J. Curran[8], J. McCormick[9], S. Fisher-Hoch[10], K. North[11], E. Gamazon[12], J. Below[13]; [1]Vanderbilt Univ., Nashville, TN, [2]Academia Sinica, Taipei, Taiwan, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [5]Univ. of North Carolina Chapel Hill, Chapel Hill, NC, [6]Univ North Carolina, Chapel Hill, NC, [7]Baker Heart and Diabetes Inst., Melbourne, Australia, [8]Univ. of Texas Rio Grande Valley, Brownsville, TX, [9]UTH SPH Brownsville, Brownsville, TX, [10]Univ. of Texas Sch. of Publ. Hlth., Brownsville, TX, [11]Univ North Carolina, Wake Forest, NC, [12]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN, [13]Vanderbilt Univ Med Ctr., Nashville, TN

Background: Large GWAS studies in Europeans identified hundreds of plasma lipid-related variants, yet these findings may not capture genetic risk factors in non-European populations. Similarly, prediction models trained on European datasets tend to have poor transferability across populations. Multiple studies have revealed that one of the major risk factors of cardiometabolic disorder, dyslipidemia, is highly prevalent in H/Ls (30%). However, H/Ls population remains underrepresented in genetic studies despite of their profound health disparities in metabolic diseases. While traditional lipid measures such as HDL and LDL are easily accessible in many cohorts, they are insufficient to characterize the dynamic and subtle changes of the entire lipidome. Alternatively, lipidomics provides a complete snapshot of the underlying lipid metabolism within individuals, providing a valuable resource to understand the biological mechanisms of dyslipidemia in genetic studies. **Methods:** Subjects from the Cameron County Hispanic Cohort (CCHC) were genotyped on the Illumina MEGA^{EX} array and imputed to the TOPMed phase 8 reference panel following standard protocols. Plasma lipidomic profiles from 2500 individuals were obtained using a chromatography-mass spectrometry pipeline. We estimated SNP-based heritability and performed lipidome-wide GWASs in 2289 individuals across 830 lipid species and 49 lipid classes, using linear mixed models adjusted for sex, age, age2, BMI, PCs and relatedness. Within the maximum independent set (N=1680) constructed by PRIMUS, we filtered variants by GWAS p-values and developed lipidomic prediction models by elastic net regression. **Results:** Our GWASs identified approximately 2500 significant associations between genetic variants and 830 lipid species from the 49 lipid classes. In addition to associations of 35 previously reported genes, we also identified novel signals on chromosomes 1,2, 5, 6, 8, 9 and 22 near genes such as BASP1, PACSIN2 and MCAT that have been previously linked to lipid binding and lipid metabolism. For lipid classes, we estimated heritability between 0.12 to 0.55, and between 0.09 to 0.89 for lipid species. Performances of our prediction models aligned with heritability estimations.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1012† A new hypothesis for the molecular mechanisms underlying dominant diseases

Authors:

D. Stainier, C. Dooley, L. Falcucci, K. Hsu, G. Jakutis, B. Juvik, V. Serobyan, J. Welker, L. Xie; Max Planck Inst. for Heart and Lung Res., Bad Nauheim, Germany

The onset and progression of dominant diseases are thought to be due to haploinsufficiency, gain-of-function, or the action of dominant negative/poison proteins. Here, we propose an alternative hypothesis, namely a newly discovered cellular response to deleterious mutations called transcriptional adaptation (TA). During TA, mutant mRNA degradation products, or their derivatives, translocate to the nucleus where they modulate the expression of so-called adapting genes. We initially identified this process in zebrafish while investigating the discrepancy between knockout and knockdown phenotypes, and subsequently in mouse and human cells in culture, as well as in *Caenorhabditis elegans*. Depending on the adapting genes whose expression is modulated, TA can lead to genetic compensation or a worsening of the phenotype. Importantly, TA is a dominant phenomenon in the sense that it can be observed in heterozygous cells and animals.
Recent studies have challenged the current concepts of haploinsufficiency or dominant negative/poison proteins as the underlying mechanism for certain dominant diseases including frontotemporal lobar degeneration (FTLD), Brugada syndrome (BrS), Marfan syndrome (MFS), Dravet syndrome, and hypertrophic cardiomyopathy (HCM). We hypothesize that for these, and other, dominant diseases, when the underlying mutations lead to mutant mRNA degradation, the phenotypes are due, at least in part, to the dysregulation of gene expression due to TA.
This presentation will briefly summarize the key findings about TA, both published and unpublished, and go over recent data from our own experiments, and others, that aim to test this new hypothesis in the context of FTLD, BrS, MFS, and HCM.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1013 A novel framework for functional annotation of ASD and ID linked variants of uncertain significance.

Authors:

A. Bhattacharya[1], P. Parlanti[1], L. Cavallo[1], E. Farrow[2], T. Spivey[2], A. Renieri[3], F. Mari[3], M. Manzini[1]; [1]Child Hlth.Inst. of New Jersey and Dept. of NeuroSci. and Cell Biology, Rutgers – RWJMS, New Brunswick, NJ, [2]Dept. of Pharmacology and Physiology, Sch. of Med. and Hlth.Sci., George Washington Univ., Washington, DC, [3]Med. Genetics, Univ. of Siena, Siena, Italy

Autism Spectrum Disorder (ASD) and **Intellectual Disability** (ID) are clinically heterogeneous neurodevelopmental disorders (NDD) with a complex genetic architecture. Over a hundred risk genes with highly penetrant, rare loss of function mutations have been discovered and clinical exome sequencing is increasingly adding to the list of ASD and ID linked variants in these risk genes. However, most of the variants discovered are variants of uncertain significance (**VUS**), which represent a major bottleneck in the field, preventing the use of genetic knowledge to inform clinical decisions. We sought to develop a framework to characterize VUS in *Coiled-coil and C2 domain containing 1A* (*CC2D1A*; MIM *610055), a gene leading to moderate to severe autosomal recessive ID with comorbid ASD in 40% of cases.We report four ASD-ID cases (three males, one female) with compound heterozygous missense VUS (p.Pro319Leu, p.Ser327Leu, p.Gly441Val, p.Val449Met, p.Thr580Ile, p.Arg886His and p.Glu910Lys) that were cloned and overexpressed either individually or in patient combination in HEK293 cells. Overexpression of VUS neither affected protein stability nor the survival of the transfected cells. CC2D1A is a signaling scaffold which modulates protein kinase A (PKA)/CREB activity by repressing phosphodiesterase PDE4D, an important node for learning and memory. To test PDE4D interaction, we immunoprecipitated Myc from cells co-transfected with *PDE4D5*-Myc and mutant (or WT) *CC2D1A* and quantified the amount of CC2D1A pulldown. Only V449M reduced PDE4D5 binding of CC2D1A. However, P319L, T580I and R886H showed a significant decrease in cAMP levels in competitive ELISA, suggesting that PDE4D activity may be affected by these variants even without disrupting binding. Next, we used luciferase assay to test their effect on CREB activation as a read out of the signaling activity. Compared to the WT, five VUSs G441V, V449M, P319L, T580I and R886H led to significantly blunted response to forskolin induced CREB activation. Since signaling activity informs about gene function, this luciferase assay can be scaled up to functionally annotate ~250 *CC2D1A* VUSs currently listed in Clinvar. CREB activation is also a common downstream target of multiple NDD signaling pathways, so our paradigm can be customized for testing VUSs in other NDD genes. VUSs disrupting PDE4D activity can be prioritized for testing against PDE4D inhibitors such as Zatolmilast (in phase III clinical trial for Fragile X syndrome) to check if the deficits are rescued. Prioritized VUSs can then be introduced into iPSCs via CRISPR and their molecular effects can be modeled via differentiation of such iPSCs into induced neurons.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1014 A novel mutation in *ITGB2* in Pakistani families causes Leukocyte Adhesion Deficiency Type I

Authors:

S. Faraz, S. Ahmed, T. Shamsi, S. Munzir; Natl. Inst. of Blood Diseases and Bone Marrow Transplantation, Karachi, Pakistan

Leukocyte adhesion deficiency I (LADI) is a type of primary immunodeficiency characterized by recurrent bacterial infections, impaired pus formation, and delayed wound healing. The genetic cause of this disorder has been linked to variations in the integrin subunit beta 2 (*ITGB2)* gene, which encodes the β-2 integrin subunit. Individuals affected by LAD1 usually display symptoms during the initial stages of their life, experiencing repeated and severe infections that can lead to death before the age of two if they do not undergo a hematopoietic stem cell transplant (HSCT). Nevertheless, detecting LAD1 is a challenging task, and even with extensive antibiotic treatment, a significant number of patients do not survive beyond their early years. To investigate the genetic basis of LADI, we performed Next-generation sequencing on two patients who were born of two consanguineous Pakistani families, which identified one novel homozygous mutation (c.778del, p. Val260CysfsTer20) in exon 7 and one previously reported (c. 186C>A, p. Cys62Ter) mutation in exon 4 of *ITGB2* gene. The patients were observed to display various clinical characteristics such as skin abscesses, delayed separation of the umbilical cord, mild omphalitis, and an increase in the number of neutrophils in their blood. These cases highlight the importance of a multidisciplinary approach to recognizing clues in patients with uncommon manifestations of a rare disease. By employing this approach, a comprehensive diagnostic evaluation for primary immunodeficiency disorders can be initiated, resulting in an enhanced understanding of the disease, appropriate patient counseling, and equipping clinicians with better tools to handle potential complications.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1015 A novel streamlined pipeline for studying RNA editing: detect the effect of RNA editing QTLs in the non-coding genome.

Authors:

C. Dai, C. Buen Abad Najar, B. Fair, Y. Li; Univ. of Chicago, Chicago, IL

Adenosine Deaminases Acting on RNA (ADAR) mediated Adenosine-to-Inosine (A-to-I) RNA editing is a post-transcriptional modification that impacts RNA processing, such as splicing and translation. This modification has been linked to several neurodegenerative and autoimmune diseases, highlighting its potential in gene regulation and cellular functions. However, most studies to date have focused on the coding regions of the genome, overlooking non-coding regions. To address this, we developed a streamlined pipeline for identifying RNA editing from RNA-seq data. Our pipeline requires minimum configuration and accelerates researchers' analyses.

We applied our novel pipeline to the GEUVADIS total RNA-seq dataset, which comprises 89 Yoruba lymphoblastoid cell lines (LCLs), and our lab-generated chromatin-enriched RNA-seq dataset on 87 Yoruba LCLs. This enabled a comprehensive identification and comparison of editing sites in different genomic contexts.

A key highlight of our study is using chromatin-enriched RNA-seq to identify RNA editing in non-coding regions. We also developed a novel Hidden Markov Model based method that identified 7,097 non-coding RNAs (ncRNA) in LCLs. This matched ncRNA annotation approach improved the identification accuracy of editing in ncRNA. We identified 1,121,568 editing sites in the chromatin-enriched RNA-seq dataset, including over 750K intronic sites and over 150K editing sites in ncRNAs, providing an unprecedented view of the RNA editing landscape in the non-coding genome.

Our analyses revealed A-to-I editing occurs faster than splicing, with over 75% of the 42,135 editing sites shared by GEUVADIS total RNA-seq and chromatin-enriched RNA-seq data showing insignificant differences in editing levels. This finding suggests the potential role of RNA editing in modulating the transcriptome in response to swift, dynamic changes in the cellular context. However, despite the extensive editing detected, we found limited effect of RNA editing QTLs in the non-coding regions. We identified 12,404 edQTLs in chromatin-enriched RNA-seq data, with limited colocalization signals - 144 with protein-coding gene eQTLs, 201 with splicing QTLs, and 206 with ncRNA eQTLs. Our results suggest that the direct influence of non-coding RNA editing on gene expression and phenotype may be limited and nuanced.

Overall, our work presents an important methodological advancement, providing researchers with a robust and efficient tool for identifying RNA editing, and offers insights into the roles of RNA editing in non-coding regions.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1016 A pooled-based screening strategy for re-classification of NPR2 missense variants to support the expansion of Vosoritide for genetic causes of short stature

Authors:

S. Covarrubias, C. Bauer, D. Shanghavi, D. Ruhrmund, D. Zhou, N. Marom, Y-S. Tang, S. Froelich; Biomarin Pharmaceuticals, San Rafael, CA

NPR2 is a bidirectional therapeutic target that is associated with various forms of short and tall stature. NPR2 possesses guanylyl cyclase activity that leads to synthesis of cyclic guanosine monophosphate (cGMP), and down-regulation of this pathway is responsible for short stature phenotypes. A C-type natriuretic peptide analog (CNP) is now approved by the FDA for Achondroplasia - a common form of short stature. Binding of CNP to its receptor (NPR2), triggers endochondral and skeletal growth via cGMP production. Loss-of-function mutations in NPR2 are responsible for dwarfism in mice and result in a lack or lowered intracellular cGMP response to CNP in cultured chondrocytes. While there is no treatment yet for other forms of idiopathic short stature (ISS), our goal is to treat any form of ISS indication with CNP. High throughput characterization of NPR2 variants will enable us to better predict novel variants and for those which occur more commonly could benefit diagnosis and clinical trial enrollment for eligible patients. Here we develop a pooled-based screening platform which allows us to screen ~160 variants in parallel using a cGMP-GFP-on reporter and applying a flow-based screening strategy. This new screening strategy represents a significant increase in bandwidth compared to previous methods. The screen identifies both loss-of-function (LoFs) and gain-of-function (GoF) variants and is consistent with previous arrayed-based screening data. Our data allows for the reclassification of ~31 VUS as LoF and 7 VUS as GoF variants and also allowes for re-classification of ~123 VUS as neutral. We show that these variant phenotypes enhance prediction of adult height when combined with polygenic scores and augment statistical power to detect phenotypic associations. Additionally, these data provide insights into the biological mechanisms of C-Type Natriuretic Peptide (CNP) signaling through NPR2 in skeletal development.

PB1017 A proactive missense variant atlas for the Autoimmune Regulator.

Authors:

A. Axakova[1], A. Berger[2], W. v. Loggerenberg[1], N. Kishore[1], M. Gebbia[1], M. Ding[1], S. Douville[1], M. Panchalingam[1], A. Cote[1], D. Tabet[1], J. Weile[1], R. Li[1], S. Kathirgamanathan[1], E. Bratland[2], S. Johansson[3], F. P. Roth[1]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Univ. of Bergen, Bergen, Norway, [3]Haukeland Univ Hosp, Bergen, Norway

Pathogenic variants in the Autoimmune Regulator (*AIRE*) gene cause Autoimmune Polyendocrine Syndrome Type 1 (APS-1), a rare primary immunodeficiency disease with symptoms including chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease. AIRE increases the expression of tissue-specific genes in the niche of developing T cells, thus triggering the elimination of emerging self-reactive T-cells and preventing autoimmunity. APS-1 diagnosis by *AIRE* sequencing is increasingly common, and earlier diagnosis can benefit patients. However, two thirds of clinical variants reported are missense, and more than half of reported clinical missense variants found to be "of unknown significance". Testing variant function in cell-based assays can provide strong evidence for variant classification, but these tests are carried out reactively, often months or years after a variant's first observation within a patient. By contrast, proactively assessing the function of all possible missense variants could provide immediate evidence for genetic diagnosis, even for never-before-seen variants. Here we describe the first saturated sequence-function map of AIRE missense variants, using an insulin promoter-driven reporter assay. Our sequence-function map of AIRE, which agrees with biochemical expectations and current pathogenicity annotations, promises to provide proactive evidence with potential to improve patient outcomes by providing more rapid and definitive genetic diagnoses of APS-1.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1018 † A single cell CRISPRi enhancer screen in microglia identifies target genes for Alzheimer's disease GWAS loci.

Authors:

A. Chesi[1], S. Laub[1], N. Tulina[1], S. Ramachandran[1], J. Pippin[2], M. Conery[1], E. Burton[3], L-S. Wang[1], G. Schellenberg[1], S. Grant[4]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]The Children's Hosp. of Philadelphia, Philadelphia, PA, [3]The Univ. of Pennsylvania, Philadelphia, PA, [4]The Children's Hosp. of Philadelphia/UPenn, Philadelphia, PA

GWAS of Alzheimer's disease (AD) have recently uncovered ~ 70 genetic loci associated with this devastating disorder. The major challenge of the post-GWAS era is mapping genetic signals to their corresponding effector genes, which is required to develop effective drug therapies. We developed a genomic approach based on high-resolution Capture C, ATAC-seq and RNA-seq to identify candidate causal variants and effector genes in brain relevant human cells (microglia, neurons, and astrocytes). We prioritized 74 candidate regulatory regions containing AD-associated SNPs by requiring them to reside in open chromatin and contact an open gene promoter. These candidate regions contacted 85 putative effector genes. To assess their effect on expression of their candidate effector genes in a high-throughput manner, we performed a pooled enhancer-targeting CRISPRi screen followed by scRNA-seq in the human microglia cell line HMC3. We performed quality control (removal of low-quality cells, doublets, and cell cycle effects) and analysis of ~ 24,000 cells using Seurat and Mixscape. Differential gene expression analyses between cells containing a single perturbation and cells containing a non-targeting guide using MAST yielded 9 hits (9 enhancer regions targeting 8 effector genes). We validated one of them, an enhancer containing three AD-associated SNPs located in an intron of *TSPAN14*, via bulk CRISPRi and luciferase assays in HMC3. Transcriptomic analyses revealed 15 downregulated and 58 upregulated genes in the enhancer knock-down condition, corresponding to several altered cellular pathways, including 'interferon alpha and beta signaling' and other pro-inflammatory pathways (upregulated), and 'SUMOylation of DNA replication proteins' and pathways related to nuclear import and the nuclear pore complex (downregulated). Further functional investigations are required to clarify the role of this gene and these cellular pathways in AD pathogenesis. We plan to expand our screens to other cell types, and we anticipate this methodology to be portable to many neurodegenerative or neurodevelopmental disease contexts.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1019 A VUS re-analysis: Understanding the likely disease-mechanism of a de novo missense variant in RALA using public bioinformatic tools

Authors:

L. van de Wiel[1], C. Reuter[2], M. Neu[1], S. Marwaha[1], D. Bonner[2], J. Kohler[2], H. R. Mendez[1], E. Kravets[1], Undiagnosed Diseases Network, E. A. Ashley[1], S. B. Montgomery[1], J. A. Bernstein[1], M. T. Wheeler[1]; [1]Stanford Univ., Palo Alto, CA, [2]Stanford Hlth.Care, Palo Alto, CA

The interpretation of missense variation in the context of Mendelian disease genes remains a major challenge. The advent of tools specializing in data-integration from vast resources has advanced our understanding of the functional impacts of genetic variants. We present a case study utilizing these tools that demonstrates that reanalysis of putative disease missense variants can lead to a better understanding and diagnosis of genetic variation.
We evaluated a 12 yo patient assigned female sex at birth who displayed developmental delay, bilateral ptosis, feeding issues, dysmorphic features, congenital cardiac defect (PDA), recurrent pancreatitis and abnormal movements from 3 months old. Genome sequencing identified a de novo missense in RALA NM_005402.4:c.(46A>G), NP_005393.2:p.(Lys16Glu). RALA missense variants may cause AD Hiatt-Neu-Cooper syndrome [OMIM:619311]. Despite phenotypic overlap with this syndrome, the identified variant was not observed in gnomAD or ClinVar.
Utilizing HOPE (www3.cmbi.umcn.nl/hope/) - a tool that elucidates the molecular effects of single missense mutations on protein 3D structure - we analyzed p.Lys16Glu. HOPE indicated that p.Lys16's positive charge, forming a salt bridge with p.Arg65 and p.Glu87 (PDB:6P0I), is disrupted by the variant residue's negative charge. p.Lys16 is 100% conserved (HSSP) and in the Ras Family domain (PF00071). We then consulted MetaDome (www.metadome.app), which annotates pathogenic variants at equivalent homologous protein domain positions, and found p.Lys16 is equivalent to 124 human codons in homologous Ras Family domains. Assessing ClinVar pathogenic information on these codons identified three pathogenic variants in KRAS; an identical p.Lys5Glu (#12596) and two structurally similar changes: p.Lys5Asn (#12594) and p.Lys5Gln (#2010214), with literature indicating structurally similar changes affecting RAS function by increasing activation and downstream signaling. Supported by this evidence, the sequencing lab reclassified the variant from VUS to likely pathogenic. Likely, the de novo RALA variant is the molecular diagnosis for this patient. This case exemplifies how freely available data-integration tools can collaboratively unveil the functional impacts of genetic variants and disease etiology.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1020 † Aberrant expression prediction in 48 human tissues

Authors:

F. R. Hölzlwimmer[1], J. Lindner[1], N. Wagner[1,2], V. Yepez[1], F. Casale[3,1], J. Gagneur[1,2,3]; [1]Technical Univ. of Munich, Munich, Germany, [2]Helmholtz Association - Munich Sch. for Data Sci., Munich, Germany, [3]Helmholtz Zentrum München, Munich, Germany

Identifying the functional and phenotypic impact of genetic variants is a major challenge. Although certain types of genetic variants are associated with aberrant gene expression, the actual impact of these variants in different tissues often remains unknown. Measuring aberrant gene expression in affected tissues can aid in identifying functional, large-effect variants. However, this approach is limited to clinically accessible tissues such as skin or body fluids. Here we set out to predict rare variants associated with aberrant underexpression across 48 human tissues. To achieve this, we established the first systematic benchmark for aberrant underexpression using OUTRIDER, an aberrant expression caller using RNA-seq count data, in 11,096 GTEx samples. We assessed and developed predictors that use DNA sequence and optionally RNA sequencing data from clinically accessible tissues. Notably, existing tools such as CADD (0.88% auPRC) and LOFTEE (1.43% auPRC) exhibited poor performance in predicting aberrantly underexpressed genes.

To address this issue, we developed AbExp-DNA, a nonlinear model to predict tissue-specific aberrant underexpression.

We find that weighting variant consequences by the proportion of affected isoforms per tissue as well as incorporating the tissue-specific gene dispersion provides valuable information to increase the predictive accuracy of AbExp-DNA. Including tissue-specific aberrant splicing annotations predicted with AbSplice and optionally transcript ablations caused by structural variants further increases the performance of AbExp-DNA. In total, AbExp-DNA achieves an auPRC of 9.84%, outperforming LOFTEE and CADD by up to 7-fold.

We demonstrate how AbExp-DNA can be used in rare variant gene association studies (RVAS) as well as phenotype prediction on the UK Biobank 200k WES dataset with 40 blood traits. Using AbExp-DNA, we identify 60% more trait-associated genes compared to a LOFTEE-based burden test. In addition, AbExp-DNA significantly improves phenotype prediction over LOFTEE in 45% of the traits.

Finally, we show that gene expression measurements from clinically accessible tissues can be incorporated to yield another two-fold enhancement in tissue-specific aberrant expression prediction performance. While such measurements are not directly transferable to other tissues, combining gene expression measurements from fibroblasts with AbExp-DNA scores allows AbExp-RNA to reach an overall auPRC of 20.61%.

By providing a first method benchmark of tissue-specific expression outliers, this work is relevant for rare variant association studies as well as DNA- and RNA-based rare disease diagnostics.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1021 Aberrant splicing prediction across human tissues.

Authors:

N. Wagner[1], M. Çelik[2], F. Hölzlwimmer[1], C. Mertes[1], H. Prokisch[3], V. Yépez[1], J. Gagneur[1]; [1]Technical Univ. of Munich, Garching bei München, Germany, [2]Univ. of California Irvine, Irvine, CA, [3]Helmholtz Zentrum Muenchen, Neuherberg, Germany

Aberrant splicing is a major cause of genetic disorders but its direct detection in transcriptomes is limited to clinically accessible tissues such as skin or body fluids. While DNA-based machine learning models allow prioritizing rare variants for affecting splicing, their performance on predicting tissue-specific aberrant splicing remains unassessed. Here, we generated the first aberrant splicing benchmark dataset, by calling aberrant splicing events on 16,213 RNA-seq samples from 49 human tissues from the GTEx dataset, comprising 8.8 million rare variants in paired genotype data from 946 individuals. At 20% recall, state-of-the-art DNA-based models SpliceAI and MMSplice achieve maximum 12% precision. We observed that many false predictions originated from inaccurate genome annotations. We constructed a tissue-specific splicing map (SpliceMap) by mapping and quantifying tissue-specific splice site usage transcriptome-wide and modeling isoform competition. Using SpliceMap together with SpliceAI and MMSplice in a combined model that we call AbSplice increased precision by three-fold at the same recall. These results replicated in two independent rare disease cohorts. Integrating RNA-sequencing data of clinically accessible tissues brought precision to 60%. After publication of the method [1], we have applied AbSplice to large rare disease (>23,000 WGS from Solve-RD European project) and cancer (>4,000 WGS from Munich Leukemia Labor) cohorts. In the Solve-RD cohort, the scores are being used to validate splicing outliers from RNA-seq data, as well as suggesting disease-causal variants. In the Munich Leukemia Labor cohort, we found an enrichment of genes with high AbSplice scores among known tumor-suppressor genes and recaptured splicing aberrations that were not detected from RNA due to nonsense-mediated decay. We provide precomputed AbSplice scores for all possible single-nucleotide variants genome-wide, publicly available software to score variants including indels directly from VCF files as well as a web interface for fast lookup of variant scores. Altogether, our results substantially contribute to non-coding loss-of-function variant identification and to genetic diagnostics design and analytics.

Hussman Inst. for Human Genomics, Miami, FL, [7]Maya Angelou Ctr. for Hlth.Equity, Wake Forest Univ., Winston-Salem, NC, USA, Winston-Salem, NC, [8]Columbia Univ, New York, NY, [9]Univ. of Miami, Miami, FL, [10]Case Western Reserve Univ, Cleveland, OH, [11]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL

Background: We previously identified a 44-base pair deletion in (ATP-binding cassette sub-family A member 7) (*ABCA7*) that is significantly associated with Alzheimer's disease (AD) in African Americans (AAs) and produces a frameshift mutation resulting in a truncated protein (p.Arg578Alafs). Previous analysis in iPSC derived cells suggested that the ABCA7 deletion alters APP processing producing increased levels of aggregation-prone Amyloid beta (Aβ) species, such as Aβ42 and Aβ40. While we have shown the mutant mRNA is present in microglia, whether it is translated into a stable protein is not known. This question has been hampered by the lack of antibodies capable of recognizing the N-terminus of endogenous ABCA7. In microglia, ABCA7 is primarily involved in the transport of lipid and amyloid-β (Aβ) clearance by phagocytosis while in neurons, ABCA7 functions in the lipid transport of and APP processing. Methods: We analyzed scRNAseq data from prefrontal cortex from AA individuals to determine *ABCA7* cell type pattern of expression. To elucidate the impact of the AA-specific deletion in protein expression and function, a recombinant version of the ABCA7 gene with and without the deletion and bearing an N-terminal flag tag was transfected into HEK cells. The transduced cells were analyzed by immunoblot and immunocytochemistry (ICC). Induced pluripotent stem cell (iPSC) lines from three unrelated AA individuals with AD who are homozygous or heterozygous for the deletion, as well as age-matched AA controls were produced and differentiated into microglia. Results: Our results showed that the ABCA7 truncated protein of ABCA7 is expressed and stable in this transfected model. Expression of *ABCA7* is highest in microglia, suggesting that iPSC derived microglia cells are a proper platform to test functionality of the truncated protein. Discussion: While the transfected cells demonstrate that the truncated protein is stable in this model, iPSC models are needed to confirm this initial finding. Our scRNAseq data indicates high expression of ABCA7 in microglia, suggesting functional relevance for microglia function that will be tested in our iPSC model.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1023 † Allele- and tissue-specific expression across 11 tissues in baboons (*Papio anubis*)

Authors:

R. Ramasamy[1], M. Raveendran[2], A. Harris[3], J. Rogers[3], S. Panda[1]; [1]Salk Inst. for Biological Studies, La Jolla, CA, [2]BCM, Houston, TX, [3]Baylor Coll. of Med., Houston, TX

The preferential expression of one allele of a gene over the other in a diploid organism has been shown to have a profound impact on numerous biological processes. We collected 11 different tissue types from 12 wild-caught olive baboons (*Papio anubis*) and sequenced their genomes using both Illumina PE 150 reads and Oxford Nanopore long reads achieving a minimum sequencing depth of 30X and 15X, respectively. We discovered 15.8 million heterozygous biallelic single nucleotide variants (SNVs) across 12 baboons with a median of 4.7 million SNVs per baboon. Across the 12 baboons, we were able to phase 96.5 to 98.5 percent of all protein-coding genes containing biallelic heterozygous SNVs into single haplotype blocks. We sequenced the complementary DNA produced from total RNA at a median depth of 25 million Illumina paired-end 150-bp reads per sample. We investigated allele-specific expression across 187,476 unique biallelic SNVs located in untranslated and coding regions of protein-coding genes with each sample containing between 12,953 and 35,507 SNVs. Between 6.9% to 14.6% of these SNVs showed allele-specific expression characteristics across 9,753 protein-coding genes. The number of SNVs with ASE patterns was slightly influenced by gene expression heterogeneity of the tissue (r=0.36). Of the genes, 7,402 were found to have ASE characteristics in more than one animal, including 109 genes that displayed ASE in all 12 animals. We found 2,686 genes with ASE patterns that were specific to one tissue type. Among the 11 tissue types we studied, the lungs had the largest number of allelic imbalanced genes specific to that tissue type.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1024 An analysis of how known SNPs affect ramp sequences in the human genome and their implications for human disease

Authors:

J. Wride[1], A. Nitz[1], M. Cloward[2], P. Ridge[2]; [1]Brigham Young Univ., Sandy, UT, [2]Brigham Young Univ., Provo, UT

Codon bias is the unequal distribution of synonymous codons across a gene or genome. Codon choice is subject to selection and is non-random. Codon choice is highly correlated with the most abundant tRNA. This is energetically desirable because the anticodons more efficiently bind to the codon during translation, unlike codons that do not bind in the wobble position. Codons may be labeled as efficient (i.e., their cognate tRNA is highly expressed) and translated quickly, or inefficient and translated more slowly. Groups of consecutive, inefficient codons appear in many genes. A ramp sequence is 30-50 consecutive inefficient codons at the 5' end of the coding region. We previously demonstrated that the presence or absence of a ramp sequence (i.e., ramp status) in a gene is highly conserved. While the exact role of ramp sequences is unknown, a common hypothesis is that the stretch of slowly translated codons spaces ribosomes along the transcript to reduce the number of ribosomal collisions. Ramp sequences are more common in highly expressed genes, and when an efficient (even synonymous) codon is substituted in the ramp sequence, the ramp sequence is destroyed and total protein reduced. This project aimed to determine how many known human SNPs change a gene's ramp status.

We compiled a list of 14 million SNPs in coding regions. We used our published software, ExtRamps, to compare the wild-type transcript to the mutant transcript for each SNP to determine if a SNP destroys an existing, or creates a new, ramp sequence. 5,133 total SNPs are located in 2,865 of the 5,377 human genes with ramp sequences. Most of these SNPs do not change ramp status. However, we identified 879 SNPs in 683 genes that destroy an existing ramp sequence and 897 SNPs in 761 genes that create a ramp sequence.

Changes in ramp status could have broad implications for understanding the functional effects of SNPs. While many synonymous SNPs are likely benign, we have few tools for predicting when synonymous changes could be functional. Moreover, 500,000 GWAS SNPs have been published, most of which have no known function. Changes to ramp sequences provide a plausible explanation for effects caused by synonymous changes.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1025 † An atlas of *trans*- genetic effects across human tissues.

Authors:

J. Li, X. Liu; Univ. of Chicago, Chicago, IL

A deep understanding of the genetic basis of gene regulation and complex traits critically relies on comprehensive, high-quality maps of *cis*- and *trans*- regulatory effects (Liu et al. 2019 *Cell*; The GTEx Consortium 2020 *Science*; Võsa et al. 2021 *Nat Genet*). While most studies focus on mapping *cis*- genetic effects, there is a scarcity of high quality *trans*-eQTLs, due to their small effect sizes and statistical challenges. In this study, we aim to build the most comprehensive maps of *trans*-eQTLs in 22 human tissues and cell types, by using an ensemble of powerful statistical methods, including *trans*-PCO (Wang et al. 2022 *bioRxiv*), GBAT (Liu et al. 2020 *Genome Biol*) and the standard univariate method. We first applied *trans*-PCO, which is a method to identify *trans*-eQTLs of co-expressed gene modules, to the GTEx dataset. We found a total of 6,570 significant *trans* eSNP-module pairs at 10% FDR in 22 GTEx tissues and cell types, which are highly replicable across datasets. For example, 73.2% of *trans*-eQTLs in GTEx whole blood (N = 670) were replicated in another blood dataset (DGN, N = 913; Bonferroni corrected $p < 0.05$). Among all the *trans*-eSNPs, 64.9% of them overlapped with either *cis*-eQTLs or *cis*-sQTLs in the corresponding tissue, suggesting that trans regulations are primarily mediated through *cis*- regulation. To investigate how the *trans*-eQTL maps can explain mechanisms of diseases, we performed colocalization analyses of *trans*-eQTLs and genome-wide association (GWAS) loci from 37 complex traits, and identified a total of 533 significant colocalization signals (PP4 > 0.5). We found that *trans*-eQTLs tend to colocalize with GWAS loci in trait relevant tissues. For example, *trans*-eQTLs in the whole blood had the highest proportion of colocalization (62%) among 29 blood traits and 3 autoimmune diseases, while other tissues showed a much lower proportion of colocalization (< 30%). In addition, the gene modules associated with the colocalized *trans*-eQTLs showed relevant biological functions to the corresponding traits. For example, we identified a colocalization between a GWAS locus of platelet count near *ARHGEF3* and a *trans*-eQTL on chromosome 3 (PP4 = 0.67). The gene module associated with the colocalized *trans*-eQTL not only exhibited enriched functions of platelet activation and hemostasis, but also had a strong heritability enrichment for platelet count (3.1 fold; Bonferroni corrected $p = 1.6 \times 10^{-5}$). In conclusion, our study will produce comprehensive maps of *trans*-eQTLs in human tissues and cell types, which will characterize *trans*- regulatory effects and mechanism, as well as shed light on detailed molecular mechanisms of complex traits.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1026 An *in silico* analysis of*rpoB*mutations to affect*Chlamydia pneumoniae*sensitivity to rifamycin

Authors:

F. Radouani[1], I. Benamri[1,2], A. Moussa[3]; [1]Inst. Pasteur du Maroc, Casablanca, Morocco, [2]Natl. Sch. of Applied Sci., Abdelmalek Essaâdi Univ., Tangier, Morocco, Tangier, Morocco, [3]Natl. Sch. of Applied Sci., Abdelmalek Essaâdi Univ., Tangier, Morocco

Chlamydia pneumoniae is a common cause of human respiratory diseases and most commonly manifests as pneumoniae and bronchitis. Furthermore, Chlamydia pneumoniae associated with other acute and chronic respiratory conditions such as: chronic obstructive pulmonary disease, asthma, and lung cancer. In addition, it is associated with atherosclerotic cardiovascular disease. Antibiotics are the commonly used drugs to treat chlamydiae infections. However, when overused or mise used this may lead to strains' resistance to antibiotics, this phenomenon represents a real health problem worldwide. Numerous studies showed the association of *Chlamydia pneumoniae* resistance with mutations in different genes. The aim of this study is to perform an *in silico* analysis of *C. pneumoniae rpoB* encoded proteins using numerous bioinformatics tools and to identify the functional and structural related effects of the mutations and consequently their impact on the bacteria sensitivity to antibiotics.The analysis revealed that the prediction of the damaging impact related to the mutations in *rpoB* encoded proteins showed eight mutations: R421S, F450S, S454F, L456I, D461E, S476F, L478S, and S519Y with big deleterious effects, and they are located in a highly conserved regions decreasing the protein's stability. Furthermore, the structures analysis showed that the mutations models had a deviation compared to the wild type. Moreover, the prediction of protein-protein network indicated that *rpoB* wild type interacts strongly with 10 proteins of *C. pneumoniae*, which are playing different roles at different levels.The present study revealed that the mutations in the encoded proteins can affect their functions and structures, in addition to their interactions with other proteins which impact the bacteria sensitivity to antibiotics. Consequently, the information revealed through this in silico analysis would be useful for deeper exploration to understand the mechanisms of *C. pneumoniae* resistance and enable managing the infection to avoid its complications. We recommend further investigations and perform deeper experimental analysis with collaboration between bioinformaticians, physicians, biologists, pharmacists, and chemistry and biochemistry scientists.

Sloan Kettering Cancer Ctr., New York, NY, [5]Dept. of Biostatistics, Harvard Sch. of Publ. Hlth., Boston, MA

Single-cell paired RNA and ATAC multiome data have shown great promise in linking regulatory elements to genes through the synchronized activity of ATAC-seq peaks and expression of nearby genes. However, existing methods (e.g. Signac, Cicero, ArchR, SCENT) differ in how they account for biological and technical noise in single-cell data as well as in their modeling assumptions; as a result, we observe low concordance in their linking scores (e.g. $r = 0.20$ for Signac vs. Cicero) and the subset of candidate links that they are able to score.

Here, we propose pgBoost, an integrative modeling framework that learns a non-linear combination of existing linking strategies to assign a probabilistic score to each peak-gene pair consisting of an ATAC-Seq peak and a nearby gene. pgBoost optimizes a gradient boosting classification task using peak-gene linking scores from Signac, Cicero, ArchR, and SCENT as features and a training set comprised of fine-mapped eSNP-eGene pairs with posterior probability (PIP) > 0.2 as positives and eSNP-eGene pairs with PIP < 0.0001 as negatives (taking the within-peak eSNP with maximum PIP for each peak-gene link). To avoid overfitting, we train the model holding out one chromosome at a time and predict peak-gene links on held-out chromosomes.

We applied pgBoost to multiome data from 10,000 PBMC cells (10x Genomics) using fine-mapped eQTL from GTEx whole blood for training. We reached 3 main conclusions. First, pgBoost attained a higher AUPRC on a held-out test set of fine-mapped eSNP-eGene pairs when trained on all 4 linking scores (0.72) than when trained on individual scores (0.52-0.64). Second, pgBoost attained a higher enrichment for the held-out test set of fine-mapped eSNP-eGene pairs (17.4±0.6x) than the constituent methods (3.0-14x); contributing to this improvement was the higher proportion of within-peak eSNPs scored by pgBoost (99%) than the constituent methods (36-97%). Third, when applied to a "silver-standard" set of 1,522 non-coding SNP-gene pairs obtained from fine-mapped variants for 12 blood-related diseases and traits with a unique fine-mapped coding variant within a 2Mb window (Weeks et al. medrxiv), pgBoost attained a SNP-gene link enrichment of 7.6±0.4x, compared to 2.3-10x for the constituent methods. Our results suggest that an optimal non-linear combination of existing peak-gene linking methods improves power to link regulatory variants to genes, supported by benchmarking analyses using both expression QTL and disease GWAS data.

Central del Caribe, Bayamon, PR, [8]CASE WESTERN RESERVE Univ., SOLON, OH, OH, [9]Case Western Resreve Univ, Cleveland, OH

BACKGROUND The impact of genetic risk variants associated with developing late onset Alzheimer's disease (AD) can be influenced by a person's ancestry via changes in the genomic regulatory architecture (GRA). To comprehensively interpret the variability associated with AD risk genes across populations, it is crucial to have a global understanding of GRA in the context of AD. Most of the currently available GRA data has been generated from individuals of European ancestry. In this study, we aimed to establish ancestry-dependent differences in the GRA using induced pluripotent cell (iPSC) derived neural spheroids with African, Amerindian, and European ancestral backgrounds. Since GRA is specific to different cell types, we focused on the oligodendroglia generated from the spheroids given the abundance of these cells in the central nervous system and the limited attention they have received in AD research. **METHODS:** We obtained cells from individuals with AD or without cognitive impairment, with >85% global ancestry of each ancestral background. These cells were reprogrammed into iPSC and then differentiated into oligodendrocyte (OL) enriched neural spheroids using a protocol that promotes oligodendroglia development. On day 76 of differentiation, we collected and lysed the cells to isolate nuclei for multiomic profiling. This involved analyzing chromatin accessibility and transcriptome using Single Cell ATAC and Single Cell RNA-seq techniques. In addition, we investigated chromatin interactions using Hi-C analysis. **RESULTS:** We identified various stages of OL lineage cells, ranging from cycling progenitors and OL precursor cells to fully mature myelinating OLs. We compared the clusters involving these cell types across ancestries, distinguishing cases from controls and considering APOE genotypes. Preliminary data shows ancestry-dependent differential gene expression of several genes in mature oligodendrocytes including AD GWAS hits such as *APOE, SORL1*, *CLU*, *PICALM*, *ANK1* and *PLCG2*. Analyses of other oligodendroglia clusters, astrocytes and neurons are still ongoing. **CONCLUSION:** Our findings provide ancestry-specific insights into the chromatin structure and gene regulation of oligodendrocytes in the context of AD. This comprehensive understanding contributes to our knowledge of a previously overlooked cell lineage in AD. These results expand the available functional resources for gene identification studies in African American and Hispanic/Latino populations.

PB1029 Annotation Query (AnnoQ): An Integrated and Interactive Platform for Comprehensive Genetic Variant Annotation on a Large Scale

Authors:

B. Queme[1], T. Mushayahama[1], D. Ebert[1], A. Muruganujan[1], P. D. Thomas[1], H. Mi[2]; [1]Univ. of Southern California, Los Angeles, CA, [2]Univ. of Southern California, Irvine, CA

The Annotation Query (AnnoQ) system (http://annoq.org/) serves as a comprehensive, dynamic platform providing the most recent functional annotations for human genetic variants. Supported by an extensive annotation database, it encompasses approximately 39 million human variants from the Haplotype Reference Consortium (HRC), all pre-annotated with over 600 distinct annotation types sourced from various resources. AnnoQ stands out due to its user-friendly and efficient interactive query tool. Unlike traditional annotation tools, which require the user to set up and execute queries, AnnoQ has already pre-annotated all possible variants, thus operating as an intuitive search tool. With its advanced search framework and API, it facilitates efficient management of large datasets, serving the needs of researchers from diverse computational and bioinformatics backgrounds. Moreover, the system features an interactive interface that allows users to conduct quick queries and review annotation results before initiating extensive analyses. AnnoQ ensures that researchers have access to the latest functional annotations by maintaining strong collaborations with renowned resources such as the Gene Ontology Consortium, Reactome, and PANTHER. By incorporating updates from these partners consistently, it guarantees that the annotation information available is always current. An additional noteworthy feature is that AnnoQ extends functional annotations to variants located in the non-coding regions. By utilizing PEREGRINE, a comprehensive genome-wide enhance-gene link database, AnnoQ associates variants in non-coding enhancer regions with their target genes, functions, and pathways. This inclusion expands the annotation scope, covering non-coding regions as well. The AnnoQ system has versatile search capabilities, thanks to its optimized Elasticsearch framework. It supports real-time complex searches, an array of search types including chromosome range, gene product IDs, variants present in VCF files, rsID lists, and free text search. To top it off, AnnoQ offers an API that enables programmatic access to annotated data. Users can avail software packages tailored for popular programming languages like R, which allows them to integrate annotation queries directly within their scripts. In conclusion, AnnoQ operates as a thorough annotation platform that caters to the diverse needs of the research community. By providing detailed and up-to-date functional annotations for human genetic variants, AnnoQ enables researchers to efficiently explore and analyze genomic data.

PB1030 Application of deep mutational scanning data for MLH1 variant interpretation

Authors:

A. Scott[1], F. Hernandez[2], S. Belhadj[2], A. Marsh[2], M. Varga[2], X. Jia[3], G. Clark[3], S. Jayakody[3], B. Burugula[3], R. Karam[2], J. Kitzman[3]; [1]Univ. of Michigan Hlth.Systems, Ann Arbor, MI, [2]Ambry Genetics, Aliso Viejo, CA, [3]Univ. of Michigan, Ann Arbor, MI

Pathogenic germline variants in the DNA mismatch repair (MMR) pathway cause Lynch Syndrome (LS), a hereditary cancer predisposition syndrome affecting more than 1 in every 300 individuals worldwide. Effectiveness of LS genetic counseling is limited by the prevalence of variants of uncertain significance (VUS), which comprise the majority of missense variants identified by clinical genetic testing. We have established deep mutational scanning (DMS) as a scalable means for functional testing to support accurate variant interpretation in LS (Jia et al, *AJHG*, 2021; Scott et al, *Genome Biol*, 2022), which we now apply to the key gene *MLH1*. We overlaid the results of an *MLH1* DMS on clinical databases comprising >15,000 individuals with MMR gene variants from a clinical genetic testing laboratory. In order to determine their applicability to patients, we first applied these results to *MLH1* germline missense variants previously classified as Pathogenic (N=23) or Benign (N=27). All variants which exhibited normal function in this screen had a benign classification, excluding one variant (c.1517T>C; p.V506A) for which the measured effect was intermediate. Conversely, most variants with abnormal function in our DMS data were previously classified as pathogenic or likely pathogenic, such that this function map provides strong evidence under the OddsPath framework (ClinGen Sequence Variant Interpretation Working Group, Tavtigian et al, *Genet Med* 2018). This cohort also included 590 VUS missense variants in *MLH1,* of which a majority (78%) scored in the normal range, consistent with incidentally discovered, benign rare variants unrelated to individual cancer history. By contrast, 12.4% of the clinical missense VUSs exhibited loss of function at the protein level and 5% were predicted to disrupt splicing: reclassification using the functional evidence for these 80 VUSs is ongoing. Saturation-scale functional testing via DMS can provide badly needed functional evidence to improve the actionability of genetic testing.

PB1031 Assessing the functional impact of *ASL* missense variants and genetic interactions between them using high throughput yeast assays

Authors:

M. Tang[1], G. Cromie[1], R. Lo[1], M. Timour[1], H. Morizono[2,3], L. Caldovic[2,3], N. Ah Mew[2,3], A. Gropman[2,3,4,5], A. Dudley[1]; [1]Pacific Northwest Res. Inst., Seattle, WA, [2]Ctr. for Genetic Med. Res., Children's Natl. Res. Inst., Children's Natl. Hosp., Washington, DC, [3]Dept. of Genomics and Precision Med., Sch. of Med. and Hlth.Sci., The George Washington Univ., Washington, DC, [4]Dept. of Neurology, Div. of Neurogenetics and Neurodevelopmental Disabilities, Children's Natl. Hosp., Washington, Washington, DC, [5]Ctr. for NeuroSci. Res., Children's Natl. Res. Inst., Children's Natl. Hosp., Washington, DC

Argininosuccinate lyase (ASL) deficiency is the second most common urea cycle disorder. Clinical presentation of ASL deficiency is variable with onset ranging from the neonatal period to later stages of life. Compared to other urea cycle disorders, individuals with ASL deficiency also experience a higher rate of neurological complications, even in the absence of hyperammonemic events. While disease severity generally correlates with enzyme activity, cases of asymptomatic individuals with undetectable ASL activity and affected individuals with high ASL activity exhibiting severe neurocognitive deficits have been observed. Clinical and genetic heterogeneity of the disease is further confounded by phenomenon of intragenic complementation, in which the combination of two variants of the same protein have activity significantly greater than what is expected based on each allele's individual activity. To better understand the molecular basis of the phenotypic variability in ASL deficiency, we developed and performed high throughput yeast assays to assess the functional impact of all single nucleotide variant (SNV)-accessible missense variants in *ASL*. The assay leverages the ability of the human *ASL* to functionally replace deletion of its yeast ortholog, *ARG4*, enabling yeast strains to grow on arginine-deficient medium. Colony growth of yeast strains harboring *ASL* variants as the sole source of the enzyme provides a quantitative readout of variant enzyme function. We estimated the functional impact of nearly 2,400 *ASL* missense variants (88% of all possible SNV-accessible variants). Approximately 20% of the tested variants displayed null growth, with 65 variants mapping to active and substrate binding sites and 111 to tetramer interface residues. We identified 25 amino acid positions beyond the active sites and tetramer interfaces that exhibited null growth in at least half of the variants tested, suggesting their importance for ASL function. In addition to measuring the functional impact of individual *ASL* missense variants, we will present results of compound heterozygous genotypes to determine the extent to which intragenic complementation can occur. Our high-throughput yeast-based assays provide a comprehensive functional assessment of *ASL* missense variants and allow us to test different *ASL* allelic combinations. Our analyses of the effects of individual mutations as well as compound heterozygotes will help gain a better understanding of disease manifestation and genotype-phenotype correlation in ASL.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1032 Assessing the relative power of constraint metrics in variant prioritisation for rare-variant association testing

Authors:

B. Hill[1], N. Baya[1], D. Palmer[2], C. Lindgren[3]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Univ. of Oxford, Big Data Inst., Oxford, United Kingdom, [3]Big Data Inst., Oxford Univ., Oxford, United Kingdom

Recent rare-variant association studies have unveiled numerous gene-phenotype associations within the human exome. These associations are enabled by set-based testing applied to prioritised collections of variants with evidence of pathogenicity. As such, our power to detect significant associations is limited by our ability to accurately predict such damaging variations. Additionally, within recent years machine learning models of the distribution of aligned protein sequence variation and utilising evolutionary constraint has enabled large advances in protein variant pathogenicity prediction.

We aim to map missense variants in the UK Biobank onto their canonical protein sequences to then apply protein variant effect predictors such as EVE and Tranception to classify damaging missense variants.

First, we evaluated the performance of these classifiers by comparing the number of significant burden tests across selected phenotypes in the UK Biobank 450K exome sequence dataset. Second, we compared the overlapping annotation sets with the existing ClinVar pathogenic labeled missense variants. During this analysis, we controlled score thresholds to fix the annotation count across the analysed prediction metrics.

When compared to the state-of-the-art annotations, EVE and Tranception successfully replicated almost all existing associations and increased the total number of associations across a wide range of phenotypes. The precision of both EVE and Tranception, when compared against ClinVar, was 68% and 57% respectively, significantly outperforming the 47% precision achieved by using PP3 moderate and/or SpliceAI > 0.2.

Our findings demonstrate that the use of protein fitness scores can significantly improve the prediction accuracy of damaging missense variants, enabling more powerful gene association tests. We anticipate that the continued development of methods integrating protein structural prediction into variant classification will further enhance accuracy and boost our ability to detect gene-phenotype associations.

PB1033 *ATXN2* knockdown in zebrafish leads to phenotypic features supporting a role for Ataxin-2 in primary open-angle glaucoma pathogenesis

Authors:

S. Rong[1], A. Larson[1], J. Wiggs[2]; [1]Mass Eye and Ear, Mass Gen. Brigham, Harvard Med. Sch., Boston, MA, [2]Harvard Med Sch, MEEI, Boston, MA

Purpose: Primary open-angle glaucoma (POAG) is the leading cause of irreversible blindness globally. Genome-wide association studies have identified significant POAG association at a chromosome 12 locus, which includes *ATXN2,* a gene known to contribute to other neurodegenerative disorders including spinal cerebellar ataxia 2 and amyotrophic lateral sclerosis. To provide additional support for a role for *ATXN2* in glaucoma, we created and characterized an atxn2-knockdown (KD) zebrafish line. **Methods**: We used in situ hybridization to locate the expression of *atxn2* in zebrafish embryos. Subsequently, *atxn2* was knocked down using a CRISPR/Cas9 system and a translation-blocking morpholino (TBMO). We further purified a line carrying an *atxn2* 58-bp deletion (c.58_115del) from the F0 edited fish. Eye size, retinal ganglion cell (RGC) count, visual motor response (VMR), and intraocular pressure (IOP) were compared between the KD fish and controls at different developmental stages. We used the KD fish for a complementation assay to test a selected group of rare (MAF < 1%) ATXN2 coding variants (CADD >15) with at least nominal evidence for POAG association ($p< 0.05$) for the rescue of eye size and VMR at 5dpf **Results**: In situ hybridization showed atxn2 expression in the RGCs in developing zebrafish ($P<0.05$). The *atxn2*-KD fish line embryos exhibited a significant reduction in eye size ($P\leq0.011$), RGC counts ($P\leq0.004$), and VMR ($P\leq0.009$) at 5dpf. These phenotypes were successfully replicated in the TBMO morphants ($P\leq0.027$). Moreover, IOP was also elevated in the adult *atxn2*-KD fish line ($P=0.01$). Complementation assays using the KD line demonstrated that selected rare, POAG-associated *ATXN2* missense variants reduced eye size ($P<0.001$) and resulted in impaired VMR ($P<0.05$). **Conclusions**: This study identifies glaucoma-related phenotypic features in an *ATXN2* knockdown zebrafish model supporting a role for *ATXN2* in glaucoma pathogenesis.

PB1034 Australia's largest primary ciliary dyskinesia cohort: exploring the genetic background

Authors:

E. Maas[1], M. Marshall[2], P. Leo[3], A. Cook[4], K. Gantert[5], L. Morgan[6], A. Change[4], E. Duncan[7], A. McIneryney-Leo[8]; [1]The Univ. of Queensland, Brisbane, Australia, [2]Australian Translational Genomics Ctr., Queensland Univ. of Technology,, Brisbane, Australia, [3]Australian Translational Genomics Ctr., Queensland Univ. of Technology, Brisbane, Australia, [4]Australian Ctr. for Hlth.Services Innovation, Queensland Univ. of Technology, Brisbane, Australia, [5]Dept. of Hlth.and Ageing, Concord Repatriation Gen. Hosp.,, Sydney, Australia, [6]Dept. of Hlth.and Ageing, Concord Repatriation Gen. Hosp., Sydney, Australia, [7]Dept. of Endocrinology, Guy's and St Thomas' NHS Fndn. Trust, London, United Kingdom, [8]Frazer Inst., The Univ. of Queensland, Dermatology Res. Ctr., Brisbane, Australia

Background: Primary ciliary dyskinesia (PCD) is a genetically heterogenous, autosomal/X-linked recessive disease. ~50% PCD patients have homozygous/compound heterozygous (CompHet) pathogenic variants in one of 72 known PCD genes.
Methods: Australia's largest PCD cohort to date (n=56 unrelated; n=4 siblings) underwent whole exome sequencing (WES), to identify causal variants using a virtual gene panel comprising known PCD and ciliopathy genes (316 genes). Filtering WES data retained good quality, nonsynonymous, rare variants (minor allele frequency <0.005).
Results: 21/60 individuals carried n=35 rare, pathogenic/likely pathogenic/variants-of-unknown-significance in 11 PCD genes (n=26/35 were pathogenic/likely pathogenic, n=21/35 were loss-of-function (LOF)). Of these, n=3 homozygotes (*RPGR*-novel, *DYX1C1* and *OFD1*-novel), and n=17 CompHet for which n=7 carried 1x novel and 1x previously reported variant, and n=2 carried novel LOF variants. While *DNAH5* accounts for the greatest number of reported international cases in literature, *DNAH11* was greatest for this Australian cohort (n=7, two were siblings). Eleven individuals carried a single rare LOF and/or pathogenic/likely pathogenic variant in a known PCD gene, but a second variant could not be identified. Expanding the filtering to include known ciliopathy genes (not associated with PCD), identified n=21 rare, variants of likely functional significance across nine genes in 10/39 individuals. *CFTR* was the most frequently mutated gene in this subset (n=7 variants across n=3 individuals) though there were no cases of previously reported biallelic *CFTR* variants.
Conclusion: This study of an Australian PCD population identified novel/rare variants in known PCD and ciliopathy genes. Further elucidation of genes involved in disease pathogenesis may inform the development of targeted therapies.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1035 Automated High-throughput System to classify pathogenic*SLC6A1*variants.

Authors:

A. Seminario[1], M. Trinidad[2], A. Wuster[3], G. Berguig[2], W. Wallace[4], J. LeBowitz[2], K. Estrada[5], S. Froelich[6]; [1]BioMarin Pharmaceutical, Greenbrae, CA, [2]BioMarin, San Rafael, CA, [3]BioMarin, San Anselmo, CA, [4]BioMarin Pharmaceuticals, San Rafael, CA, [5]BioMarin, South San Francisco, CA, [6]BIOMARIN, San Rafael, CA

Protein-coding variants in SLC6A1 are associated with early onset epilepsy, autism, and schizophrenia. SLC6A1 encodes the GABA transporter GAT1 and is expressed at the synapses of GABAergic neurons. The primary function of neuronal GAT1 is to re-uptake the inhibitory neurotransmitter GABA from the synaptic cleft to sustain its synaptic concentrations. Recently, variants in SLC6A1 have been associated with a spectrum of epilepsy syndromes and neurodevelopmental disorders. Pediatric patients present with seizures, neurodevelopmental delay, autism-like behaviors, and other neurological and developmental symptoms. The average age of onset of seizures is 3.7 years. De novo mutations in SLC6A1 have also been associated with schizophrenia. Schizophrenia patients with SLC6A1 mutations are typically diagnosed in early adulthood and do not present with the symptoms seen in pediatric patients.

Although advances in genomic sequencing have enabled aggregation of patient variants and observed clinical manifestations, the functional impact of many of the disease associated variants remains unknown. Experimental characterization remains a valuable method for validating the impact of variants. To speed up experimental characterization of these SLC6A1 missense-variants, we built a system composed of a MICROLAB STAR liquid-handling robot (Hamilton Robotics, Reno, NV), a 96-well Shuttle nucleofector (Lonza, Basel, Switzerland). Both instruments were controlled by a single PC through Hamilton Venus software. The use of this automated system allowed researchers to screen 180+ rare SLC6A1 missense-variants in four months rather than one year.

Samples were analyzed downstream by mass spectrometry to assess GAT1 transporter activity. Our results find this method to be highly concordant with variant activities previously reported in the literature. These results enable us to classify variants based on activity to generate a more accurate estimate of the prevalence of SLC6A1-associated disorders, and to better understand the molecular biology of SLC6A1-associated conditions. The acquired knowledge will help guide therapeutic decisions and enable the development of targeted therapies that enhance transporter function and improve symptoms.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1036 Automatic detection of complex genome structural variation across human populations and PsychENCODE brains implicate their associations with neuropsychiatric disorders

Authors:

H. Guo[1], B. Zhou[1], J. Arthur[1], T. Kim[2], Y. Huang[1], R. Pattni[1], H. Lee[1], H. Ji[1], G. Song[2], D. Palejev[3], X. Zhu[4], W. Wong[1], A. Urban[1]; [1]Stanford Univ., Stanford, CA, [2]Pusan Natl. Univ., Busan, Korea, Republic of, [3]Bulgarian Academy of Sci., Sofia, Bulgaria, [4]The Pennsylvania State Univ., University Park, PA

Complex structural variation (cxSVs) are major sources of natural human genetic variation, but their genome biology is not well characterized due to difficulties in detecting them from individual genomes. To address this, we developed Automated Reconstruction of Complex Variations (ARC-SV) which combines probabilistic modeling with machine learning to enable the accurate detection of cxSVs from standard whole-genome sequencing (WGS) at unprecedented accuracy, allowing for cxSVs detection on a population-scale. Applying ARC-SV to 4,262 human genomes from all super-populations, we identified and catalogued 8,493 cxSVs belonging to more than 12 subclasses. Overall, cxSVs are significantly enriched in regions prone to recombination and germline *de novo* mutations. Interestingly, rare cxSVs show significant enrichment in genes of neural processes and loci undergoing rapid evolution (including recently evolved cis-regulatory regions relevant to human corticogenesis). Furthermore, by integrating ARC-SV with single-cell multiome analysis for 40 PsychENCODE brains, we found strong colocalized effects of cxSVs on gene expression and on psychiatric disorders. We also identified significant associations of cxSV with gene expression and with chromatin accessibility. Our study paves the way for the automatic integration of cxSVs detection for future population-scale WGS studies and provides valuable insights into the genome biology of cxSVs in human disease.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1037 Body mass index has a broad causal effect on fecal 16S microbiome and plasma metabolome variation.

Authors:

D. Hughes[1], L. J. Corbin[2], C. Hatcher[1], K. H. Wade[1], J. Raes[3], N. J. Timpson[4]; [1]Univ. of Bristol, Bristol, United Kingdom, [2]Univ Bristol, Bristol, United Kingdom, [3]KU Leuven–Univ. of Leuven, Leuven, Belgium, [4]Bristol Univ., Bristol, United Kingdom

Variation in the accumulation of body fat, body composition, and obesity can all be proxied by body mass index (BMI) which itself is a recognized risk factor for numerous health outcomes including life expectancy, various cancers, and cardiometabolic diseases. What remains unclear is the complete picture of how BMI influences health. Two possible factors are variation in the microbiome and metabolome, which previous research has demonstrated to be strongly correlated with BMI. Here, we use genetic contributions to BMI from the Flemish Gut Flora Project (n=2257) to estimate causal associations between BMI and (1) gut flora and (2) the plasma metabolome. Undertaking one-sample Mendelian randomization (MR) analysis, using a polygenic score reliably associated with BMI, yielded evidence from total and sex-specific sub-analysis suggesting the presence of causal effects of BMI on gut flora and the metabolome. In total, 1058 metabolites from the Metabolon platform and 215 microbiome traits (MTs), including three alpha-diversity, one beta-diversity, 115 presence (vs. absence), 40 zero-truncated abundance, and 51 abundance traits, were included in all analyses. After correcting for multiple testing, 495 metabolites and 67 MTs were associated with a standard deviation change in BMI (~4.5kg/m2) in (generalized) linear modeling. MR-derived effect estimates were strongly correlated with estimates from (generalized) linear models. After correcting for multiple testing, 55 metabolites and 14 MTs retained evidence for a strong causal association with BMI in the total population. This includes 24 lipids and 13 amino acids such as alanine, valine, and isoleucine, and it includes genera Sporobacter and Barnesiella, family Porphyromonadaceae, beta-diversity MDS1, two alpha diversity metrics, and the enterotype Bact2. These 55 metabolites and 14 MTs yield a BMI driven network of 327 metabolite-MT connections including all 14 MTs and 44 metabolites. The strongest MT-metabolite correlation is between beta-diversity (MDS1) and 3-phenyl-propionate - a xenobiotic - with a Spearman's rho of 0.54. We might conclude that microbiome diversity drives variation in 3-phenyl-propionate but at present it is equally likely that BMI is having independent but correlated effects on microbiome and metabolome variation. Overall, results support a conclusion that the plasma metabolome and gut microbiome variation can be causally influenced by variation in BMI and that while BMI driven microbiome and metabolome variation is intercorrelated caution is warranted when making further inferences of causality.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1038 Brain development mutations in the beta-tubulin TUBB result in defective ciliogenesis

Authors:

A. Mollica[1], S. Omer[2], S. L. Evagelou[1], S. Naumenko[3], S. Walker[4], L. Li[1], A. Teeling[1], K. Lindsay[1], S. Erwood[1], A. Vig[1], R. M. Vernon[1], J. D. Forman-Kay[1], M. Shroff[1], R. E. Harrison[2], R. D. Cohn[1], E. A. Ivakine[1]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]Univ. of Toronto Scarborough, Toronto, ON, Canada, [3]Harvard Chan Sch. of Publ. Hlth., Boston, MA, [4]Genomics England, London, United Kingdom

Tubulinopathies and neurodevelopmental ciliopathies are two groups of genetic disorders characterized by abnormal brain development resulting in structural brain malformations. Tubulinopathies are caused by dominant missense mutations in genes encoding for tubulins, the building blocks of microtubules. Neurodevelopmental ciliopathies are mostly recessive disorders caused by defects in the function of the primary cilium, a sensory organelle that modulates signaling pathways important for brain development. Though more than 40 genes have been associated with neurodevelopmental ciliopathies, many patients still do not have an identified genetic etiology. Here, we present a novel *de novo* heterozygous missense variant in Tubulin Beta Class I (*TUBB*) identified through whole-genome sequencing analysis in a patient with both ciliopathy and tubulinopathy brain features. While microtubules are fundamental to primary cilia formation and function, no association between mutations in tubulin genes and neurodevelopmental ciliopathies has been found to date. Using patient-derived cells and gene-edited isogenic cell lines, we show that the identified variant impairs the early stages of cilia formation by altering microtubule dynamics and structure. Furthermore, we demonstrate that the disease mechanism is not haploinsufficiency and that other patient mutations in *TUBB* affect cilia formation *in vitro*, putting forward defective ciliogenesis as a contributing pathogenic factor in a subset of tubulinopathy patients.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1039 CACNA1E (c.5365-2A>G) de novo splicing variant as a potential mechanism of pathogenicity: a novel in silico study.

Authors:

J. Lopez Rivera[1], C. Estrada[1], T. Castro[1], O. Londoño[1], M. Arcos[1], M. Chaparro[1], P. Rueda[1], L. Rios[1], D. Rodriguez[1], D. Moreno[1], C. Rucinski[2], G. Ardila-Patino[3], J. Vélez[4], O. Vidal[4]; [1]Clínica Colsanitas, Bogotá, Colombia, [2]Univ. Natl. de Colombia, Bogota, Colombia, [3]Clínica Colsanitas, Bogota, Colombia, [4]Univ. del Norte, Barranquilla, Colombia

Missense variants in CACNA1E gene have been described as causative for autosomal dominant Developmental and epileptic encephalopathy-69, characterized by early-onset seizures, hypotonia, and severe impaired development. We report a novel likely pathogenic de novo variant at the splicing site (c.5365-2A>G) for an 8-year-old patient with a behavioral disorder without seizures. Recent literature has reported several patients with similar phenotypes with splicing site variants, which suggests a pathogenicity mechanism, however it has not been reported in reference databases. Therefore, we performed an in silico study to determine the effect of this variant in the resulting protein and compare it with previous studies for missense variants. Our results suggest a different protein effect that could be associated to the wide expressivity and possible incomplete penetrance of the phenotype given by each type of variant. However, further functional studies are needed to support this hypothesis.

Erwin[1,2,7]; [1]Lieber Inst. for Brain Dev., Baltimore, MD, [2]Dept of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [3]Dept. of Molecular Biology and Genetics, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [4]Dept of BioMed. Engineering, Johns Hopkins Univ., Baltimore, MD, [5]Dept of Neurology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [6]The Collaborative Ctr. for X-linked Dystonia-Parkinsonism, Massachusetts Gen. Hosp., Boston, MA, [7]Dept of NeuroSci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

X-linked Dystonia Parkinsonism is a rare, inherited neurodegenerative condition caused by insertion of SINE-VNTR-Alu (SVA) element into intron 32 of TATA-box binding protein associated factor 1 (*TAF1*). Present in ~2,700 copies in the human genome, SVAs contain a canonical hexameric repeat (CCCTCT)n and similar to Huntington's Disease, the length of this hexameric sequence correlates with disease of onset in XDP patient brains. Previous studies of neurodevelopmental models have focused on the impact of SVA insertion on the differential transcription of *TAF1* in XDP cells, however, *TAF1* transcriptional differences between XDP and healthy are negligible in mature neurons. Thus, there is a need to better understand the molecular pathology in neurons, including expansion of the XDP SVA hexamer. Using a ventral forebrain organoid (VFO) model derived from XDP patient iPSCs, we performed Cas9-targeted Nanopore sequencing on the XDP SVA locus, along with four autosomal SVA_F, two SVA_D, *FMR1* (a gene associated with repeat expansion disorder), and *TP53* as a control. Combining both long-read and PCR-based methods, we evaluated the instability of the XDP SVA locus and identified both expansion and retraction of the XDP SVA hexameric sequence. Additionally, we characterized the methylation status and instability of the XDP SVA and six autosomal SVA loci to contextualize our findings. Future work will focus on understanding the source of the genomic instability at the XDP SVA locus and evaluating this phenomenon in SVAs across the human genome.

Res., Royal North Shore Hosp., Sydney, NSW, Australia

Short tandem repeats (STRs) are variations in the genome defined by repeating copies of a small (2-6bp) motif. There are over one million known STR loci, comprising approximately 3-5% of the human genome. Variation in STR repeat length modulates gene expression and can influence biological function. STR variants cause over 60 Mendelian disorders, including Huntington's disease and Fragile X Syndrome, and can influence complex traits such as dyslipidemia.

Despite their biological importance, STRs remain poorly understood due to limitations in discovery and genotyping with short-read sequencing technology. Repeat-containing reads are also difficult to align to the reference genome precisely. These challenges mean that STRs are often excluded from whole genome sequencing (WGS) pipelines and therefore represent a crucial gap in our understanding of genetic variation and their downstream biological impact on gene expression.

We genotyped 164,847 STR loci in a cohort of 1,055 Australian adults for whom both WGS and single-cell RNA sequencing (scRNA-seq) data from approximately 1,000 peripheral blood mononuclear cells are available for each individual. We have completed single nucleotide polymorphism (SNP) genotyping and are generating STR calls for a separate cohort of 985 Australians. The final cohort of 2,040 individuals, phase 1 of the TenK10K program, will be the largest cohort of paired human WGS and scRNA-seq data generated to date, enabling not only the characterisation of STR variation genome-wide but also novel analysis of the effect of STRs on gene expression using single-cell transcriptomic data.

After filtering the STR catalogue and performing stringent QC on the variant calls from ExpansionHunter, we identified 157,551 loci that are confidently variable in the first 1,055 individuals. The motif distribution of the STR loci is mainly composed of dinucleotides (60%) and tetranucleotides (23%). The mean STR length genotyped was 26bp (max: 505bp, min: 2bp), and the mean number of distinct alleles genotyped per locus was 6.8.

This robust catalogue of STR variation will now be combined with the paired scRNA-seq data to identify gene expression-modulating STRs in a cell type-specific context.

PB1042 *CD33* SNP rs2455069: A hypothesis that arginine/glycine substitution affects CD33 functional role in microglial activation.

Authors:

E. Vitale[1], A. Angiolillo[2], A. Di Costanzo[2], A. Donizetti[3]; [1]Inst. of Biochemistry and Cell Biology, Natl. Res. Council (CNR), Napoli, Italy, [2]Ctr. for Res. and Training in Med. of Aging, Dept. of Med. and Hlth.Sci. "V. Tiberio", Univ. of Molise, Campobasso, Italy, [3]Dept. of Biology, Univ. of Naples Federico II, Napoli, Italy

Modifications in the CD33 gene identified by genome-wide association studies (GWAS) make it one of the highest ranked risk factors for Alzheimer Disease (AD). CD33 is a sialic acid-binding immunoglobulin (Ig)-type lectin (Siglec) receptor expressed in myeloid cells, including microglial cells. Its binding to sialic acid-modified glycoproteins and glycolipids leads to inhibition of cellular functions such as phagocytosis. We have identified rs2455069-A>G (R69G), a Single-Nucleotide-Polymorphism (SNP) in CD33 exon 2 and demonstrated that patients carrying this SNP had an increased risk of AD. However, beyond an association with a few reported cases, the function, and potential mechanisms of most of the CD33 SNPs in promoting AD remains elusive. To try to attribute a functional role to this polymorphism, we demonstrated, using bioinformatics analyses, that the CD33-R69G variant protein has an increased binding affinity to sialic acid, and consequently, a more efficient binding to sialic acid-containing gangliosides at lower concentrations than the wild-type variant. We hypothesize that the binding of the CD33-R69G form to sialic acid could have long-term cumulative effects and may explain a form of late-onset of Alzheimer's disease, by an inefficient removal of β-amyloid peptide. To test our hypothesis for a role for the CD33 variant and identify a potential mechanism for its causative effects in LOAD, we plan to generate a human cell-based system, similar to one reported by Wißfeld et al. [Sci Rep. 2021], by using the Flp-In™-293 Cell Line and Flp-In system. The system will be based on fusing the extracellular CD33 domain to TYROBP/DAP12 to monitor the activation of the CD33 by sialic acid binding. As redout of the activation, we will analyze the level of pSYK and calcium. We will evaluate differences in CD33 signaling resulting from an altered binding capacity of CD33-R69G for gangliosides. In addition, we will approach a putative therapeutic strategy, using the antagonistic effects of the anti-CD33 antibody in combination with different concentrations of gangliosides as proof of principle of an existing interrelation between anti-CD33 therapeutic efficacy and ganglioside metabolism. This strategy will test, for the first time, whether this treatment approach can be developed for addressing late onset Alzheimer's disease.

PB1043 Challenges and solutions in variant analysis and therapy testing in the retinal dystrophies.

Authors:

R. Jamieson, T. Loi, J. Grigg, A. Cheng, S. Eamegdool; Eye Genetics Res. Unit, Children's Med. Res. Inst., Sydney Children's Hosp. Network, Save Sight Inst., Univ. of Sydney, Sydney, Australia

Background: The increasing number of genetic therapies and clinical trials for patients with inherited retinal disorders (IRDs) is a tremendous step forward. Eligibility for these therapies requires a clearcut genetic diagnosis. Genomic investigation may lead to variants of uncertain significance (VUS) using ACMG criteria. We have developed a pipeline of investigation using patient-derived or genome edited induced pluripotent stem cells (iPSCs) differentiated to retinal organoids (iROs) or retinal pigment epithelium (iRPE). Expression and omic studies were used in criteria assessment for VUS reclassification, as well as for novel therapy investigation. Methods: Patient-derived iPSC lines were created, and isogenic controls as well as known pathogenic or variants for investigation were generated. Guide RNAs were selected and homology directed repair templates were used to introduce the relevant variant sequence or create isogenic controls for VUS in *RPGRIP1* and *PDE6B.* Variant and control iPSC lines were differentiated to iROs. Organoids were examined for morphological markers of photoreceptor outer segment development and function. RT-PCR, transcriptomic and immunofluorescence studies were used to assess variations in expression and protein interactions. Results: Human iROs with VUS in *RPGRIP1* and *PDE6B* were successfully generated. Lines with VUS demonstrated abnormal morphology, protein expression, or transcriptomic abnormalities, compared with control lines. Abnormal localisation of outer segment photoreceptor proteins was a key finding. Transcriptomic analysis identified characteristic signature pathways in those with pathogenic variants, compared with controls. Conclusions: Novel VUS in IRD genes, *RPGRIP1* and *PDE6B*, showed markers of pathogenicity using patient-derived and genome edited iPSCs differentiated to iROs. Analyses of morphological features, protein trafficking, RNA studies and transcriptomic profiling, were useful as indicators for VUS reclassification. This approach is valuable in assessment of VUS and pre-clinical assessment of novel therapies.

PB1044 Characterization of allele-specific expression in Alzheimer's Disease

Authors:

V. Subramaniam, Z. Wang, R. Vaza, M. Wang, K-l. Huang; Icahn Sch. of Med. at Mount Sinai, New York, NY

Alzheimer’s disease (AD) is the leading cause of dementia, accounting for 50-70% of cases worldwide. Previous studies profiling gene expression in heritable AD have identified several loci conferring disease risk. However, the mechanism of pathogenesis remains ambiguous. Allele-specific expression (ASE) is the phenomenon through which one allele is preferentially expressed through *cis*-acting regulators and may explain how risk variants lead to AD. We assessed ASE in AD using DNA- and RNA-sequencing data from the Mount Sinai Brain Bank (MSBB) and Religious Orders Study/ Memory and Aging Project (ROSMAP) databases. The databases included samples from various brain regions as well as clinical variables related to AD. Analysis of both sample sets showed ASE prevalence of 1-2% across the AD genome. As expected, imprinted genes carried more ASE variants compared to other genes. Many ASE variants were shared between all four brain regions. However, symptomatic AD individuals showed greater ASE in Brodman area 22 compared with Brodman 36, 44, and 10. At the chromosome level, 18 risk sample variants were identified through a linear mix model applied to each brain region. Chromosomes 6, 14, and 15 were enriched for ASE variants in both control and AD cohorts, while chromosome 7 was enriched for ASE variants exclusively in the AD cohort. At the chromosome band level, regions 14q32 and 15q11, which have previously demonstrated higher minor allele expression in autism spectrum disorder, were enriched for ASE in our AD sample. Finally, we observed that nearly all variants located at chromosome 9 q13, and chromosome 7 q32.2 demonstrated ASE in both AD and control cohorts . Overall, we have provided a comprehensive characterization of ASE in AD, Further analysis is necessary to understand the implications of these variants in AD pathogenesis and regulation.

PB1045 Characterization of extracellular vesicles from fibroblast-derived osteoblast-like cells in patients with *SGMS2*-related osteoporosis.

Authors:

K. Määttä[1,2], S. Pihlström[1,2], R. Mäkitie[1,2,3], O. Makitie[1,2,4,5], M. Pekkinen[1,2,4]; [1]Inst. of Genetics, Folkhälsan Res. Ctr., Helsinki, Finland, [2]Res. Program for Clinical and Molecular Metabolism, Faculty of Med., Univ. of Helsinki, Helsinki, Finland, [3]Dept. of Otorhinolaryngology – Head and Neck Surgery, Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland, [4]Children´s Hosp., Helsinki Univ. Hosp. and Univ. of Helsinki, Helsinki, Finland, [5]Dept. of Molecular Med. and Surgery and Ctr. for Molecular Med., Karolinska Inst.t, Stockholm, Sweden

Pathogenic variants in *Sphingomyelin Synthase 2 (SGMS2)*, an essential gene in sphingomyelin metabolism, associate with a rare autosomal dominant skeletal disorder characterized by low bone mineral density, increased spinal and peripheral fractures and sclerotic doughnut-shaped lesions in cranial bones. Sphingomyelin metabolism sustains skeletal homeostasis through yet unknown molecular mechanism. Extracellular vesicles (EVs) are nanoparticles secreted by various cell types. EVs possess important roles in various biological processes, such as osteogenic differentiation, by functioning as cell-to-cell communicators. Aim of the study was to characterize EVs from pathogenic *SGMS2* p.Arg50* mutation carriers and healthy controls by using fibroblast-derived osteoblast-like cells. EVs were isolated from the media of the cell cultures of 4 patients and 4 healthy controls in both fibroblast-stage (day 0) and osteoblast-like stage (differentiation of 27 days) using ultracentrifugation-based method and characterized by size, concentration and the presence of protein markers using nanoparticle tracking analysis, immuno electron microscopy and dot blot method. In addition, the RNA-content of EVs will be analyzed by RNA sequencing. As a result, the average EV concentration increased in patients from 2.0E+11 (range 1.7-2.4E+11) particles/ml (day 0) to 5.1E+11 (range 3.7-6.6E+11) particles/ml (day 27) (p=0.03) and in controls from 2.0E+11 (range 1.7-2.3E+11) particles/ml (day 0) to 5.0E+11 (range 3.1-7.8E+11) particles/ml (day 27) (p=0.03). The average EV median size increased in patients from 109.9 nm (range 104.6-117.2 nm) (day 0) to 121.1 nm (range 112.0-129.3 nm) (day 27) (p=0.11) and in controls from 107.4 nm (range 98.5-119.8 nm) (day 0) to 121.9 nm (range 115.5-133.4 nm) (day 27) (p=0.11) indicating increased cargo content. No statistically significant difference in EV concentration and median size between patients and controls was observed at timepoints 0 and 27 days. Protein content-based EV characterization confirmed presence of markers CD9, CD63, CD81 and HSP70 and the absence of ER marker calnexin. RNA cargo analyses are ongoing. In conclusion, fibroblast-derived osteoblast-like cells can provide an alternative approach for osteogenic EV studies aiming to gain novel insights into the molecular mechanisms and therapeutic applications of EVs in skeletal fragility.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1046 Characterizing genetic variation in the regulation of the ER stress response through computational and *cis*-eQTL analyses

Authors:

N. Russell, L. B. Jorde, C. Y. Chow; Univ. of Utah, Salt Lake City, UT

Misfolded proteins in the endoplasmic reticulum (ER) elicit the ER stress response, a large transcriptional response driven by three well-characterized transcription factors. This transcriptional response is variable across different genetic backgrounds. One mechanism by which genetic variation can lead to transcriptional variability in the ER stress response is through altered binding and activity of the three main transcription factors: XBP1, ATF6, and ATF4. This work attempts to better understand this mechanism by first creating a computational pipeline to identify potential binding sites throughout the human genome. We utilized GTEx datasets to identify *cis*- eQTLs that fall within predicted transcription factor binding sites (TFBSs). We also utilized the ClinVar database to compare the number of pathogenic versus benign variants at different positions of the binding motifs. Finally, we performed a *cis*- eQTL analysis on human cell lines experiencing ER stress to identify *cis*- eQTLs that regulate the variable ER stress response. The majority of these *cis*- eQTLs are unique to a given condition: control or ER stress. Some of these stress-specific *cis*- eQTLs fall within putative binding sites of the three main ER stress response transcription factors, providing a potential mechanism by which these *cis*- eQTLs might be impacting gene expression under ER stress conditions through altered TF binding. This study represents the first *cis*- eQTL analysis on human samples experiencing ER stress and is a vital step towards identifying the genetic components responsible for variation in the ER stress response.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1047 Characterizing the genetic architecture of comprehensive inflammatory markers and their associations with obesity

Authors:

B. Truong[1], Z. Sun[2], Z. Wang[3], V. Sarsani[2], J. Hu[2], Z. Wang[2], L. Liang[4], J. Li[5]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Dept. of Epidemiology, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [3]Dept. of Biostatistics, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [4]Harvard Sch Publ. Hlth., Boston, MA, [5]Brigham & Women s Hosp., Harvard Med. Sch., Boston, MA

Systemic inflammation in obesity is postulated to play a pathogenic role in the development of obesity-related diseases including type 2 diabetes, cardiovascular disease, and cancers. However, the genetic architecture of inflammatory markers and their casual relationships with obesity is yet to be elucidated. To address this gap, we curated large-scale GWAS summary statistics for 138 cellular and molecular markers of inflammation by meta-analyzing data from several cohorts and recent proteomics GWAS (median N = 39,747, ranging from 2,538 to 516,121), and for obesity and adiposity traits (i.e., body mass index [BMI], and subcutaneous, visceral, liver, and pancreas fat volumes) from the UK Biobank (median N = 40,796, ranging from 21,705 to 337,000).
We identified 83 markers with significant heritability ranging from 2.7% to 50% (FDR < 5%). Hierarchical clustering analysis on pairwise genetic correlations of 83 significant markers identified 3 subclusters with averaged pairwise correlations greater than 0.7, for example, interleukins - TNFa/b - growth factors, blood cells - C-reactive protein, and PDL-1 - VCAM1 - TNFaR1/R2. In contrast, adiponectin, MMP2, and DNER showed negative genetic correlations with most other inflammatory markers. Pairwise bidirectional Mendelian Randomization (MR) identified 35 pairs of suggestive causations (FDR < 5%) between specific inflammatory markers (e.g. WBC - lymphocyte, and TRAILr1 on MMP16), highlighting the potential regulation of inflammatory pathways. Colocalization with tissue-specific eQTLs suggested that most of these inflammatory markers are expressed in multiple tissue types, especially in whole blood, adipose tissues, thyroid and nerve tibial tissues. Further examination of obesity/adiposity traits revealed significantly positive genetic correlations between leptin, CRP, interleukins, and TNF families with obesity/adiposity (rg ranged from 0.07 to 1), whereas adiponectin, MMP2, and DNER showed negative genetic correlations with obesity/adiposity (rg ranged from -0.03 to -1). Finally, MR highlighted the causality of obesity on inflammatory markers such as BMI on IL6, TNF receptor 2 and VEGF (effect = 0.16-0.3), waist-hip-ratio adjusting for BMI on adiponectin (effect = -0.4) and CCL25 (effect = 0.3).
Our study provided a comprehensive map of the genetic architecture of inflammatory markers and their shared genetics with obesity/adiposity. Given the pivotal role of inflammation in diseases and aging, a better understanding of the complex relationships between obesity and inflammatory signaling could inform novel therapeutics for the prevention of obesity comorbidities and complications.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1048 Chromatin accessibility QTL mapped in 138 liver tissue donors identify functional variants and genes at GWAS loci.

Authors:

K. Currin[1], H. J. Perrin[1], A. S. Etheridge[1,2], S. Vadlamudi[1], A. E. Musser[1], G. K. Pandey[1], A. A. Alkhawaja[1], K. A. Broadaway[1], J. D. Rosen[1], A. Varshney[3], A. S. Chaudhry[4], P. J. Gallins[5], Y. Zhou[5], S. C. J. Parker[3], L. Raffield[1], F. Wright[5], E. Schuetz[4], F. Innocenti[2,6], K. L. Mohlke[1]; [1]Dept. of Genetics, Univ. of North Carolina, Chapel Hill, NC, [2]Eshelman Sch. of Pharmacy, Univ. of North Carolina, Chapel Hill, NC, [3]Dept. of Computational Med. & Bioinformatics, Univ. of Michigan, Ann Arbor, MI, [4]Dept. of Pharmaceutical Sci., St. Jude Children's Res. Hosp., Memphis, TN, [5]Bioinformatics Res. Ctr., North Carolina State Univ., Raleigh, NC, [6]Lineberger Comprehensive Cancer Ctr., Univ. of North Carolina, Chapel Hill, NC

The majority of GWAS loci contain variants within regulatory elements, but existing regulatory element maps for many tissues are based on a small number of donors and may not capture individual variability in activity. To identify individual differences in regulatory element activity in liver tissue, we mapped chromatin accessibility using ATAC-seq from 138 donors and identified 358,304 regulatory elements (peaks) present in at least 7 donors. Compared to peaks found in many donors, peaks found in fewer donors are less likely to overlap DNase-seq peaks from ENCODE or promoter and enhancer states from Roadmap liver, indicating that some peaks are not captured by existing datasets. To identify peaks that differ by genotype, we mapped chromatin accessibility QTL (caQTL) and identified 35,361 peaks with a caQTL (caPeaks, FDR<5%, FastQTL). CaQTL variants are more likely to disrupt motifs of specific transcription factors (TFs), including the liver key regulators HNF4A, FOXA1/2/3, and CEBPB. We identified 2,126 caQTL signals that contain multiple caPeaks (coordinated caPeaks), including 271 signals that show long-range coordination (> 100 kb). Signals with coordinated caPeaks are more likely to colocalize (coloc PP H4>0.8) with GTEx liver eQTL compared to signals with 1 caPeak (OR=4.1, p=8E-99), even after adjusting for transcription start site (TSS) proximity (OR=3.7, p=4E-85). We predicted 16,198 links between caPeaks and target genes using TSS proximity, eQTL colocalization, Hi-C, and coordination of distal and promoter peaks. The 9,019 unique target genes of caPeaks include 384 TFs, 550 drug response genes, and 130 liver-enriched genes defined by the Protein Atlas. Using summary statistics of 703 traits (UK Biobank, Neale lab), caPeaks are enriched for heritability of 21 traits (LDSC, FDR<5%), including liver enzymes, cholesterol, albumin, and C-reactive protein. CaQTL colocalized with dozens of GWAS signals for liver-relevant traits, including 113 for total cholesterol and 54 for the liver enzyme gamma-glutamyl transferase (GGT). To validate regulatory activity, we focused on a GGT GWAS signal colocalized with a caQTL signal containing 40 coordinated caPeaks that was linked to TENM2 by eQTL colocalization and promoter-distal caPeak coordination. We observed significant allelic differences in transcriptional activity in HepG2 reporter assays for rs7726117, which was the only variant at the locus in a caPeak (forward fold change (FC) 1.5, p<1E-4, reverse FC 1.3, p<1E-4). These results show the utility of increased sample size for identifying unannotated regulatory elements and for mapping caQTL to identify functional variants and genes at GWAS loci.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1049 Chromatin interaction inferences based on the paired transcriptome and chromatin accessibility datasets identify candidate risk genes of autoimmunity.

Authors:

H. Hatano[1], A. Suzuki[2], M. Nakano[1], A. Oguchi[3], Y. Murakawa[3], C. Terao[4], K. Yamamoto[2], K. Ishigaki[1]; [1]Lab. for Human Immunogenetics, RIKEN Ctr. for Integrative Med. Sci., Yokohama, Kanagawa, Japan, [2]Lab. for Autoimmune Diseases, RIKEN Ctr. for Integrative Med. Sci., Yokohama, Kanagawa, Japan, [3]RIKEN-IFOM Joint Lab. for Cancer Genomics, RIKEN Ctr. for Integrative Med. Sci., Yokohama, Kanagawa, Japan, [4]Lab. for Statistical and Translational Genetics, RIKEN Ctr. for Integrative Med. Sci., Yokohama, Kanagawa, Japan

Genome-wide association studies (GWAS) have identified numerous risk variants associated with autoimmunity onset. Risk variants are frequently found within cell-type specific gene regulatory regions predicted to interact physically with the promotors of the risk gene via the chromatin interaction and regulate its expression level. Therefore, previous studies inferred the chromatin interactions between the cis-regulatory elements (CRE) harboring risk variants and the promotor regions of surrounding genes using functional genomic assays (e.g., HiC). However, such assays usually evaluated cell lines due to the requirement of large input material and failed to detect the chromatin interaction specific to primary immune cells. To overcome these limitations, we sought to infer functional chromatin interactions of primary immune cells by developing a novel experimental and analytical approach. We first obtained peripheral blood from 70 healthy donors and fine-sorted 26 distinct immune cell subsets by FACS and conducted RNA sequencing (RNA-seq) and Assay for Transposase-Accessible Chromatin sequencing (ATAC-seq). The canonical correlation analysis confirmed cell-type specific covariations between RNA- and ATAC-seq datasets, supporting the feasibility of the paired dataset integration. The stratified LD score regression found that the CREs detected by ATAC-seq explained a substantial fraction of the autoimmunity's heritability, such as T cell lineage subsets for rheumatoid arthritis (RA) and B cell lineage subsets for systemic lupus erythematosus (SLE). We then comprehensively tested the associations of each gene's expression level with the accessibility of all CREs within ±1 Mb of the gene's TSS. We evaluated the entire associations using the mashr software and confirmed that the CRE-gene associations preserved immunologically reasonable cell-type specific patterns. Among all 10,902,917 CRE-gene pairs, 29,277 associations (0.27%) were significant (local false sign rate<0.1) in at least one cell type, and 14,592 associations (0.13%) were specific to only one cell type. The significant CRE-gene pairs were enriched within the previously reported HiC datasets, supporting that our results reflect the physical chromatin interactions. Finally, we leveraged the CRE-gene associations to infer the autoimmunity risk genes. We overlayed the autoimmunity risk variants onto the CRE and found multiple candidate risk genes: e.g. 73 genes for RA and 77 genes for SLE. Together, our rich resource of primary immune cell-specific CRE-gene association database improved our understanding of autoimmunity pathology.

PB1050 Clinical interpretation of partial duplication and deletion involving neurodevelopmental genes

Authors:

J. England[1], G. Huguet[2], K. Jizi[3], C. Poulain[4], E. Douard[3], Z. Saci[3], S. Jacquemont[5]; [1]Université de Montréal, Montréal, QC, Canada, [2]CHU Ste justine, Montréal, QC, Canada, [3]CHU Sainte-Justine, Montréal, QC, Canada, [4]Montréal Univ., Montreal, QC, Canada, [5]CHU Sainte justine Res. Ctr., Montreal, QC, Canada

Chromosomal microarrays are routinely used to detect copy number variants (CNV) in patients with neurodevelopmental disorders including intellectual disability and autism spectrum disorder and the diagnostic yield is around 20%. A gene fully deleted or duplicated has clear consequences with a significant decrease or increase in transcription respectively. These changes in known dosage sensitive neurodevelopmental (ND) genes are mostly observed *de novo.* However, CNVs involving only a portion of a known ND gene are frequently observed in the diagnostic setting and whether these variants are gene disrupting is difficult to establish, especially for duplications. Our aim is to quantify the deleteriousness of partial deletions and duplications involving known ND genes.
We used a list of 614 ND genes based on literature (McRae JF et al. 2015, Coe et al. 2019, Satterstrom et al. 2020), PanelApp and ClinGen. We studied transmission of CNVs in 8113 individuals with microarrays performed at the CHU Sainte-Justine diagnostic laboratory. We compared the proportion of inherited and *de novo* CNVs by Fisher's test. The analysis was replicated in the DECIPHER database.
Partial duplications of ND genes (n= 38) almost never occurred *de novo* (3%) and this was not significantly different from the frequency of *de novo* partial duplications in non-ND genes (1%), which is also the probability that a neutral CNV is observed *de novo*. On the other hand, the proportion of duplications fully including a ND gene observed *de novo* was significantly higher (43%, $p= 2.68 \times 10^{-5}$); also higher ($p=1.07 \times 10^{-10}$) than the complete duplications of non-ND genes (14%). On the other hand, the proportion of *de novo* complete (80%) and partial (71%) deletions involving ND genes were both very high and not significantly different.
Complete CNVs of ND genes are more often *de novo* which suggest that haploinsufficient genes are also triplosensitive. Complete and partial deletion of ND genes have a similar pattern of inheritance, we conclude that the mechanism of action is probably loss of function. Partial duplications of ND genes are rarely *de novo* (a rate similar to the probability of a neutral CNV occurring *de novo* and to the non-ND genes in our dataset). As opposed to partial deletions, partial duplications appear to be benign in the vast majority of cases. This could be explained by the fact that the duplicated segment is in tandem and do not disturb the function of the gene or the segment is located elsewhere in the genome and doesn't disrupt the function of a gene.
In conclusion, partial duplications can be interpreted as benign in most cases and clinician should pursue additional genetic testing for the phenotype of the patient.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1051 Cluster analysis identifies genes with distinct patterns of loss of function variants

Authors:

R. Beaumont[1], C. Wright[2]; [1]Univ. of Exeter Med. Sch., Exeter, United Kingdom, [2]Univ. of Exeter, Exeter, United Kingdom

Background: Genetic variants that severely alter protein products (e.g. stop-gain, start-loss) are often associated with disease. For some genes, these predicted loss-of-function variants (pLoFs) are observed throughout the gene in population cohorts, while in others they occur only at specific locations. We hypothesised that for disease genes with incomplete penetrance, regions with pLoF variants present in a population cohort may be those where pLoFs are tolerated. To test this, we investigated whether pLoF location could explain instances of incomplete penetrance of variants expected to be pathogenic for Mendelian conditions.
Methods: We used exome sequence data in 454,773 individuals in UK Biobank (UKB) to investigate locations of pLoFs in a population cohort. We counted numbers of unique pLoF, missense, and synonymous variants in UKB in each quintile of the gene, and clustered the variants using Gaussian mixture models. We limited analyses to genes with coding sequence >1000bp and ≥5 variants of each type (11,050 genes). We compared locations of pLoFs in UKB with all theoretically possible pLoFs and pathogenic pLoFs from ClinVar, and performed simulations to estimate the false-positive rate of non-uniformly distributed variants.
Results: For most genes, synonymous, missense and all possible pLoF variants fell into clusters representing uniform variant distributions. Of these, pLoFs were not uniformly distributed for 625 genes. Notably, genes causing developmental disorders via haploinsufficiency were less likely to have uniform pLoF distribution than other genes ($P<0.001$). For two such genes, *DYRK1A* and *ODC1*, pathogenic pLoFs were located approximately uniformly across the gene, whilst likely benign pLoFs were clustered in specific locations, suggesting rescue via translation reinitiation, alternative splicing or other mechanisms. We also found that fluid intelligence was lower (-0.02 units) in individuals carrying pLoF variants in genes where pLoFs altered plasma protein levels than those where pLoFs did not alter protein levels (0.003 units).
Conclusions: Our results suggest potential benefits of localised constraint metrics and that location of pLoF variants should be considered when interpreting variants.

PB1052 Comparison of blood group serology and whole genome sequencing identifies rare blood group alleles in Oman.

Authors:

P. Haffener[1], A. Al-Riyami[2], S. Al-Zadjali[3], G. Busby[4], M. Al-Rawahi[5], S. Al Hosni[2], A. Al Marhoobi[5], A. Al Sheriyani[6], E. M. Leffler[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]Sultan Qaboos Univ. Hosp., Muscat, Oman, [3]Sultan Qaboos Comprehensive Cancer Ctr., Muscat, Oman, [4]Allelica, New York, NY, [5]Sultan Qaboos Univ., Muscat, Oman, [6]Royal Oman Police Hosp., Muscat, Oman

The earliest human genetics studies focused on blood group variation, beginning with the ABO blood group. Today, there are 44 recognized blood groups that are determined by genetic variation in 49 different genes. These blood group variants are curated in resources such as the ISBT database, which has allowed for genotype-based methods to be developed for inferring patient blood types. However, for these to be of clinical use, rare and population-specific variants must be more widely surveyed and included. Failing to do so could increase the risk for transfusion rejections in repeat-transfusion patients due to blood type incompatibility. For instance, a recent study in Oman compared serological phenotypes with blood groups inferred from targeted genotyping assays and found that few blood groups had 100% concordance. To identify population-specific and rare blood group variants responsible for these discrepancies, here we expand to whole genome sequencing in an independent set of 100 Omani donors. We performed both variant calling and serological testing across 10 blood groups: ABO, RHD, RHCE, MNS, Lutheran, Lewis, Kidd, Kell, Duffy, and P. Only two blood groups, Kidd and Kell, had 100% concordance. With the exception of MNS which had a concordance of 85%, the remaining blood groups had 95%-99% concordance. Further investigation of alleles carried by discordant samples resulted in the first reports in Oman of Fy^X, a common variant in the Duffy blood group system known to reduce expression of Fy^b, and of the Henshaw variant of the MNS blood group, the most common cause of the S-s-U^{+var} blood type in African populations. We also identified the RHD(psi) variant which is a common cause of the RH(-) phenotype in Africa and can result in fetal hemolytic disease of the newborn. Lastly, we report a rare frameshift resulting in a null phenotype of the Duffy blood group, serologically identical to the Fy^{ES} allele thought to have been selected in sub-Saharan Africa due to protection against malaria. Through this approach, we show that the comparison of whole genome sequencing to serology is a valuable strategy to identify additional variants that should be accounted for to predict blood types from genetic data. These results add to our knowledge of causes of blood group variation in Oman, which will inform future testing in blood banks and transfusion services.

PB1053 Comprehensive detection of *trans*-regulatory signal in pooled single-cell CRISPR screens

Authors:

N. Babushkin, X. Liu; Univ. of Chicago, Chicago, IL

Single-cell RNA-seq screens with pooled CRISPR perturbations (Perturb-seq) have emerged as a powerful technique in the field of functional genomics. In this study, we used a unified pipeline to process several large-scale Perturb-seq datasets in K562 cells and comprehensively identified *trans*- regulatory signals across the genome. The datasets in Gasperini 2019 Cell, Morris 2023 Science, Replogle 2022 Cell, and Xie 2019 Cell Rep. targeted a total of 13,729 genes, enhancers, and cCREs, totaling 3,948,462 cells. However, we found that RNA-sequencing reads mapped to multiple homologous locations on the genome lead to around 70% of the false *trans*-signals in Perturb-seq datasets, agreeing with the findings in bulk RNA-seq datasets (Saha 2019 F1000R). To reduce false positive *trans*- signals, we first thoroughly removed reads mapped to genomic regions of low mappability. We then applied SCEPTRE (Barry 2021 Genome Bio.) to identify a set of high-quality *trans*-regulatory signals. In total, we found 3,417 significant *trans*- regulatory gene pairs in three of the datasets. These significant pairs contained a reduced percentage of cross-mappable genes across all three datasets after mappability correction. To assess whether Perturb-seq could serve as a validation strategy for *trans*-eQTLs discovered in RNA-seq datasets, we compared the significant signals to *trans*- eQTLs discovered in the DGN dataset (whole blood). We found that none of the 165 significant *trans*-eQTL signals in DGN were replicated in the Perturb-seq analysis, agreeing with recent findings (Yao 2023 bioRxiv). To examine replication between different Perturb-seq studies, we tested for replication of significant *trans*- regulatory signals. We found that up to 7% of the *trans*- regulatory signals replicate between the four Perturb-seq datasets. In conclusion, our work presents a uniform data analysis pipeline and applies a well-calibrated association test to comprehensively discover high-quality *trans*- regulation signals in Perturb-seq datasets.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1054 Comprehensive functional characterization of *SGCG* coding variants accurately predicts pathogenicity in limb-girdle muscular dystrophy type R4/2E

Authors:

G. Haller[1], C. Li[1], J. Wilborn[2], J. Daw[1], S. Pittman[1], J. Alonso-Pérez[3], J. Díaz-Manera[4], C. Weihl[1]; [1]Washington Univ., St. Louis, MO, [2]Univ. of Utah, Salt Lake City, UT, [3]Hosp. Univ.rio Nuestra Señora de Candelaria, Tenerife, Spain, [4]Newcastle Univ., Newcastle, United Kingdom

The majority of clinically sequenced patients with limb-girdle muscular dystrophy (LGMD) carry variants of unknown significance (VUS) in myopathy-causing genes, leaving them without a genetic diagnosis. α-, β-, γ-, and δ-sarcoglycan form a transmembrane complex (SGC) and loss of function mutations in any subunit causes LGMD. We utilized deep mutational scanning to perform high-throughput screening of SGCB and SGCA membrane localization for all 6340 possible amino acid changes in *SGCB*. Variant functional scores were bimodally distributed and perfectly predicted pathogenicity of known variants. Variants with less severe functional scores more often appeared in patients with slower disease progression, implying a relationship between variant function and disease severity. Positions intolerant to variation mapped to points of predicted inter-SGC interactions, validated *in silico* structural models and enabled accurate prediction of pathogenic variants in other SGC genes. These results enable immediate clinical interpretation of newly discovered *SGC* gene variants.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1055 † Comprehensive genomics across cardiovascular diseases using DRAGEN

Authors:

S. Behera[1], M. Rossi[2], S. Truong[2], S. Mehtalia[2], J. Han[2], F. Zhang[2], G. Metcalf[1], S. Catreux[2], R. Mehio[2], M. Ruehle[2], G. Parnaby[2], F. Sedlazeck[3]; [1]Baylor Coll. of Med., Houston, TX, [2]Illumina Inc., San Diego, CA, [3]Baylor Coll. Med., Houston, TX

Different genetic variations, such as small variants (SNVs), short tandem repeats (STRs), structural variants (SVs) and copy number variations (CNVs) impact various human health outcomes, from complex human diseases to predisposition to specific conditions. Detecting these different variant classes accurately and comprehensively on a single assay and sequencing technology is challenging. The presence of repetitive, heterogeneous regions and errors or biases within the reference genome further complicates the accurate detection of these variants.
In this study, we showcase the DRAGEN germline pipeline that allows us to comprehensively study the human genome across different variant types, at scale and speed (~30min for 30x WGS). DRAGEN employs a novel multigenome alignment method whereby alternate paths representing genetic diversity in the population are added to the reference. This approach significantly improves the mapping, especially in difficult-to-map regions of the genome. Combined with advancements in the variant caller, DRAGEN achieves superior variant calling accuracy compared to other pipelines, including those using recent pangenome graph implementations.
DRAGEN facilitates a comprehensive representation by simultaneously reporting SNVs, SVs, CNVs, STRs and targeted callers across eight highly medically relevant genes (e.g. *SMN*1&2, *GBA*, *LPA*, etc.). This provides deep insights into genetic diseases, such as the *LPA* caller being able to report phased KIV-2 CNV that more accurately reflects measured Lp(a) and thus cardiovascular risk. We assessed all novel features across HG001-07 control samples and 3,202 samples from 1kGP. We validated the improved performance by benchmarking over GIAB truth sets and comparing them with other pipelines. For the HG002 sample on small variants (<50bp), genome-wide and in challenging medically relevant regions respectively, DRAGEN (F-score: 99.85% and 98.64%) performs better than BWA-GATK (99.07% and 95.19%) and BWA-DeepVariant (99.62% and 97.29%). For SV, it achieves a higher F-score (76.9% and 82.6% for INS and DEL respectively) than Manta (34.9% and 70.08%), Lumpy (0% and 66.8%) and Delly (4.7% and 68.3%). DRAGEN performs significantly better (F-score: 94.6%) for CNVs with lengths 1-10Kbp when compared to CNVnator (50.5%).
We applied DRAGEN on ~30,000 samples with rich medical records from a diverse cardiovascular cohort of African-, Hispanic- and European-American populations. By leveraging DRAGEN's comprehensive variant representation and multigenome approach, we will uncover novel insights with association studies and disease-related gene discovery, previously unattainable.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1056 Comprehensive statistical analysis on the impact of missense mutations toward improving variant interpretation

Authors:

S. Kwon, J. Safer, S. Iqbal; Broad Inst. of MIT and Harvard, Cambridge, MA

Accurate interpretation of the pathogenicity of missense variations in the protein-coding genes is essential in clinical genetics, requiring the understanding of variants' effects in the context of protein structure and function. We addressed a challenge in the scalable linking of cross-disciplinary genomics and protein structural data through our discovery portal, Genomics 2 Proteins (G2P;g2p.broadinstitute.org). Combining the resources from G2P portal and AlphaFold database, we aim for the most comprehensive characterization of the structural and molecular effects of missense variants for the entire protein-coding human genome. We aggregated over 4.8M missense variations from ClinVar (N=1,054,009), HGMD (N=183,113), and the genome aggregation database/gnomAD (N=3,587,776), covering 17,836 protein-coding genes. Using MANE transcript to protein isoform mapping, we mapped 91% of variations onto protein sequence/structure. Variants were further annotated with 66 protein and genomic features including physicochemical properties of amino acid, protein structural and functional features, and DNA base-pair changes. We carefully filtered the dataset based on their clinical significance and remove duplicates, resulting in a dataset of 572,226 pathogenic and 2,742,585 population variations. Through Fisher's exact test, we identified 41 pathogenic (odds ratio/OR>1 and corrected p<0.05) and 23 population (OR<1 and corrected p<0.05) variant-enriched features. Furthermore, we accounted for the rarity of population variants by analyzing subsets of rare (allele frequency/AF<0.001) and common (AF > 0.01) variants. We observed a consistent number of features enriched by pathogenic and population variants regardless of the rarity of population variants, highlighting the relevance of those features in variant interpretation. Interestingly, our results differentiated between pathogenic variant-enriched features with a consistent, high effect size (~17-fold for intramolecular disulfide bond) versus those with an increased effect size when compared with rare or common population variants (e.g., protein core residues, OR=3 to 6). Notably, the rare population variants tend to share common features with pathogenic variants, with 14 features enriched with rare variants over common variants coinciding with pathogenic variant-enriched features. Our analyses show a spectrum of the effect size of protein features in variant pathogenicity aligned to the allele frequency spectrum of population variants, highlighting the importance of considering protein features associated with both rarity and pathogenicity in variant interpretation.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1057 Consistent effect sizes of molecular quantitative trait loci observed across diverse African populations

Authors:

D. Nachun[1], M. Degorter[1], P. Goddard[1], C. Smith[1], R. Ungar[1], N. Abell[1], B. Balliu[2], D. Gurdasani[3], S. Montgomery[1]; [1]Stanford Univ. Sch. of Med., Stanford, CA, [2]UCLA David Geffen Sch. of Med., Los Angeles, CA, [3]Queen Mary Univ. of London, Cambridge, United Kingdom

Molecular quantitative trait loci (QTLs) have been primarily mapped in subjects of European descent and studies comparing QTLs between populations have been limited to reporting whether a variant has a non-zero effect size in each population. The multivariate adaptive shrinkage model (*mash*) can estimate posterior effect sizes and standard errors for QTLs tested in multiple conditions that incorporate sharing of effects between the conditions, usually for the purpose of testing if a QTL has a non-zero effect in each condition. We have extended the *mash* model to allow us to directly test for differences in QTL effect sizes across populations by using general linear hypothesis testing to fit post-hoc contrasts from posterior effect sizes and covariance matrices for each QTL. We applied this framework to molecular QTLs generated in lymphoblastoid cell lines (LCLs) from six African populations (ESN, GWD, LWK, MKK, MSL, YRI; N = 41 - 166) sampled by the 1000 Genomes and HapMap projects to test for evidence of population differences in QTL effect sizes. We found pairwise significant ($p < 1x10^{-5}$) differences in effect sizes in only 0.07-1.3% of expression QTLs and 0.006-0.18% of splicing QTLs across the six population samples we compared, implying that population differences molecular QTL effect sizes, if they exist, are too small to detect with our current sample sizes. To test if Eurasian admixture, which has been identified in several of the populations sampled for our study, affects gene expression, we inferred global and local West African and Eurasian ancestry in our samples. We used Yoruba (YRI) as a reference for West African ancestry and six additional populations as references for Eurasian ancestry (BEB, STU, CHB, JPT, TSI, CEU) and found that mean global West African ancestry varied between populations, from 79% in MKK to 100% in ESN. We tested for associations between proportion of global and local West African ancestry and gene expression and found expression of 1,393 genes and 248 genes were significantly associated with global and local West African ancestry, respectively. These results demonstrate that while admixture may affect gene expression, differences in admixture between populations does not lead to large differences in QTL effect sizes. Future studies with larger samples sizes will be able to test if smaller population differences in QTL effect sizes exist and if sharing of effect sizes is also seen in lower frequency variants. Data from other cell types and tissues and additional diverse populations will be needed to determine if these findings generalize beyond LCLs and are applicable to other populations.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1058 † Context-aware single-cell multiome approach identified smoking and cell-type specific lung cancer susceptibility genes

Authors:

E. Long[1], J. Yin[2], S. Ju Hye[3], Y. Li[1], A. Kane[2], J. Xia[4], Y. Han[5], J. Byun[5], T. Zhang[2], W. Zhao[2], M. Landi[2], N. Rothman[2], Q. Lan[2], Y. Chang[3], C. Amos[5], J. Shi[2], J. Gu[3], E. Kim[3], J. Choi[2]; [1]Chinese Academy of Med. Sci. and Peking Union Med. Coll., Beijing, China, [2]NCI/NIH, Rockville, MD, [3]Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of, [4]Creighton Univ., Omaha, NE, [5]Baylor Coll. of Med., Houston, TX

Genome-wide association studies (GWAS) have identified over fifty genomic loci that are associated with lung cancer risk. However, the genetic mechanisms and target genes underlying these loci are largely unknown, as most variants associated with lung cancer might *cis*-regulate gene expression in a context specific manner. Here, we generated the first barcode-shared transcriptome and chromatin accessibility map of 117,911 human lung cells from sex/age-matched Korean ever- (n=8) and never-smokers (n=12) with an enrichment of epithelial cell types to represent lung cancer relevant exposures and cells of origin. This resource enabled variant-peak colocalization and direct peak-gene linkage with cell-type information, which is used to characterize 2,574 candidate causal variants (CCVs) of 51 loci from 4 different lung cancer GWAS. A total of 323 CCVs (12.5%) of 35 GWAS loci (68.6%) colocalized with an accessible peak from one or more of 23 cell types, indicating an efficient variant prioritization for most GWAS loci. Importantly, 48% of the CCV-colocalizing peaks were only detected in epithelial (28%) or immune (20%) cell types. Epithelial and immune cells also presented the highest trait relevance scores by variant-to-context mapping, highlighting their importance in lung cancer etiology. Notably, accessible peaks of rare epithelial populations implicated as lung cancer origins provided support for multiple GWAS loci. Namely, AT2-proliferating cells (0.13%) colocalized with 17 CCVs from 12 GWAS loci, and CCVs in telomerase-encoding *TERT* overlapped a peak specific to basal cells (1.8%) - self-renewing progenitor cells. Linkage between accessible peaks and gene expression identified 64 high-confidence target genes from 18 lung cancer loci. Notably, 53% of them from 14 GWAS loci were differentially expressed based on smoking status in at least one cell type. Four linked *HLA* genes in the locus at chr6p21.33 contributed to the significantly elevated cellular interactome of MHC-I pathway in smokers, highlighting potential smoking-responsive mechanisms. Moreover, our data suggested that CCVs in linkage disequilibrium could regulate one or more context-dependent target genes via multiple peaks. In the locus at chr8p12, three CCVs were linked to *NRG1* via three separate but co-accessible peaks. In the locus at chr11q23.3, immune cell-specific CCV-colocalizing peaks were correlated with *JAML*, while an adjacent epithelial cell-specific CCV-colocalizing peak was correlated with *MPZL3* expression. Overall, we provide a unique single-cell resource to characterize lung cancer GWAS loci and highlight context-dependent gene regulation underlying the risk.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1059 Contribution of genetic ancestry to changes in the urinary metabolites of extremely preterm infants.

Authors:

T. MALAVE-MENDEZ[1], M. Guardado[2], C. Chapin[1], M. Steurer[1], R. Hernandez[3], P. Ballard[1], D. Torgerson[4]; [1]Univ. OF CALIFORNIA SAN FRANCISCO, SAN FRANCISCO, CA, [2]Univ. of California, San Francisco, San Francisco, CA, [3]UCSF, Oakland, CA, [4]UCSF, San Francisco, CA

The human biofluid metabolome is influenced by environmental and genetic factors, the latter of which may include genetic ancestry-linked variation. Genetic ancestry is an indicator of varying patterns of genetic variation that differ by continental origin; however, the contribution of genetic ancestry to the metabolome remains poorly understood. We aimed to identify metabolites that associate with continental genetic ancestry in the urine of extremely premature infants at high risk of developing bronchopulmonary dysplasia. Our study included 171 infants < 29 weeks gestational age from the Trial of Late Surfactant study (TOLSURF), including those of maternal self-reported Hispanic White, non-Hispanic White, or Black/African American race/ethnicity. Untargeted metabolomics was performed using UHPLC-MS/MS on urine from each infant collected at two timepoints between days 6-14 and 23-30 postnatal age. Ancestry proportions were inferred from >800,000 genotypes assuming a 3-population model of continental African (AFR), European (EUR), and Amerindigenous (AMR) ancestry. We then tested for an association between proportions of each genetic ancestry and quantitative measures of individual metabolites using linear regression, adjusting for maternal race/ethnicity, sex, birthweight, TPN status, BPD, and gestational age. Analyses were also performed separately within each racial/ethnic group. Among all infants combined, we identified 130, 72, and 58 metabolites that associated with proportions of AFR, EUR, and AMR ancestry at $p<0.05$, respectively, at timepoint 1, and 64, 33, and 39 metabolites, respectively, at timepoint 2. Twelve metabolites were associated with the same ancestry, and in the same direction at both timepoints. In sub-analyses stratified by race/ethnicity, 16 metabolites were associated with AFR ancestry, 5 with EUR ancestry, and 10 with AMR ancestry at $p<0.05$; 22 of these were associated in the same direction with the same genetic ancestry in >1 racial/ethnic group. Among metabolites that met significance criteria, 8 were involved in metabolic pathways, 2 were xenobiotics, 6 were unknown or partially characterize metabolites, and 6 were involved in other pathways. Our study suggests that genetic ancestry plays a role in the urinary metabolome of premature infants and highlights the importance of considering genetic ancestry in metabolomic studies involving diverse populations.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1060 Co-occurrence of Congenital Disorder of Glycosylation Type IIm and Biglycan-Related Disorder in a 3-Year-Old Puerto Rican Male: A Case Report Emphasizing the Role of Biochemical Testing in Confirming Variants of Uncertain Significance

Authors:

E. Albino[1], F. A. Benitez-Rios[2], S. Carlo[3], A. Cornier[4], F. Velez-Bartolomei[5]; [1]Univ. of Puerto Rico - MSC, San Juan, PR, [2]Ponce Hlth.Sci. Univ., Ponce, PR, [3]Ponce Hlth.Sci. Univ., Cabo Rojo, PR, [4]San Jorge Children s & Women s Hosp., San Juan, PR, [5]Hosp. Pediatrico Univ.rio Dr. Antonio Ortiz, San Juan, Puerto Rico

Congenital disorder of glycosylation type IIm (CDG2M) (OMIM #300896) is an X-linked dominant disorder caused by mutations in the *SLC35A2* gene. It is characterized by hypotonia, infantile-onset seizures, EEG abnormalities, dysmorphic facies, developmental delay, intellectual disability, and lack of speech. Biglycan (*BGN*)-related disorder, or spondyloepimetaphyseal dysplasia (SEMDX) (OMIM #300106), is an X-linked recessive disorder caused by mutations in the *BGN* gene. Its clinical features include severe short-trunk dwarfism, brachydactyly, waddling gait, normal facies, and normal intelligence. The prevalence of these disorders is yet to be determined. Definitive diagnosis relies on genetic testing following clinical suspicion. We present the case of a 3-year-old Puerto Rican male diagnosed with CDG2M and SEMDX. Exome sequencing identified a hemizygous likely pathogenic c.351+1G>T (NM_001711.6) in *BGN*, and a hemizygous variant of uncertain significance (VUS) c.194T>C (p.Phe65Ser) (NM_005660.3) in *SLC35A2*. The patient exhibits severe generalized hypotonia, postnatal growth restriction consistent with spondyloepimetaphyseal dysplasia, and global developmental delay. He presents with dysmorphic features including temporal narrowing, a mildly elongated face, flat nasal bridge, low-set ears, and a high-arched palate. Physical examination reveals hypermobile extremities and pale, doughy skin. Management includes D-galactose supplementation, therapy, sleep study, laboratory testing, and regular follow-up visits. Our patient presents with co-occurring CDG2M and SEMDX. CDG2M is associated with mutations in the *SLC35A2* gene located on chromosome Xp11.23. The missense variant (c.194T>C (p.Phe65Ser)) in *SLC35A2* is predicted to cause protein damage, resulting in the observed phenotypic expression. SEMDX, on the other hand, is caused by mutations in the *BGN* gene found on chromosome Xq28. The splice site variant (c.351+1G>T) in *BGN* likely disrupts normal RNA splicing, affecting protein function and/or expression. This case highlights the importance of genetic testing in diagnosing and managing patients with suspected genetic disorders. Furthermore, performing biochemical tests to confirm variants of uncertain significance plays a critical role in establishing accurate diagnoses. Further research is needed to determine the prevalence of these disorders and explore potential treatment options.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1061 Coronary artery disease-associated splicing variants in vascular smooth muscle cells

Authors:

N. Perry, M. Murali, J. Korchak, B. Jordan, N. Bhuiyan, D. Lue, K. Hudson, G. Sheynkman, M. Civelek; Univ. of Virginia, Charlottesville, VA

BACKGROUND: Coronary artery disease (CAD) is the leading cause of death in the United States despite advances in lipid-lowering and anti-hypertensive drugs. Heritability estimates for CAD vary from 40% to 70%, suggesting strong genetic contributions to disease risk. Through genome-wide association studies (GWAS), more than 300 loci have been associated with risk for CAD. Despite the success of GWAS, the mechanisms whereby the majority of CAD-associated GWAS loci contribute to disease susceptibility are unknown; however, associated SNPs are predicted to function by regulating targeted effector gene expression in the vascular wall, where smooth muscle cells (SMCs) make up the medial layer. During the initiation and progression of atherosclerosis (the underlying cause of CAD), SMCs exhibit a high level of phenotypic plasticity that leads to both atheroprotective and atherogenic contributions to disease. Understanding the genetic regulatory mechanisms of vascular smooth muscle cells (VSMCs) that underlie GWAS findings will identify susceptible mechanisms in the vessel wall for possible therapeutic targeting of CAD. METHODS: An in-depth characterization of genetic regulation of splicing in aortic SMCs of 151 heart transplant donors from various genetic ancestries was performed, followed by PacBio long-read sequencing of six aortic SMC donors to detect alternative splicing (AS) in full-length isoforms from the long-read sequence data for confirmation of splicing predictions of the 164 colocalized splicing and CAD-associated genes. RESULTS: We identified 164 genes with colocalized genetic signals between splice effect associations (splicing quantitative trait loci (sQTL)) and CAD risk associations. We prioritized sQTLs in or nearby splice acceptor and donor sites at exon skipping or cryptic splice site events within the long read data, and focused only on sQTLs that are explicitly captured in CAD GWAS loci. Six genes (*ITGA1, WIPI1, PARP12, RAB5C, MRAS, PRDM16*) contained SNPs that were both within CAD GWAS loci and highly predicted to affect SMC-specific AS events. At the *PARP12* locus, the risk allele of the CAD-associated missense variant, rs2286196, is associated with an AS event that skips exon 10 and results in the loss of the PARP catalytic domain. An active PARP catalytic domain is required for PARP12 to activate NFkB signaling, a major signaling pathway involved in atherosclerosis. SUMMARY: Our results suggest that the CAD-associated *PARP12* locus may function through AS mechanisms affecting the ability of PARP12 to regulate NFkB signaling and downstream inflammatory contributions to disease development.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1062 COVID-eQTL: Genetic dissection of COVID-19 susceptibility

Authors:

J. Lee[1], E. Jeon[1], L. Yu[2], S. Zhao[2], M. Choi[1]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Dartmouth Coll., Hanover, NH

A world-wide pandemic caused by SARS-CoV-2 virus provided an unprecedented opportunity to investigate the genetic susceptibility of virus infection and severity determination. For example, genome-wide association analysis on a cohort of more than 100K infected individuals by COVID-19 Host Genetics Initiative has identified genetic variants associated with COVID-19 severity. However, the molecular mechanisms of how genetic variants affect disease severity and prognosis remain to be elucidated. To address this, we took advantage of the multi-omics data of COVID-19 patients with mild or severe symptoms generated by the support of Korean Disease Control and Prevention Agency and performed quantitative trait loci (QTL) analysis. The data set is composed of whole genome sequencing, blood-based single cell RNA-seq, cytokine profiling, TCR/BCR, and HLA data from 313 individuals with mild or severe COVID-19 symptoms over three time points. Our QTL discovery pipeline applied on these multi-omics data uncovered a number of signals that are specific to severity and disease progression from various cell types and serum cytokine levels. This approach identified a number of variant-gene associations that are differentially regulated by disease status and their molecular upstream signals that eventually modulate disease progression in different individuals.

PB1063 CRISPR/Cas9-mediated knock-in of late-onset Alzheimer's disease-risk variant, SHARPIN G186R, lessens the NF-κB pathway and accelerates Aβ secretion

Authors:

Y. Asanomi[1], T. Kimura[1], N. Shimoda[1], D. Shigemizu[1,2], S. Niida[3], K. Ozaki[1,2]; [1]Med. Genome Ctr., Res. Inst., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [2]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [3]Ctr. for Core Facility Admin., Res. Inst., Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan

Despite the identification of many novel genetic variants associated with late-onset Alzheimer's disease (LOAD), our understanding of the direct biological relevance of these variants to the disease remains largely unclear. In our previous report (Asanomi *et al*., *Mol Med*. 2019), we identified a rare functional variant of *SHARPIN*, rs572750141 (p.Gly186Arg), that is significantly associated with LOAD in the Japanese cohort comprising 4563 LOAD patients and 16459 controls (odds ratio = 6.1). Moreover, recent large-scale meta-analyses of genome-wide association studies have identified other *SHARPIN* common missense variants associated with the risk of LOAD, indicating the important role of *SHARPIN* in LOAD pathogenesis. Although functional analyses of the G186R-type SHARPIN protein in previous studies have revealed aberrant cellular localization of this protein and attenuated activation of the NF-κB pathway, all these analyses used exogenous gene transfer. To elucidate the biological relevance of LOAD-risk variants to the disease pathogenesis, more direct ways of examining the function of mutant SHARPIN protein are desired.

In this study, we used the CRISPR/Cas9 system to perform a knock-in of the LOAD-risk variant into HEK293 cells and generated cell lines with the homozygous SHARPIN G186R mutation. Although the efficiency of the knock-in was modest (<1%), the desired knock-in cells were successfully obtained through high-throughput screening by using a PCR-Invader assay. We then used these knock-in cells to investigate the effects of the *SHARPIN* variant. TNF-α-induced activation of the NF-κB pathway, a central mediator of inflammatory and immune responses, was strongly suppressed in the G186R knock-in cells, but aberrant cellular localization of the mutant protein was not apparent. Previous findings have suggested that neuroinflammation in the central nervous system plays a significant role in the pathogenesis of LOAD. The attenuated NF-κB activity caused by the *SHARPIN* variant may increase the risk of LOAD onset by altering inflammatory and immune responses in the central nervous system. Furthermore, the amount of amyloid-β (Aβ), which was implicated in LOAD pathogenesis, secreted into the culture medium was significantly increased in the G186R knock-in cells, although no significant change in the ratio of Aβ40 to Aβ42 was observed. These findings from the *SHARPIN* knock-in cells provide the importance and new biological insight on SHARPIN functions in the pathogenesis of LOAD. Further investigation of the SHARPIN-associated pathways may elucidate the mechanism underlying the onset of LOAD.

PB1064 CRISPR-mediated allele substitution of a human genetic variant rs10071329 modulates*PPARGC1B* expression and alters brown adipocyte phenotype.

Authors:

S. Kalamajski, M. Huang, D. Coral, P. Franks; Lund Univ., Malmö, Sweden

Human genetic variation in *PPARGC1B* has been associated with adiposity, but the genetic variants that affect *PPARGC1B* expression have not been experimentally validated. Guided by previous observational data, here, we used CRISPR/Cas9 D10A nickase to edit the alleles of a candidate causal genetic variant rs10071329 in human brown adipocyte cell line (hBAs). Changing the rs10071329 genotype from A/A to G/G enhanced *PPARGC1B* expression throughout the adipogenic differentiation, identifying rs10071329 as a *cis*-eQTL. The higher *PPARGC1B* expression in G/G cells coincided with higher accumulation of triglycerides, and higher expression of mitochondria-encoded genes, but without marked effect on adipogenic marker expression. Furthermore, G/G cells had improved basal- and norepinephrine-stimulated mitochondrial respiration, possibly relating to the improved mitochondrial gene expression. The G/G cells also had higher norepinephrine-stimulated glycerol release, indicating improved lipolysis. Altogether, this shows that rs10071329 is a *cis*-eQTL, with the G allele conferring enhanced *PPARGC1B* expression, with consequent improved mitochondrial function and response to norepinephrine in brown adipocytes. This genetic variant, a previously unidentified eQTL, resides downstream of the *PPARGC1B* gene and probably constitutes a part of a gene expression-regulatory enhancer element that could play a causal role in energy metabolism and adiposity. It remains to be shown if people with different rs10071329 genotypes respond differently to e.g. weight loss intervention, where *PPARGC1B* could play an important role in mitochondrial activity.

Heart, Lung, and Blood Inst., NIH, Bethesda, MD, [6]Framingham Heart Study, Framingham, MA, [7]Univ. of Arizona, Tucson, AZ, [8]Stanford Univ., Stanford, CA, [9]Boston Univ. Sch. of Publ. Hlth., Boston, MA, [10]Brigham & Women's Hosp., Boston, MA, [11]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [12]Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA, [13]Brigham and Women's Hosp., Boston, MA, [14]Lundquist Inst., Harbor-UCLA Med. Ctr., Torrance, CA, [15]Stanford Univ. Sch. of Med., Stanford, CA, [16]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Most genetic variants associated with complex traits occur in non-coding genomic regions and are hypothesized to affect gene expression. To identify variants that regulate gene expression, we performed *cis*- and *trans*-expression quantitative trait locus (*cis*/*trans*-eQTL) analyses using whole blood RNA-seq and whole genome sequencing data from the NHLBI Trans-Omics for Precision Medicine (TOPMed) program from 6,602 samples of predominantly European (68%), African (21%) and Indigenous American (10%) ancestry. We hypothesized that many *trans* signals would overlap *cis* signals, enabling identification of candidate genes mediating *trans* effects.

At a MAF ≥ 0.01, we identified 19,422 genes with ≥ 1 *cis*-eQTL (5% FDR; *cis*-eGenes) and 71,092 total independent *cis*-eQTLs (SuSiE 95% credible sets). At MAF ≥ 0.05, we identified 1,743 *trans*-eGenes. *Trans*-eVariants were enriched for overlap with *cis*-eQTL credible sets (Fisher's exact test against MAF-matched variants; odds ratio = 8.4; $p = 3x10^{-45}$; 30% of unique *trans*-eVariants overlap *cis*-eQTL) and *cis*-eGenes for *cis*-eQTL overlapping *trans*-eQTL were 3.5-fold enriched for transcription factor genes ($p < 5x10^{-4}$). 167 variants were *trans*-eQTL for >1 gene (1,075 total genes). For example, one *cis*-eVariant for *ERN1*, which encodes endonuclease IRE1a, was a *trans*-eVariant or in high LD (>0.9) with a *trans*-eVariant for thirteen *trans*-eGenes, including known *ERN1* downstream target *XBP1* and *XBP1* target genes including *DNAJB9*. *ERN1* is a regulator of the endoplasmic reticulum (ER) stress response, and five of the twelve *trans*-eGenes in the KEGG database were in the "Protein processing in ER" pathway (31.6-fold enrichment; nominal $p=1.8x10^{-7}$). Among ER response pathways IRE1a-XBP1 is the most highly conserved, with an emerging role in regulation of inflammation and immune response.

To identify *trans*-eGenes that may share multiple signals with a potentially regulatory *cis*-eGene, we finemapped *trans*-eQTL signals within the 2Mb window centered on each *trans*-eGene's lead *trans*-eVariant. Within the 2Mb windows, 300 of the 1,743 *trans*-eGenes had >1 *trans*-eQTL (2,080 total *trans*-eQTL credible sets). We found 31 *cis*-eGenes with > 1 *cis*-eQTL signal colocalizing with > 1 *trans*-eQTL signal from at least one *trans*-eGene (145 unique *cis*-eGene - *trans*-eGene pairs). For example, *trans*-eGene *BTN3A3* showed 4 *trans*-eQTL credible sets that colocalized with 4 *cis*-eQTL credible sets for its known regulator *NLRC5*. This example provides proof-of-principle for our hypothesis.

In summary, this dataset demonstrates the utility of large eQTL studies to provide insight into regulatory pathways involving *trans*-eQTLs mediated by *cis*-eGenes.

PB1066 Cross-protein transfer learning using deep mutational scanning data substantially improves proteome-wide disease variant prediction

Authors:

C. Ye, M. Jagota, C. Albors, R. Rastogi, A. Koehl, N. Ioannidis, Y. S. Song; Univ. of California, Berkeley, Berkeley, CA

Genetic variations within the human genome significantly influence individual disease susceptibility. Numerous computational strategies have been developed to predict missense variant impacts, using a variety of predictive signals. Nevertheless, the etiological impacts of a vast number of variants remain unknown. Deep Mutational Scanning (DMS) experiments, which perform saturation mutagenesis on proteins, can assess the functional impacts of a large proportion of possible mutations for each protein. However, DMS experiments are currently limited to a select few proteins and do not scale easily to the entire proteome. To address this, we introduce a robust learning framework that harnesses DMS data to construct precise computational predictors of disease variant pathogenicity. We train a cross-protein transfer (CPT) model using DMS data from only five proteins and achieve state-of-the-art performance on clinical variant interpretation for unseen proteins across the human proteome. High sensitivity is crucial for clinical applications and our model CPT-1 particularly excels in this regime, substantially improving on recently developed deep learning models (such as ESM and EVE) for protein sequences. Furthermore, for proteins not used to train REVEL, a supervised method widely used by clinicians, we show that CPT-1 compares favorably with REVEL.

Our framework combines predictive features derived from general protein sequence models, vertebrate sequence alignments, and AlphaFold2 structures; and it is adaptable to the future inclusion of other sources of information. We find that vertebrate alignments provide a strong signal for variant effect prediction that is non-redundant with recent deep learning-based models trained on massive amounts of protein sequence data. The utility of integrating vertebrate alignments across the human proteome points to exciting future directions. There are ongoing efforts to sequence a large number of vertebrate genomes; as these data become available, we anticipate that more powerful models could be applied to deeper vertebrate alignments.

PB1067 De novo decipherment of genetic architecture with language models

Authors:

S. Bhate; Broad Inst. of MIT and Harvard, Cambridge, MA

We observe that the genetic architecture of single-cell gene expression exhibits consistency with phenotypic geometry and with genomic syntax. Specifically, molecularly similar cell types have similar genetic associations, and syntactically similar genomic loci have similar phenotypic associations. We show that assuming, a priori, consistency of genetic architecture with phenotypic geometry and genomic syntax enables identifying quantitative trait loci (QTLs) for phenotypes with a geometric structure de novo: from only phenotypic data and the reference genome sequence - without genetic variation, annotations or external data. We develop Phenotype Syntax Alignment (PSA), an optimization algorithm that, searches de novo through possible genetic architectures for a phenotype in a reference genome to find one consistent with phenotypic geometry and with genomic syntax, using language models. PSA identifies de novo from the geometry of single-cell gene expression, cis-, trans- and causal expression QTLs in a cell-type, tissue and gene specific manner to 10kb resolution, as well as regulators of gene expression empirically validated by CRISPR perturbation. Moreover, PSA identifies, de novo from immunofluorescence imaging, causal genetic pathways regulating the tumor microenvironment as well as QTLs for its cellular composition. Consistency with phenotypic geometry and genomic syntax is thus a general principle underlying the genetic architectures of molecular phenotypes enabling their de novo decipherment.

PB1068 *De novo* variants in *PLCG1* are associated with neurological issues and other clinical features.

Authors:

M. Ma[1], Y. Zheng[2], S. Lu[3], X. Pan[3], K. Worley[4], L. Blieden[1], A. Allworth[5], D. Li-Kroeger[3], J. Rosenfeld[3], D. Dutta[3], S. Yamamoto[3], M. Wangler[6], I. Glass[7], P. Prontera[8], S. Lalani[9], H. Bellen[3]; [1]Baylor Coll. of Med., HOUSTON, TX, [2]Xiamen Univ., Xiamen, China, [3]Baylor Coll. of Med., Houston, TX, [4]Baylor Coll. Med., Houston, TX, [5]Univ. of Washington, Seattle, WA, [6]Molecular and Human Genetics, Baylor Coll. of Me, Houston, TX, [7]Univ of Washington, Seattle, WA, [8]Med. Genetics Unit, Univ. and Hosp. of Perugia, Perugia, Italy, [9]Baylor Coll. Med., Sugar Land, TX

Phospholipase C isozymes hydrolyze phosphatidylinositol 4,5-bisphosphate into inositol 1,4,5-trisphosphate and diacylglycerol, important signaling molecules involved in many cellular processes. *PLCG1* encodes the PLCγ1 isozyme that can be activated by receptor tyrosine kinases. *PLCG1* is broadly expressed, and hyperactive somatic mutations of *PLCG1* are frequently observed in multiple cancers. However, germline variants of *PLCG1* have so far not been associated with Mendelian diseases. Here, we report three independent individuals with *de novo* missense variants in *PLCG1* (p.D1019G, p.H380R, and p.D1165G), who present with hearing, vision, heart, brain structure and immune system issues as well as other phenotypes. However, they do not share all phenotypes. To assess the impact of the three variants *in vivo*, we generated and modeled the variants in the *Drosophila* orthologue, *small wing* (*sl*) (p.D1041G, p.H384R, and p.D1184G). We created a sl^{T2A} allele by inserting a splicing acceptor-T2A-GAL4-polyA cassette into the first coding intron of *sl*. The polyA tail arrests transcription and creates a strong loss-of-function mutation. The GAL4 that is produced allows us to assess the endogenous expression pattern of *sl* by using a *UAS-fluorescent reporter*. We show that *sl* is broadly expressed, including in wing discs, eye discs, and a subset of neurons and glia. Loss of *sl* is known to cause a reduced wing size, ectopic wing veins and additional photoreceptors which are all observed in sl^{T2A}. Although the mutant flies are homozygous viable we show that they have a reduced lifespan and display severe locomotion defects. Expressing wild type *UAS-sl* fully rescues the loss-of-function phenotypes of sl^{T2A} mutants. In contrast, the three *UAS-sl* variants cause lethality, suggesting that the variants are toxic and cause a gain-of-function or neomorphic effect. We also performed ectopic expression assays to test the human *PLCG1* variants in fly. Expressing the p.H380R cDNA causes mild phenotypes indistinguishable from expressing the reference cDNA. However, expressing the p.D1041G or p.D1184G cDNA results in phenotypes that differ from those observed in loss-of-function mutants but resemble the phenotypes of expressing a established hyperactive variant, again arguing that they are gain-of-function rather than dominant-negative alleles. In summary, our data indicate that the p.D1041G and p.D1184G are strong gain-of-function variants while the p.H380R is a mild gain-of-function variant. Our data also argue that these *de novo* missense variants in *PLCG1* may be causative for the features observed in the probands.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1069 Deciphering the molecular and cellular impact of epilepsy-associated *GNAI1* variants.

Authors:

E. Fathi[1], H. Chen[2], E. Almanza Fuerte[1], L. Sadleir[3], M. Innes[4], S. Sheppard[5], H. Mefford[6]; [1]St. Jude Children's Res. Hosp., Memphis, TN, [2]St Jude Children s Res. Hosp., Memphis, TN, [3]Univ. of Otago, Wellington, New Zealand, [4]Univ. of Calgary, Alberta, AB, Canada, [5]NICHD/NIH, Rockville, MD, [6]St. Jude Children`s Res. Hosp., Memphis, TN

Developmental and epileptic encephalopathies (DEE) are a genetically heterogenous group of severe epilepsy disorders characterized by intellectual disability, developmental delay, intractable seizures, and autistic features. *De novo* mutations in the *GNAI1* gene, encoding the inhibitory G protein subunit alpha I1 ($G\alpha_{i1}$), are one genetic cause of DEE for which there is no effective treatment. When bound to GDP, $G\alpha_{i1}$ forms an inactive heterotrimer with β and γ G-protein subunits. Upon activation, GDP is exchanged for GTP, the α subunit dissociates from the βγ complex, and each (α and βγ) are now active and can act on downstream signaling pathways including cAMP, mTOR, and MAPK/ERK. Most pathogenic variants are missense variants that affect the GTP binding pocket; *de novo* truncating variants in *GNAI1* have not yet been reported. The impact of reported pathogenic variants on protein function (gain vs. loss of function) is not known but is critical for targeted therapy development. We hypothesize that pathogenic variants in *GNAI1* impair GTP binding and hydrolysis and disrupt downstream signaling pathways.To investigate the molecular and cellular function of *GNAI1* disease-causing variants, we created heterozygous CRISPR-engineered U87-MG (glioblastoma origin) cell lines with a pathogenic variant (Gly40Cys, Thr48Lys, Lys270Arg, Gln172del) or a premature truncation (Ile49Ter) as a control for LOF. Our preliminarily result showed no significant change in mRNA and protein expression of CRISPR-engineered cells (except early termination) when compared to control. We produced purified $G\alpha_{i1}$ WT and mutant proteins to measure GTPase activity using a fluorescent GTP analog, BODIPY-GTP. While $G\alpha_{i1}$ WT binds to BODIPY-GTP, the mutant proteins are incapable of binding to GTP and hydrolyzing it. These data suggest that the clinically observed $G\alpha_{i1}$ pathogenic variants in *GNAI1*-related DEE lose their ability to bind to GTP and hydrolyze it, which is critical in modulating important pathways such as mTOR and MAPK/ERK. Indeed, in heterozygous cells lines we saw significant increase in phosphorylated S6 in CRISPR-engineered cells, indicating activation of the mTOR pathway.We will validate our preliminary results using *in vitro* studies in 2D/3D neurons from patient cells. This study will uncover the molecular mechanism of the *GNAI1* pathogenic variants, which will be critical for developing treatments. Our engineered and patient patient-derived cells represent a valuable tool to characterize the effect of pathogenic variants on $G\alpha_{i1}$ function and the impact on downstream cellular pathways.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1070 Deciphering the molecular basis of a *GRIA2* related neurodevelopmental disorder

Authors:

R. Segel[1,2], L. Berkun[1], A. Porecki[3], Y. Stern-Bach[3]; [1]Med. Genetics Inst., Shaare Zedek Med. Ctr., Jerusalem, Israel, [2]Faculty of Med., the Hebrew Univ., Jerusalem, Israel, [3]Dept. of Biochemistry & Molecular Biology, IMRIC Faculty of Med., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

GRIA2 encodes GluA2, a central component of AMPA-type glutamate receptors that play a crucial role in fast excitatory neurotransmission in the brain. These receptors facilitate synapse formation and trigger activity-dependent processes underlying learning and memory. Mutations in *GRIA2* have been associated with intellectual disability (ID) and intractable seizures. In this study, we investigated a de novo missense variant (L772W) in *GRIA2* identified through exome sequencing in a girl with severe ID and microcephaly, but no seizures. The patient exhibited significant developmental delay at the age of 1 year with limited abilities to sit unsupported, was non-verbal, and had a short attention span. She began walking at the age of 3 years, but at the age of 5 she still had no words, showed autistic behavior but still had no seizures. Physical characteristics were normal, including facial features, weight, length, and head circumference. She had cortical visual impairment and mild ventricular enlargement in brain imaging. Genetic analysis included chromosomal microarray analysis and trio whole-exome sequencing, which revealed *de novo* missense variant in *GRIA2:* c.2315T>G, p.Leu772Trp. This variant was classified as a variant of uncertain significance based on ACMG criteria. Functional analysis in heterologous cells demonstrated that the mutated protein exhibited normal expression level, membrane localization, and maturation into functional receptors. However, the mutation altered receptor kinetics, resulting in faster desensitization compared to wild-type receptors. This alteration led to a shortened open channel duration, ultimately resulting in reduced overall receptor activity. The reduced channel activity caused by the variant may explain the patient's phenotype through decreased overall excitatory neurotransmission. Alternatively, reduced GluA2 activity might trigger compensatory mechanisms, leading to increased excitatory activity through calcium-permeable AMPA receptors formed by the GluA1 unit, potentially causing cell death. Further investigations are necessary to differentiate between these possibilities for better understanding of the underlying mechanisms.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1071 Deep mutational scan of TAP2 reveals residues of functional importance for MHC-I cell-surface presentation.

Authors:

G. Nagy, M. Diabate, R. Hardy, H. Jeon, T. Banerjee, S. Dhar, K. Burgess, D. Chung, P. N. Tsichlis, J. D. Parvin; The Ohio State Univ., Columbus, OH

Defects in cell-surface presentation of MHC-I bound to peptide can lead to immune evasion of cancer cells, conferring a worse prognosis for the cancer patient. One mechanism by which MHC-I is downregulated on the cell surface is through impaired function of the Transporter Associated with Antigen Processing (TAP) complex, which contains a heterodimer of TAP1 and TAP2. Exploring how to upregulate or restore functional expression of the TAP complex in tumors with nonfunctional TAP could improve the response of the immune system to a tumor cell. Nonfunctional TAP2 may be due to mutation or post-translational modification (PTM), and functional evaluation of missense variants and PTM mimetics can illuminate the functional constraints of TAP2. Here we present a deep mutational scan of TAP2, in which an amino acid within the protein is exchanged for all twenty possible substitutions (nineteen other amino acids and one stop codon). We have targeted 96 amino acid residues for analysis, and we have functional results for 878 missense variants and 24 nonsense variants of TAP2 with clear hyper- and hypo- functional outliers identified. The functional effects of selected variants, both hypo- and hyper-active, were confirmed when tested singly for MHC-I localization. Some of these functional outliers suggest phosphorylation changes that can regulate TAP2 activity. This is one of the first deep mutational scans of a protein involved in MHC-I cell-surface presentation. Identifying PTMs that modify TAP transporter activity may reveal regulatory processes that can be targeted for therapy that would promote an increase in MHC-I cell-surface presentation and improved immune response to tumors and increased efficacy of immunotherapy.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1072 Defining critical *MECP2* cis-regulatory elements towards identifying genetic candidates for male-biased autism

Authors:

R. Meyer-Schuman[1,2], H. Zoghbi[1,2,3,4]; [1]Dept. of Human and Molecular Genetics, Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst. at Texas Children's Hosp., Houston, TX, [3]Howard Hughes Med. Inst., Baylor Coll. of Med., Houston, TX, [4]Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX

The levels of methyl-CpG binding protein 2 (MeCP2), encoded by the X-chromosome gene *MECP2*, must be precisely controlled in the developing brain. Loss-of-function mutations in *MECP2* cause the progressive neurological disease Rett syndrome in females with mosaic expression and males with hypomorphic mutations. Gain-of-function *MECP2* duplications cause an equally severe neurodevelopmental disorder primarily in males. In mice, even partial loss-of-function or partial gain-of-function *MECP2* mutations cause neurological phenotypes. Male mice with a 30% decrease or 50% increase in MeCP2 levels show autism-like phenotypes, including altered anxiety, activity, and social behavior. This sensitivity to MeCP2 dosage indicates that *MECP2* gene expression must be tightly regulated. It also suggests that mutations in *cis*- or *trans*- acting factors that modulate MeCP2 levels could be candidates for autism phenotypes in humans. Such mutations may disproportionately impact males, who have only one copy of *MECP2* and are thus more sensitive to even modest changes in MeCP2 levels.

Previous studies identified four mouse *Mecp2* cis-regulatory elements (CREs), two of which were only present in mice and two of which were conserved in humans. We hypothesize that additional CREs buffer *MECP2* expression in humans, which may have evolved since the human and mouse lineages diverged. Multiple human brain ATAC-seq datasets were analyzed to identify two regions of open chromatin within or near the *MECP2* locus. Each corresponding sequence was deleted in human induced pluripotent stem cells (iPSCs) using CRISPR-Cas9 mediated genome editing. These iPSCs were then differentiated into glutamatergic neurons and *MECP2* RNA and protein levels were assessed. Preliminary data indicates that one candidate CRE acts as a *MECP2* repressor element and the other as an enhancer. Future work will further pinpoint the critical regulatory sequences within these larger elements, as well as their associated transcription factors.

This study will ultimately provide a foundation for identifying pathogenic non-coding mutations that change *MECP2* levels, as well as mutations in transcription factors that regulate *MECP2*. Such mutations are likely to cause neurodevelopmental phenotypes in humans and may contribute to some of the observed sex bias in neurological conditions like autism spectrum disorder.

Background: DNA biobanks have the potential to identify medically actionable variation that can help explain disease risk, susceptibility or underlying conditions in research study participants. In the GENCOV/HostSeq study, participants were able to receive their genetic results back during the COVID-19 pandemic. Databases such as ClinVar provide clinical classifications to help inform variant interpretations. However, evidence from ClinVar relies on aggregated data across multiple submitters, often with conflicting interpretations. ClinVar is also replete with false positive and negative classifications and captures only a limited proportion of human variation. Here we summarize medically actionable pathogenic variation in HostSeq participants using a clinically derived variant classification pipeline to determine the relative concordance to ClinVar classifications.
Aims: 1) Provide a summary of the frequency of medically actionable genetic variants identified in HostSeq participants. 2) Evaluate the accuracy and concordance of ClinVar interpretations of pathogenicity to variant classifications assessed in-house.
Methods: Variants from the first 1281 individuals in the cohort were annotated with ANNOVAR to detect those found in ClinVar, and filtered to those classified as pathogenic by two or more reputable laboratories. The ACMG secondary findings v3.0 panel and a custom carrier screening panel were used. Variants were analyzed in-house following ACMG criteria and compared to ClinVar. The frequency of pathogenic variation was analyzed by ancestry.
Results: In total, 1006 variants from 1281 individuals were identified with a pathogenic ClinVar classification after filtration. Of these, 373 variants were observed exactly once. There were 42 variants detected from the ACMG panel (0 homozygous) and 471 variants from the carrier screening panel (3 homozygous). There were 689 individuals (54%) that had at least one pathogenic variant, with an average of ~1.5 per participant. Two individuals were compound heterozygous for a pathogenic variant. To date, our in-house pipeline confirmed 1523 pathogenic variants from 392 individuals, 1321 of which were identified in ClinVar (87%). However, only 500 of these variants had a concordant pathogenic classification in ClinVar (38%).
Conclusion: This study summarizes pathogenic variation using a clinically curated pipeline as compared to ClinVar in an ostensibly healthy population of Ontario adults. Our in-house pipeline was more accurate for the detection and classification of pathogenic variation. Accurate interpretations are crucial for diagnosis, clinical correlation and management.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1074 Determining pathogenicity of Variants of Uncertain Significance in genes the Sonic Hedgehog Pathway via high-throughput experimental approaches.

Authors:

D. Baldridge, J. Shepherdson, B. Cohen; Washington Univ. in St. Louis, Saint Louis, MO

One major limitation for the molecular diagnosis of individuals with suspected monogenic disorders is the abundance of Variants of Uncertain Significance (VUS) due to insufficient evidence for determining if variants are pathogenic or benign. High-throughput functional assessment of variant effects offers a scalable solution to this critical problem in genomic medicine. We demonstrate the value of these studies by deploying recently developed experimental approaches involving the simultaneous assessment of hundreds to thousands of variants in a protein of interest, using reliable, carefully calibrated, cell-based assays. We have successfully completed a parallelized mutational scan for nearly 200 clinically observed variants in the gene, *GLI2*, part of the sonic hedgehog signaling pathway. Pathogenic variants in the transcription factor *GLI2* cause Culler-Jones syndrome which involves endocrine and skeletal patterning abnormalities. Using cells engineered with a GFP reporter and transduced with lentivirus expressing *GLI2* variants, we conducted a SortSeq experiment, coupling fluorescence-activated cell sorting (FACS) to sequencing, to demonstrate the functional effects of these variants. Our results are highly reproducible and show near perfect discrimination of known pathogenic and benign variants in *GLI2*. We use this system to assay all 170 clinically relevant variants in *GLI2* that were submitted to ClinVar, including about 100 missense VUS, many of which may be reclassified as likely pathogenic or benign based on these results. We also identify potentially mis-classified variants and emphasize limitations of the current “gold standard” ACMG variant classification approach. Further, we provide evidence to support the expansion of this approach to include at least three other clinically relevant genes in the sonic hedgehog pathway, demonstrating the feasibility for a pathway-based approach for scaling up mutational scanning to study many genes in the genome.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1075 Development of the first two Charcot-Marie-Tooth Disease Type 4C (*SH3TC2*) models using CRISPR-Cas9 Base Editing Strategies on human induced pluripotent stem cells (hiPSCs).

Authors:

C. Loret[1], A. Pauset[2,3], P-A. Faye[1,4], V. Prouzet-Mauléon[2,3], A. Nizou[1], F. Miressi[1], F. Sturtz[1,4], F. Favreau[1,4], B. Turcq[2,3], A-S. Lia[1,4,5]; [1]NeurIT UR 20218, GEIST Inst., Univ. of Limoges, Limoges, France, [2]CRISP'edit, TBMCore UAR CNRS 3427, US Inserm 005, Univ. of Bordeaux, Bordeaux, France, [3]Modeling transformation and resistance in leukemia, BRIC Inserm U1312, Univ. of Bordeaux, Bordeaux, France, [4]Dept. of Biochemistry and Molecular Genetics, CHU Limoges, Limoges, France, [5]Dept. of Bioinformatics, CHU Limoges, Limoges, France

The Charcot-Marie-Tooth disease (CMT) is the most prevalent inherited peripheral neuropathy. More than 100 altered genes have been identified as responsible for this disease. Most of them, such as *SH3TC2*, the most frequently mutated gene for the demyelinated autosomal recessive CMT form (AR-CMT), are expressed predominantly in neuronal cells. To study the pathophysiology of the disease and to test new therapeutic approaches, it is crucial to develop appropriate cellular models. Human induced pluripotent stem cells (hiPSCs) offer a powerful tool to study neuropathological disorders when the affected cells are inaccessible in patients.
However, the hiPSCs reprogramming is a time-intensive process, and clones generated for various alterations possess different genetic background. Furthermore, to our knowledge, there is currently no hiPSCs model available for CMT4C corresponding to *SH3TC2* variations. Our goal was to generate the first two *SH3TC2* models starting from one of our healthy individuals' iPSCs using the CRISPR-Cas9 technology: a model with the variation c.2860C>T, resulting in p.Arg954* and another one with the variation c.211C>T, resulting in p.Gln71*.
We selected a CRISPR-Cas9 Cytosine Base Editing (CBE) approach, facilitating the specific conversion of a base pair (C>T) in the targeted DNA sequence. As hiPSCs are time-consuming and expensive to grow and to engineer, it is quite challenging to test different pairs of sgRNA-CBE for each desired alteration. Herein, we decided to optimize the generation of variations in *SH3TC2* using CBE, on cultivable and transfectable HEK-293T cells to quickly and easily evaluate different gRNA-CBE possibilities.
Subsequently, we applied the selected CRISPR-Cas9 Base Editing strategies to hiPSCs, derived from a healthy individual, we achieved 90.5% and 93% On-Target activity for c.211C>T, p.Gln71* and c.2860C>T, p.Arg954* respectively, ensuring correct editing in at least one allele.
In conclusion, we present here the creation of the first two *SH3TC2* hiPSCs models using CRISPR-Cas9 Base Editing. These hiPSCs models will be then differentiated into neuronal cells in order to investigate the pathophysiology of CMT4C, they would also be interesting models to test therapeutic strategies.

Univ.ire de France, Paris, France

Fragile X syndrome (FXS) is a neonatal- to child-onset neurodevelopmental disorder characterized by intellectual disability, abnormal behaviors and characteristic physical features. FXS results from the loss of expression or function of the *FMR1* gene encoding the RNA binding protein FMRP with an impact on the post-transcriptional control of hundreds of neuronal mRNA targets. Among its numerous mRNA targets, FMRP most strongly interacts with diacylglycerol kinase kappa (DGKk) mRNA in cortical neurons to promote DGKk protein synthesis. DGKk converts diacylglycerol (DAG) to phosphatidic acid (PA), two signaling lipids regulating cytoskeletal rearrangement and protein synthesis downstream of G-protein coupled receptors. In FXS condition, the absence of FMRP leads to the defect of expression of DGKk associated with an imbalance of DAG and PA in the brain of FXS patients and the *Fmr1*-KO mouse model. Re-expression of DGKk with adeno-associated viruses (AAVs) in the *Fmr1*-KO mouse corrects its behavioral phenotypes. To determine the role of DGKk in FXS condition, here we analyzed the phenotypes of *Dgkk*-KO mouse model and show that it shares behavioral (hyperactivity, stereotypies) and physiological (overgrowth) similarities with the *Fmr1*-KO model suggesting that the absence of DGKk is sufficient to recapitulate core FXS phenotypes. Analyses of *Dgkk*-KO neurons revealed overactivation of the DAG signaling in association with abnormal dendritic spine morphology, deregulated synaptic activity and increased rate of neuronal protein synthesis, hallmarks of FXS. To date, the *DGKk* gene has never been directly associated with a pathology, potentially due to its misannotation until recently as a non-coding gene. Analyses of patient exomes (and NGS) identified *DGKk* missense variants in unrelated patients with intellectual disability or cardiomyopathy. Functional analysis of these *DGKk* variants in non-neuronal and neuronal cells showed that a number of them respectively have membrane or dendritic mislocalization, suggesting an impairment of *DGKk* function correlates with patient condition. Altogether our data support the involvement of *DGKk* in intellectual disability conditions, including FXS.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1077 Discovery and functional validation of genes associated with muscular fitness and cardiometabolic traits.

Authors:

T. Schnurr[1], C. Jin[1], E. Bielczyk-Maczynska[1], M. Slocumb[1], P. Saliba-Gustafsson[1], M. Gloudemans[1], T. Hansen[2], E. Ashley[1], I. Carcamo-Orive[1], J. W. Knowles[1]; [1]Stanford Univ., Stanford, CA, [2]Univ. of Copenhagen, Copenhagen, Denmark

Background: Handgrip strength is a proxy for muscular fitness and is associated with insulin resistance, glucose metabolism, and metabolic disease. Genome-wide association studies have identified more than 100 loci associated with handgrip strength. Genetic correlations with handgrip strength are enriched for cardiometabolic traits, and Mendelian randomization suggests a causal effect of handgrip strength on cardiometabolic traits. The mechanisms linking muscular fitness to cardiometabolic health outcomes are incompletely understood.
Aim: To apply colocalization analysis to identify candidate causal genes for muscular fitness and explore their overlap with cardiometabolic traits by integration of expression and splicing quantitative trait loci (QTLs) for handgrip strength and cardiometabolic traits in skeletal muscle tissue, and to functionally validate these candidate genes in an immortalized human skeletal muscle cell line (HMCL-7304).
Results: We identified three muscle-specific candidate genes by integrating our custom LD-adjusted colocalization analysis for handgrip strength and nine cardiometabolic traits combined with expression and splicing QTLs from metabolically relevant tissues from GTEx v8. For functional analysis, we successfully established stable HMCL-7304 cell lines for gene knockdown (using CRISPRi) and cDNA overexpression of candidate genes. Preliminary results from RNA-seq highlight shared pathways across the candidate genes including ATP processes, cell adhesion and calcium ion binding.
Conclusion and next steps: We identified candidate genes for handgrip strength with relevance for cardiometabolic traits. Our preliminary data from functional analysis in an immortalized human skeletal muscle cell line suggests that shared pathways include ATP processes, cell adhesion and calcium ion binding. We are conducting functional assays with focus on metabolic readouts, mitochondrial function, and contractility.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1078 Discovery and validation of novel insulin resistance loci implicated in adipocyte function.

Authors:

P. Toh[1], M. García-Ureña[1], T. Kilpeläinen[2]; [1]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Copenhagen, Denmark, [2]Univ. of Copenhagen, Copenhagen, Denmark

Insulin resistance is a pathological condition where cells are unable to respond to insulin, resulting in elevated blood glucose levels. It presents an increased risk of developing various cardiometabolic diseases such as type 2 diabetes, a significantly prevalent disease as the global population gradually becomes more obese. Previous studies have identified 53 insulin resistance loci by triangulating genome-wide association studies (GWAS) results for three hallmark traits of insulin resistance: higher fasting insulin, higher triglycerides, and lower HDL cholesterol. Many of the identified loci were implicated in dysfunctional peripheral adipose storage capacity and adipocyte function. We aim to discover further insulin resistance loci by leveraging the results from the latest and largest GWAS and validate the function of the prioritised loci in SGBS preadipocytes. We identified 210 independent insulin resistance loci with joint genome-wide significant association ($P<5x10^{-8}$) with increased fasting insulin adjusted for BMI, increased triglycerides, and decreased HDL cholesterol. We prioritised novel insulin resistance genes in the loci based on differential expression in the adipose tissue (eQTL) and expression in adipocytes or adipose stem and progenitor cells. Five genes (*TNFAIP8*, *ZNF703*, *KCNU1*, *MT1HL1* and *SPON1*) were selected for further validation *in vitro* using SGBS preadipocytes. We observed that *MT1HL1* and *ZNF703* expression decreases during differentiation, while the other three genes show opposing effects. We are currently performing knockdown of these target genes using siRNA. We will track changes during differentiation in the absence or presence of insulin and follow up with functional analyses for insulin sensitivity in the mature adipocytes to measure glucose uptake, triglyceride accumulation and intracellular glycerol levels. Our studies will provide insights into these novel insulin resistance loci and their associated genes, to further understand the underlying mechanisms that lead to the development of insulin resistance.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1079 Discovery of target genes at lipid and metabolic disease loci in liver through a targeted CRISPRi screen.

Authors:

G. Pandey[1], S. Vadlamudi[2], A. Moxley[3], K. Currin[3], J. Nicholas[4], J. McAfee[1], K. Broadaway[2], K. Mohlke[5]; [1]Univ. of North Carolina, Chapel Hill, Chapel hill, NC, [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [3]UNC Chapel Hill, Chapel Hill, NC, [4]Univ. of North Carolina, Chapel Hill, Chapel Hill, NC, [5]Univ North Carolina, Chapel Hill, NC

Genome-wide association studies (GWAS) have identified hundreds of risk loci for liver disease and lipid-related metabolic traits, although most target genes and mechanisms remain unknown. In a previous study, we generated a catalog of metabolic GWAS variants that may alter liver regulatory elements (peaks) by colocalizing GWAS signals with chromatin accessibility quantitative trait loci (caQTL). We predicted target genes of these peaks using colocalization with liver tissue eQTL, proximity to transcription start sites, correlation of distal caQTL peaks with promoter peaks, and/or chromatin conformation. In the current study, we sought to validate target genes at these loci using functional assays. We focused on loci for which a proxy GWAS variant overlapped a liver caQTL peak linked to a gene using ≥2 methods. We did transcriptional reporter assays in HepG2 cells to test the regulatory effects of variants. We observed significant allelic differences in transcriptional activity for variants at 4 GWAS signals for liver enzymes or lipid traits: rs13395911 near *EFHD1*, rs11644920 near *LITAF*, rs34003091 near *ZNF329*, and rs9556404 near *GPR180*. For the two non-promoter regulatory elements (rs13395911 and rs11644920) linked to *EFHD1 and LITAF*, we used CRISPRi with an inducible dCas9-KRAB system in HepG2 cells to assess effects of enhancer knockdown on expression of the predicted target and nearby genes. We introduced ≥6 gRNAs for each element into cells via lentiviruses and measured gene expression 72 hours after transduction. Compared to cells infected with non-targeted control gRNAs, cells infected with gRNAs targeting enhancers surrounding rs13395911 and rs11644920 showed significantly (P<.05) lower expression levels of *EFHD1* (23.7% decrease) and *LITAF* (24.7% decrease). At both loci, directions of effect matched the caQTL and eQTL associations. Near *LITAF*, expression level was also reduced for adjacent genes in the same topological domain, *SNN* and *TXDC11*. In a second round of analyses, we identified 476 GWAS signals that colocalized with liver caQTL, but that doesnot have an eQTL-target gene. Among these, we selected 25 caQTL elements containing a GWAS proxy variant for which the peak is detectable and predicted genes are expressed in HepG2; CRISPRi knockdown of these elements to identify target genes is underway, and further studies will investigate effects of enhancer knockdown on cellular processes. In summary, we used a scalable framework to validate predicted regulatory effects of liver lipid GWAS variants and identified their target genes, which will aid identification of cell mechanisms and elucidate the causes of liver disease.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1080 DisCO-VG: Disease-specific optimization method for prioritizing variant-target gene pairs.

Authors:

E. Chou, A. Guerra, S. Li, T. Qin, K. Wang, Z. Zhang, J. T. Elder, L. C. Tsoi, M. A. Sartor; Univ. of Michigan, Ann Arbor, MI

Prioritizing GWAS-identified variants and linking them to their target genes are critical steps in predicting regulatory noncoding variants in disease and prioritizing genes for drug targets. Methods such as the combined SNP-to-gene linking strategy (cS2G) and Single-Cell Enhancer Target gene mapping (SCENT) have shown excellent results pinpointing causal variants and disease genes. However, these methods have limitations. For one, SCENT prioritizes singular enhancer-gene pairs, while it is known that enhancers containing variants can regulate several genes. Furthermore, cS2G does not necessarily prioritize SNP-gene-disease triplets with cell type or tissue specificity. Here, we apply a statistical learning approach, DisCO-VG (Disease-specific CTMC Optimization for Variant-Gene pairs), for prioritizing cell type-specific, disease-associated noncoding variant-target gene pairs. DisCO-VG leverages CTMC (Coupled Tensor-Matrix Completion), for which excellent performance has been observed in drug-target interaction and chemical exposure-target gene predictions. By approaching the problem of linking variants to target genes as a matrix completion problem, where variants make up the rows and genes make up the columns, we apply biological knowledge of a variant affecting multiple genes by design. Utilizing significant GWAS associations, eQTLs, predicted enhancer-gene links, and distance between variant and gene, the variant-gene pairs will have entries in this matrix ranging from 0 to 1, with a higher score representing a higher probability of targeting. DisCO-VG also utilizes supporting information in the form of tensors describing gene-gene and variant-variant relationships, respectively. These coupled tensors can incorporate multiple sources of evidence. The input into these tensors include GTEx expression correlation across cell types and GO term similarities for gene-gene similarities; for variant-variant similarities, they include belonging to similar transcription factor binding motifs and having similar ATAC-Seq profiles across multiple experimental conditions. Our initial application is studying psoriasis, where we are using data derived from peripheral blood mononuclear cells of both healthy and psoriatic samples to benchmark DisCO-VG against existing methods. Ultimately, we output a list of prioritized cell type- and disease-specific variant-gene pairs that can be experimentally validated and become the basis for potential drug targets.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1081 Dissect the genetic architecture of congenital vertebral malformation in the context of the developing spine

Authors:

N. Wu[1], S. Zhao[2], L. Zhao[1], G. Li[3], Z. Zhao[1], K. Xu[1], J. Cai[1], Q. Li[1], Z. Wu[4], J. Zhang[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]Baylor Coll. of Med., Houston, TX, [3]Peking Union Med. Coll. Hosp., beijing, China, [4]Peking Union Med. Coll. Hosp., Chinese Academy of Med. Sci., Beijing, China

Congenital vertebral malformation (CVM), affecting 0.13-0.50 per 1000 live births, has an immense locus heterogeneity and complex genetic architecture. In this study, we analyzed exome/genome sequences from 873 probands with CVM and 3794 control individuals. Clinical interpretation identified Mendelian etiologies in 12.0% of the probands and revealed a muscle-related disease mechanism. Gene-based burden test of ultra-rare variants identified risk genes with large effect sizes (ITPR2, TBX6, TPO, H6PD, and SEC24B). Exome-wide association study (EWAS) uncovered the polygenic architecture. To dissect the complex genetic architecture of CVM, we estimated the proportion of heritability explained by burden and EWAS signals. The five burden test signals and the three independent EWAS signals accounted for 4.2% and 11.5% of the phenotypic variance in CVM patients without a molecular diagnosis, respectively (3.7% and 10.1% in all CVM patients). Taking together the Mendelian etiology and burden/EWAS heritability, we were able to explain around 25.8% of the overall heritability of CVM. To further investigate the biological relevance of the genetic association signals, we performed single-cell RNA-seq on human embryonic spines. The burden test and EWAS signals were enriched in the notochord at early developmental stages and myoblast/myocytes at late stages, suggesting their critical role in the developing spine. The combined analysis of genetic data and embryonic single-cell transcriptome data provides insights into the developmental biology and pathology of the human spine.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1082 Dissecting the genetic basis of cell-type specific immune activation across indigenous Cameroonians.

Authors:

D. Kelly[1], N. Xie[1], Y. Feng[1], W. JIA[1], E. Basner-Tschakarjan[1], W. Beggs[1], C. N. Folkunang[2], A. K. Njamnshi[2], C. Ye[3], E. Luning Prak[1], S. A. Tishkoff[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Faculty of Med. and BioMed. Sci., Univ. of Yaoundé I, Yaoundé, Cameroon, [3]UCSF, San Francisco, CA

The intensity and nature of the immune response to infection varies globally across individuals, affecting susceptibility to both communicable and non-communicable diseases. This variation is shaped by environmental factors, such as pathogen exposure and treatment accessibility, as well as genetic factors that have, in turn, been shaped by evolution. A valuable model for studying inter-individual variation in immune activation is the *in vitro* stimulation of immune cells; when *in vitro* stimulation is combined with state-of-the-art single-cell transcriptomic techniques, expression changes following immune activation can be studied in an individual, stimulation, and cell type-specific manner. As with the majority of genomic studies, however, most *in vitro* stimulation and transcriptomic studies have focused on individuals of Eurasian ancestry or westernized settings. To broaden our understanding of how human immune variation is shaped by environmental and genetic factors, we have performed *in vitro* stimulation of peripheral blood mononuclear cells (PBMCs) using LPS and IFN-β in a Cameroonian cohort comprised of 58 Tikari agriculturalists, 58 Fulani pastoralists, and 44 Central-African Rainforest Hunter Gatherers (CRHGs). After performing single-cell mRNA-sequencing of approximately 1.5 million stimulated and unstimulated PBMCs we find extensive population and cell type variation in gene expression across control and stimulation conditions, as well as variation in the intensity of the stimulation response. Combining these data with genetic data from the same individuals, we map quantitative trait loci (QTLs) regulating expression across cell-types and conditions. Finally, integration of QTL data with scans of natural selection allows us to understand how evolution has shaped genetic variation controlling the immune response in these populations.
This work has been funded by the Chan Zuckerberg Initiative, NIH grant R35 GM134957-01, and the American Diabetes Association Pathway to Stop Diabetes grant #1-19-VSN-02.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1083 Dynamic effects of disease-associated variants on chromatin accessibility across human immune cells

Authors:

Z. Mu; Univ. of Chicago, Chicago, IL

A small fraction (~25%) of autoimmunity-associated variants from genome-wide association studies (GWAS) is explained by steady-state expression quantitative trait loci (eQTL) discovered in bulk RNA-seq studies (Mu et al., Geno. Biol., 2021). Epigenetic variation may offer novel insights in understanding the remaining loci. Here we created a large, unified single-cell chromatin accessibility (scATAC) map in peripheral blood of 56 rheumatoid arthritis (RA) and healthy donors, comprising ~220,000 cells.

We applied a novel topic modeling method, fastTopics, to single-cell count data and identified cell trajectories associated with RA. We observed an effector T cell trajectory leading to a rare CD8+ T cell population in RA patients that is masked in standard cluster analyses. Notably, this trajectory is enriched in RA heritability (OR=28.2, p=1.3E-8) and tracks the activation of known RA genes like IL2, CXCL13 and LILRB1. Next, we identified 25,107 cis-regulatory elements (cREs) with significant chromatin accessibility QTL (caQTL, 10% FDR) with RASQUAL in whole blood and seven immune cell types, quadrupling the hits compared with previous study. RASQUAL uses allelic-imbalance to increase power, but its output is incompatible with most downstream analysis. To overcome this, we used a single-cell Poisson mixed-effects model to estimate standard summary statistics for significant caQTLs. We found that caQTLs show higher levels of sharing across cell types than eQTLs do; consequently, shared caQTLs often colocalize with eQTLs in just a few specific contexts, raising the possibility that many caQTLs are nonfunctional in many contexts. Last, we colocalized caQTLs with 47 GWAS of autoimmune diseases and blood phenotypes. Remarkably, caQTL explained ~50% more GWAS loci than eQTLs. When GWAS loci colocalize with both caQTL and eQTL in the same contexts, we are more likely to nominate putative causal genes (OR=1.6, p=2.7E-7). However, 57% of colocalized GWAS loci only have caQTL colocalization, and we found that they may represent cases where the causal effect is mediated through nearby cREs but in an as yet uncharacterized context.

To conclude, we show that caQTLs greatly complement eQTL in explaining disease GWAS, but the large number of caQTL-GWAS colocalization could be due to the widespread sharing of caQTL across contexts. Thus, even in the presence of clear colocalization signals, pinpointing the causal context for these GWAS loci remains difficult. Our findings indicate that we must broadly study disease-relevant contexts and conduct experimental validation on the identified cREs in order to truly understand the mechanism of disease SNPs.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1084 Effects of pathogenic variation in *ADAMTSL4* on vascularsmooth muscle cell function relevant to spontaneous coronary artery dissection.

Authors:

C. Pinnock, K. Hunker, S. Ganesh; Univ. of Michigan, Ann Arbor, MI

Spontaneous coronary artery dissection (SCAD) is the cause of 1.7-4% of acute coronary syndromes (ACS), with a strongly sex-biased prevalence, with more frequency occurrence in female individuals. In a whole exome sequencing study of SCAD, we recently reported exonic variants in *ADAMTSL4* that were predicted to be deleterious by in silico analysis. We and others have previously reported a robustly associated common variant, rs12740679 at chromosome 1q21.2, identified by genome-wide associations study of SCAD that demonstrated a colocalized expression quantitative trait locus effect on *ADAMTSL4*, with reduced gene expression associated with the SCAD risk allele. Expression of myc-tagged *ADAMTSL4* construct of the coding variant *ADAMTSL4 c.2263dupG (p.Gly758Trpfs*59)* in 293T cells demonstrated 50% reduction in the secretion of *ADAMTSL4* from the transfected cells (N = 3), as compared to the *ADAMTSL4 WT*-transfected control. Based upon this finding, which is concordant with the GWAS risk allele association with reduced *ADAMTSL4* expression, we modeled these effects by transient siRNA transfection of female human coronary artery smooth muscle cells (huCASMCs) and performed in vitro studies to understand the function of *ADAMTSL4* in the huCASMC extracellular matrix. We hypothesized that we would observe effects on fibrillogenesis and ECM maturation/stability owing to previously described interactions of *ADAMTSL4* with fibrillin 1 (*FBN1*) and lysyl oxidase (*LOX*), respectively. After achieving an 88±9.73% (N = 5) knock down of *ADAMTSL4* mRNA expression following transfection we observed a significant increase in cell migration (N = 5) and wound healing (N = 3). Cell adhesion and contraction was quantified using a traction force microscopy (TFM) assay, and a significant increase in traction force (N = 6) was observed following *ADAMTSL4* loss of function. Biomaterial properties were assessed via tensile testing engineered tissue rings (ETR) created with *ADAMTSL4* siRNA transfected female huCASMCs, showed a significant decrease in ultimate tensile strength, elastic modulus, and failure strength following candidate gene knock down (N = 3). A microfibril assay using *ADAMTSL4* siRNA transfected huCASMCs cultured in conditioned media with excess secreted *ADAMTSL4 WT* or *ADAMTSL4 c.2263dupG (p.Gly758Trpfs*59)* via immunofluorescence staining showed a decrease in *FBN1* binding and fibrillogenesis when cells were cultured in the *ADAMTSL4* variant-conditioned media. These findings support a role for *ADAMTSL4* in arterial smooth muscle and suggest that *ADAMTSL4* loss may cause abnormal cellular and extracellular effects which can lead to arterial destabilization in SCAD.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1085 Elucidating ancestral differences in expression quantitative trait loci architecture relative to Alzheimer's Disease Status.

Authors:

M. Mews[1], N. Wheeler[1], P. Benchek[1], T. Gu[2], L. Gomez[2], C. Kosanovic[3], M. Cornejo-Olivas[4], B. Feliciano-Astacio[5], G. Beecham[2], G. Byrd[6], J. Haines[1], M. Pericak-Vance[3], A. Griswold[2], W. Bush[1]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Univ. of Miami, Miami, FL, [3]Univ. of Miami Miller Sch. of Med., Miami, FL, [4]Inst. Natl. de Ciencias Neurologicas, Lima, Peru, [5]Univ. Central del Caribe, Bayamón, PR, [6]NC A&T State Univ, Greensboro, NC

Alzheimer's disease (AD) has increased prevalence in African American (AA) and admixed Hispanic (HISP) populations relative to Non-Hispanic Whites (NHW). While it is known that the underlying genetic risk for AD differs between genetic ancestries, we understand less about how these differences in the genetic architecture of AD may contribute to the observed prevalence differences. To explore how the genetic components underlying gene expression may differ among the populations and whether AD status contributes to changes in gene expression, we performed expression quantitative trait loci (eQTL) analysis from whole-blood RNAseq gene expression and genome-wide genotyping data from AA, HISP, and NHW individuals.

RNAseq data was processed using the Alzheimer's Disease Sequencing Project (ADSP) FunGen-xQTL computational protocol. Genotyping array data was imputed using the TOPMed imputation panel and filtered to include variants with an imputation accuracy prediction of r2 > 0.8 and those directly genotyped by the array. We then performed eQTL analysis stratified by population and AD status.

We identified 147,893 genome-wide significant eQTLs for NHW (N=236) individuals, 106,062 eQTLs for HISP (N=339), and 17,533 eQTLs for AA (N=224). By comparing these groups, we identified 4,204 shared significant variants amongst all populations with effect size directions 100% concordant. Within the groups, we identified AD-specific eQTLs with 507 found within NHW, 214 within HISP, and 26 within AA. From cognitively unimpaired (CU) individuals, we identified CU-specific eQTLs with 688 found within NHW, 143 within HISP, and 269 within AA. *No AD-specific or CU-specific eQTLs were shared amongst or between the three populations*. Among the significant AD-specific variants within each population, 27% of NHW variants (139/507), 37% of HISP variants (79/214), and 77% of AA variants (20/26) were not previously identified as significant eQTLs in eQTLGen, the European-descent blood eQTL analysis of 31,684 individuals (Võsa & Claringbould et al. 2021). Similarly, among the significant CU-specific variants within each population, 36% of NHW variants (247/688), 63% of HISP variants (90/143), and 45% of AA variants (121/269) were not previously identified as significant eQTLs in eQTLGen.

Our results suggest prominent differences in eQTL architecture between populations with AA samples exhibiting at least an 80% reduction in eQTLs relative to NHW and HISP. The presence of AD and CU-specific variants solely found within each population highlight the importance of personalized risk assessment informed by genetic ancestry.

PB1086 Elucidating therapeutic pathways for disease through the integration of fine-mapping and genetic colocalization applied to 2,923 circulating proteins in 38,697 UK Biobank participants

Authors:

C. Robins[1], Q. Wang[2], N. Bowker[2], J. Davitte[1], A. Cortes[2], T. Richardson[2], R. Scott[2]; [1]GSK, Collegeville, PA, [2]GSK, Stevenage, United Kingdom

Trait-associated protein quantitative trait loci (pQTL) are a valuable source of evidence to support drug development. In this study, we developed an innovative approach that integrates fine-mapping and genetic colocalization to systematically evaluate the impact of 2,923 circulating proteins on 340 disease phenotypes and biomarkers. We performed genome-wide pQTL and fine-mapping analyses using genetic and plasma proteomic data from 38,697 UK Biobank (UKB) participants of European ancestry. These results were integrated with fine-mapped summary statistics from GWASs of curated UKB disease and biomarker phenotypes using genetic colocalization methods. We identified a total of 76,369 protein-trait pairs with colocalization evidence (posterior probability >80%), which suggests shared causal variants underlying both plasma protein levels and disease. Of the identified protein-trait pairs, 2.8% (2,135) have colocalization evidence at *cis* loci (within 1 Mb of the protein-coding gene), while 99% (75,662) have colocalization evidence at *trans* loci. The majority of the protein-trait pairs with *cis* evidence were identified only through conditional colocalization (60%, 1,279 pairs) and would not have been identified without conditional analysis to resolve distinct signals. This included 273 protein-trait pairs supported by multiple independent *cis*-pQTL colocalizations. For instance, multiple independent *cis*-pQTL for LPL provided evidence of colocalization with triglyceride levels, highlighting the lipoprotein lipase pathway as a therapeutic target for treating atherosclerosis. Additionally on this pathway, secondary *cis*-pQTL for ANGPTL3 colocalize with lipoprotein lipid traits. This is further consolidated by rare protein truncating variants in the coding region of *ANGPTL3* that were identified through exome sequencing in UKB. Of the protein-trait pairs with *cis*-pQTL colocalization evidence, 67% (1,428/2,135) were also supported by *trans* pQTL colocalization evidence. Many of these *trans* pQTL findings reveal known biology, including protein-protein interactions and shared disease mechanisms. For example, ANGPTL3 *trans*-pQTL located at the *APOA5* locus colocalize with lipoprotein lipid traits. APOA5 is another member of the lipoprotein lipase pathway, highlighting a coordinated system of effects which may have been overlooked without jointly considering evidence from *cis*- and *trans*-pQTL. Taken together, our approach can identify and harness independent secondary pQTL signals and allelic series to improve downstream causal inference and develop our understanding of the relationships between proteins and disease.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1087 Engineering a synthetic humanized*RET*mouse to model multifactorial Hirschsprung disease

Authors:

R. Fine[1], A. Chakravarti[1], J. Laurent[1], J. Boeke[1], B. E. Low[2], A. Zuberi[2], M. V. Wiles[2]; [1]NYU Sch. of Med., New York, NY, [2]The Jackson Lab., Bar Harbor, ME

Hirschsprung disease (HSCR) is multifactorial but with ~50% of attributable risk from the receptor tyrosine kinase RET gene. To understand the genetic and cellular events that lead to aganglionosis in HSCR, we have built a humanized mouse model with an intact 77kb human RET genomic locus inserted into the Rosa26 safe-harbor locus using direct zygote injection and recombination with the Bxb1 serine-integrase. Our approach takes advantage of cutting-edge "Big-DNA" technology in budding yeast and E. coli to synthetically construct these loci. We have confirmed integration using nanopore Cas9-targeted sequencing (nCATS) as well as Illumina short-read sequencing. The intact locus includes all intron sequences and ~10kb upstream of the RET promoter, which enables direct modeling of known coding and regulatory human pathogenic variants in mice. We have functionally confirmed expression of the human RET gene using qRT-PCR. While this initial model will answer a number of outstanding questions, the majority (42%) of HSCR risk can be further defined from three HSCR-associated noncoding variants, rs2506030, rs7069590, and rs2435357, within RARB, GATA2 and SOX-10 binding RET enhancers. We have demonstrated topological chromatin interactions between the three enhancer variants and the RET promoter by 5C-ID sequencing in CHP212 cells. The 77kb strain harbors the susceptibility alleles at rs7069590 and rs2435357. To further increase our model's accuracy, we have additionally constructed a 179kb locus in yeast with a defined risk haplotype to include the remaining distal enhancer. We are further advancing an mSWAP-IN delivery approach in mouse embryonic stem cells to deliver the 179kb locus directly to the mouse Ret locus. We will present our approach, the progress towards the various RET humanized mouse strains harboring noncoding regulatory variants and their transgenic phenotypes at the genetic, gene expression, cell behavior and aganglionosis levels.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1088 Enhancer RNA transcriptomics-wide association study reveals an atlas of pan-cancer susceptibility eRNAs

Authors:

W. Chen, L. Li; Shenzhen Bay Lab., Shenzhen, China

Increasing evidence has evidenced that enhancer RNAs (eRNAs) play essential roles in human disease. However, it is still a major challenge to comprehensively identify the subset eRNAs relevant to disease. Here we constructed the first atlas of common and rare genetic influences on enhancer RNA expression across 49 human tissues. We identified 11,757 eRNA quantitative trait loci (eRNA-QTLs) associated with the expression of 89.75% annotated eRNAs. eRNA-QTLs significantly contribute to cancer heritability, and 28.48% of cancer variants are co-localized by eRNA-QTLs. We performed an enhancer RNA transcriptome-wide association study (eTWAS) and identified 259 cancer susceptibility eRNAs for 23 cancer types. Their nearby target genes of these eRNAs were strongly enriched in oncogenes. More interestingly, rare functional variants associated with extreme eRNA expression can also substantially affect cancer risks. Additionally, we developed a comprehensive and flexible data portal for exploring the genetic basis of eRNAs. Overall, this study revealed the systematic landscape of genetic effects on eRNAs across human tissues and significantly expanded the diseases-associated eRNAs.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1089 Enhancer-promoter compatibility and cellular context in disease-associated gene regulation

Authors:

A. Tovar, Y. Kyono, K. Nishino, M. Bose, A. Varshney, J. Kitzman, S. Parker; Univ. of Michigan, Ann Arbor, MI

Complex diseases arise from the combined effects of genetic, environmental, and lifestyle factors. Recent genome-wide association studies have revealed that the majority of complex disease-associated loci are found in noncoding regions. However, the framework to translate these noncoding variants to specific transcriptional processes is ill-defined, unlike the codon-amino acid system for coding variants. Massively parallel reporter assays (MPRAs) have emerged as a useful method to screen large collections of putative regulatory elements, efficiently prioritize candidate causal variants at disease loci, and learn principles of disease-associated regulatory variation. Previously, we used a modular MPRA to discover sequence features associated with cell- and sequence context-specific regulatory activity. Using a panel of type 2 diabetes (T2D)-associated fragments paired with a synthetic housekeeping promoter (SCP1) or the biologically relevant human insulin promoter (*INS*), we discovered a subset of fragments displaying higher enhancer activity with the *INS* promoter. Interestingly, these fragments were enriched for pancreas- and neuroendocrine-relevant transcription factor motifs, including HNF1 family members. Exonic mutations in *HNF1A*/*HNF1B* cause maturity onset diabetes of the young (MODY) while T2D-associated variants are found in their cognate binding motifs, suggesting genetic convergence between rare and common genetic variation. We used a follow-up MPRA library to investigate two main questions: (1) do HNF1 binding motifs contribute to *INS* promoter-biased enhancer activity? and (2) is this phenomenon present in other promoter and cellular contexts? We indeed observed several instances where deletion or mutation of HNF1 motifs disrupted the *INS* promoter-biased enhancer activity. By contrast, when we delivered the same library to the LHCN-M2 human skeletal muscle line, we observed that many of these fragments displayed low enhancer activity that was not disrupted by HNF1 motif deletion or mutation, including when cloned with the promoter for the muscle-specific gene *MYBPC2*. Additionally, we observed instances where variants displayed allelic activity only in the presence of the *MYBPC2* promoter in LHCN-M2 cells and not in other contexts. Together, our study suggests that cell-specific regulatory activity is partially influenced by enhancer-promoter compatibility, and indicates that careful attention should be paid when designing MPRA libraries to capture context-specific regulatory processes at disease-associated genetic signals.

PB1090 Enhancing the activity of YKL-39: investigating mutations and enzymatic properties.

Authors:

T. Kanaizumi, K. Suzuki, M. Ohkura, K. Okawa, **F. Oyama**; Kogakuin Univ, Tokyo, Japan

YKL-39, also known as CHI3L2, is a secretory protein that lacks chitinase activity. Despite its enzymatic inactivity, YKL-39 is expressed in healthy individuals and found to be overexpressed in various diseases such as osteoarthritis (OA), rheumatoid arthritis (RA), glioblastoma, multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), and certain cancers. This highlights its potential as a biomarker and therapeutic target. The absence of chitinase activity in YKL-39 is attributed to mutations in the conserved catalytic sequence. Previous studies have demonstrated that introducing two specific amino acid mutations can activate YKL-39 (Schimpl et al., Biochem. J., 446, 149-157, 2012). In our study, we aimed to further enhance the activity of YKL-39 by introducing three substitutions in the catalytic motif of the wild-type protein, resulting in MT-YKL-39. The comparative evaluation revealed increased activity of MT-YKL-39 compared to WT-YKL-39, with an optimal pH of 5.0, similar to chitotriosidase (CHIT1), an active human chitinase. Furthermore, we generated a chimera by fusing MT-YKL-39 with CHIT1 and conducted a chitinase activity assay, which indicated increased chitinase activity levels in some chimeras. Future investigations will focus on detailed studies of the enzymatic properties and pH dependence of chitinase activity in the chimeras. Our ongoing research aims to activate and further understand the potential of MT-YKL-39.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1091 Enrichment of incidental/secondary genetic findings of G6PD, TTR, TTN, RYR1, and BRCA2 in a cohort of 8667 African-American pediatric subjects.

Authors:

E. Bhandari[1], A. Saeidian[1], M. March[1], L. Youssefian[2], D. Watson[1], M. Harr[1], G. Kazemioula[3], F. Aliazami[4], F. Mentch[1], X. Wang[1], A. Saeidian[5], H. Vahidnezhad[6], M. Akbarzadeh[7], L. Tsoi[8], J. Gudjonsson[8], J. Glessner[1], H. Hakonarson[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]UCLA, Los Angeles, CA, [3]Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of, [4]Azad Univ., Tehran Med. Sci., Dept. of Genetics, Tehran, Iran, Islamic Republic of, [5]Iran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, [6]Univ. of Pennsylvania, Philadelphia, PA, [7]Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, [8]Univ. of Michigan, Ann Arbor, MI

Purpose: We utilized clinical next-generation sequencing to identify pathogenic sequence variations not associated with a patient's primary diagnosis in a large pediatric cohort. These variations are referred to as incidental findings (IFs), secondary findings (SFs), or unsolicited findings (UFs). Our cohort was specifically enriched for Black children, which comprises 52% (8667) of the total cohort (16713) at the Center for Applied Genomics at The Children's Hospital of Philadelphia. The inclusion rate for Black individuals (adults and pediatrics) in published genome-wide studies is less than 3%; this highlights a dire need for genetics research on this population. The strong representation of Black subjects in our cohort allows us to yield information on the types and frequency of pathogenic IFs primarily affecting Black children and families. **Methods:** We searched for pathogenic (P) and likely pathogenic (LP) variants in disease-causing genes, specifically in 78 ACMG recommended and 93 non-ACMG genes that met the definition of IFs in patients of four large pediatric cohorts. The list of 93 non-ACMG genes was compiled from a literature review for genes proposed for addition to the ACMG list. Variants were filtered by P/LP classification as per ACMG/AMP guidelines, CADD vs Mutation Significance Cutoff (MSC) scores, variant type, presence in disease-causing variant databases, and IGV visualization for manual variant quality inspection. We divided the patient's P/LP variants into four disease categories: metabolic, cancer, cardiovascular, and other. We further divided our patients by self-reported ethnicity. **Results:** We report a distinctive distribution of types and frequency of IFs in Black individuals. Black subjects were 335/350 (95%) of total subjects with P/LP variants in the G6PD gene, 307/320 (96%) in TTR, 62/146 (42%) in TTN, 29/48 (60%) in RYR1, and 24/46 (52%) in BRCA2. Out of 335 Black subjects with P/LP variants in G6PD, the most common variant (327) was p.V98M. Homozygous females comprised 39/327 (12%) of this specific P/LP variant. Out of 307 Black subjects with P/LP variants in TTR, the most common variant (304) was p.V142I. The other 3 variants were p.V50M, p.V113M, and p.D119V. **Conclusions:** Our data on IFs in a large pediatric cohort enriched for Black subjects provides valuable data on P/LP variants which mainly affect Black children. The implications of identifying such in an underrepresented patient population are vast, as many previous studies on IFs has been dominated by White cohorts. This will inform medical management, reproductive planning, and additional family member genetic testing for Black children and families specifically.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1092 eQTL analysis of canine testes identifies gene expression patterns associated with canine body size.

Authors:

R. M. Buckley[1], A. C. Harris[1], J. Hale[1], D. T. Whitaker[1], S. E. Lana[2,3], E. A. Ostrander[1]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]Coll. of Vet. Med. and BioMed. Sci., Colorado State Univ., Fort Collins, CO, [3]Flint Animal Cancer Ctr., Colorado State Univ., Fort Collins, CO

The role of breed-associated genetic variation in shaping morphological diversity of dogs is difficult to assess, as most of this variation is non-coding. To overcome this, we initiated the canine eQTL project. Bulk RNA-seq and low-pass WGS data was collected and analyzed for 143 canine testes samples. To address the effects of cell-type heterogeneity in bulk RNA-seq data we performed cell-type deconvolution with human single cell testes expression profiles to estimate cell-type composition of dog samples. We tested the efficacy of this approach by focusing on the well-characterized IGF1 small body size allele and its association with serum IGF1 levels. We found testes IGF1 expression was only associated with the IGF1 small body size allele when cell-type covariates were included in our models, highlighting the importance of correcting for cell-type heterogeneity in detecting eQTLs. Moreover, inclusion of cell-type covariates led to the identification of an additional 1,138 eGenes. To identify genes potentially regulating morphological traits in breeds, we performed colocalization analysis for 28 breed height and breed weight loci. Two loci, one on chromosome 7 and the other on chromosome 34, which affect both breed height and breed weight, were supportive of eQTL colocalization (posterior probability > 0.5). The chromosome 7 locus was associated with SMAD2 expression and the chromosome 34 locus was associated with IGF2BP2 expression. The expression of both genes was positively correlated with breed height and breed weight, indicating how expression changes in SMAD2 and IGF2BP2 regulate canine body size. Finally, we investigated eQTL activity within a chromosome X locus that is > 1Mb in size and is known to contribute to proportionately large breed size. IRS4 and ACSL4 were previously identified as candidates in this region as they contained missense variants and similar functional roles in other species. However, IRS4 and ACSL4 showed no significant expression change in the presence of the large breed size allele. Alternatively, AMMECR1 and CHRDL1, genes associated with short stature and bone growth in other systems, showed decreased expression with the large breed associated allele, providing as novel candidates for regulating canine body size. The canine eQTL project has identified a total of 1,838 eGenes and has helped to identify novel gene candidates for common traits in dogs. As this resource matures, it will continue to facilitate the detection of target genes from GWAS and provide a framework for comparing genetic architecture across species.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1093 eQTLGen phase 2: Genome-wide *trans*-eQTL analysis in blood in over 35,000 individuals provides insight into the genetic architecture of molecular traits.

Authors:

R. Warmerdam[1,2], A. van der Graaf[3], eQTLGen Consortium, T. Esko[4], Z. Kutalik[3], H-J. Westra[1,2], L. Franke[1,2], U. Võsa[5]; [1]Univ. Med. Ctr. Groningen, Univ. of Groningen, Dept. of Genetics, Groningen, Netherlands, [2]Oncode Inst., Utrecht, Netherlands, [3]Univ. of Lausanne, Lausanne, Switzerland, [4]Estonian Genome Ctr., Inst. of Genomics, Univ. of Tartu, Tartu, Estonia, Tartu, Estonia, [5]Estonian Genome Ctr., Inst. of Genomics, Univ. of Tartu, Tartu, Estonia

Gene expression quantitative trait loci (eQTL) analysis has become an essential tool for understanding complex disease mechanisms. However, previous eQTL studies have been limited by sample size and have therefore mainly focused on *cis*-regulatory effects. We recently performed a *trans*-eQTL analysis in 31,684 samples (eQTLGen), but were only able to study ~10,000 genetic variants, due to computational challenges. Here, we present interim results from eQTLGen phase 2, the largest-scale genome-wide *trans*-eQTL analysis to date.

We have developed robust pipelines to perform automated, comprehensive data quality control and genotype imputation in individual cohorts. Methodology adapted from the HASE framework allows for genome-wide meta-analyses for thousands of phenotypes and samples, while limiting data transfer sizes and ensuring participant privacy. We have successfully applied the method to 12,384 available samples and are currently expanding the analysis to more than 35,000 samples.

Currently, we have been able to identify 25,796 independent *trans*-eQTLs, and we expect this to increase as we expand to 35,000 samples, providing substantially more power. This will provide us with a more complete understanding of gene expression regulation, and reveal gene-to-gene interactions through comprehensive fine-mapping, colocalization and Mendelian randomization analyses. Moreover, our findings will provide a resource for the genetics research community and offer a foundation for future functional genomics studies.

In conclusion, we highlight the importance of large-scale *trans*-eQTL analysis in understanding gene expression regulation and its implications for complex disease biology.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1094 Examining the impact of natural genetic variation on meiosis and fertility in hybrid mice using single-cell chromatin accessibility and gene expression

Authors:

I. Agarwal, B. Myers, M. Houlard, E. Bitoun, S. Qu, A. Hinch, S. Myers; Univ. of Oxford, Oxford, United Kingdom

Meiosis involves progression through several short-lived but key transcriptional events (e.g., PRDM9 expression), and critical instances of chromatin remodeling, including PRDM9 binding to recombination hotspots, synapsis between homologous chromosomes, and silencing of unsynapsed chromatin. Many of these processes are difficult to study directly as they are stochastic properties of individual cells in very transient cell populations.
Here, we take advantage of genetic diversity in a sample of fertile B6, infertile (PWDxB6) F1 and variably-fertile PWDx(B6xCAST) F1 hybrid mice, together with simultaneous gene expression profiling by RNA-seq and mapping of open chromatin by ATAC-seq in single cells, to characterize the genetic regulation of the entire meiotic process. These mice possess ~10-fold greater genetic diversity than humans, greatly facilitating identification of allelic differences. We identify key binding events that control meiotic gene expression during specific meiotic stages, including transient allele-specific opening of chromatin and histone repositioning at Prdm9 binding sites, lagging RNA expression of Prdm9. We show how broad-scale gene-expression and chromatin patterns change in a coordinated fashion throughout meiosis: two examples are X-chromosome inactivation, and compaction of chromatin in spermatids. We identify cell stages throughout the meiotic program, including cells that have undergone the first and second meiotic division; moreover, we can identify sites of crossovers and instances of aneuploidy in single cells.
Studying hybrids with variable levels of fertility in particular allows us to examine how mutations impact regulatory binding and drive differential expression in the germline, and to investigate the molecular basis of infertility in these mice. Together, these approaches provide a powerful and generalizable toolbox to study the mechanisms of germline development, and to dissect the effects of common genetic variation on a number of molecular traits in the male germline that are directly relevant to fertility.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1095 Exploring dual and triplets genetic variants in nucleotide excision repair-related genes: unraveling their impact on disease severity and structural consequences in patients with late-onset Xeroderma pigmentosum phenotype.

Authors:

A. BOUAZIZ[1,2,3,4,5], F. FRIKHA[6], N. KHERIJI[7], L. ROMDHANE[8,9], M. ZGHAL[10], O. MESSAOUD[1]; [1]BioMed. Genomics and Oncogenetics Lab., Inst. Sch. of Computer Sci. , Université de Manouba, Manouba, Tunisia, [5]Higher Inst. of Biotechnology of Sidi Thabet, Université of Manouba, Sidi Thabet, Tunisia, [6]Faculty of Sci. of Sfax (FSS), Univ. of Sfax, Sfax, Tunisia., Sfax, Tunisia, Sfax, Tunisia, [7]BioMed. Genomics and Oncogenetics Lab., Inst. Pasteur of Tunis, Tunis, Tunisia, Tunis, Tunisia, [8]Département des Sci. de la Vie, Faculté des Sci. de Bizerte, Université Carthage, 7021 Jarzouna, BP 21, Tunisie., Bizerte, Tunisia, [9]Lab. of BioMed. Genomics & Oncogenetics, Inst. Pasteur de Tunis, Université Tunis El Manar, 13, Place Pasteur BP 74, 1002 Tunis, Belvédère, Tunisie., Tunis, Tunisia, [10]Dept. of Dermatology, La Rabta Hosp., Tunis, Tunisia., Tunis, Tunisia

Xeroderma pigmentosum (XP) is a genetic condition primarily characterized by compromised DNA repair capabilities, resulting in a heightened vulnerability to ultraviolet (UV) radiation and a propensity towards skin cancer. Our previous work on the largest cohort worldwide enabled us to identify causative founder and private genetic variants. For a small fraction of patients, with a mild phenotype, the genetic etiology has not yet been identified. The goal of our research was to unravel the genetic basis of late-onset XP forms.

We implemented exome sequencing in three Tunisian XP patients. The Agilent SureSelect XT Human All Exon v6 panel was used for exome capture, followed by high-throughput sequencing via the NovaSeq6000 platform. The raw sequence data were meticulously processed and aligned against the human reference genome (GRCh38). Variants' pathogenicity was evaluated using several bioinformatics in-silico prediction tools as well as protein structure through advanced homology modelling and molecular dynamics. For proteins with no reference structure, domain modelling using threading and ab initio methods was applied.

Our analysis unveiled a previously unexplored genetic landscape associated with mild XP. Indeed, we have identified not only pathogenic variants in *DDB2*, *UVSSA*, *ERCC5*, and *ERCC6* genes, but, more notably, at least two homozygous variants were identified for every patient. For the first patient, we observed a variant in the *UVSSA* gene (p.620L) along with a second variant in ERCC5 (p.G1053R). The second patient exhibited two variants in the *ERCC5* gene (p.G1053R and p.G1080R), and a variant in the *ERCC6* gene (p.R382K). Lastly, the third patient presented three variants, including a variant in *DDB2* (p.A128P), a variant in *UVSSA* (p.P620L), and a variant in *ERCC5* (p.G1053R). The pathogenicity of all these variants was confirmed by at least 5 in-silico prediction tools. Furthermore, their impact on the structural stability and function of the protein was demonstrated. Indeed, structural modelling and 100ns molecular dynamics simulations revealed a destabilizing effect of the Ala128Pro substitution in the *DDB2* protein. Similarly, we observed a significant disparity in stability between the wild-type and mutated proteins.

In conclusion, this is the first study reporting double homozygous mutants in XP patients. Moreover, our integrated methodologies, including network analysis and structural characterization, contributed to a deeper understanding of the functional repercussions of the identified variants and their implications on the variable severity degree between the investigated patients.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1096 Exploring long non-coding RNAs at skin cancer risk loci

Authors:

M. H. Law[1,2,3], I. Rivera[1], M. Seviiri[1,2], J. Beesley[1], L. T. Koufariotis[1], N. Waddell[1,4], S. MacGregor[1], M. T. Landi[5], M. M. Iles[6,7], K. M. Brown[5], J. French[1], S. Edwards[1]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Sch. of BioMed. Sci., Faculty of Hlth., Queensland Univ. of Technology, Brisbane, Australia, [3]Sch. of BioMed. Sci., The Univ. of Queensland, Brisbane, Australia, [4]Faculty of Med., The Univ. of Queensland, Brisbane, Australia, [5]Natl. Cancer Inst., Bethesda, MD, [6]Leeds Inst. for Data Analytics, Univ. of Leeds, Leeds, United Kingdom, [7]NIHR Leeds BioMed. Res. Ctr., Leeds Teaching Hosp. NHS Trust, Leeds, United Kingdom

Cutaneous melanoma, basal cell carcinoma and squamous cell carcinoma are the three most frequent types of skin cancers and share common risk factors. Genome-wide association studies have identified over 100 independent or shared risk loci for these cancers. While analyses incorporating methylation and protein-coding expression data have identified putative gene targets for many cutaneous melanoma loci, basal and squamous cell carcinoma lag behind, and across the three cancers, many loci remain uncharacterised.

As with other complex traits many skin cancer risk SNPs lie in transcriptional enhancers or other regulatory elements. In addition to protein-coding genes, these SNPs may regulate the expression of long non-coding RNAs (lncRNAs). Previous research has indicated that some lncRNAs are involved in important biological pathways including those relevant to skin cancers.

To map novel skin lncRNAs we extracted RNA from melanocytes, fibroblasts and keratinocytes and performed de novo assembly. Following assembly by Trinity, the data was validated, filtered and optimised using BUSCO and TransRate. Transcripts were processed with ezLncPred using three different methods to predict coding potential (CPAT, CPC2, CNCI) parallel to using FEELnc to identify lncRNAs.

Following the exclusion of protein-coding or annotated genes we identified 16,076 novel, credible, lncRNAs. The expression of 7,589 of these lncRNAs was measurable in 106 primary melanocyte cultures and quantitative trait loci (lncQTLs) were identified for 7,400 autosomal transcripts using fastQTL. PEER factors were used to control for technical or confounding effects in the analyses.

646 of the lncRNAs had a QTL SNP significant after accounting for multiple testing. Testing for colocalisation with known skin cancer risk loci identified 12 transcripts for melanoma, seven for basal cell carcinoma and two for squamous cell carcinoma. Risk loci exhibiting lncRNA colocalisation included one on chromosome 15 containing the *OCA2* gene. There the lead SNP rs12913832, known for being the main determinant of blue vs brown eye colour, its association with skin cancer risk, and transcriptional regulation of *OCA2*, was also associated with the expression of two novel lncRNAs. We will next expand our lncRNA discovery set to include additional melanoma tumour sets, increasing our power to detect lncRNAs relevant to the development of skin cancers.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1097 Exploring the evolutionary arms race between human PKR and poxvirus K3

Authors:

M. Chambers[1,2], T. Dever[3], M. J. Sadhu[1]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]Georgetown Univ., Washington, DC, [3]NICHD, Bethesda, MD

The interfaces between host and viral proteins can be dynamic spaces in which genetic variants are continually pursued, giving rise to evolutionary arms races. One such scenario is found between the mammalian innate immunity protein PKR (protein kinase R) and the poxvirus antagonist K3. Once activated, PKR phosphorylates the natural substrate eIF2α, which halts translation within the cell and prevents viral replication. K3 acts as a pseudosubstrate antagonist against PKR by directly antagonizing this halt in translation, enabling poxviruses to replicate in the cell. Exploring the impact of genetic variants in both PKR and K3 is necessary not only to highlight residues of evolutionary constraint and opportunity but also to elucidate the mechanism by which human PKR is able to subvert a rapidly evolving viral antagonist. To systematically explore this dynamic interface, we have generated a combinatorial library of PKR and K3 missense variants to be co-expressed and characterized in a high-throughput yeast selection assay. This assay allows us to characterize hundreds of thousands of unique PKR-K3L genetic combinations in a single pooled experiment. Our results highlight specific missense variants available to PKR that subvert the K3 antagonist. We find that improved PKR variants are readily available at sites under positive selection, with limited opportunity at sites interfacing with K3 and eIF2α. Additionally, we find few functional variants that improve K3 antagonism, suggesting the antagonist is optimized. We reason that this approach can be leveraged to explore the evolutionary plasticity of many other host-virus interfaces.

PB1098 Exploring the regulatory potential of the human genome.

Authors:

J. Srivastava, I. Ovcharenko; NIH, Bethesda, MD

The robust regulatory landscape of the human genome results from a multi-dimensional control of gene expression involving concerted action of chromatin accessibility and organisation, transcription factor binding, alternative splicing, control by regulatory RNAs, etc. Mutations affecting these processes result in a phenotypic outcome that is dependent on the robustness of the system. Enhancers are major drivers of gene regulation and mutations in these regions can result in insignificant to lethal phenotypes. This begets fundamental questions about robustness of enhancer-based regulation. Does the level of deleteriousness correspond to enhancer categories, i.e., do mutations leading to less severe phenotype occur in developmental and pioneer factor binding enhancers (mutation resistant enhancers)? Or do they reflect shadow enhancers that have evolved to offset deleterious effects from loss-of-function mutations? Second, what are the biological processes that benefit from such robustness, and those vulnerable to mutations due to lack thereof? We use a forward genetics approach to address these questions. We generate synthetic genomes by introducing mutations at random 2% sites (quantified as the percent of single nucleotide variations between the human and chimpanzee genome) in the whole genome sequence by retaining nucleotide substitution rates between the two organisms. We then use deep learning models in various cellular contexts to identify enhancers from wild type and mutant whole genome sequences. Our preliminary results show that stem cell derived, embryonic and blood cell lines gain enhancers while differentiated cell lines representing muscle and epithelial cells lose enhancers in the event of random mutations. In addition to addressing the questions above, we are currently evaluating the number of mutations that would result in complete loss of enhancer activity among wild type enhancers and map these regions to biological pathways to assess their disease vulnerability. By comparing our data with documented genome variants, we can assess the critical sites of regulatory regions and delineate their significance in biological function.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1099 Expression CROP-sequencing identifies causal variants in *cis*-eQTL for genes associated with inflammatory bowel disease.

Authors:

E. Greenwood[1], M. Cao[2], C. Lee[3], B. Moyo[2], G. Bao[2], G. Gibson[1]; [1]Georgia Tech, Atlanta, GA, [2]Rice Univ., Houston, TX, [3]Univ. Coll. Cork, Cork, Ireland

This study fine-maps immune expression quantitative trait loci (eQTL) to the nucleotide level in a myeloid cell line, revealing considerably greater regulatory complexity than is generally appreciated. Although statistical fine-mapping of eQTL has been widely used, extensive linkage disequilibrium limits resolution to a credible set of probable variants. Credible sets often range from tens to hundreds of variants, and it is unclear whether one or multiple of these are responsible for the eQTL signal. Here, using expression CROP-sequencing (eCROP-seq), we combine the power of CRISPR-Cas9 and single cell RNA-sequencing (scRNA-seq) to identify causal variants in *cis*-eQTL for genes implicated in inflammatory bowel disease (IBD). Each variant in an eQTL is assigned a unique gRNA that will target that region for a double stranded break. Following scRNA-seq, cells that received this perturbation are detected via the readable gRNA transcript, and gene expression of the IBD target gene in these cells are compared to all other cells in the pool that did not receive this gRNA. We select 61 IBD associated genes that are adequately expressed in the immortalized myeloid cell line, HL-60, and target ~4,400 variants in *cis*-eQTL for these genes. In 79% of genes, we identify one or more causal variants that significantly alter target gene expression at a Bonferroni-adjusted *p*-value, corrected for the number of comparisons at each locus. Our findings suggest that multiple causal variants explain the full eQTL effect for the majority of target genes and that different causal variants explain each peak if a locus has more than one eQTL signal. Additionally, we describe four classes of eQTL structure and show that the distribution of causal variants within the peak differs among the classes. Future work will include repeating eCROP-seq analysis for all IBD associated genes expressed in the immortalized T lymphocyte cell line, Jurkat. Preliminary results suggest causal variant cell-type specificity when comparing significant variants in Jurkat cells to those in HL-60 cells for the same eQTL. Our results imply that GWAS signals should often be interpreted as haplotype effects rather than single variant signals and have implications for understanding regulatory architecture and evolution.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1100 Extensive co-regulation of neighboring genes limits the utility of eQTLs in target gene prioritization.

Authors:

R. Tambets[1], A. Kolde[1], P. Kolberg[1], M. I. Love[2], K. Alasoo[1]; [1]Univ. of Tartu, Tartu, Estonia, [2]UNC-Chapel Hill, Chapel Hill, NC

Identifying causal genes underlying genome-wide association studies (GWAS) is a fundamental problem in human genetics which is mainly rooted in the pleiotropic nature of gene expression - a single gene can be regulated by several enhancers and a single enhancer can regulate several genes. The accompanying lack of ground truth makes it difficult to benchmark models for determining causality on real-world data. To generate such a ground truth dataset, we focused on the large collection of fine mapped gene expression and protein quantitative trait locus (QTL) data from the eQTL Catalogue and the INTERVAL study. Assuming that the most likely causal gene underlying each cis-pQTL association is the gene coding for the protein allowed us to identify 872 high-confidence gene-protein pairs.

We compared three Bayesian colocalization methods (coloc.susie, coloc.abf and CLPP) and two Mendelian randomization (MR) approaches (inverse-variance weighted MR and MRLocus). We found that assigning fine-mapped pQTL variants to their closest protein coding genes outperformed all colocalization methods both in terms of precision (67% vs 72%) and recall (55% vs 77%). Furthermore, the colocalization method with the highest recall (coloc.susie - 55%) also had the lowest precision (38%). Importantly, restricting the analysis to gene-protein pairs with at least two independent colocalizing signals increased precision to 71%, but at the cost of significantly lower recall (7%).

We next used MR to further assess if multiple colocalizing variants had consistent effect size direction and magnitude on gene and protein levels. Unexpectedly, the standard inverse variance weighted MR had a very high false positive rate. In multiple cases, variants with opposite effects on gene and protein levels still yield highly significant non-zero causal effect estimates. Many of these false positives were removed by the Bayesian MRLocus approach, further increasing the precision to 75%. The remaining false positives seemed to be primarily driven by strong co-regulation between neighboring genes.

Our results highlight that linking disease-associated variants to their causal target genes remains challenging using eQTL evidence alone. Prioritizing target genes at truly novel loci likely requires triangulation of evidence from multiple sources, including rare protein altering variants and splicing QTLs that are likely to be less pleiotropic. Furthermore, MR methods need to be carefully adapted for use with eQTL signals, where high uncertainty in instrument effect size estimates must be accounted for.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1101 Factors Influencing the Portability of Gene Expression Imputation across genetic ancestries in TWAS

Authors:

Y-H. Chang[1], A. Bhattacharya[1], Y. Ding[2], B. Pasaniuc[2]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]UCLA, Los Angeles, CA

Transcriptome-wide association studies (TWAS) investigate genetic associations potentially mediated by gene expression, increasing power compared to genome-wide association. TWAS relies on imputation of gene expression based on models trained in reference expression quantitative trait locus (eQTL) datasets. Previous studies have identified that models trained in majority European-ancestry cohorts are unable to predict gene expression in external datasets of individuals of different ancestry. Here, through extensive simulations based on data from the 1000 Genomes Project (1000G), we examine potential factors that drive this lack of portability of expression models.

Across 1,000 simulations at 22 gene loci (one per chromosome), we simulate a training eQTL dataset of European samples and test sets of both European and African populations based on the linkage disequilibrium (LD) patterns in 1000G and across a variety of genetic architectures. We vary the heritability and number of causal eQTLs. We build a sum of single effects (SuSiE) linear regression model in the training dataset and predict expression in the test datasets. To assess the predictive performance of these models, we calculated the percent variance explained (PVE) in the test sets.

Our findings indicate that, in general, as the proportion of causal eQTLs increases from 1% to 10% and the heritability is 0.05, PVE decreases by 62% and 66% in the European and African test sets, respectively. We also examine differences in PVE across three factors in genetic architecture. First, we examined the impact of varying allele frequencies of the causal eQTLs and found no significant differences, except in cases where the causal proportion was extremely high or low. Second, we explored the effect of changing the ratio of heritability between African and European populations and observed a decrease of 0.028 in the PVE difference as the ratio changed from 0.1 to 2. Third, we are investigating how differences in LD across the datasets are associated with differences in performance.

In conclusion, our findings emphasize the importance of explicitly considering differences in heritability, causal eQTL proportion, and LD when aiming to improve the portability of gene expression imputation across ancestry.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1102 Female neonate with bilateral microphthalmia, vermis hypoplasia, and foot deformities, new case report, case series, and phenotypic delineation ofAlkuraya-Kucinskas syndrome.

Authors:

H. Alakeel, F. AlMutairi; Natl. Guard For Hlth.Affairs, Riyadh, Saudi Arabia

We hereby report a 1 day old female neonate, with bilateral microphthalmia, ankyloblepharon, absent vermis, clenched fest, anterior placement of anus, sacral dimple with hair tuft, ASD II, and talipes equinovarus, her WES has confirmed Alkuraya-Kucinskas syndrome; Homozygous likely pathogenic mutation in KIAA1109 gene; c.4672-1G>T. ALKKUCS, OMIM # 617822, is an autosomal recessive severe neurodevelopmental disorder characterized by arthrogryposis, brain abnormalities associated with cerebral parenchymal underdevelopment, and global developmental delay. Most affected individuals die in utero or soon after birth. Additional abnormalities may include hypotonia, dysmorphic facial features, and involvement of other organ systems, such as cardiac or renal. The few patients who survive have variable intellectual disability and may have seizures. To our current literature review we have found reported 15 patients, we are hereby analyzing their phenotypic presentation, expanding it’s spectrum, and comparing their molecular finding in order to have a better understanding of Alkuraya-Kucinskas syndrome, it’s genotypic-phenotypic correlation, and estimate it’s prognosis based on current diagnosed patients.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1103 Fewer than 2% of all possible *SPINK1* coding single-nucleotide variants affect splicing

Authors:

J. Chen[1], J-H. Lin[2,3], X-Y. Tang[4,2], W-B. Zou[2,3], S. Schutz[1], E. Masson[1,5], D. N. Cooper[6], C. Ferec[1], Z. Liao[2,3], H. Univ., Shanghai, China, [3]Shanghai Inst. of Pancreatic Diseases, Shanghai, China, [4]Dept. of Prevention and Hlth.Care, Eastern Hepatobiliary Surgery Hosp., Naval Military Med. Univ., Shanghai, China, [5]Service de Génétique Médicale et de Biologie de la Reproduction, CHRU Brest, Brest, France, [6]Inst. of Med. Genetics, Sch. of Med., Cardiff Univ., Cardiff, United Kingdom

INTRODUCTION: Single-nucleotide variants (SNVs) occurring within the coding sequence of any gene have the potential to affect splicing. In this regard, it has been reported that up to 10% of known disease-associated missense variants alter pre-mRNA splicing. Moreover, the number of synonymous SNVs altering splicing is also steadily increasing. However, to date, a precise estimation of the prevalence and extent of the impact on splicing of all possible SNVs within the coding sequence of any gene is lacking. Herein, we sought to provide such an estimation for the four-exon *SPINK1* gene, taking advantage of the availability of a highly accurate full-length gene splicing assay (FLGSA) on the one hand and the availability of the highly reliable artificial intelligence-based splicing prediction tool, SpliceAI, on the other.
METHODS: All 720 possible SNVs within the 240 nucleotides of the entire *SPINK1* coding sequence were subjected to SpliceAI prediction. The accuracy of SpliceAI prediction was first evaluated in the context of 27 known *SPINK1* coding SNVs (24 missense and 3 synonymous) that were previously analyzed by means of FLGSA. Based upon SpliceAI-predicted delta scores, 35 possible SNVs in 16 coding nucleotide positions (with delta scores ranging from 0 to 0.93) were selected for FLGSA characterization.
RESULTS: In total, 62 *SPINK1* coding SNVs were functionally analyzed, accounting for 8.6% of all possible coding SNVs. They affected 42 (17.5%) of the 240 coding nucleotides. Notably, all three possible SNVs in 9 nucleotide positions, were functionally characterized. Of the 62 FLGSA-analyzed SNVs, 12 were found to affect splicing. Of these 12 splice-altering variants, 9 generated both wild-type and aberrant transcripts whereas the remaining 3 generated only aberrant transcripts. The splice-altering SNVs only occurred in exons 1 and 2, and predominantly affected the first and/or last coding nucleotide of the respective exon. Importantly, SpliceAI prediction and experimentally obtained findings were found to concur in all cases of the 62 analyzed SNVs. This excellent correlation, taken together with the fact that we have included all variants with a significant delta score for functional characterization, suggest that none of the not functionally analyzed SNVs should have any appreciable impact on splicing. Therefore, only 1.67% (n = 12) of the 720 possible coding *SPINK1* SNVs would be considered to affect splicing.
CONCLUSION: Combining SpliceAI-predictions with FLGSA-derived data from a large number of known and prospectively generated SNVs, we confidently conclude that fewer than 2% of all possible *SPINK1* coding SNVs affect splicing.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1104 Fine-mapping of functional traits using fSuSiE reveals local genetic influences of epigenetic and transcriptomic regulation in human brains.

Authors:

H. Sun[1], W. Denault[2], P. Carbonetto[2], The FunGen-xQTL Consortium, M. Stephens[2], G. Wang[1]; [1]Columbia Univ., New York, NY, [2]Univ. of Chicago, Chicago, IL

Many genetic variants identified in genome-wide association studies are located in epigenetic regulatory elements such as histone modification and DNA methylation (DNAm). These epigenetic processes have been implicated in complex disease etiology through their effects on gene activities. Therefore, we would like to understand the underlying regulatory genetic mechanisms by interrogating available genomic, epigenomic, and transcriptomic data sets. Here we describe the results of our efforts to fine-map epigenomic QTLs—that is, identify putative causal epigenomic quantitative trait loci (QTLs)—from H3K9ac (haQTL) and DNAm (meQTL) data across 877 topologically associated domains (TADs) in the human prefrontal cortex from the ROSMAP project, and integrate them with 15,339 fine-mapped expression QTLs (eQTLs) identified in the same brain subjects. The fine-mapping of this heterogeneous data is based on a newly developed method, fSuSiE ("Functional Sum of Single Effects"), which can account for both spatial correlations of hundreds of epigenomics marks and linkage disequilibrium between genetic variants. fSuSiE identified numerous credible sets (CSs) that impact 29,853 transcription starting sites through complex regulatory effects, hence allowing us to gain insight into the genetic regulation of such epigenetic marks. In particular, fSuSiE identified: 10,642 fine-mapped CSs for DNAm, 1070 of them intersecting eQTL CSs, and 2,562 CSs for haQTL, 605 of them intersecting eQTL CSs. We identified 310 CSs affecting DNAm and H3K9AC (shared CSs). Overall, we found that the CSs affect the transcription starting site (TSS) in 23,238 genes through DNAm and over 12,804 through H3K9ac. Interestingly, many of the CSs affect multiple TSSs, and we found that 53% of mQTL CSs and 40% of haQTL CSs are located more than 500 kb from their epigenomic targets on the most distal TSS. Of the CSs shared between the two epigenomic marks, 77 associate with the same TSS through both marks, whereas 50 affect TSS solely through DNAm and 44 only through H3K9ac. Fine-mapped effect sizes across epigenetic marks in the shared CSs show a strong correlation (-0.6). We identify several examples where fine-mapped epigenomic QTL are likely to impact gene expression through complicated multi-omics regulations, such as those observed in genes *PSCA* and *TMEM131L*, where multiple independent QTL are involved. Our work offers promising future research directions on *cis*-regulatory networks underlying complex disease etiology.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1105 Five novel mutations in ribosomal proteins in 11 Diamond Blackfan Anemia (DBA) patients: An Indian outlook

Authors:

P. Kedar, R. Dongerdiye; Natl. Inst. of Immunohematology (ICMR), Mumbai, India

Diamond Blackfan Anemia (DBA) is an inherited bone marrow (BM) failure syndrome characterized by a paucity of erythroid differentiation, congenital anomalies, and a predisposition for malignancies. DBA is mainly caused by the mutations in ribosomal protein(RP) genes, hence classified as ribosomopathy. More than 20 RP genes are known to be associated with DBA. The most frequent mutations are observed in RPS19, RPL5. However non-RP genes are also known to be associated with DBA. Approximately 50% of the DBA patients have physical anomalies like craniofacial defects, renal anomalies, limb anomalies, and cardiac defects. Patients usually have normochromic and macrocytic, severe anemia with reticulocytopenia. In the study, we report 11 cases of DBA identified by next generation sequencing (NGS). We have identified five novel mutations in RPL5, RPL27, RPL35A and RPS17 gene. In 10 of 11 patients, bone marrow examination suggested pure red cell aplasia which is the most prominent feature of DBA. Short stature is observed in two patients bearing mutation in RPL5 and RPL26 genes. NGS have revealed seven missense mutations in different RP gene- RPL27 (p.Ile25Thr), RPL35A (p.Ile101Ser), RPL5 (p. Asp234Gly, p.Tyr253Cys), RPS19 (p.Met1X), RPS24 (p.Val192Met), RPS26 (p.Met115Thr); two large base deletions in RPL35A, RPS17; one frameshift mutation in RPL5 (p. Asp59Tyrfs*53) and one splice site mutation in RPS26 (c.3+1G>T). In addition, increased levels of erythrocyte adenosine deaminase (e-ADA) were detected in all cases. The functional consequences of the variants were assessed and its effect on the protein structure were investigated using PyMOL. Genotype-phenotype correlation were established, although clinical heterogeneity makes it difficult to analyse. In India, DBA patients are managed by steroids, blood transfusion support, or bone marrow transplantation. Conclusively, the genome sequencing has resulted in significant advancement in understanding rare diseases like DBA.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1106 From benign to pathogenic and back: the effect of context on genetic variants.

Authors:

T. Ciesielski[1], G. Sirugo[2], S. Iyengar[3], S. Williams[4]; [1]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Case Western Reserve Univ., Cleveland, OH, [4]Case Western Reserve Univ, Cleveland, OH

Here we address a fundamental problem that hampers the clinical utility of genetic research: the characterization of variant effects on a single continuum from benign to pathogenic. While useful in some ways, this approach oversimplifies what we know about genetic variation and it ignores the fact that context often determines variant impact. Overall, we argue that we need to better probe the determinants of penetrance and implications of pleiotropy. For example, genetic and environmental factors often alter variant effects and thus we should expect lower variant penetrance in large studies with diverse ancestry groups and environments. When over 5000 ClinVar pathogenic and loss-of-function variants were assessed in two large biobanks, UK Biobank and BioMe, the mean penetrance was only 7%. This indicates that the participants in most of the family-based, clinical, and case-control studies that first identified these variants were more homogenous and enriched for etiologic cofactors. This effectively produced a selection bias that overestimated the average effect in the average context, but this language of bias distracts us the primary point: the average effect is not a very useful measure. We want to know what the variant means in a specific population or patient. When pleiotropy is also considered, it becomes apparent that context can change not only the likelihood of one outcome but it may completely shift the outcome of primary concern. For example, the variant that causes hemoglobin S can increase the risk of death from sickling, lower the risk of death from malaria, or increase the risk of kidney disease. The phenotypic spectrum is strongly modified by infections, the second allele, and co-inherited variants at other loci (e.g., alpha or beta thalassemia). Overall, annotation on a single contextual continuum from benign to pathogenic attempts to shoehorn a complex phenomenon into an overly simplistic framework. There is no panacea, but we propose two recommendations. First, we need to routinely evaluate contexts such as sex and genetic ancestry by conducting stratified analyses and considering female-to-male allele proportion ratios. Here we demonstrate the value of sex ratios by revealing how putatively dangerous high ratio variants can evade detection in sex-agnostic assessments. Second, we need to consistently document what we know about effect modifiers in our annotation databases. These are not the only possible approaches, but they represent the first steps on a path that can create useful annotations for specific patients and clinical scenarios. We cannot achieve accuracy until we acknowledge that there is more than one target.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1107 From Uncertainty to Clarity: Decoding the Molecular Consequences of Two *KPTN* Gene Variants for the Diagnosis of a Rare Neurodevelopmental Disorder

Authors:

C. Washington[1], D. B. Everman[2], K. Howard[3], K. M. Butler[3], R. J. Louie[4]; [1]Greenwood Genetic Ctr., Greenville, SC, [2]Evermed Genetics and Genomics Consulting, Greenville, SC, [3]Greenwood Genetic Ctr., Greenwood, SC, [4]Greenwood Genetic Ctr., Portland, OR

This work adds to the existing evidence for *KPTN*-related disorder (MIM: 615637) by expanding its clinical and mutational spectrum. The research and evaluation of our now 12-year-old female patient offer insights into two novel biparentally-inherited sequence variants in the *KPTN* gene, NM_007059.2: c.863G>C (p.Arg288Pro) and NM_007059.2: c.863G>A (p.Arg288Gln) both located at the exon-intron boundary of exon 9. Through targeted cDNA analysis of the proband and her parents, our team observed two aberrant splicing effects: intron retention and exon skipping for the *KPTN* RNA, leading us to reclassify these uncertain variants as likely pathogenic for our patient. The re-classification of these variants provided a diagnosis for the family and informed genetic counseling for future reproductive risk. Clinically, our patient has typical features of *KPTN*-related disorder, including macrocephaly, intellectual disability, and behavior problems. Yet, our patient does not have seizures and, to our knowledge, is the second reported individual with co-morbid precocious puberty, suggesting phenotype variability. Two key points are raised in this case presentation. First, it supports whole exome sequencing as a first-tier test for individuals presenting with neurodevelopmental delay, as this approach would have decreased the time to diagnosis by seven years for our patient. Second, additional molecular analysis of suspicious sequence variants by a laboratory with expertise in RNA diagnostics is suggested. Without this additional evaluation, the diagnosis of *KPTN*-related disorder would have remained speculative. Overall, this study provides additional clinical and molecular descriptions of an individual with a *KPTN*-related disorder, supporting the need for larger cohort studies and genotype-phenotype correlations in the future.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1108 Functional analysis of *LDLR* variants using flow cytometry.

Authors:

K. Konecna[1,2], L. Tichy[1], T. Loja[3], T. Prerovska[2], L. Fajkusova[1]; [1]Ctr. of Molecular Biology and Genetics, Univ. Hosp. Brno, Brno, Czech Republic, [2]Natl. Ctr. for Biomolecular Res., Faculty of Sci., Masaryk Univ., Brno, Czech Republic, [3]Central European Inst. of Technology, Masaryk Univ., Brno, Czech Republic

Familial hypercholesterolemia (FH) is one of the most common autosomal dominant disorders. It is characterized by elevated low-density lipoprotein (LDL) cholesterol and contributes to higher risk of cardiovascular diseases. The most common cause of FH are genetic variants in the low-density lipoprotein receptor gene (*LDLR*). As of May 2023, there are over 3000 known variants in the *LDLR* gene, however, the clinical significance of many variants is uncertain. The purpose of this study is to functionally characterize 16 variants in the *LDLR* gene found in patients with phenotypic FH, to help determine their pathogenicity.

We performed *in vitro* functional assays based on transient expression of wild-type and mutant LDL receptors in LDLR-deficient Chinese hamster ovary (CHO) cells. To analyze the relative amount of LDL receptors expressed on the cell surface (compared to a control benign variant Ala391Thr), we labeled live cells with fluorescently tagged anti-LDLR antibody and analyzed fluorescence intensity by flow cytometry. We also analyzed the expression and maturation of LDLR protein in transfected CHO cells by Western blot.

The functional study indicated that out of 16 studied variants, 3 exhibited normal cell-surface expression of LDLR, while 13 variants exhibited lowered cell-surface expression of LDLR, potentially giving rise to FH. To further determine the effect of the studied variants on the whole LDLR cycle, we will also analyze the ability of mutant LDL receptors to internalize labeled LDL particles by flow cytometry. This information will be useful for identifying disease-causing variants in patients with phenotypic FH, allowing for cascade testing of potentially affected relatives.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1109 Functional analysis of*MFSD3*associated with dementia with Lewy bodies.

Authors:

T. Kimura[1], M. Suganuma[1], K. Sawamura[1], Y. Asanomi[2], T. Hosoyama[1], N. Shimoda[1], N. Ogiso[1], S. Niida[1], K. Ozaki[3], D. Shigemizu[4]; [1]Natl. Ctr. for Geriatrics and Gerontology, Obu City, Japan, [2]Natl. Ctr. for Geriatrics and Gerontology, Obu City, Aichi Prefecture, Japan, [3]The Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [4]Med. Genome Ctr., Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan

With an increasing life expectancy, the incidence and prevalence of dementia increases, and a better understanding of the etiology and pathogenesis of dementia becomes ever more urgent. Dementia with Lewy bodies (DLB) is the second most common form of degenerative dementia in elderly people. The clinical feature of DLB includes cognitive impairment, visual hallucinations, parkinsonism, fluctuating attention, decreased brain acetylcholine levels, and apathy. Three genes, *SNCA* (α-synuclein), *APOE* (apolipoprotein E), and *GBA1*(glucosylceramidase beta 1), have been convincingly demonstrated to be associated with DLB. Our previous studies reported that a variant in *MFSD3* (rs143475431, c.888T>A:p.C296*) is associated with DLB in Japanese population by whole-genome sequencing and association studies. However, the functional understanding of the variant underlying DLB remains to be elucidated. Here, we performed function analyses of the *MFSD3* variant by using zebrafish, mice, and human neural stem cells. We generated the homologous *MFSD3*knockout zebrafish and mice using the CRISPR/Cas9 system. We found that the knockout zebrafish showed a significant increase of butyrylcholinesterase in the brain tissues and the knockout mice had significantly reduced levels of curiosity and activity in the novel environment compared with wild-type mice. These results are reminiscent of symptoms such as decreased brain acetylcholine levels and apathy in DLB patients. In addition, a decrease of the cell growth rate was observed in the *MFSD3* variant homozygous human neural stem cells. Totally, the *MFSD3* variant can play an important role in the pathogenesis of DLB. Further functional verification will contribute to the elucidation of the DLB pathogenesis mechanism.

PB1110 Functional characterizationof eQTLs and asthma risk loci with scATAC-seq

Authors:

j. wei[1], J. Resztak[1], A. Alazizi[1], H. Mair-Meijers[1], R. Slatcher[2], S. Zilioli[3], X. Wen[4], F. Luca[1,5], R. Pique-Regi[1]; [1]Ctr. for Molecular Med. and Genetics, Wayne State Univ., Detroit, MI, [2]Dept. of Psychology, Univ. of Georgia, Athens, GA, [3]Dept. of Psychology, Wayne State Univ., Detroit, MI, [4]Dept. of Biostatistics, Univ. of Michigan, Ann Arbor, MI, [5]Dept. of Biology, Univ. of Rome "Tor Vergata", Rome, Italy

Cis-regulatory elements (CREs) control gene transcription dynamics in response to the environment. In asthma, multiple immune cell types play an important role in the inflammatory process. Genetic variants in the CREs can also affect gene expression response dynamics and contribute to asthma risk. However, the regulatory mechanisms underlying genetic control of transcriptional dynamics and their contribution to disease remain to be elucidated. Single cell ATAC-seq enables characterization of the genome-wide CREs at the single cell level and provides a unique opportunity to study gene expression regulatory mechanisms across cell-types and environmental contexts, and to annotate regulatory variants. We activated peripheral blood mononuclear cells (PBMC) from 96 children with asthma with phytohemagglutinin (PHA) or lipopolysaccharide (LPS), and treated with anti-inflammatory glucocorticoids (dexamethasone, DEX). We previously studied the transcriptional response with scRNA-seq; we now performed scATAC-seq in 16 individuals for 98,818 cells. Across four major cell-type clusters (B-cell, Monocyte, NK-cell and T-cell) and treatments, we identified 62,424 differentially accessible regions (DARs) (FDR<10%, $|\log_2 FC|>0.5$). Both LPS and PHA preferentially activated monocytes . We analyzed chromatin accessibility genome-wide to measure motif activity and identified 354 response factors with significant motif activity changes. We observed strong positive linear dependence between motif response and their target gene expression changes, but negative in variability changes. This result suggests that an increase of TF binding tightens the variability of gene expression around the mean. We then annotated genetic variants in peaks and in response motifs and performed computational fine-mapping of eQTL signals from a pediatric asthma cohort. We found that eQTLs were highly enriched in peaks with response motifs. Integrating the fine-mapped eQTLs with asthma GWAS, we refined a credible set of 70 risk genes (FDR<10%) supported by both TWAS and colocalization analysis, 33 genes of which had eQTLs in response motifs. In conclusion, scATAC-seq enhances the understanding of molecular mechanisms of individual variants contributing to asthma risk mediated by gene expression.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1111 † Functional dissection of metabolic trait-associated variants in steady state and stimulated human skeletal muscle cells

Authors:

K. Nishino, A. Tovar, J. Kitzman, S. Parker; Univ. of Michigan, Ann Arbor, MI

Type 2 diabetes (T2D) is a common metabolic disorder characterized by dysregulation of glucose metabolism. Genome-wide association studies have defined hundreds of signals associated with T2D and related metabolic traits, most of which are found in noncoding regions. Given their central role in insulin production and glucose homeostasis, much focus has been devoted to investigating T2D-associated genetic variation in pancreatic islets; however, metabolic disease pathogenesis and risk is distributed across other important metabolic tissues, including the liver, adipose, and skeletal muscle. Here, we used a massively parallel reporter assay (MPRA) to characterize the regulatory activity of T2D-associated variants in human skeletal muscle cells at basal and multiple stimulatory states. We constructed a library of 1,255 oligos spanning 333 metabolic trait-associated variants, half of which were previously characterized using luciferase reporters or in MPRA libraries in any metabolic tissue, and therefore serve as positive controls. We delivered this library to LHCN-M2 human skeletal muscle myocytes in one of four conditions: (1) undifferentiated or differentiated with (2) basal media, (3) media supplemented with the AMP analog 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) to mimic physiological effects of exercise or (4) media containing sodium palmitate which is known to induce insulin resistance. Across all oligos, we identified 293 (23.3%) with significant enhancer activity in undifferentiated cells, 128 (10.2%) in basal differentiated cells, 199 (15.9%) in AICAR-stimulated cells, and 276 (22%) in palmitate-stimulated cells (FDR < 0.05). Across all conditions, we identified a shared set of 95 (28.5%) variants with significant allelic activity (FDR < 0.05). Further, we identified several instances of condition-specific allelic bias: 25, 5, 6, and 10 variants in undifferentiated, basal differentiated, AICAR-stimulated, and palmitate-stimulated, respectively. Several of these variants have been previously characterized in skeletal muscle cells or other metabolic tissues; however, none have been studied in these stimulated states. Together, this work identified a set of variants with regulatory activity in skeletal muscle cells and defined conditions in which they are active. We plan to extend these analyses by incorporating existing functional genomic data (e.g., ATAC-seq, ChIP-seq, chromatin state annotations) to explore regulatory features of these variants and better understand their role in regulating disease-relevant gene expression.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1112 Functional evaluation of melanosomal pH regulation and melanin production for *OCA2* variants found in patients with oculocutaneous albinism type 2

Authors:

M. Gillis[1], L. Lundh[1], S. Wincovitch[1], H. Dorward[1], F. X. Donovan[1], NISC Comparative Sequencing Program, V. Gotea[1], L. Elnitski[1], W. S. Oetting[2], W. J. Pavan[1], W. A. Gahl[1], S. K. Loftus[1], D. R. Adams[1]; [1]NIH, Bethesda, MD, [2]Univ. of Minnesota, Minneapolis, MN

Oculocutaneous albinism (OCA) is an autosomal recessive disorder characterized by a reduction of pigment in the hair, skin, and eyes, foveal hypoplasia, optic nerve misrouting, and increased risk of skin cancer. OCA is phenotypically and genetically heterogeneous, with variants identified in *TYR*, *OCA2*, *TYRP1*, *SLC24A5*, *SLC45A2*, *LRMDA*, and *DCT*. *OCA2*, the gene responsible for OCA type 2, encodes a chloride channel on melanosomal membranes critical for maintaining a favorable pH for melanin production. 352 OCA probands were screened using a high-depth, short-read, custom capture sequencing approach, targeting 37 OCA- and pigmentation-related genes. A total of 85 *OCA2* rare variants were identified in 146 probands, including 62 single-nucleotide and small indels, 10 predicted splice, and 13 structural variants. Applying the American College of Medical Genetics framework of Richards et al. (2015) and incorporating *OCA2* specific criteria, we assessed the pathogenicity of *OCA2* variants. This led to 54 (64%) *OCA2* variants being defined as pathogenic or likely pathogenic and 31 (36%) as being of uncertain significance. To assess the pathogenicity of the remaining variants of uncertain significance, we have developed a cell-based functional assay for *OCA2* alleles. Through transfection of human *OCA2* constructs into melan-p5 (murine pink-eyed dilution (*Oca2*$^{p\text{-}J}$/*Oca2*$^{p\text{-}J}$) immortalized mouse melanocytes, we can assess the degree of pigmentation and rescue of melanosomal pH. Variants that demonstrate near wild-type pigmentation and neutralization of pH in melanosomes would be classified as benign, whereas those with minimal pigmentation and highly acidic melanosomes would be pathogenic. This analysis provides a more complete understanding of *OCA2* gene function and thus allows for phenotype-genotype analysis to be performed.

PB1113 Functional genomic analysis of rs73352950: A rare, major depressive disorder (MDD) risk variant in Mexican Americans.

Authors:

S. Kumar[1], J. Curran[2], J. Granados[1], M. Aceves[1], A. Leandro[2], J. Peralta[2], S. Williams-Blangero[2,1], D. Glahn[3,4], J. Blangero[2]; [1]UTRGV, Sch. of Med., McAllen, TX, [2]UTRGV, Sch. of Med., Brownsville, TX, [3]Boston Children s Hosp. & Harvard, Boston, MA, [4]IOL & Yale, Hartford, CT

Major depressive disorder (MDD) is a common and potentially life-threatening disease. Recent genome-wide association studies (GWAS) focusing mainly on common genetic variation and overwhelmingly in individuals of European ancestry have identified several MDD risk loci but there have been no unequivocal (or experimentally validated) causal gene discoveries. Furthermore, while the heritability estimates for MDD and recurrent MDD among Hispanics are similar to those reported in individuals of European ancestry, GWAS in Hispanics reported minimal evidence of overlap with loci previously identified in non-Hispanic whites. GWA analysis in our Genetics of Brain Structure Study (GOBS) of Mexican American families identified a rare non-synonymous variant rs73352950 in the γ-adducin (*ADD3*) gene, which shows a highly significant association (Odds Ratio = 3.88, $p = 3.1x10^{-9}$) with MDD. Follow-up experiments in induced pluripotent stem cell (iPSC) derived neural epithelial/stem cells (NSCs) from 16 individuals who were heterozygous carriers for the identified variant and 13 controls suggest that the variant affects the adherens junctions (AJs) and the overall apical-basal polarity of the NSCs. In monolayer culture, NSCs derived from the variant carriers showed diminished adherens junction (AJ) reassembly indicated by fewer rosette-like structures and defused co-localization of the AJ proteins N-cadherin and γ-adducin in the rosettes. In a 3D neurosphere assay, NSCs of the variant carriers showed significantly higher cell migration ($p = 0.0031$) as a result of higher differentiation and significantly diminished self-renewal capacity. During development and in adult neurogenesis, apical/basal polarity and NOTCH signaling regulates NSC self-renewal and differentiation. Genome-wide gene expression analysis of the same carrier and control NSC samples identified 104 significantly ($p \leq 0.05$ and FC-abs ≥ 1.5) differentially expressed genes, which were significantly enriched in neuron differentiation ($p = 2.9x10^{-7}$), heparan sulfate proteoglycan (HSPG) metabolic process ($p = 3.7x10^{-5}$), visual perception ($p = 1.8x10^{-4}$), and extracellular structure organization ($p = 2.6x10^{-4}$) gene ontology (GO) processes. Interestingly, the NOTCH signaling inhibitor genes *TSPAN15* and *DLK1* were significantly downregulated. HSPGs regulate NSC self-renewal, differentiation, and overall central nervous system homeostasis and several studies have indicated a role for proteoglycans in MDD. Overall, our results show that rs73352950 in *ADD3* affects NSC self-renewal and differentiation capacity and is plausibly associated with MDD risk.

PB1114 † Functional genomics studies in Xenopus can be used to inform clinical interventions in rare genetic diseases

Authors:

D. Baralle[1], A. Godwin[2], S. Ennis[3], S. Martin[4], J. Lord[1], C. Jaramillo-Oquendo[1], T. Fletcher[4], E. Seaby[3], M. Guille[4]; [1]Univ. of Southampton, Faculty of Med., Southampton, United Kingdom, [2]Univ. of Portsmouth, European Xenopus Resource Ctr., Portsmouth, United Kingdom, [3]Univ. of Southampton, Southampton, United Kingdom, [4]Univ. of Portsmouth, Portsmouth, United Kingdom

High throughput, next generation DNA sequencing has revolutionised understanding of human genetic diseases by enabling clinical research to identify causal variants within a gene. For many patients, the link between the gene identified by sequence comparisons and their disease is insufficiently robust for clinical decision making. With the backing of the European *Xenopus* Resource Centre (https://xenopusresource.org/about-us) we have established a UK government funded multidisciplinary team of clinicians, geneticists, bioinformaticians and developmental biologists focused on discovering the genetic and molecular basis of rare diseases in the South of England. Here we report some recent findings arising from this collaboration using the model organism *Xenopus tropicalis* to test genotype-phenotype correlations in syndromic models of dysmorphology, intellectual disability and developmental syndromes. We show how F_0 CRISPR screens in *Xenopus tropicalis* can test the genotype-phenotype correlations of candidate variants of unknown significance and prioritise those suitable for precision modelling. We also compare findings between the F_0 and F_1 CRISPR generations in autosomal dominant disease presentation, demonstrating the creation of stable lines for elucidating the developmental origin of disease, studying cellular or molecular mechanisms in greater detail and screening novel or re-purposed therapeutics. This work includes developing a pipeline to screen phenotypes in these disease models including high-resolution imaging techniques and novel behavioural parameters of working memory, anxiety, and motility in tadpoles, that are comparable to higher vertebrates. To date we have strong evidence for more than 20 novel disease-causing genes, including recently published work supporting the description of novel intellectual disability syndromes (*copb1* and *gria1*). These results not only strengthen disease modelling in *Xenopus* tadpoles but also advance knowledge of human gene function, supporting the goal to both reveal further novel genotype-phenotype associations and strengthen evidence for genotype-phenotype associations within known disease genes.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1115 Functional validation of non-coding GWAS variants in inflammatory bowel disease (IBD) using high-throughput Lenti-MPRA.

Authors:

S. Ghosh[1], C. Espinoza[1], C. Lu[1], F. Rahimov[1], A. Alsheikh[2], A. den Hollander[1]; [1]AbbVie, North Chicago, IL, [2]AbbVie, Cambridge, MA

The functionalization of genetic variants and pinpointing causal genes in disease-associated loci identified by genome wide association studies (GWAS) remain a significant challenge. To identify causal mechanisms behind non-coding variant associations in inflammatory bowel disease (IBD), we implemented a Lentivirus-based massively parallel reporter assay (Lenti-MPRA) to screen for SNPs that disrupt enhancer activity in IBD- associated GWAS loci in colonic epithelial cells. Lentivirus-based MPRA has the advantage of generating 'in-genome' readouts, is a scalable and cost-effective approach and can be executed in difficult-to-transfect cells such as immune cells. In this study, we screened SNPs in the primary human immortalized colon cell line T0570 and colonic epithelial adenocarcinoma cell line Caco2, in presence and absence of IBD stimulation conditions (IFNϒ and TNF-α). We profiled H3K27Ac marks to map colon epithelial enhancers in T0570 and Caco2, and overlayed the enhancer regions with SNPs in LD (> r2 0.6) with top SNPs in IBD-associated GWAS loci. This approach led to a selection of 226 IBD colon epithelial specific GWAS SNPs, in addition we screened 45 SNPs from the *TNRC18* locus identified as the strongest IBD-associated locus in the Finnish population (FinnGen), along with 56 positive controls and 79 negative controls. Among the 226 IBD SNPs we identified 22 SNPs in Caco2 and 29 SNPs in T0570 with strong allele-specific enhancer activity (FDR < 0.001). Several SNPs with the strongest effects are in introns of genes previously implicated in IBD, such as *ERRFI1* (rs34768550) and *CARD9* (rs 4078099). We also narrowed down the functional (causal) SNPs in the FinnGen *TNRC18* locus to rs79032618 and rs182361057, which overlap with enhancers between the *WIPI2* and S*LC29A4* genes. In conclusion, this study identified functional variants in IBD GWAS loci, and reinforces Lenti-MPRA platform as a solid framework for prioritization of non-coding GWAS variants.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1116 Functional validation of variants in cardiac troponin T using stem cell-derived cardiac muscle bundles.

Authors:

A. Renberg, O. Merritt, B. Elder, S. Friedline, J. Meisner, E. Smith, Y-C. Tsan, A. Helms; Univ. of Michigan, Ann Arbor, MI

Hypertrophic cardiomyopathy (HCM) is a heart muscle disorder most often caused by variants in sarcomere genes, including cardiac troponin T (*TNNT2).* However, variant interpretation is a major hurdle in ascribing pathogenicity of rare variants in *TNNT2* and other sarcomere genes. Functional testing with induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs) may improve variant interpretation but has been limited by throughput and reproducibility. We hypothesized that high throughput contractile analysis of aligned, two-dimensional, micropatterned cardiac muscle bundles generated from iPSC-CMs (CMBs) could be used to functionally adjudicate pathogenicity of *TNNT2* variants. To test this hypothesis, we selected two *TNNT2* variants from the Sarcomeric Human Cardiomyopathy Registry (SHaRe). The *TNNT2* variant R286C is associated with highly-penetrant, severe HCM, while the R278C variant has been classified as a variant of unknown significance but is associated with low penetrance HCM (odds ratio for SHaRE vs general population, 9.9 [95% CI 6.9, 14.1]). These two variants and WT (control) *TNNT2* were cloned into lentiviral vectors. IPSC-CMs were transduced and selected (puromycin) to attain >95% replacement of endogenous *TNNT2*. These iPSC-CMs were then replated onto 8 kPA silicone polymer substrates micropatterned with human fibronectin to generate CMBs. CMBs were imaged using live cell microscopy at two calcium concentrations, and contractile analyses were performed. R278C CMBs exhibited increased maximal fractional shortening vs WT and R286C (5.1±1.5% vs 6.9±1.4% and 6.1±1.4%, $p<0.002$). R286C CMBs exhibited reduced relaxation velocity compared to both R278C and WT (3.5±0.7µm/sec vs 4.3±0.97µm/sec and 4.5±0.97µm/sec, $p<0.002$). The relaxation velocity of R278C increased less than WT when exposed to increased calcium (high/low 1.2±0.3 vs 1.5±0.5, $p<0.01$). R286C had no significant difference in increased relaxation velocity with higher calcium concentration compared to WT or R278C (high/low 1.3±0.4 vs 1.5±0.5 and 1.2±0.3, $p>0.5$). These data demonstrate that contractile analysis of iPSC-derived CMBs can be used to detect phenotypic differences due to cardiomyopathy causing variants. Additionally, different variants may cause distinct effects on contractile and relaxation parameters, as we found in the case of a strongly penetrant *TNNT2* variant (R286C) more profoundly affecting relaxation velocity than a lower penetrance variant (R278C). These findings have implications for future systematic use of functional testing to adjudicate pathogenicity of potential cardiomyopathy associated variants.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1117 Gene Expression Predictions from Enformer Show Improved Patterns of Cross-population Portability over Existing Methods

Authors:

S. Gona[1], T. Adeluwa[2], B. Liu[3], R. Madduri[4], H. Im[1]; [1]Univ. of Chicago, Chicago, IL, [2]The Univ. of Chicago, Chicago, IL, [3]Natl. Univ. of Singapore, Singapore, Singapore, [4]Argonne Natl. Lab., Naperville, IL

Advances in prediction of disease risk based on genetics is clinically promising, but the poor portability of current population-based prediction models to non-European populations is a major health equity issue.Notably, much of the intuition of what drives poor portability in existing population-based models doesn't apply to alternative modeling strategies. Enformer, a deep learning model investigated here, is an example of an alternative strategy. Enformer is trained using information across a single genome, rather than across individuals in a population as is typical of current models. As poor portability in polygenic score models stems from cross-population genetic variation patterns such as linkage disequilibrium, it stands to reason that single genome deep learning models could show better portability. Still, no systematic examination has been done to confirm this.Addressing this gap, we examined portability of Enformer gene expression predictions between EUR and AFR ancestries on 448 individuals from the GEUVADIS cohort. We compared these results with the existing expression European population-based prediction method, PrediXcan. We first examined Enformer performance on a set of genes (n=3387) for which confident PrediXcan results can be obtained. We found that PrediXcan has higher overall personalized prediction accuracy in both EUR and AFR than Enformer with a mean R2 of 0.035 against mean R2 of 0.015 for Enformer across all genes (including lowly-heritable genes). This is expected since PrediXcan models are trained to maximize cross-individual correlation over hundreds of individuals, whereas Enformer has no cross-individual training. In terms of portability, defined as the log2 ratio of performance in AFR samples versus EUR samples, Enformer predictions appear less susceptible to European bias. Genes in the upper 50th percentile of prediction accuracy for PrediXcan, which represent the bulk of significantly heritable genes, show mean portability of -0.39 and -0.068 in PrediXcan and Enformer respectively.The difference in portability suggests that population-agnostic training strategies such as that used for Enformer can be used to improve prediction portability to non-European populations.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1118 Genetic analysis of HLA polymorphism in tribal and non-tribal populations of Maharashtra, India: A pilot study.

Authors:

P. Mahajan[1], S. Das[2], K. V. Somasundaram[3]; [1]Drake Univ. Coll. of Pharmacy & HS, Des Moines, IA, [2]Ctr. for Biotechnology, Pravara Inst. of Med. Sci., Loni, Maharashtra State, India, [3]Sch. of Publ. Hlth.and Social Med., Pravara Inst. of Med. Sci., Loni, Maharashtra State, India

Our long-term objective is to understand the effects of genomic diversity on the health of different subpopulations in India. Currently we are focusing on employing genomic analysis for reducing adverse drug reactions (ADRs). Recent reports have documented incidence of Steven Johnson Syndrome (SJS)/toxic epidermal necrosis (TEN) in India is ranging between 3%-19.5%. Therefore, we investigated utility of a simple, low-cost genotyping method for HLA-A*31:01, a marker for carbamazepine induced SJS/TEN in the gene-rich HLA locus of human genome. Using the Amplicon Fragment Length Polymorphisms (AFLP) assay we assessed genetic diversity of HLA-A*31:01 in the populations served by the Pravara Institute of Medical Sciences Hospital Loni, India. One hundred family trios (300 individuals) from indigenous tribes (Mahadev Koli and Thakar) as well as non-tribal population from the Bhandardhara region of the Akole Tribal Block of Maharashtra were tested in this study. Primers specific for HLA-A*31:01 were used to amplify a 662 basepair fragment from individual genomic DNA samples and subjected to restriction digestion by BtsCI. Our results confirm utility of the AFLP genotyping assay as a rapid and relatively inexpensive method than the conventional HLA typing for identifying patient risk of carbamazepine related SJS/TEN. Interestingly, only 217 out of the total 300 or roughly 72% samples produced the expected 662bp amplicon. Moreover, only three of the 204 amplicons analyzed exhibited the expected restriction pattern in the BtsCI assay. Using beta globin primers as internal control, we confirmed that lack of amplification of HLA-A*31:01 in ~28% of samples was not due to the presence of some unknown PCR inhibitor in these samples nor a technical failure. Our preliminary results confirm utility of the simple AFLP assay for HLA-A*31:01 genotyping. However, our data strongly indicate substantial heterogeneity even at this single biomarker within the HLA locus in the study populations. Further in-depth studies including complete sequencing of the HLA Locus from the study population are needed to fully understand genetic implications of the potential heterogeneity to individualized medicine.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1119 Genetic and Functional Activity Analyses of *ADA2* in Patients with Deficiency of Adenosine Deaminase 2.

Authors:

E. Everest[1], M. Ozkilinc Onen[1], T. Demirci[1], A. Timucin[2], S. Sahin[3], O. Kasapcopur[3], E. Tahir Turanli[2]; [1]Istanbul Technical Univ., Faculty of Sci. and Letters, Dept. of Molecular Biology and Genetics, Istanbul, Turkey, [2]Acibadem Univ., Faculty of Engineering and Natural Sci., Dept. of Molecular Biology and Genetics, Istanbul, Turkey, [3]Istanbul Univ.-Cerrahpasa, Cerrahpasa Med. Faculty, Dept. of Pediatric Rheumatology, Istanbul, Turkey

Deficiency of Adenosine Deaminase Type 2 (DADA2) is an autosomal recessive autoinflammatory disease caused by biallelic mutations in the *ADA2* gene. Here, we analyzed *ADA2* mutations in six patients with DADA2 and measured the total adenosine deaminase (ADA) activity in the peripheral blood mononuclear cells of eight patients, including those six, and five healthy controls using an ADA Activity Assay Kit (Abcam, ab212093). Additionally, we conducted a computational study involving stability analyses, 100 ns molecular dynamics simulations, and molecular mechanics Poisson-Boltzmann Surface Area analyses. Three patients had the homozygous p.G47R variant, two patients had the compound-heterozygous p.G47R/p.G321E variant, and one patient had a novel homozygous variant (c.467C>T) in the *ADA2* gene. Total ADA activity was significantly lower in patients than in healthy controls (p=0.0009). Moreover, ADA activity was significantly lower in patients possessing compound-heterozygous p.G47R/G321E than in patients with homozygous p.G47R (p=0.004). It was previously shown that dimerization of the ADA2 protein is essential for its catalytic activity and secretion and that p.G47R in the dimerization domain affects the stability of the homodimer. Our computational analysis investigating the combined impact of p.G47R and p.G321E on the catalytic activity of ADA2 showed that these mutations, particularly in their compound heterozygous form, can interfere with dimerization of ADA2. Altogether, these results suggest that the p.G321E variant in *ADA2* plays an important role in the catalytic activity of ADA2.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1120 Genetic determinants of metabolic profiles of multiple dietary patterns and type 2 diabetes risk

Authors:

H. Yun[1], J. Hu[1], V. Sarsani[2], Z. Wang[1], F. Wang[1], O. Zeleznik[3], A. Eliassen[3], F. Hu[1], L. Liang[2], J. Li[4]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., BOSTON, MA, [2]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [3]Channing Div. of Network Med., Dept. of Med., Brigham and Women's Hosp. and Harvard Med. Sch., BOSTON, MA, [4]Brigham & Women s Hosp., Harvard Med. Sch., Boston, MA

Healthy dietary patterns are critical for type 2 diabetes (T2D) prevention, but individuals may respond differently to the same diet. Circulating metabolites may capture dynamics in metabolic homeostasis as a result of combined effects of dietary intakes and other risk factors. In prior studies examining 6 well-established dietary patterns (including a Mediterranean diet [AMED], alternate healthy eating index [AHEI], an anti-hypertensive diet [DASH], and 3 plant-based dietary indices [PDIs]), we identified a metabolomic signature (MS) that robustly assessed the adherence to each of the 6 dietary pattern and predicted T2D risk. However, a large proportion of variation in the MS cannot be fully explained by dietary intakes. Here, given the role of genetics in modulating dietary metabolism, we performed genome-wide association studies for the 6 MS among 6669 participants in the Nurses' Heath Studies and Health Professionals Follow-up Study. Genetic variants explained an average of 26.5% (h^2 =16.5-34.5%) of the total variance in the MS ($P < 0.05$). We identified 7 loci associated with the MS; these include, *FADS1/2* (encode the fatty acid desaturase; $P < 3.0\times10^{-11}$) associated with all dietary patterns, *ALMS1* and *ALMS1P1* (involve in microtubule/cilia function that are vital in energy metabolism; $P < 3.4\times10^{-14}$) associated with five dietary patterns, *CERS4* (involve in ceramide synthesis, $P = 1.4\times10^{-15}$) associated with plant-based diet, and *SLCO1A2*, *SLCO1A2B1*, *DGCR5* ($P < 2.8\times10^{-8}$). Lead variants on *FADS1/2*, *ALMS1/ALMS1P1*, and *CERS4* were significantly associated with expressions of the encoded genes in tissues relevant to glucose/insulin response (e.g., pancreas, liver, muscle, and adipose) and endocrine regulation (e.g., hypothalamus, thyroid, and pituitary) (all $P < 2.7\times10^{-5}$). Genome-wide gene-diet interaction analysis revealed a locus, *OLFM4* (involved in color mucosal defense), only influencing MS through interacting with AHEI ($P = 1.9\times10^{-8}$). Leveraging a recent large-scale GWAS for T2D (80154 cases and 853816 controls), a two-sample mendelian randomization analysis showed that, the genetically predicted MS of 4 dietary patterns (i.e., AMED, AHEI, PDI, and unhealthy PDI) were associated with 8-11% difference in T2D risk (adjusted $P < 0.05$). In summary, the MS of dietary patterns may reflect the combined effects of both dietary intakes and metabolic responses determined by genetics, and potentially point to causal metabolic pathways related to T2D pathophysiology. Multi-omics profiling could identify biological factors affecting individual dietary metabolism and inform personalized nutritional strategies for effective diabetes prevention.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1121 Genetic determinants of the human plasma proteome in a Chinese population reveal substantial ancestry diversity and identify new drug development opportunities

Authors:

S. Said[1], A. Pozarickij[1], S. Morris[1], C. Kartsonaki[1], L. Liming[2], R. Clarke[1], I. Y. Millwood[1], Z. Chen[1], R. G. Walters[1], China Kadoorie Biobank Collaborative Group; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Peking Univ., Peking, China

The proteome is fundamental to understanding human biology and disease. Genetic association analyses of plasma levels of 1,451 proteins in 3,974 Chinese adults were conducted and compared with the corresponding analysis in adults of European ancestry. In Chinese, we identified pQTLs for 1,081 proteins, of which 743 (69%) had at least one *cis*-pQTL. Fine-mapping defined credible sets for 3,343 independent signals, of which 25% had no overlap with pQTL signals identified for the same proteins in Europeans. We further assessed 741 *cis*-pQTLs in phenome-wide Mendelian randomization analyses and identified significant associations for 199 protein-phenotype pairs. Out of the 37 identified pQTL-disease pairs, 13 derived from East Asian-specific analyses. Evaluation of current drug development highlighted opportunities for repurposing of 13 drugs either under trial or already approved, and for exploration of 19 potential drug targets. These findings emphasise the importance of extending genome-wide plasma proteomic analyses to non-European ancestry populations, for identification of potential novel biomarkers and drug targets for major diseases.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1122 Genetic effects on chromatin accessibility and nucleosome positioning using snATAC data across 281 skeletal muscle biopsies.

Authors:

X. Wang[1], C. C. Robertson[1,2], A. Varshney[1], N. Manickam[1], P. Orchard[1], M. Laakso[3,4], J. Tuomilehto[5], T. A. Lakka[3], K. L. Mohlke[6], M. Boehnke[7], L. Scott[7], H. A. Koistinen[5], F. S. Collins[2], S. C. J. Parker[1,7,8]; [1]Dept. of Computational Med. and Bioinformatics, Univ. of Michigan, Ann Arbor, MI, [2]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [3]Inst. of Clinical Med., Internal Med., Univ of Eastern Finland, Kuopio, Finland, [4]Dept. of Med., Kuopio Univ Hosp., Kuopio, Finland, [5]Dept. of Publ. Hlth.and Welfare, Finnish Inst for Hlth.and Welfare, Helsinki, Finland, [6]Dept. of Genetics, Univ North Carolina, Chapel Hill, NC, [7]Dept. of Biostatistics and Ctr. for Statistical Genetics, Univ. of Michigan, Ann Arbor, MI, [8]Dept. of Human Genetics, Univ. of Michigan, Ann Arbor, MI

Insulin resistance in skeletal muscle is a central process contributing to type 2 diabetes (T2D) and related metabolic traits. Among 13 cell types we identified in single-nucleus RNA (snRNA) and ATAC (snATAC) data from skeletal muscle, type 1 muscle fiber was the most abundant. Studying genetic variants that affect chromatin accessibility and nucleosome positioning in type 1 muscle fiber can provide mechanistic insights at GWAS signals for T2D and related traits, and allow for causal inference of local chromatin dynamics (e.g., which transcription factors (TFs) causally position nucleosomes?). We profiled the chromatin landscape using snATAC of muscle from 281 individuals from the FUSION project and focused our analyses on type 1 fibers. We used two methods to infer nucleosome free regions (NFR), which represent TF-occupied regions, and nucleosomal positioning, which represents nucleosomal phasing that may be induced by a primary TF-binding event. Using a hidden Markov model (HMMRATAC), we inferred NFR (N=44,763 peaks) and their adjacent nucleosomal chromatin regions (N=89,526 peaks). Using the NucleoATAC method, which used the 2D fingerprint from the ATAC data to generate nucleosome maps, we found corresponding NFR (N=66,041 peaks) and nucleosomal positions (N=239,944 peaks). For each of the samples, we used Multi-Otsu statistical thresholding to categorize whether the ATAC reads originated from nucleosome-free or nucleosome-bound fragments. Subsequently, we utilized the reads from nucleosome-free fragments to create the NFR count matrix, and we used the reads originating from nucleosome-bound fragments to build the nucleosomal count matrix. Using QTLtools, we performed a cis-QTL analysis (cis window of 10kb) on both NFR (nfrQTL) and nucleosome positioning (nucQTL). From HMMRATAC, we identified 12,819 nfrQTLs and 6,544 nucQTLs at 5% FDR. Through the NucleoATAC method, we identified 14,417 nfrQTLs and 19,265 nucQTLs. We observed significant enrichment in both the nfrQTL HMMRATAC (ln-enrichment=2.03, CI=[0.967, 2.70]) and NucleoATAC (ln-enrichment=3.30, CI=[2.59, 3.83]) predicted NFR peaks when analyzing with T2D GWAS summary statistics. We are now performing formal colocalization analyses to assess whether the nfrQTLs and the nucQTLs are driven by the same variant or if nfrQTLs mediate the nucQTLs. Meanwhile, we will investigate the overlapping nfrQTL and nucQTL signals with T2D GWAS signals to nominate locus-specific chromatin mechanisms. Overall, these analyses provide us with a deeper understanding of regulatory mechanisms underlying T2D genetic risk in skeletal muscle, which could inform T2D diagnosis and treatment in the future.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1123 Genetic epistasis between *RET* and *ELP1* explains gastrointestinal motility dysfunction in Familial Dysautonomia patients.

Authors:

S. Chatterjee[1], M. Chaverra[2], F. Lefcort[2]; [1]NYU Sch. of Med., New York, NY, [2]Montana State Univ., Bozeman, MT

Familial dysautonomia (FD) is a rare disorder in the Ashkenazi-Jewish population that is characterized by developmental failure of the autonomic nervous systems; key phenotypes include cardiovascular instability, autonomic crises and gastrointestinal motility (GI) dysfunction. Almost all cases are due to a founder point mutation in the *ELP1* gene though the phenotypic diversity points to the presence of undiscovered modifier alleles. Pathology studies have revealed a severe reduction of enteric neurons in FD patients, raising the possibility that there is an overlap between the mechanisms leading to GI motility dysfunction in FD and a genetically distinct disorder, Hirschsprung disease (HSCR). HSCR is a developmental disorder marked by aganglionosis of the GI tract resulting from the proliferative failure of the enteric nervous system (ENS). HSCR is associated with pathogenic variants in 24 genes comprising a gene regulatory network (GRN) controlling the development of the ENS, but ~50% of patients contain pathogenic variants in the gene *RET*. Studies in HSCR families have demonstrated linkage to the *ELP1* locus, along with coding variants in *RET* providing evidence of genetic interaction between the 2 genes. To tease apart the cellular changes in the ENS in FD and HSCR, we created knockout mouse models of *Elp1* and *Ret* followed by single cell RNA-seq in E14.5 embryonic gut. We show that both *Ret* and *Elp1* deficiency leads to significant loss of inhibitory motor neurons driven by proliferative defects in these cells marked by loss of expression of DNA replication (*Pcna*, *Mcm3*), and cell cycle regulation (*Rgcc*, *Mad2l1*) genes. Other major neuronal and glial cells are largely unaffected. There are 131 common transcriptionally affected genes in both disease models among them 52 transcription factors including *Sox10* a ENS regulator. To recapitulate the effects in human cells, we independently knocked out *ELP1* and *RET* in the neuroblastoma cells SK-N-SH using CRISPR/Cas9 followed by RNA-seq. *ELP1* heterozygous cells have 20% and 15% reduction of *RET* and *SOX10* expression (both $p \leq 0.01$) along with expression changes in multiple ENS expressed genes. Conversely, *RET* heterozygous cells show a 50% ($p=1.8\times10^{-3}$) reduction in *ELP1* expression along with significant ($p \leq 0.01$) drop in expression of *SOX10* (80%) and *EDNRB* (25%) another HSCR gene, along with multiple ENS genes. These mutant cells also display significant proliferative defects measured by WST1 assay. This work provides a conceptual framework for the discovery of modifier genes with functional roles in rare diseases whose individual mutational burden might not cross statistical threshold in genome scale sequencing studies.

PB1124 † Genetic insights into causal genes and directionality through large-scale colocalization of metabolite and protein QTLs

Authors:

J. Chiou[1], X. Yin[2], B. Ryan[3], M. Laakso[4], X. Wen[3], M. Boehnke[3], E. Fauman[1]; [1]Pfizer, Cambridge, MA, [2]Nanjing Med. Univ., Nanjing, China, [3]Univ. of Michigan, Ann Arbor, MI, [4]Univ. of Eastern Finland, Kuopio, Finland

Translating findings from large-scale studies of molecular QTLs into biological insight is challenging because it requires a thorough understanding of genetic mechanisms, including the causal genes and their direction of effect. The intersection of metabolite QTLs (metabQTLs) and protein QTLs (pQTLs) provides a unique opportunity to interrogate metabolite genetic mechanisms at scale because metabolite regulation is intrinsically rooted in biochemistry, enabling direct comparisons between proteins encoding enzymes and their metabolic substrates and products. To systematically identify shared genetic signals for metabQTLs and pQTLs, we first applied fine-mapping methods (SuSiE and DAP-G) to detect 4,486 conditionally independent signals for 1,391 metabolites assayed in plasma from 10k Finnish METSIM cohort individuals and 44,749 signals for 2,682 proteins assayed in plasma from 35k European UK biobank participants. We performed colocalization tests with coloc for 441,431 pairs of metabQTL and pQTL signals and identified 75,106 colocalized pairs at $PP_{H4} > 0.8$ and $r^2 > 0.6$ between lead variants, nearly all of which involved *trans* pQTLs. Of all colocalized pairs, 76.2% (57,208) were also found using fastENLOC (LCP > 0.5). For 459 colocalized pairs involving *cis* pQTLs, we compared the observed directionality from pQTLs with predicted directionality based on expert knowledge in biochemistry. In a blinded analysis, the predicted biochemical and observed pQTL directionality were concordant for 82% (189/231) of pairs involving *cis* pQTLs where the metabolite was predicted as a substrate or product. For example, decreased CDA protein levels were also associated with increased 2'-O-methycytidine (substrate) and decreased uridine (product) levels, concordant with the biochemical activity of CDA as a cytidine deaminase. Across 29 pairs of proteins and metabolites with multiple independent colocalized *cis* signals, 26 were directionally consistent across all signals. As a novel example, decreased MRI1 protein levels were consistently associated with increased levels of an uncharacterized metabolite (X-12411) across 5 independent signals. The observed directionality, combined with the known function of MRI1, suggested X-12411 was likely a substrate similar to methylthioribose-1-phosphate. We are currently conducting additional analyses to map the causal genes and directionality for colocalized pairs involving *trans* pQTLs. In sum, our results reveal genetic mechanisms for hundreds of metabolites, and more broadly, how genetics can be used in combination with biochemistry to uncover novel findings.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1125 Genetic susceptibility to inflammatory bowel disease impacts on epithelial barrier integrity.

Authors:

I. Hébert-Milette[1,2], C. Lévesque[2], J. Paquette[2], M-È. Rivard[2], P. Goyette[2], G. Charron[2], J. Rioux[2,1]; [1]Université de Montréal, Montréal, QC, Canada, [2]Montreal Heart Inst., Montreal, QC, Canada

Introduction: Intestinal permeability is increased in unaffected 1st degree relatives of patients with inflammatory bowel disease (IBD), and is considered a risk factor for the development of IBD, likely increasing the interactions between intestinal microorganisms and the immune system. We recently reported that *C1ORF106*, a gene located within a genomic region associated with IBD, regulates epithelial permeability. We further demonstrated that a rare coding variant within *C1ORF106* (p.Y333F) decreases protein stability and that lower levels of C1ORF106 protein leads to altered stability of adherens junctions and to an increase in intestinal epithelial permeability.
Hypothesis: In addition to altering adherens junctions, we believe that C1ORF106 is also involved in the regulation of tight junction (TJ) formation, which impacts on epithelial permeability and cell polarity establishment.
Objectives: The objectives of the project were to (a) validate the impact of C1ORF106 on TJ formation and cell polarity establishment and (b) verify the impact of *C1ORF106* IBD-associated variants on intestinal barrier integrity.
Results: We observed that knocking down the expression of *C1ORF106* in Caco-2 cells leads to a number of phenotypes in human epithelial monolayer (2D) and spheroid (3D) cultures that are associated with alterations in TJs. Specifically, when studying the dynamic reformation of TJs in 2D cultures after transient withdrawal of calcium, which is required for TJ stability, we observed that lower levels of *C1ORF106* resulted in (1) decreased recovery of barrier function as measured by transepithelial electrical resistance (TEER) and (2) an alteration of TJ protein localization. Moreover, in 3D cultures, we observed an altered spheroid formation associated with an impaired epithelial cell polarization. We also observed an impaired spheroid permeability suggesting an altered TJ function. In addition, our studies in human induced pluripotent stem cell-derived epithelial cultures support that Y333F heterozygotes also have an altered spheroid formation.
Conclusion: Our observations indicate an important role of C1ORF106 in epithelial barrier integrity through the regulation of TJ formation and of cell polarity establishment. TJ formation is important for epithelial repair after an injury and its dysregulation impairs the formation of an impermeable epithelial barrier, which likely facilitates the passage of microorganisms and the induction and maintenance of intestinal inflammation.

PB1126 Genetic variants associated with within-individual gene expression dispersion at single-cell resolution reveal a new mechanism of genome regulation

Authors:

A. Xue[1,2], S. Yazar[1], J. Alquicira-Hernandez[1,3], A. Cuomo[1,4], J. Powell[1,5]; [1]Garvan-Weizmann Ctr. for Cellular Genomics, Garvan Inst. of Med. Res., Sydney, Australia, [2]Sch. of BioMed. Sci., Univ. of New South Wales, Sydney, Australia, [3]Inst. for Molecular BioSci., The Univ. of Queensland, Brisbane, Australia, [4]Ctr. for Population Genomics, Garvan Inst. of Med. Res., Sydney, Australia, [5]UNSW Cellular Genomics Futures Inst., Univ. of New South Wales, Sydney, Australia

The expression levels of a gene can vary substantially across cells, even when they are the same cell type. Understanding the relationship between genetic variation and gene expression is vital to dissecting mechanisms of genome regulation. However, the genetic control of gene expression variability among the cells within individuals has yet to be extensively examined, primarily due to limited samples and statistical challenges such as adjusting mean-variance dependence. Here, we present a genome-wide association analysis to identify genetic variants associated with the intra-individual variation of single-cell gene expression (intra-veQTLs). Using single-cell RNA-seq data of ~1.2 million peripheral blood mononuclear cells from ~1,000 human donors (OneK1K cohort), we identified 14 ~ 3,488 genes (referred to as vGenes) with significant intra-veQTLs (q-value < 0.05) across different blood cell types, 2,103 of which were shared across more than one cell type. We further detected 55 intra-veQTLs (in 34 unique genes) showing significant association with intra-individual dispersion (intra-deQTLs) regardless of the mean-variance dependence, and these dGenes were enriched in the biological process relevant to immune response and viral infection. We highlight the SNP rs1131017, a significant intra-deQTL in the 5'UTR of *RPS26*, which shows a consistent direction of dispersion effect in all 14 cell types and higher intra-individual dispersion level is associated with lower auto-immune disease risk, including rheumatoid arthritis and type 1 diabetes. Our study demonstrates an efficient and robust statistical method to identify genetic variants associated with gene expression variability and how these associations and their involved pathways confer auto-immune disease risks. This is also the first time that genetic effects on the gene expression dispersion level across single cells were identified. We anticipate our analytical framework will open a new gate to unravelling the genetic regulation of gene expression at the single-cell resolution, thereby advancing our understanding of complex biological processes.

PB1127 Genetic variation in a distal enhancer modifies cardiac transcription factor HAND2 expression and function

Authors:

N. Xie[1], Y. Feng[1], S. Tishkoff[1,2,3]; [1]Dept. of Genetics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [2]Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA, [3]Ctr. for Global Genomics and Hlth.Equity, Univ. of Pennsylvania, Philadelphia, PA

Genome-wide association studies (GWAS) have identified a large number of genetic variants that are associated with increased risk of cardiovascular disease. However, the mechanism by which these variants contribute to disease risk is not well understood. Expression of cardiac genes is under the regulatory control of distal enhancers, and genetic variation in enhancers may modulate their activity. To investigate the functional impacts of genetic variants associated with cardiovascular diseases, we overlapped genetic variants from published GWAS datasets with genomic regions predicted to be functional regulatory regions, based on human heart-derived DNase-seq, ATAC-seq, and ChIP-seq data for the cardiac transcription factors GATA4, TBX5, and NKX2.5. Intersection of these data sets identified GWAS variants located within predicated enhancer regions close to genes important for heart development. Specifically, we identify a variant located in a predicted heart-specific enhancer of the HAND2 (heart and neural crest derivatives expressed 2) gene, a key transcription factor for cardiac morphogenesis. This variant is located 100 kb upstream of HAND2 gene and is associated with atrial fibrillation. Using a luciferase reporter assay, we found this predicted enhancer displayed significant regulatory activity in human cardiomyocytes derived from embryonic stem cells. Moreover, the variant markedly reduced enhancer activity, indicating its essential role in modulating enhancer function in cardiomyocytes. CRISPR gene editing to inhibit or remove the enhancer that harbors this variant markedly reduced HAND2 expression in human cardiomyocytes. We are further investigating the effect of this variant on cellular function and cardiac development. This study demonstrates an integrated approach for identifying functionally important variants that may play a role in cardiovascular disease. Funded by NIH grant 1U01HG012047-01, 1R35GM134957, R01AR076241, and ADA 1-19-VSN-02.

Ctr., Helsinki Inst. of Life Sci., Univ. of Helsinki, Helsinki, Finland, [8]Dept. of Surgery, Massachusetts Gen. Hosp., Boston, MA

Schizophrenia (SCZ) is a severe psychiatric disorder with hundreds of genetic variants contributing to its risk across the allele frequency spectrum. The Schizophrenia Exome Sequencing Meta-Analysis (SCHEMA) study recently reported 32 rare variant SCZ risk genes at a 5% false discovery rate and highlighted overlapping genetic signals between SCZ and other neurodevelopmental disorders. Characterizing the functional roles and pathways of the high-confidence SCHEMA genes in relevant cell types of the human brain could elucidate the connections between these disorders and facilitate development of effective treatments and therapeutics. Therefore, we performed interaction proteomics for 14 SCHEMA genes in human iPSC-derived neural progenitor cells (NPCs) and excitatory neurons (ExNs). The resulting protein-protein interaction (PPI) networks contain ~89% newly reported PPIs, reflect cell-type-specific biology in NPCs vs. ExNs, and are the convergence point for genetic, transcriptomic, and proteomic perturbations associated with SCZ. In terms of genetics, both the NPC-specific and ExN-specific networks are enriched for rare variant risks of developmental and autism spectrum disorders, while only the ExN-specific networks are enriched for rare variant risk of schizophrenia. In terms of transcriptomics, the ExN-specific networks are enriched for differentially expressed genes identified in superficial and deep layer cortical neurons of individuals with SCZ vs. controls. To assess whether this type of convergence is also present at the proteomic level, we performed proteomic profiling of iPSC-derived neurons from 22q11.2 deletion carriers with SCZ diagnosis vs. controls. Strikingly, several ExN-specific networks that were down-regulated at the RNA level in postmortem brains of SCZ individuals with varied genotypes were also down-regulated at the protein level in iPSC-derived neurons from SCZ individuals carrying the 22q11.2 deletion. Overall, our findings recapitulate the known genetic correlations between SCZ and neurodevelopmental disorders using cell-type-specific PPI data, implicate the ExN-specific networks as a convergent point that concentrates both transcriptional and translational dysregulation in SCZ, and prioritize numerous genes and interactions in these networks for further functional investigation of SCZ-related biology.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1129 Genetically predicted efficacy and safety profiles of anticoagulant targets.

Authors:

E. Gagnon; Unversité Laval, Quebec, QC, Canada

Introduction. Anticoagulant therapies allow prevention of life-threatening thrombosis at the expense of increased bleeding risk. Optimal anticoagulant targets must be safe (cause low bleeding risk) and efficacious (prevent thrombosis risk). **Objective.** To prioritize coagulation cascade proteins with the most favourable efficacy and safety profiles using Mendelian randomization. **Methods**. We investigated the association of genetically predicted reductions of 27 coagulation factors levels with risk of venous thromboembolism, cardioembolic and ischemic stroke, bleeding outcomes, and lifespan. We leveraged genetic data from three blood proteins genome-wide association study (GWAS) datasets and performed Mendelian randomization and genetic colocalization. We also include bulk RNA sequencing data from explanted liver samples obtained from 246 participants of the IUCPQ Obesity Biobank and GWAS summary statistics on 1589 diseases (>1000 disease cases) from FinnGen. **Results.** We found converging evidence that thrombin and Factor 11 (FXI) had the most optimal efficacy versus safety profiles. Thrombin triggers FXI activation which ultimately promotes coagulation. Thrombin inhibition was more efficacious to prevent venous thromboembolism than FXI inhibition (odds ratio per 1 standard deviation (SD) lower blood protein: 0.45 95% CI=0.38-0.54, p=1.9e-19 for thrombin vs. 0.67 95% CI=0.61-0.73, p=3.4e-19 for F11). Thrombin inhibition was also mor efficacious to prevent cardioembolic stroke than FXI inhibition (0.58 95% CI=0.50-0.68, p=3.2e-12 for thrombin vs. 0.81 95% CI=0.77-0.85, p=2.5e-17 for FX1). However, thrombin inhibition increased bleeding risk (1.09 95% CI=1.00-1.17, p=4.1e-02), whereas FXI inhibition did not (1.00 95% CI=0.97-1.02, p=7.8e-01). To further assess thrombin and FXI inhibition safety, we performed a phenom-wide Mendelian randomization on the effect of genetically predicted thrombin and FXI on 1,589 diseases in the FinnGen cohort. Thrombin and FXI genetic inhibition appeared to be overall safe. Both proteins are specifically expressed in the liver and are then secreted in the bloodstream. We found that hepatic gene expression was causally associated with thrombotic diseases but had lower effect than blood protein levels. **Conclusions.** Thrombin inhibitors are already being used for prophylaxis and treatment of venous thromboembolism and acute coronary syndrome. Phase 3 trials investigating the health effects of FXI inhibition are underway. This Mendelian randomization study supports thrombin and FXI inhibition as efficacious and safe therapeutic targets.

PB1130 Genetics of Long QT Syndrome: iPSC-Derived Cardiomyocyte Approach

Authors:

A. Shen, D. W. Mitchell, B. Kroncke; Vanderbilt Univ. Med. Ctr., Nashville, TN

Long QT syndrome (LQTS) is associated with sudden unexplained death in young populations. LQTS is an inherited heart arrhythmia syndrome characterized by a prolonged corrected QT interval on an electrocardiogram. Individuals with LQTS are at high risk for life-threatening arrhythmia torsades de pointes. Although LQTS is responsible for a significant proportion of sudden unexplained deaths in the young and sudden infant death syndrome cases, its genetic basis and underlying mechanisms remain poorly understood. LQTS often presents with incomplete penetrance and variable expressivity, indicating a complex interplay of monogenic and polygenic factors. This study aims to generate human induced pluripotent stem cell-derived cardiomyocytes from individuals with extreme polygenic liability for QT interval duration to gain insights into the mechanisms underlying QT variability and the interaction between polygenic and monogenic variation in driving LQTS. To address the challenge of incomplete penetrance and heterogeneous expressivity, we investigated iPSC lines derived from individuals with LQTS liabilities significantly deviating from the mean (3+ standard deviations). We collected and reprogrammed peripheral blood mononuclear cells (PBMCs) from these patients into iPSCs. Specifically, we generated iPSC lines: two with low LQTS risk scores of 0.35% and 0.1%, two with mean scores of 50%, and two with high scores of 99.8% and 99.18%. The resulting iPSCs were differentiated into cardiomyocytes and interrogated for conduction properties. We validated pluripotency for all cell lines. We compared RNA transcript changes between high and low QTc-polygenic risk cell lines, focusing on genes associated with QT interval GWAS loci. We also compare in vitro correlates of prolonged QT interval, action potential recordings, extracellular field potential using CardioExcyte96. By interrogating the biological basis of underlaying mechanisms and the impact of small effect-size genetic variants, we aim to unravel mechanisms underlying the presentation of LQTS. This study expands our understanding and provides a valuable template for investigating other disorders with significant polygenic and monogenic contributions. Through the use of iPSC-derived cardiomyocytes, this study offers insights into the complex genetic and mechanistic interplay of Long QT syndrome. By elucidating the influences of various factors, we aim to enhance risk assessment, identify therapeutic targets, and enable early interventions for patients. Our findings will contribute to a deeper understanding of disease mechanisms and advance personalized medicine strategies.

PB1131 Genome Wide CRISPR Screen in a*TUBB* Hypomorphic Background Reveals Novel Genetic Interactions

Authors:

D. Thomson Taylor[1,2], H. J. Lim[1], P. Mero[2], K. Chan[2], K. Brown[2], M. Costanzo[1], M. Billmann[3], C. Myers[4], B. Andrews[1], C. Boone[1], J. Moffat[2,1]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]The Hosp. for Sick Children, Toronto, ON, Canada, [3]Univ. of Bonn, Bonn, Germany, [4]Univ. of Minnesota, Minneapolis, MN

Background: GWAS have successfully linked genetic variation to disease phenotypes however there remains a large percentage of heritability that cannot be explained. The interaction between multiple genetic variants has been able to explain the presence of phenotypes that are otherwise absent when only a subset of the genetic variants is present. Using a genetic interaction (GI) screening approach, a global GI network of the *Saccharomyces Cerevisiae* model organism has been constructed. This demonstrated that genes essential for cell fitness (EGs) act as GI hubs and can predict the functions of uncharacterized genes with highly correlated GI profiles. The human genome is larger and more complex than lower eukaryote genomes and therefore to condense the human GI network we are profiling GIs of EGs in a model human cell line. **Methods:** As a pilot study we selected *TUBB*, a common essential gene, for GI profiling. We utilized fitness data from genome wide CRISPR fitness screens to identify guide RNAs (gRNAs) that can generate hypomorphic variants of *TUBB* in the haploid chronic myelogenous leukemia cell line HAP1. We used the CRISPR-Cas9 gene disruption system to construct stable HAP1 cell lines harbouring hypomorphic mutations in *TUBB.* We then performed a fitness screen using the genome wide Toronto Knockout Library which contains gRNAs that target 18,053 human protein coding genes to identify GIs of *TUBB.* We also performed chemical GI screens with tubulin-destabilizing drugs nocodazole and colchicine to analyze the quality of the *TUBB* GI profile. **Results:** Our *TUBB* mutant cell lines are highly sensitive to the tubulin-destabilizing drugs nocodazole and colchicine. By RT-qPCR analysis we confirmed that all *TUBB* mutant cell lines had decreased transcript levels and the *TUBB* paralogue, *TUBB4B*, had increased transcript levels. This reliance on *TUBB4B* for cell fitness was confirmed by analysis of the GI profile of the *TUBB* mutant cell line where *TUBB4B* was one of the top negative GIs of *TUBB.* Additionally, analysis of the top GIs showed strong enrichment for mitosis and microtubule-related functions. We also discovered *TUBB* GIs with genes not reported to be functionally associated with *TUBB* in the literature as well as genes with uncharacterized or poorly characterized functions. **Conclusion:** This pilot study demonstrated the feasibility of constructing and profiling GIs of EG mutants in a human model cell line. Our screen uncovered known functional interactors of *TUBB* and identified an uncharacterized gene that is synthetic lethal with our *TUBB* mutation.

PB1132 Genome-wide annotation of fitness-linked regulatory elements

Authors:

M. ter Weele[1], T. Klann[1], A. Barrera[1], A. Ettyreddy[1], R. Rickels[1], J. Bryois[2], S. Jiang[1], S. Adkar[1], N. Iglesias[1], P. Sullivan[3], T. Reddy[1], A. Allen[4], G. Crawford[1], C. Gersbach[1]; [1]Duke Univ., Durham, NC, [2]Univ Geneva, Geneva, Switzerland, [3]Univ North Carolina, Chapel Hill, NC, [4]Duke Univ, Durham, NC

Noncoding regulatory elements control gene expression and govern all biological processes. Epigenomic profiling assays have identified millions of putative regulatory elements, but systematically determining the function of each of those regulatory elements remains a substantial challenge. Here we adapt CRISPR-dCas9-based epigenomic regulatory element screening (CERES) technology to screen all 111,619 putative non-coding regulatory elements defined by open chromatin sites in human K562 leukemia cells for their role in regulating essential cellular processes and proliferation. In an initial screen with 1,084,704 gRNAs, we implemented a new analysis framework to quantify element-level significance and effect size and discovered approximately 11,000 regulatory elements with evidence of impact on cell fitness. These essential elements were, on average, closer to essential and more highly expressed genes and were enriched for stronger chromatin contacts, H3K27ac signal, and chromatin accessibility. However, fitness-linked elements were also diverse, spanning a wide range of chromatin states and chromHMM annotations including candidate enhancers, insulators, and Polycomb repressed elements. RNA sequencing of significant gRNAs revealed examples of perturbations affecting fitness through various pathways, including differentiation, cell metabolism, and immune activation. We validated over 1,000 of the element hits in a secondary screen in K562 cells, evaluated cell-type specificity in a second cancer cell line, and identified target genes of 350 distal regulatory elements using epigenetic perturbations combined with single cell RNA-seq. This comprehensive and quantitative genome-wide map of essential regulatory elements represents a framework for extensive characterization of noncoding regulatory elements that drive complex cell phenotypes and for prioritizing non-coding genetic variants that may contribute to common traits and disease risk.

The placenta is of utmost importance in maternal-fetal interactions, and the central organ to study in the context of the Developmental Origins of Adult Health and Disease hypothesis that postulates that early-life environments can impact later-life health. Growing evidence indicates that the associations among an adverse intrauterine environment, genetics, and health outcomes could be driven by placental epigenetic marks like DNA methylation (DNAm). In this study, we aimed to elucidate genetic factors contributing to disease susceptibility through placental DNA methylation. We performed the largest meta-analysis of placental methylation Quantitative Trait Loci (mQTLs) including more than 1,700 samples across seven cohorts from the Pregnancy and Childhood Epigenetics Consortium. In each cohort, placenta DNA methylation array and imputed genotype data were used to map mQTLs in *cis* (0.5 Mb window) using tensorQTL. The quality control of mQTLs was performed with EasyQC and the meta-analysis with GWAMA. We discovered more than 25 million associations between fetal genotypes and placental DNA methylation levels, including 3,531,259 SNPs and 210,476 CpGs. The vast majority of the SNP-CpG pairs in *cis*-mQTLs were located close to each other with a median distance of 250 bp, indicating that genetically modulated DNAm is typically close to the implicated variant. Furthermore, most of the mQTLs showed consistent effect direction across cohorts. DNAm sites in mQTLs were enriched in genomic features with intermediate methylation values, including CpG island shelves and shores, as well as open sea regions. Additionally, we observed a significant depletion from gene promoters and CpG islands. With the eFORGE software, we were able to detect enrichment in fetal placenta-specific DNase I hotspots and H3K4me1 broadPeaks, that mark accessible chromatin and enhancer regions, respectively. Finally, we performed Summary data-based Mendelian Randomization (SMR) analyses to study the genetic susceptibility acting through placental methylation in more than 40 GWAS traits including anthropometric measurements, and metabolic, cardiovascular, immune, digestive, respiratory, and neurologic diseases. Our results suggest that placental mQTLs may have a widespread impact in disease-associated loci with relevant implications in the prenatal origins of human complex disease.

PB1134 Genome-wide microRNA QTL mapping and integration with GWAS links brain microRNAs to neuropsychiatric disorders

Authors:

S. Vattathil[1], E. Gerasimov[1], S. Canon[1], A. Lori[1], Y. Liu[1], E. C. Lai[2], D. A. Bennett[3], T. S. Wingo[1], A. P. Wingo[1,4]; [1]Emory Univ., Atlanta, GA, [2]Sloan Kettering Inst., New York, NY, [3]Rush Univ. Med. Ctr., Chicago, IL, [4]VA Atlanta Hlth.Care System, Atlanta, GA

MicroRNAs (miRNAs) are small non-coding miRNAs that function as post-transcriptional regulators. Given their broad influence on gene expression, characterizing the genetic regulation of miRNA variation can shed light on the role miRNAs play in the complex biological networks that link population genetic variation to brain traits and disease. To this end, we mapped brain miRNA eQTls (miR-QTLs) using genome-wide small RNA sequencing profiles from 604 donors of European ancestry. We detected miR-QTLs for 224 miRNAs (48% of 470 tested miRNAs) at false discovery rate < 1%, demonstrating that miRNAs are subject to extensive genetic regulation. The miR-QTLs were more likely to be upstream than downstream of the miRNA gene and were enriched in brain promoters. We then integrated the brain miR-QTLs with GWAS results from 16 psychiatric and neurodegenerative diseases using multiple independent approaches (miRNome-wide association analysis with FUSION, colocalization analysis with COLOC, and summary statistic-based Mendelian randomization with SMR). This approach prioritized five miRNAs (miR-92b-3p, miR-1908-5p, miR-499a-5p, miR-1255a, miR-190b-5p) that may mediate the effect of genetic variation on complex brain traits including bipolar disorder, major depression, neuroticism, post-traumatic stress disorder, schizophrenia, and Parkinson's disease. The results we report provide a basis not only for follow-up studies aimed at clarifying the role of brain miRNAs in relation to brain traits, but also for future analyses aimed more generally at understanding the regulation of miRNA expression.

PB1135 Harnessing HT-SELEX and CAP-SELEX data for predictive modeling of transcription factor binding.

Authors:

R. Chung[1], G. Loeb[2], N. Ioannidis[1]; [1]Univ. of California, Berkeley, Berkeley, CA, [2]UCSF, San Francisco, CA

Despite being an in vitro assay, high throughput systemic evolution of ligands by exponential enrichment (HT-SELEX) remains one of the main experiments used for discovering transcription factor (TF) binding preferences in TF motif databases such as JASPAR. Previous works modeling DNA binding preferences of TFs using HT-SELEX datasets (e.g. DeepBind and DeepSELEX) have shown limited transferability to in vivo TF binding assays, such as ChIP-seq, for some transcription factors. The more recent CAP-SELEX assay identifies pairs of TFs that cooperatively bind to a DNA sequence.In order to understand the different types of information captured by HT-SELEX and CAP-SELEX data, we modeled both data sets jointly using a shared convolutional neural network (CNN). We found that a model trained on SOX2-OCT4 CAP-SELEX data outperformed a model trained on SOX2 HT-SELEX data at identifying SOX2 ChIP-nexus peaks (0.777 vs. 0.628 AUROC, respectively). Similarly, a model trained on E2F1-ELK1 CAP-SELEX data outperformed a model trained on E2F1 HT-SELEX data in predicting ChIP-seq peaks (AUROC 0.732 vs 0.533).These preliminary results suggest that the gap between in vitro and in vivo data is partially explained by TF cooperativity. Furthermore, a CNN that jointly models HT and CAP-SELEX datasets may learn shared DNA binding motifs between experiments. Our goal is to use this model, trained on all publicly available SELEX data, to augment existing genome interpretation models, like Basenji, which have only been trained on the human genome which lacks sequence diversity.

PB1136 High-resolution 3D reconstruction of spatial conformations for the human genome decodes the context-specific mechanisms of long-range genetic associations.

Authors:

J. Wang, H. Wang, J. Yang, S. D. Adhikari; Michigan State Univ., East Lansing, MI

One of the fundamental challenges in disease genetics is to delineate the molecular mechanisms linking the disruptive effects of genetic variants to complex phenotypes, especially for non-coding SNPs that are located distal to target genes. While the spatial chromosomal conformations in 3D space have been demonstrated to play pivotal roles in modulating long-range genetic associations, current experimental data of chromatin contacts (*e.g.* Hi-C and Capture-C) are highly limited to a few cellular-contexts. The datasets have extremely high rates of missing data, making high-resolution characterization of detailed genome folding challenging. Excessive missing data of chromatin contacts also makes the interpretation of long-range genetic associations infeasible. Here **we develop a family of computational models, FLAMINGO and its variants, which are able to reconstruct 1kb-resolution spatial configurations of the human genome (*i.e.* the highest resolution to date) across diverse cell types and even at single-cell specific levels**. FLAMINGO consistently demonstrates superior accuracy, orders-of-magnitude boost in scalability, and strong robustness against high rates of missing contacts. Integrative analysis of reconstructed 3D genome structures with context-specific multi-omics data and genetic association studies (such as eQTLs, hQTLs and GWAS SNPs) revealed a series of novel discoveries, including the detection of super long-range QTLs (>900kb), single-cell specific genetic associations, spatial 3D hubs of orchestrated regulatory activities around SNPs, and improved prioritization of causal SNPs. **Beyond 1D genomic analysis and traditional association studies, our predictive and analytical framework opens up a new paradigm to decipher the molecular mechanisms of SNPs associated with complex human diseases from the systems-level view of high-resolution 3D genomes across diverse cellular contexts**.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1137 High-throughput identification of deep intronic splice-disrupting variants in an undiagnosed rare disease cohort using a novel massively parallel minigene splicing assay

Authors:

S. Younger, A. L. Martinez-Bengochea, J. C. Means, T. Pastinen; Childrens Mercy Kansas City, Kansas City, MO

Improved DNA sequencing technologies and decreases in the cost of DNA sequencing have enabled the use of whole genome sequencing in a clinical setting. While the application of this technology has facilitated the identification of disease-associated genetic variants, the rate of diagnosis for rare disease remains below 50%. A major factor in these poor diagnostic rates is that most disease-associated genetic variants occur in noncoding regions of the genome with no prior annotation and no predictable functional consequences. Noncoding genetic variants within intronic sequences, which constitute ~35% of the human genome, can disrupt proper RNA splicing and lead to disease. However, the molecular consequences of intronic variants are difficult to predict and the potential contribution of these variants to disease etiology is commonly overlooked. Rapid, robust, and scalable experimental methods for deciphering the impact of intronic variants on RNA splicing and gene function would hold the promise of dramatically expanding the sequence space of the human genome that is amenable to clinical interpretation. To achieve this goal, we have developed a massively parallel minigene splicing assay that enables the empirical validation of the molecular consequences of deep intronic variants at scale. Our assay utilizes a GFP minigene composed of two exons separated by a short human intron that contains a central cloning site. Individual genomic sequences of interest can be cloned into the assay vector and, following introduction into cultured cells, splicing outcomes can be evaluated using RT-PCR. Alternatively, we have engineered a multiplexed barcoding system that facilitates the simultaneous assessment of thousands of genomic sequences in a pooled format using a high-throughput sequencing-based readout. Notably, this sequencing-based approach enables the characterization of splicing aberrations at single nucleotide resolution. To validate our assay, we leveraged the pediatric data repository generated by our institute's rare disease initiative, Genomic Answers for Kids, to curate a selection of >4500 rare deep intronic variants identified in undiagnosed rare disease patients. Our assay illuminated multiple variants that reproducibly disrupted RNA splicing across diverse cellular contexts. For a subset of variants, we generated patient-derived cellular models and performed RNA-seq to confirm the presence of splicing aberrations matching those observed in our assay. We anticipate that the assay described here will eventually contribute to diagnoses for many children that are impacted by rare disease and have long been searching for answers.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1138 † Human embryoid bodies reveal dynamic genetic regulation in diverse differentiation trajectories

Authors:

J. Popp[1], K. Rhodes[2], K. Barr[2], R. Jangi[1], M. Li[1], B. Strober[3], Y. Gilad[2], A. J. Battle[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Univ. of Chicago, Chicago, IL, [3]Harvard Sch. of Publ. Hlth., Brookline, MA

Large-scale efforts to identify genetic variants associated with nearby gene expression levels (cis expression quantitative trait loci, or cis-eQTLs) have focused primarily on healthy adult tissues. The scarcity of data from transient cell states such as those arising during differentiation presents a key bottleneck to the identification of target genes and mechanisms underlying disease-associated genetic loci, some of whose regulatory effects may present only during dynamic processes. In this work we examined genetic regulation of gene expression across diverse differentiating cell states with an efficient, unified experimental framework based on embryoid bodies. Embryoid bodies are three-dimensional aggregates derived from induced pluripotent stem cells (iPSCs) that spontaneously differentiate into a wide variety of cell types, including derivatives of all three germ layers. We generated embryoid bodies from 53 donors, and collected single cell RNA-sequencing data for over 900,000 cells. We called cell type-specific eQTLs across 29 cell types, and identified thousands of eQTLs displaying varying degrees of context specificity. While a majority of these loci overlap with eQTLs previously identified by GTEx, the eQTL genes without overlap were enriched for multiple developmental processes. We next interrogated context specificity using unsupervised machine learning, which revealed hundreds of variants with regulatory effects that vary across the differentiation landscape. The asynchronicity of differentiation across individual cells in this system enables us to reconstruct entire differentiation trajectories, from stem cells to developmentally relevant intermediate stages to differentiated cells. We therefore additionally called dynamic eQTLs along the differentiation trajectories from iPSCs to neurons, to cardiomyocytes, and to hepatoblasts, characterizing regulatory dynamics across all three germ layers in a single experimental framework. We intersected these newly discovered dynamic regulatory effects with known disease loci, and highlight an example dynamic eQTL along the neuronal trajectory which overlaps a previously identified schizophrenia risk locus. This work expands the identification of genetic regulatory effects to underexplored cell states arising during cellular differentiation for a wide array of cell types, accelerating the identification of regulatory mechanisms underlying disease risk loci.

PB1139 Human Leukocyte Antigen-C and Haplotypes Associations with Resistance and Susceptibility to HIV-1 Infection among Serodiscordant Couples in Nigeria

Authors:

N. Otuonye[1], L. Luo, Dr[2], N. N. Odunukwe, Prof[1]; [1]Nigerian Inst. of Med. Res., Yaba, Nigeria, [2]Natl. Microbiol. Lab., Winnipeg, WA, Canada

Introduction The Human Leucocyte Antigen (HLA) class-1 is known to play a significant role in mediating resistance or susceptibility to HIV infection in the clinical course of AIDS. Recent studies have identified HLA-C as a key molecule that affects HIV disease progression. However, the role of HLA class 1 in heterosexual HIV-1 susceptibility or resistance in serodiscordant couples is not known in Nigeria. Therefore, this study evaluated the association between HLA-C susceptibility and resistance in HIV-1 transmission amongst heterosexual serodiscordant couples in Nigeria. **Methods** A total of 271 serodiscordant, concordant HIV positive and negative couples who gave informed consent were enrolled into this study. Extracted genomic DNA was sequenced for high resolution HLA-C class 1 genotypes using allele-specific primers (on exons 2 and 3) for HLA-C sequencing and typing. **Results** The highest frequency distribution of high-resolution HLA-C alleles observed in the HIV positive subjects were: HLAC*040101 178 (35.0%) followed by C*0701 124 (24.9%) compared with HIV negative subjects: C*040101 108 (39.0%) followed by C*0701 64 (24.7%). Alleles C*070201 (OR = 4.19, $P < 0.05$) and C*0804 (OR = 3, $P < 0.045$) were found to be independently associated with HIV-1 susceptibility in the cohort of serodiscordant couples. HLA-C*0802 (OR = 0.5. $P < 0.005$) and C*0304 (OR = 0.34. $P < 0.002$) were significantly associated with HIV-1 resistance to HIV-1 infection among the cohort. **Conclusion** The result has contributed to the importance of how host HLA-C genetic factors can influence HIV-1 disease susceptibility (HLA-C*070201; C*0804) and resistance (HLA-C*0802; C*0304) in serodiscordant couples. This information may contribute to the development of future effective HIV vaccine in Nigeria. **Keywords** Serodiscordant Couples, HLA-C Class 1 Resistance Allele, HLA-C Class I Susceptible Allele, HIV-1 Plasma Viral Load, and Nigeria

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1140 Hundreds of repeat polymorphisms influence splice site usage via diverse mechanisms.

Authors:

R. Mukamel[1], R. Handsaker[2], M. Sherman[3], A. Barton[4], M. Hujoel[5], S. McCarroll[1], P-R. Loh[6]; [1]Harvard Med. Sch., Boston, MA, [2]Broad Inst., Cambridge, MA, [3]Massachusetts Inst. of Technology, Cambridge, MA, [4]Harvard Univ., Cambridge, MA, [5]Brigham & Women s Hosp./Harvard Med. Sch., Boston, MA, [6]Brigham and Women s Hosp. / Harvard Med. Sch, Boston, MA

Gene expression and splicing are strongly regulated by nearby sequence variation, but studies of gene regulation have mostly been limited to SNP and indel variants. Here, we examined thousands of regions in the genome that vary in length due to variable numbers of tandem repeats (VNTRs) but are challenging to genotype from short-read sequencing. We analyzed sequencing depth-of-coverage together with SNP haplotypes to estimate the lengths of 9,561 autosomal VNTRs in 838 GTEx donors and test them for association with expression and splicing quantitative traits. Statistical fine-mapping analyses identified 702 repeat polymorphisms that appeared to influence expression or splicing of a nearby gene ($P<1 \times 10^{-10}$, FINEMAP PIP>0.5 in at least one tissue). These VNTRs were enriched near relevant genomic features: 25% (CI=21-29%) of expression-altering VNTRs overlapped an annotated promoter or enhancer (compared to 8% of analyzed VNTRs), while 18% (CI=14-22%) of splicing-altering VNTRs were within 100bp of an affected splice site (compared to <0.1% of all tested VNTRs). Moreover, VNTRs were 7-fold enriched among lead variants at quantitative trait loci, indicating that they contribute substantially more to gene regulation than SNPs on a per-variant basis. Associations in GTEx suggested transcriptional roles for a sizable fraction (18/58) of the VNTRs we recently linked to complex traits in UK Biobank (Mukamel et al.; medRxiv preprint), including a VNTR 1kb downstream of *GPIHBP1* (which encodes an HDL binding protein) that associated with increased HDL ($P=2.6 \times 10^{-41}$; PIP=0.99), apparently by influencing *GPIHBP1* expression ($P<1 \times 10^{-10}$, PIP>0.5 in 13 tissues).

Examining the genomic context of splice-altering VNTRs together with sequence-level information about splice junctions available in RNA-seq reads suggested that repeat polymorphisms influence splicing by a diverse set of mechanisms, with VNTRs apparently capable of modulating usage of both proximal and distal splice sites. For example, VNTR allele length in *UPF3A* and *TUBGCP2* appeared to modulate the size of arrays of within-repeat alternative splice sites. At *PLIN5*, the length of a 24bp-repeat 5bp upstream of a canonical splice acceptor associated with intron retention. The pyrimidine-rich composition of this VNTR (75% pyrimidines) suggested that VNTR alleles influence branch point recognition by modulating the distance between the branch point and the splice acceptor. Repeats at *CUL4A* and *CNN2*, by contrast, appeared to influence usage of distal splice sites (>800bp away). These results indicate a substantial and previously underappreciated role of VNTRs in regulating gene expression and splicing.

PB1141 Hypothesis-free Mendelian Randomisation Identifies New Metabolites Linked to Risk of ALS

Authors:

E. Alhathli[1], T. Julian[2], C. Harvey[1], T. Moll[1], D. Wang[3,4], Project MinE sequencing consortium, P. Shaw[1], J. Cooper-Knock[5]; [1]Univ. of Sheffield, Sheffield, United Kingdom, [2]The Univ. of Manchester, Manchester, United Kingdom, [3]Univ. of Sheffield, Sheffield, South Yorkshire, United Kingdom, [4]Imperial Coll. London, London, United Kingdom, [5]Univ. Of Sheffield, Sheffield, United Kingdom

ALS, a rapidly developing and invariably fatal neurodegenerative disorder, is characterised by the progressive loss of motor neurons. ALS is an archetypal complex disease, with 10% of patients suffering from a monogenic disease; the vast majority of cases are sporadic, caused by a combination of genetic and environmental factors. With two-sample Mendelian randomisation (MR), causal inference can be made between various exposures and disease risks, such as serum concentrations of the entire set of metabolites. Summary statistics from genome-wide association studies (GWAS) of 575 metabolites were compared with those from a GWAS of amyotrophic lateral sclerosis (ALS) consisting of 29,612 ALS patients and 122,656 controls. Unbiased MR using the inverse variance weighted (IVW) estimate and weighted median causally associated five metabolites with risk for ALS after stringent Bonferroni multiple testing correction. Two hits are in the carnitine synthesis pathway - carnitine has been previously linked to the severity of ALS via a role in energy metabolism within motor neurons; this is the subject of an ongoing clinical trial (ALSUntangled). The remaining hits are being investigated with a combination of protein, metabolite and rare variant analyses. Follow-up studies will include evaluation within in vitro and in vivo models of ALS.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1142 IBD-focused eQTL analysis identifies an increased rate of IBD GWAS colocalizations and novel target genes using diseased tissue compared to normal tissue eQTL

Authors:

N. Nishiyama[1], S. Silverstein[1], A. Bharadwaj[1], R. Ganesan[2], K. Clough[1], K. Darlington[1], G. Lian[1], C. Beasley[1], M. Schaner[1], S. Sheikh[1], T. Furey[3]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]Carnegie Mellon Univ., Pittsburgh, PA, [3]Univ North Carolina, Chapel Hill, Chapel Hill, NC

While genome-wide association studies (GWAS) have identified over 200 loci associated with inflammatory bowel diseases (IBD), the functional mechanism and target gene of most loci remains unknown. Furthermore, eQTL mapped using any normal tissue such as the Genotype-Tissue Expression (GTEx) project only explain about 20% of GWAS loci, including IBD. Context-specific eQTL have identified regulatory mechanisms that may only be detected under specific conditions or stimuli and have provided additional explanation of GWAS loci. Therefore, we have performed the largest single-tissue diseased-focused eQTL analysis using colon tissue from IBD patients to increase our power to detect IBD GWAS colocalization and identify novel target genes. We hypothesize that eQTL mapped using diseased tissue will be enriched for disease-relevant molecular effects compared to normal tissue eQTL.

We performed paired genotyping and bulk RNA-sequencing on uninflamed colonic mucosa samples from 190 IBD patients (CD n=137; UC n=53). We mapped eQTL using IBD tissue for 30,173 genes using 6.7M genetic variant sites with a MAF > 0.05 +/- 1 Mb around the TSS of each gene. eQTL were compared to normal colon eQTL reported by GTEx. We then colocalized eQTL with 241 reported IBD GWAS loci to identify likely target genes using linkage disequilibrium (LD R2 > 0.4) and a Bayesian colocalization method, *coloc*. We compared eQTL-GWAS colocalizations between IBD and normal colon tissue to identify novel IBD GWAS colocalizations and target genes.

We have mapped 293,064 significant eQTL in diseased colonic tissue, associated with 2961 genes. Twenty-two lead eQTL signals using IBD tissue colocalized with 18 distinct IBD GWAS loci (*coloc* H4 Posterior Probability > 0.5). These colocalizations included well-known IBD GWAS candidate genes such as *ERAP2*, *FUT2* and multiple HLA MHC class II genes. eQTL mapped in IBD tissue were >2 times more likely to colocalize with IBD GWAS loci compared to eQTL mapped using normal tissue (Fisher's exact test p = 6.72x10-3), despite an IBD sample size one-half smaller (GTEx transverse colon n=368). Using diseased tissue, 60% of eQTL colocalizations are novel. Furthermore, we can detect distinct eQTL signals that colocalize with IBD GWAS loci for reported eGenes that do not colocalize using normal tissue eQTL. We report the first candidate target gene for the *CAMK2A* locus through a novel colocalization for *CAMK2A*. Additionally, our results implicate functionally relevant candidate target genes such as *TNFRSF14* for IBD GWAS loci that are missed by normal tissue eQTL, highlighting the advantages of using diseased tissue eQTL to prioritize trait-relevant candidate genes for GWAS loci.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1143 Identification and characterization of the SNPs in the human *ZP2* gene and their role in female infertility.

Authors:

G. Gahlay, N. Rajput; Guru Nanak Dev Univ., Amritsar, India

ZP2 is an important component of the zona matrix which surrounds mammalian oocytes and facilitates fertilization. Recently, some studies have linked SNPs in genes encoding the zona matrix to female infertility. Single nucleotide polymorphisms (SNPs) are the most common type of genetic variations observed in a population. According to the dbSNP database, approximately 8,013 SNPs are reported in the human *ZP2* (*ZP2*) gene. In our previous research, we conducted an extensive *in silico* analysis of the SNPs in the *ZP2* gene, which had been reported in the dbSNP database, using six different computational tools, including SIFT and PolyPhen-2. This analysis predicted 18 non-synonymous SNPs (nsSNPs) as deleterious, with 12 of them likely to affect the structure or functional properties. These nsSNPs were predominantly located either in the N-terminal region crucial for sperm-zona interaction or within the zona domain which is responsible for the formation of zona matrix. To validate our *in silico* findings, we analyzed genomic DNA from female patients (n=15) with idiopathic infertility. The aim was to investigate the presence of these predicted nsSNPs in the *ZP2* gene, as well as other novel SNPs. Our analysis identified 8 nsSNPs, including 7 novel ones and 1 which has already been documented in the dbSNP database. Similar to the nsSNPs from our *in silico* studies, these mutations were also predominantly located in the N-terminal region or the zona domain. Four of these nsSNPs were predicted to be deleterious by *in silico* analysis and have structural/functional effects. To further investigate the impact of these changes, we have expressed (4 each from patient samples and *in silico* studies) the shortlisted deleterious SNPs and are currently conducting sperm binding assays to assess their effects on sperm interaction. This comprehensive approach will provide invaluable insights into the functional consequences of these SNPs and their implications on fertility. Understanding how these SNPs affect sperm-zona interaction and the zona domain can guide us to enhance the diagnosis of female infertility and/ improve the efficiency of in vitro fertilization (IVF). This, in turn, may help improve the success rates of fertility treatments, leading to higher pregnancy rates.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1144 Identification of an elastin long-range *cis*-regulatory element.

Authors:

S. S. Procknow[1,2], K. M. Tsang[3], T. R. Luperchio[2], C. J. Billington[4], K. Small[5], A. E. Scheuerle[6], D. Tegay[7,8], P. Fernandez-Ferri[9], J. Meck[10], E. Totten[11], S. R. Braddock[11], K. Hornick[12], N. Redekar[12], B. Kozel[2]; [1]Washington Univ. in St. Louis, Saint Louis, MO, [2]Natl. Heart Lung and Blood Inst., NIH, Bethesda, MD, [3]NICHD, NIH, Bethesda, MD, [4]Univ. of Minnesota, Minneapolis, MN, [5]Northwell Hlth., Manhasset, NY, [6]Univ. of Texas, Southwestern Med. Ctr., Dallas, TX, [7]Northwell Hlth., Mount Sinai, NY, [8]IQVIA, Durham, NC, [9]GeneDX, Gaithersburg, MD, [10]Gene Dx, Gaithersburg, MD, [11]Saint Louis Univ., Saint Louis, MO, [12]Natl. Inst. of Allergy and Infectious Diseases, NIH, Rockville, MD

Supravalvar aortic stenosis (SVAS), a narrowing of the aorta just distal to the aortic valve, is often caused by elastin insufficiency. Elastin insufficiency is commonly seen in patients with Williams-Beuren Syndrome (WBS), a recurrent microdeletion syndrome spanning 26-28 genes including elastin (*ELN*), and in patients with loss-of-function single nucleotide variants and exon level deletions in the *ELN* gene. However, in some patients, and even families with SVAS, genetic evaluation fails to identify a causative variant. To investigate the genetic basis of SVAS in the absence of *ELN* variation, we identified a cohort of 4 individuals with SVAS and atypical 7q11.2 deletions that spare the *ELN* gene. The deletions share a region of approximately 200 kb that extends to 90 kb upstream of the *ELN* gene. Using bulk RNAseq (Illumina), we evaluated allele balance using known heterozygous single nucleotide polymorphisms (SNPs) to overcome differences in *ELN* expression with age and culture conditions. In contrast to fibroblasts from unaffected individuals which demonstrated biallelic *ELN* expression, a single predominant *ELN* allele was detected in affected fibroblasts, suggesting transcription off a single allele. Genomic DNA from patient fibroblasts was assessed by long-read sequencing (PacBio) which demonstrated that the suppressed allele was in *cis* with the upstream deletion. These data suggest the presence of a long-range *cis*-regulatory element (CRE) contained within the patients' deletions affecting *ELN* transcription. Using data available from ENCODE and GeneHancer, we identified key areas within the shared deletion region that have chromatin marks consistent with CREs including high H3K27ac and H3K4me1 in *ELN* expressing cell lines. We subsequently identified a fifth patient with SVAS and a smaller, novel ~47 kb deletion located within the shared deletion region upstream of *ELN*, containing one such putative CRE. This putative CRE was removed from IMR-90 cells using CRISPR technology. Further studies to characterize *ELN* expression in these cells and potential disruption of chromatin structure are underway. These findings collectively suggest the presence of a novel long-range CRE upstream of *ELN* that may identify the genetic etiology of as yet undiagnosed patients with SVAS. Further characterization of this region may identify potential therapeutic targets in patients with elastin-mediated disease. Moreover, this approach may be more broadly applicable to identifying the mechanism of disease in patients with suspected genetic disease in which current testing methods fail to identify causative variants.

PB1145 Identification of bidirectional regulatory regions for *FADS1*and *FADS2*

Authors:

S. Yang[1], H. Zhang[2], K. Ye[2]; [1]Univ. OF GEORGIA, Athens, GA, [2]Univ. of Georgia, Athens, GA

Long-chain polyunsaturated fatty acids (LC-PUFAs) play critical roles in human health, and the *FADS1* and *FADS2* genes encode the two rate-limiting enzymes in the biosynthesis process of LC-PUFAs. These two genes are located adjacent to each other in a head-to-head orientation, suggesting a shared regulatory region. GTEx data revealed that in this region, two previously experimentally supported causal regulatory variants, rs174557 for *FADS1* and rs968567 for *FADS2*, have opposite effects on the two genes. However, the underlying mechanism is still unclear. We performed bidirectional reporter assays for the regions harboring each causal variant, but no bidirectional regulatory activity was observed. ChIP-seq data for HepG2 cells from ENCODE revealed that these two causal variants both lie in binding sites for transcription factor SP1 and SREBP1c. Therefore, we conducted CRISPRi to block each binding site and overexpressed SP1 and SREBP1c, respectively, to see if there is any competing regulation. We found that overexpression of SREBP1c could increase the expression of *FADS1* and *FADS2*, while SP1 only increased *FADS2 expression*. Meanwhile, when we blocked the binding site in the *FADS1* intron 1, both *FADS1* and *FADS2* decreased expression, and *SREBP1c* increased while *SP1* decreased. To further confirm how these two causal variants in the shared region regulate *FADS1* and *FADS2*, we generated HEK293 cells with homozygous single-nucleotide edits for both variants using prime editing. Similar single-nucleotide editing will be performed in HepG2 and their effects on the expression levels of *FADS1* and *FADS2* will be examined. Taken together, findings from this study will enhance our understanding of *FADS* expressions and facilitate the development of genome-informed LC-PUFAs supplementation for preventing associated complex diseases.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1146 Identification of genetic variation associated with cell state regulatory networks in human induced pluripotent stem cells.

Authors:

T. Arthur[1], J. Nguyen[1], A. D'Antonio-Chronowska[1], H. Matsui[1], N. Silva[1], I. Joshua[1], iPSCORE Consortium, W. Greenwald[1], M. D'Antonio[1], M. Pera[2], K. Frazer[1]; [1]Univ. of California, San Diego, La Jolla, CA, [2]The Jackson Lab., Bar Harbor, ME

Human induced pluripotent stem cells (hiPSCs) exhibit a range of interconvertible pluripotent cell states that resemble different stages of early embryonic development. Most hiPSC lines are primarily comprised of cells in the primed state which has a diminished differentiation capacity relative to the smaller fraction of cells in the formative state. Unraveling the genetic and epigenetic processes governing transitions between these states is crucial for understanding early embryonic development and advancing hiPSC applications. Here, we analyzed RNA-seq and ATAC-seq data from 143 hiPSC lines using a machine learning algorithm, which resulted in the identification of 24 gene network modules (GNMs) and 20 regulatory network modules (RNMs). Comprehensive characterization revealed strong correlations between GNMs and RNMs, indicating that the RNMs underlie the coordinated co-expression of genes in the GNMs and allowing us to elucidate their pivotal roles in pluripotency and self-renewal. Remarkably, we discovered non-canonical epigenetic profiles within RNMs, unveiling novel regulatory networks active during formative and primed states. Genetic investigations further identified 2,234 regulatory variants that disrupted transcription factor binding, leading to altered co-accessibility of regulatory elements and increased stability of specific pluripotency states. Notably, we highlighted the significant impact of rs9350250, located within an *E2F3* intronic regulatory element, which completely disrupted co-accessibility and was associated with increased prevalence of the formative state of pluripotency. These findings reveal novel pluripotency and self-renewal regulatory mechanisms and provide a valuable resource for future stem cell research to generate genetic signatures that can potentially identify hiPSC lines that are likely to have improved differentiation outcomes.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1147 Identification of multiple *cis*-regulatory enhancer variants underlying *NOS1AP* QT interval GWAS locus.

Authors:

K. Vickery[1], E. Sanchez[1], D. Lee[2], A. Kapoor[1]; [1]UTHlth.Houston, Houston, TX, [2]Harvard Med. Sch. & Boston Children s Hosp., Boston, MA

Electrocardiographic QT interval, an index of ventricular de- and re-polarization, is a clinically relevant heritable quantitative trait as prolongation or shortening of the QT interval is associated with increased risk of cardiac arrhythmias and sudden cardiac death. Genome wide association studies (GWAS) have identified the *NOS1AP* locus as a major regulator of the QT interval variation. Although, in our prior work we identified a single enhancer polymorphism that affects human cardiac *NOS1AP* expression and underlies trait association, causal variants underlying multiple independent GWAS signals at the *NOS1AP* locus remain unknown. Following a *cis*-regulatory mechanistic hypothesis, we performed an enhancer screen for all QT interval-associated *NOS1AP* locus variants that overlap cardiac open chromatin regions, a hallmark of *cis*-regulation. First, we identified all bi-allelic variants (*n*=788) observed in 1000 Genomes European ancestry populations within 500 kb of the sentinel hit at the NOS1AP locus that are common (minor allele frequency>1%) and in high linkage disequilibrium (r^2>0.9) with any of the genome-wide significant ($P<5\times10^{-8}$) GWAS hits. Next, we used variant overlap with human cardiac left ventricle DNase-seq regions (extended 1 kb on either side of peak summits) to filter 160 candidate variants. Following variant-centered PCR amplicon design, where 154 variants in 95 amplicons passed the primer design parameters (amplicon size range 414-785 bp; median 624 bp), and amplification from genotyped 1000 Genomes/HapMap reference DNA samples, both alleles of 138 variants along with flanking sequence in 84 amplicons were successfully cloned upstream of a minimal promoter-driven firefly luciferase gene in pGL4.23. Mouse cardiomyocyte HL1 cells, seeded in 24-well plates, were transfected with test constructs and *Renilla* luciferase vector (for transfection normalization) in quadruplicate and luciferase assays were performed 48 h later. Compared to the empty vector control, we identified five amplicons encompassing six variants with enhancer activity and with significant allelic difference (*t* test $P<0.05$), including the GWAS sentinel variant rs12143842. These six enhancer variants are being evaluated further, including assessing their combined impacts on *NOS1AP* cardiac expression using expression quantitative trait locus datasets, assessing *in vivo* activities using zebrafish transient enhancer assays, and assessing the dependency of enhancer activity on variant and flanking sequence using variant-centered small deletion (± 5 bases) constructs.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1148 Identifying Cell and State Specific Genetic Effects on Gene expression through Comprehensive Analysis of Human Microglia Transcriptomics.

Authors:

B. Jang[1,2], A. Ravi[1], E. Brophy[1], M. Rosen[1], R. Kubler[1], K. BP[1], W. Cuddleston[1], H. Seo[1], M. Park[2,3], J. Humphrey[1], H-H. Won[2,4], T. Raj[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Sungkyunkwan Univ., Seoul, Korea, Republic of, [3]Genome Inst. of Singapore, Agency for Sci., Technology and Res. (A*STAR), Singapore, Singapore, [4]Samsung Genome Inst., Samsung Med. Ctr., Seoul, Korea, Republic of

Background: Research into neurodegenerative diseases such as Alzheimer's disease (AD) and Parkinson's disease (PD) has made significant progress through genome-wide association studies (GWAS), identifying over a hundred of genetic loci associated with disease. Human microglia have emerged as a crucial cell type in understanding the underlying mechanisms of neurodegeneration. However, despite these findings, the causal variants, genes, and pathways specific to microglia underlying disease pathogenesis remain largely elusive, hindering our ability to develop a comprehensive mechanistic understanding of the disease.
Methods: To address this challenge, we conducted a large-scale meta-analysis of primary human microglia from published studies (Lopes, Kosoy, and Young) from 391 donors. Additionally, we harmonized microglia nuclei data from Fujita, Gabitto (unpublished) and Bryois (published) single-nucleus RNA-seq datasets, encompassing a total of about 180,000 microglia nuclei from 678 donors. We performed eQTL mapping and employed statistical fine-mapping, transcriptome-wide association study (TWAS), colocalization analysis and co-expression network analysis. We are performing state eQTL (st-QTL) and co-expression QTL (coQTL) analysis, which considers different microglial cell states at single-cell resolution.
Results: Our meta-analysis of human microglia datasets, incorporating both sorted and single-nuclei resolutions identified 2,542 cis-eQTLs at a false discovery rate (FDR) <0.05. Among these, 34 and 18 eQTLs colocalized with AD risk loci and PD (PP.H4 > 0.7), respectively, and many of these were also prioritized using a TWAS approach. Moreover, our analysis revealed that many AD/PD-associated eGenes are specifically expressed in specific microglia states including disease-associated microglia (DAM I and II), lipid metabolism, phagocytosis, and homeostatic, as evidenced by single-cell/nuclei microglia data.
Conclusion: Our study represents the most extensive collection of human microglia transcriptomic data to date, encompassing both bulk and single-cell resolutions. By identifying specific eQTLs, prioritizing functional variants and genes, and considering microglial cell states, we have taken a significant step forward in understanding the underlying mechanisms of AD and PD.

PB1149 Identifying cell and tissue types where host genetic variation acts to impact gut bacterial abundance

Authors:

N. Huntley, E. Davenport; Pennsylvania State Univ., University Park, PA

Our microbiome influences our health and therefore characterizing how the microbiome is determined is an important step towards understanding disease treatments. Environmental factors such as diet, medication, and exercise influence the microbiome, but it is becoming increasingly clear that host genetics also plays a role in determining microbiome composition. Recently there has been a growth of genome-wide association studies (GWAS) to identify variants in the human genome that are associated with the relative abundances of common taxa found in feces. While we are starting to gain insight into the genomic variants associated with microbial composition, we lack an understanding of where in the body those variants may act to affect microbial abundance and function. Methods have been developed to identify 'pathogenic tissues' for diseases with and without known etiology by integrating GWAS results with gene expression data. Integrating GWAS with bulk-RNA sequencing has shown that there are differences in expression of genes across tissues that are not intuitively associated with disease, and single-cell RNA sequencing (scRNA-Seq) has taken this a step further by providing a more detailed picture of the variability of expression at the cellular level within tissues. These approaches have not been applied to microbiome-GWAS data, therefore we lack an understanding of the relevant host tissues and cell types in which host genetic variation acts to influence the abundances of microbial taxa in the gut. To address this gap, we intersected publicly available microbiome GWAS summary statistics from greater than 18,000 individuals with scRNA-Seq datasets from 16 different studies for a total of 1.3 million cells from 31 tissues collected from mouse and human subjects by applying single cell disease relevance score methodology to identify host cell types with enrichment of microbiome associated quantitative trait loci. This study is allowing us to identify which cell types host genetic variation acts to influence gut microbiome composition.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1150 Identifying deleterious noncoding variation through gain and loss of CTCF binding site activity.

Authors:

C. Tubbs[1], M. Benton[2], E. McArthur[3], J. Capra[4], D. Ruderfer[1]; [1]Vanderbilt Univ., Nashville, TN, [2]Baylor Univ., Waco, TX, [3]Univ. of Washington, Seattle, WA, [4]Univ. of California San Francisco, San Francisco, CA

Background: CCCTC-binding factor (CTCF) regulates 3D genome organization by binding its DNA sequence motif at thousands of sites throughout the genome. Genetic variation in these CTCF Binding Sites (CBSs) have clinical impact; their disruption occurs at high frequency in cancers and has been linked to the etiology of rare disease. However, while many variants affecting CBSs exist, only a small number are characterized, and few approaches exist to systematically interpret them. Here, we introduce new methodology to functionally annotate single nucleotide variants (SNVs) in CBSs. We do this by explicitly connecting changes in predicted affinity for the CTCF sequence motif to the experimentally observed probability of DNA binding. **Methods:** For each CBS in the human genome, we related its predicted binding affinity to its observed DNA binding activity by calculating the likelihood its precision-weight-matrix (PWM) score will be detected in experimentally supported motifs from the UniBind database. We call this measure *CBS Activity*. For each SNV overlapping a CBS in gnomAD, we annotated its impact by taking the difference in activity scores (*ΔCBS Activity*) between the reference and alternate alleles. We then characterize the relationship between a variant's function (*ΔCBS Activity*), mutability adjusted proportion of singletons (MAPS), and the impact on gene expression in 773 post-mortem human brain samples from the CommonMind Consortium (CMC). **Results:** We calculated *ΔCBS Activity* for 2.7 million SNVs (gnomAD) overlapping 657,593 CBSs. *ΔCBS Activity* scores range from negative one (complete loss of binding activity) to one (complete gain of binding activity). We discover 2,402 high-impact variants (*ΔCBS Activity* > +/- 0.75). These variants are under stronger constraint (MAPS=0.09) than missense variants (MAPS=0.03) in gnomAD (MWU, $p < 1x10\text{-}6$). Next, we assessed each variant's impact on gene expression in the CMC by calculating the mean absolute standard deviation (MAD) of expression z-scores for carriers. Carriers of high-impact CBS variants associated with more aberrant patterns of expression among genes within 1 Mb compared with other CBS variants (high-impact MAD=0.36, other-CBS MAD=0.32, MWU, $p = 5.5x10\text{-}4$). **Conclusion:** Our approach identifies genetic variants that create or destroy functional CBSs genome-wide. These variants are more constrained than other functional classes (missense) and induce detectable changes in gene expression in the human brain. This work represents a critical step in understanding a previously uncharacterized class of variation and will enable improved prioritization of non-coding variants in future disease studies.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1151 Identifying differential protein binding of Noncoding AMD risk-associated Single Nucleotide Polymorphisms

Authors:

E. Santi[1], J. Dunn[2], C. Berlinicke[1], H. Zhu[1], J. Qian[1], D. J. Zack[1]; [1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [2]Johns Hopkins Univ., Baltimore, MD

Age-related Macular Degeneration (AMD) is a retinal neurodegenerative disorder that causes central vision loss in the elderly population throughout the world; currently there are 20 million known cases in the United States alone. Anti-VEGF treatments have proven to be effective in managing and slowing the progression of neovascular ("wet") AMD and have been in use for almost 20 years. On the other hand, for the far more prevalent atrophic ("dry") AMD, pegcetacoplan, a drug that targets the complement cascade, has only just been approved by the FDA and its wide-scale effectiveness is yet to be determined. A better understanding of the underlying genetics that contribute to AMD etiology could potentially lead to the design of complementary therapeutic options, and in fact data from genome-wide association studies (GWAS) demonstrated the connection between AMD and the complement system. The connection between the many other AMD risk-associated single nucleotide polymorphisms (SNP) to AMD, though, remains poorly understood. Determining the mechanism of action of AMD risk associated SNPs is especially difficult, as many of the identified SNPs fall within noncoding genomic regions. Methods normally used to investigate the role of non-coding disease-associated SNPs include expression quantitative trait loci (eQTL) studies as well as chromatin immunoprecipitation sequencing (ChIP-seq), but such methods have not been done in AMD-relevant cell types in addition to only accounting for a small number of human TFs in a limited number of cell types, respectively. Therefore, to determine the potential functional relevance of non-coding AMD associated SNPs, we are performing a proteome-wide analysis of disease-associated SNPs (PWAS) study. PWAS can survey the entire human TF repertoire by probing protein-chip arrays, containing up to 1700 human proteins and isoforms, with SNP-carrying fluorescently labelled DNA oligomers. By assaying risk SNP probes vs Non-risk SNP probes, we will determine whether there are any proteins in which there is differential binding. The rationale of this approach stems from the hypothesis that functional AMD-related DNA SNPs are likely to execute their function via allele-specific interactions with specific proteins. PWAS-identified differential protein to SNP-allele interactions will then be functionally assessed using in vitro retinal pigmented epithelia (RPE) and photoreceptor (PR) cells derived from human stem cell lines containing the two different alleles. Functional assays to be used include the Massively Parallel Reporter Assay (MPRA) for downstream transcriptional expression and ChIP-seq for binding verification.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1152 Identifying key underlying regulatory networks and predicting targets of orphan box C/D *SNORD116* snoRNAs in Prader-Willi Syndrome.

Authors:

R. Gilmore, Y. Liu, G. Carmichael, J. Cotney; UConn Hlth., Farmington, CT

Prader-Willi Syndrome (PWS) is a neurodevelopmental disorder linked to loss of paternal expression of an imprinted region on chromosome 15 (15q11-q13). PWS is characterized by initial hypotonia and failure-to-thrive, followed by hyperphagia and obesity. Other symptoms include mild intellectual disability, short stature, and a range of behavioral and sleep problems. Any therapeutic intervention for this disorder is focused on ameliorating symptoms as there is no cure. Most PWS cases exhibit megabase-scale deletions encompassing the imprinted 15q11-q13 locus which harbors multiple protein coding genes including *MAGEL2*, *NDN*, and *SNRPN*, and various non-coding RNA species, including tandem arrays of small nucleolar RNAs, *SNORD116* and *SNORD115*. Recently, several PWS patients have been identified harboring a much smaller deletion that encompasses primarily the *SNORD116* gene array. These genetic findings suggest that this gene cluster may be a direct driver of PWS phenotypes. The SNORD116 gene cluster is composed of 30 copies of individual *SNORD116* box C/D snoRNAs. These snoRNAs are classified as 'orphans' because no known targets have been identified and their sequences show no significant complementarity to rRNA. It is crucial to identify the targets and functions of *SNORD116* snoRNAs because all reported PWS cases lack their expression. To address this gap in knowledge, we engineered two different deletions at the 15q11-13 locus modeling deletions similar to those identified in PWS patients. The deletions were performed in two distinct human embryonic stem cell lines to control for effects of genetic background. To study the effects of loss of these loci in a neuronal context, we utilized an inducible Neurogenin-2 (*NEUROG2*) expression system to enable quick and reproducible differentiation into neurons. Performing bulk RNA-sequencing on these resulting neurons allowed us to identify a novel list of approximately 40 genes consistently transcriptionally dysregulated in our PWS-like systems. Importantly, our results showed that it is critical to compare differential expression from isogenic pairs of multiple cell lines with distinct genetic backgrounds as this enabled us to eliminate a large number of spuriously affected genes. By employing the recently described box C/D snoRNA binding prediction tool snoGloBe, we found our list of dysregulated genes is significantly enriched for predicted *SNORD116* snoRNA targeting versus multiple levels of control analyses. Our results indicate a gene regulatory network likely controlled by *SNORD116* is perturbed in PWS patients.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1153 Identifying non-coding causes of congenital heart defects: Abnormal RNA splicing with multiple novel isoforms as a mechanism for heterotaxy.

Authors:

J. Wells, M. Padua, A. Haaning, S. Ware; Indiana Univ. Sch. of Med., Indianapolis, IN

Heterotaxy is a disorder characterized by severe cardiovascular defects and abnormal left-right patterning in other thoracic and/or abdominal organs. Previous clinical and research-based genetic testing has mainly relied on functional evaluation of coding variants to identify causative heterotaxy variants. The potential for non-coding variants causing congenital heart defects (CHDs), including heterotaxy, has been largely neglected. Mutations in Zinc finger of the cerebellum 3 (*ZIC3*), a transcription factor with 5 zinc finger DNA binding domains, cause X-linked heterotaxy. Our lab identified an X-linked heterotaxy pedigree without a coding mutation in *ZIC3*. Whole genome sequencing in this family revealed a novel, intronic variant (*ZIC3* c.1224+3286A>G) predicted to alter RNA splicing. An *in vitro* minigene splicing assay confirmed this variant can act as a cryptic splice acceptor. We then used CRISPR/Cas9 to introduce the *ZIC3* c.1224+3286A>G variant into human embryonic stem cells (hESCs) and demonstrated it acts as a cryptic splice acceptor resulting in pseudoexon inclusion. Intriguingly, cDNA amplification and Sanger sequencing of *ZIC3* amplicons revealed that this variant triggers multiple abnormal splicing events, resulting in several novel exons and isoforms. Many of these isoforms lack a portion of a DNA binding domain and the nuclear localization signal. Short read mRNA sequencing confirmed the initial, abnormal splicing patterns detected, but also identified additional novel exons not seen in control hESCs. In total, our results suggest a minimum of six novel exons: three alternative splicing patterns of a canonical exon, one pseudoexon with the *ZIC3* c.1224+3286A>G variant acting directly as a splice acceptor, and two additional pseudoexons created by the activation of cryptic splice sites. Long read mRNA sequencing of *ZIC3* c.1224+3286A>G and wildtype hESCs is ongoing to determine the relative abundance of the full-length novel transcripts. In addition, functional evaluation of the most abundant novel transcripts is in progress using *in vitro* (subcellular localization) and *in vivo* (RNA rescue in *Xenopus laevis*) methods. These results are the first reported instance of pseudoexon inclusion associated with heterotaxy. Our results suggest the importance of non-coding variants in heterotaxy and the need for improved methods to identify and classify non-coding variation that may contribute to CHDs.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1154 Immunolocalization and functional characterization of PFE1445C: a novel integrin alpha-like cell adhesion protein in *Plasmodium falciparum.*

Authors:

C. Donkeu[1,2], R. Keumoe[1,2], M. Biabi[3,2], B. Fogang[1,2], E. Essangui[3,2], S. Kemleu[4,2], C. Else Eboumbou[3,2], R. Grailhe[5], F. Njiokou[1], L. Ayong[2]; [1]Univ. of Yaounde 1, Yaounde, Cameroon, [2]Ctr. Pasteur Cameroon, Yaounde, Cameroon, [3]Univ. of Douala, Douala, Cameroon, [4]Univ. of Buea, Buea, Cameroon, [5]Technology development division, Inst. Pasteur of Korea, institute Pasteur of Korea, Cameroon

Background: The cytoadherence/sequestration process of Plasmodium parasites is organ selective and thought to be mediated by a combination of specific ligands and receptors that are located in trans on both the parasite or infected erythrocyte surface membrane and the associated host cells. Whereas the cytoadherence protein, PfEMP-1 had been identified as the most important ligand for mature asexual stage parasite cytoadherence to microvasculature endothelia, the protein ligands responsible for sexual stage sequestration in collagen-rich bone marrow tissues have remained unknown. Here, we describe the initial characterization of a novel Plasmodium falciparum integrin-like protein with potential to mediate both asexual and sexual parasite sequestration in collagen-rich tissue linings. **Methods:** *Plasmodium falciparum* integrin-like proteins were identified by structural classification of proteins (SCOP) hierarchical search of integrin superfamily protein domains in malaria parasites. Polyclonal antibodies (anti-PfINT) reactive to the Plasmodium integrin alpha-like protein was elicited by immunization of rabbit with synthetic peptides derived from the membrane-proximal extracellular domain of PFE1445C, and used in both Western immunoblot analysis and fluorescence microscopy examination of the protein in fixed cells. Protein function was further analyzed by investigating the effect of anti-PfINT on parasite growth *in vitro* as well as determining the association of anti-PfINT antibody carriage with protection against malaria. **Results:** Bioinformatics analysis of protein domains revealed a single protein in the Plasmodium falciparum 3D7 protein database with domain combinations consistent with those of classical integrin alpha proteins. No integrin beta tail domain proteins were observed using SCOP. Western blot analyses detected a single expected protein band at 82 kDa. This protein was predominantly expressed in Plasmodium trophozoites and schizonts where it appeared to localize to the developing merozoite surface. Anti-PfINT antibodies exhibited significant growth inhibitory effects against *P. falciparum* 3D7 culture, suggesting an effect on merozoite invasion *in vitro*. Anti-PfINT antibody levels were significantly high in sub-microscopically infected and asymptomatic endemic individuals compared to malaria patients, further indicating a role of anti-PfINT antibodies in natural protection against malaria. **Conclusion:** Taken together, our data suggest a role for PFE1445C in asexual development of *P. falciparum* parasites both in vitro and in vivo in humans.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1155 Impact of environmental air composition on immune responses and cardiometabolic risks: insights from a Canadian cohort study

Authors:

M-J. Fave[1], E. Bader[2], E. Gbeha[2], V. Bruat[3], M. Agbessi[2], D. Soave[4], P. Awadalla[2]; [1]Ontario Inst. for Cancer Res., Montreal, QC, Canada, [2]Ontario Inst. for Cancer Res., Toronto, ON, Canada, [3]MaRS Ctr., 661 Univ. Avenue, suite 510, Toronto, ON, Canada, [4]Wilfrid Laurier Univ., Waterloo, ON, Canada

Climate change, in conjunction with various natural and anthropogenic health stressors, will greatly impact human health and disease. However, humans exhibit remarkable variability in their individual immune responses to environmental challenges. Cytokines, key regulators of inflammation and immune responses, act at the interface of physiology and environmental exposures and have been implicated in diseases such as asthma, cardiometabolic disorders, and cancer. The World Health Organization estimates that nearly the entire human population resides in areas with high levels of air pollutants. Episodes of harmful air composition can arise from specific atmospheric conditions, excessive motor vehicle usage, residential or industrial emissions, or wildfires.

In a study involving over 7000 participants from the Canadian Partnership for Tomorrow's Health (CanPath), we have demonstrated an association between serum cytokine protein profiles and harmful air composition. Elevated levels of cytokines, including IL1b, members of the VEGF cascade, and CCL5, involved in angiogenesis and macrophage recruitment, were observed in response to high levels of PM2.5. These findings align with our observations linking IL1b to lung adenocarcinoma following PM2.5 exposure in mice and humans. Aged individuals exposed to deleterious air composition exhibit increased levels of these pro-angiogenic proteins, potentially contributing to elevated health risks. Notably, after accounting for age and BMI, air pollution explains most of the remaining variation in cardiometabolic risk within our cohort.

By analyzing data from 1400 CanPath individuals using either single-cell RNA sequencing or bulk RNA sequencing, we have identified cell type-specific eQTLs in genes encoding cytokine levels associated with air quality. This indicates that individual genetic variation and cell type specificity can modulate health risks and responses to environmental challenges. Specifically, we found an eQTL for *CCL5* in monocytes that is specific to aged individuals, as well as eQTLs affecting *VEGF* levels in plasmablasts. Additionally, we have replicated the dysregulation of cytokines in response to air quality for several biomarkers, including *VEGFB* and *IL1b*, using bulk RNA sequencing across regions in Canada that experience varying air quality profiles.

Our work shed light on the complex interplay between environmental factors, individual genetic variation and function, and human health, emphasizing the need for targeted interventions to mitigate the adverse effects of air pollution.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1156 Improved multi-ancestry fine-mapping of gene expression data identifies more cis-regulatory mechanisms

Authors:

N. Mancuso[1], Z. Lu[1], J. Jung[1], D. Yuan[1], S. Gazal[2]; [1]Univ. of Southern California, Los Angeles, CA, [2]USC, Los Angeles, CA

Expression quantitative trait (eQTL) analyses have identified numerous variants associated with gene expression levels, but distinguishing causal *cis*-eQTLs from nearby tagging variants is challenging due to linkage disequilibrium (LD). Multiple works have shown that multi-ancestry fine-mapping approaches improve fine-mapping precision by leveraging LD heterogeneity. However, existing methods are computationally expensive and assume that causal variant effect sizes are independent across ancestries, which fails to reflect shared genetic architectures.

To solve these limitations, we present the Sum of Single Shared Effects (SuShiE) model to fine-map eQTL data across multiple ancestries. We note that SuShiE 1) improves fine-mapping precision by leveraging LD heterogeneity under shared causal assumptions; 2) learns the prior correlation of effect sizes across ancestries; 3) estimates ancestry-specific effect sizes under this correlation structure, which boosts statistical power in downstream transcriptome-wide association studies (TWAS); 4) does so using a highly-scalable variational inference framework. Through simulations, SuShiE places higher Posterior Inclusion Probabilities (PIPs) on causal eQTLs, outputs smaller credible sets, and exhibits greater precision ($P<5E-9$) than existing fine-mapping approaches. In addition, SuShiE estimates more accurate ancestry-specific effect sizes ($P<1E-7$), thus increasing the power for TWAS ($P<1E-31$).

Next, we analyze expression levels measured in PBMCs from individuals of EUR, AFR, HIS, and EAS ancestries (N=1,194) in the TOPMed MESA study together with LCL expression levels from individuals of EUR and AFR ancestries (N=813) from the GENOA study. Compared to a simple baseline, SuShiE identified more putative causal cis-eQTLs (18,631/35,764 eGenes vs 10,570) while outputting smaller credible set sizes, higher PIPs and credible sets with PIPs > 0.9 more frequently ($P<0.05$). SuShiE estimates 93% of genes exhibit 1-3 shared cis-eQTLs and infers highly correlated posterior effect sizes on average (rho=0.74) across ancestries, thus reflecting shared eQTL architectures.

To validate our results, we perform an enrichment analysis using candidate *cis*-regulatory element (cCRE) annotations from snATAC-seq in PBMCs. Focusing on MESA, PIPs inferred by SuShiE are more enriched in relevant regulatory features ($P=2.1E-6$). For example, we find 1.36x, 1.17x, and 1.15x relative enrichment of PIPs in TSS, native-T, and cytotoxic-NK cCREs compared with existing approaches.

Overall, our approach sheds light on understanding the genetic architecture of gene expressions across multiple ancestries.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1157 Improving metabolite QTL discovery using metabolite ratios

Authors:

S. D. Slack[1], A. Romero[1], L. Vanderlinden[1], S. S. Rich[2], M. Rewers[3], O. Fiehn[4], J. M. Norris[5], R. K. Johnson[1]; [1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [2]Univ. of Virginia, Scottsville, VA, [3]Barbara Davis Ctr. for Diabetes, Aurora, CO, [4]UC Davis Genome Ctr., Davis, CA, [5]Colorado Sch. of Publ. Hlth., Aurora, CO

Characterizing the genetic control of molecular traits through identification of quantitative trait loci (QTLs) can provide insight into the biochemical processes underlying disease. Ratios between metabolites more directly reflect flux through chemical reactions than individual metabolites, potentially offering a clearer connection between the metabolome and genome. As proof-of-concept, we compared heritability and QTL loci discovered through metabolome-wide association of individual features to those discovered from pairwise ratios of metabolites in a multi-national prospective study of children at high-risk for type 1 diabetes. We combined genotypes from a customized exome array, imputed to the TOPMed reference panel, with untargeted metabolomics data from The Environmental Determinants of Diabetes in the Young study for 338 islet autoimmunity cases and 921 controls matched on age, sex, country, and family history. SNP-based heritability (H) was calculated for 2,505 metabolites and 1,241,053 ratios from all pairwise combinations of metabolites using Genome-wide Complex Trait Analysis constrained restricted maximum likelihood, adjusted for case-control status and genetic relatedness. Heritability was similar (P = 0.13) for significantly heritable ratios (mean H = 0.37, IQR: 0.25-0.44) and individual metabolites (mean H = 0.38, IQR: 0.25-0.46). P-gain was calculated as a quantitative measure of the gain in heritability significance for each ratio compared to its more significant metabolite. 4,064 ratios (0.3%, mean H = 0.87, IQR: 0.77-0.99) had a Bonferroni significant p-gain at alpha 0.05, corresponding to an average heritability increase of 0.22 (IQR: 0.14-0.31) for the ratio over the metabolite. Matrix eQTL software identified metabolite QTLs for the prioritized 4,064 ratios and corresponding 496 individual metabolites, adjusted for case-control status and genetic relatedness. After Bonferroni correction, we identified 45,243 metabolite-SNP pairs and 12,949 ratio-SNP pairs (P < 1.1x10-11) which were combined into 21,301 loci of 287 individual metabolites and 3,887 loci of 450 ratios. 561 (14.4%) ratio loci, involving 153 ratios, were uniquely discovered in ratio QTL analyses; over 25% of these controlled pairs of ether phosphocholine levels. Our results suggest that analysis of metabolite ratios may provide novel insights into the genetic control of metabolism missed by QTL analyses of individual metabolites. Analysis of ratios may offer a more direct biological connection to genetic control of the metabolome via enzymatic reactions while potentially improving power by decreasing technical noise.

PB1158 Incidental/secondary ACMG and non-ACMG genetic findings in a multiethnic cohort of 16,713 pediatric patients.

Authors:

A. Saeidian[1], M. March[1], D. Watson[1], X. Wang[1], L. Youssefian[2], E. Bhandari[1], F. Aliazami[3], G. Kazemioula[4], A. Saeidian[5], H. Vahidnezhad[1], M. Harr[1], F. Mentch[1], M. Akbarzadeh[6], L. Tsoi[7], J. Gudjonsson[8], J. Glessner[1], H. Hakonarson[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]UCLA, Los Angeles, CA, [3]Azad Univ., Tehran Med. Sci., Dept. of Genetics, Tehran, Iran, Islamic Republic of, [4]Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of, [5]Iran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, [6]Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, [7]Univ. of Michigan, Ann Arbor, MI, [8]Univeristy of Michigan, Ann Arbor, MI

Purpose: Clinical next-generation sequencing can identify pathogenic sequence variants that are medically actionable for patients and their families but are not associated with the patient's primary diagnosis. These variants are incidental findings (IFs), secondary findings (SFs), or unsolicited findings (UFs). To date, there is no report of types and frequencies of SFs in a large pediatric cohort including a substantial percentage of African-American children. We sought to investigate the types, frequencies, and rates of SFs as well as the effects of SF disclosure on patients and families at the Center for Applied Genomics at The Children's Hospital of Philadelphia. **Methods:** We searched for pathogenic and likely pathogenic variants in disease-causing genes, specifically in 78 ACMG recommended and 93 non-ACMG genes that met the definition of SFs/IFs in patients of four pediatric cohorts. The 93 non-ACMG genes were compiled from literature reviews of additional proposed genes to the ACMG list. Variants were filtered by P/LP classification as per ACMG/AMP recommendations, CADD vs Mutation Significance Cutoff (MSC) scores, variant type, presence in disease-causing variant databases, and IGV visualization for manual variant quality inspection. We divided the patient's P/LP variants into four disease categories: metabolic, cancer, cardiovascular, and other. **Results:** We report a distinctive distribution of types and frequency of 1901 P/LP variants of SF/IFs in 16,713 subjects. There were 702 (4.2%) previously reported P/LP variants in 35 ACMG genes and 294 (1.8%) in 31 non-ACMG genes. In addition, 543 (3.2%) previously not reported P/LP variants in 56 ACMG genes and 543 (3.2%) in 46 non-ACMG genes. The most frequent variants among the ACMG and non-ACMG genes were TTR and G6PD, respectively. In our patients, we found 177 P/LP variants in 12 ACMG and 189 P/LP variants in six non-ACMG cancer-predisposing genes. Additionally, we found 442 P/LP variants in 12 ACMG and 41 P/LP variants in 10 non-ACMG cardiac disease-causing genes. Variants of potential medical importance were identified in 8% of participants. Challenges in reporting SFs included variants associated with adult-onset disease within a pediatric cohort, loss of an "open future," pre-symptomatic testing, variable expressivity, incomplete penetrance, and unknown family history of phenotype. **Conclusions:** Our data on SF findings in a large pediatric cohort provide several implications, such as medical actionability with pharmacogenetic implications, family planning, additional family genetic testing, and genetic counseling strategies to manage the impact of SF disclosure to patients and families.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1159 Initial screening of large >10 Kb deletions from long-read sequencing of 1,000 Emiratis

Authors:

S. Elavalli[1], G. Katagi[1], L. Paulin[2], F. Sedlazeck[3], J. Quilez[1], T. Magalhaes[1], The Emirati Genome Program; [1]G42 Hlth.care, Abu Dhabi, United Arab Emirates, [2]Baylor Coll. of Med., Houston, TX, [3]Baylor Coll. Med., Houston, TX

The Emirati Genome Program (EGP) aims to whole-genome sequence at ~30X the ~1 million Emirati nationals in the United Arab Emirates (UAE). Two key features of EGP are the sequencing of tens of thousands of participants using long-read Oxford Nanopore Technologies (ONT), and the aim to translate genomics into clinical practice. Amongst the advantages of ONT is the capacity to detect structural variants (SV), which are important to better understand their contribution to biology and disease.

Here we present an initial characterization of SV in the Emirati population based on ~1,000 (1K) EGP participants whole-genome sequenced on ONT. We first assessed the quality of such dataset. We achieved satisfactory median read length (4.79 Kb), mapping coverage (41X) as well as percentage of mapped bases (94%) and genome covered (>99%). Using Sniffles2 and in line with previous studies, we called ~24,000 SV per genome irrespective of coverage. Besides, we further demonstrated the power of Sniffles2 to merge SV across all genomes and thus recall variants which had been missed in the individual calling (increasing to 24,500 SV per genome). Across all 1K individuals, we identified a total of unique 131,570 SV regions (46.2% deletions, 3.2% duplications, 49.1% insertions and 0.5% inversions) - this split between SV types is in line with previous studies.

We restricted our subsequent analysis to large (>10 Kb) deletion regions (LDR). We argue that (i) it is easier to predict the effect of deletions on the genes they overlap, compared to other SV types, and (ii) large events are more likely to have an impact on gene function. We detected ~45 LDR per genome (range = ~30-60) and a total of 2,300 LDR across the 1K genomes. We observed the expected Poisson-like minor allele frequency (MAF) distribution, with many singletons (n=868, 37.74%) and few common (MAF>5%) deletions (n=88, 3.83%). In between were events detected in >1 individual but with MAF<5%, which represented >58% (n=1,344) of the LDR. Of all LDR, 25% exceeded 25 Kb and ~200 were >100 Kb. As expected, relatively common LDR were <100 Kb and none >1 Mb reached a MAF>10%.

Finally, we screened our cohort of 1,000 Emirati genomes for homozygous common gene-overlapping LDR. We defined them as LDR with >1 individual homozygous for the alternate allele, with a MAF>5% and overlapping >=1 gene. We identified 32 of such regions each present in 0.10-71.90% of the cohort (median = 6.95%) and 5.10-44.70% MAF. On average, these regions were ~16 Kb (IQR = 10.30-31.40 Kb) and mostly comprised a single gene. We propose these regions as candidates for validation, further investigation and matching with clinical information.

PB1160 Integrating genetics, metabolomics, and gene expression to dissect the sphingolipid pathway in Parkinson's disease.

Authors:

R. De Paula[1], C. Shaw[1], S. Elsea[1], J. Shulman[2,1]; [1]Baylor Coll. of Med., Houston, TX, [2]Duncan Neurological Res. Inst., Houston, TX

Parkinson's disease (PD) is a common, complex, and incurable condition that causes progressive motor disability and increased risk for cognitive impairment. This disease is neuropathologically defined by the formation of alpha-synuclein (aSyn) aggregates and loss of dopaminergic neurons in the substantia nigra. Accurate PD biomarkers remain to be developed to better stratify PD subtypes. Rare variants in genes associated with lysosomal storage disorders (LSD) have been linked to increased PD risk and may help to explain PD molecular heterogeneity, but metabolic evidence linking most LSD genes and PD is unavailable. Many LSD genes have key roles on the sphingolipid pathway, and mutations in those genes are potentially linked to disruption of sphingolipids. For example, *GBA* loss of function may cause the accumulation of glucosylceramide, disrupt lysosomal function, and affect aSyn accumulation. Importantly, aSyn aggregates seem to inhibit GBA enzyme, highlighting the existence of *GBA*-aSyn interactions. With that in mind, we hypothesize that the cumulative effect of LSD gene variants disrupts the sphingolipid pathway in PD via gene dysregulation and interactions with aSyn. We leveraged genome sequencing and metabolomic profiles from the Religious Orders Study and Rush Memory and Aging Project (n = 514 brain autopsies). We examined putative damaging, single nucleotide variants in 54 LSD genes (minor allele frequency (MAF) <3% and CADD scores >12.37). We used the likelihood-ratio test to compute dysregulated metabolites between subjects with and without subclinical PD pathology, and partition around medoids clustering to find multivariate patterns of sphingolipid dysregulation and their association with LSD gene variants. Our analysis revealed some significant dysregulated sphingolipids in PD brains, and clustering of subjects based on levels of 9 ceramide species revealed that *GBA*, *GALC*, and *SMPD1* variants are associated with higher ceramide levels. Consistent results were obtained in an analysis considering overall LSD genetic variant burden. Further integration with brain transcriptome and proteome data from the same human cohort reveals significant dysregulation of sphingolipid-related enzymes in PD. Similar result was observed in our lab using a *Drosophila melanogaster* model of aSyn pathology. Our results are potentially consistent with a model in which gene expression changes and metabolic perturbations mediate the impact of LSD genetic variants on aSyn pathology. Such findings increase our understanding of PD molecular mechanisms and may aid the development of more accurate PD risk scores in the future.

PB1161 † Integration of cerebrospinal fluid pQTL and GWAS prioritizes novel candidate genes involved in Alzheimer's disease

Authors:

D. Western[1], J. Timsina[1], L. Wang[1], C. Wang[1], A. Ruiz[2], M. Marquié[2], M. Boada[2], I. de Rojas[2], I. Alvarez[3], M. Aguilar[3], P. Pastor[4], D. J. Pulford[5], Y. Sung[1], C. Cruchaga[1]; [1]Washington Univ. in St. Louis Sch. of Med., St. Louis, MO, [2]ACE Alzheimer Ctr. Barcelona, Barcelona, Spain, [3]Memory Disorders Unit, Univ. Hosp. Mutua Terrassa, Terrassa, Spain, [4]Univ. Hosp. Trias i Pujol and the Germans Trias i Pujol Res. Inst., Badalona, Spain, [5]GlaxoSmithKline, Stevenage, United Kingdom

Background: The integration of quantitative trait loci (QTLs) with disease genome-wide association studies (GWAS) has proven successful at prioritizing candidate genes at disease-associated loci. While tissue-specific genetic regulation of RNA transcripts is robustly analyzed, most studies assaying the genetic regulation of proteins have been limited to plasma. We have previously demonstrated that pQTL associations are highly tissue-specific. Given the relevance of cerebrospinal fluid (CSF) to Alzheimer's disease (AD), we developed a CSF-specific pQTL atlas and integrated it with AD GWAS to identify novel candidate genes for AD. **Methods:** We generated CSF proteomics (Somalogic, 7,584 analytes) data for 3,107 individuals. We integrated genomic and proteomic data through pQTL analysis using a three-stage approach: discovery, replication, and meta-analysis. We analyzed the tissue- and molecule-specificity of our associations by comparing to plasma & brain pQTLs and various eQTLs. We performed a proteome-wide association study (PWAS) and Mendelian randomization (MR) to prioritize proteins affecting AD. We determined shared protein-disease genetic regulation using colocalization. Using AD-associated proteins, we built prediction models for AD biomarker status. **Results:** Our meta-analysis identified 2,316 significant pQTLs (1,247 in *cis* and 1,069 in *trans*) for 1,960 proteins, of which 1,228 were not observed in plasma. Through PWAS, we identified 473 proteins associated with AD risk. MR prioritized 40 proteins as causal and colocalization identified 158 proteins that share genetic etiology. 42 of these overlap between at least two of these methods and are enriched in immune and lysosomal pathways. Multiple (including PILRA, PRSS8, and SIRPA) represent novel candidate proteins. A prediction model using the PWAS-identified proteins outperforms a PRS at predicting CSF amyloid/tau status across ages (AUC $\geq$ 0.972) and *APOE* genotypes (AUC $\geq$ 0.989). **Conclusions:** We have developed the largest CSF pQTL analysis to date and confirmed that CSF pQTLs are largely tissue-specific. Through a rigorous approach combining three methods, we have identified high-confidence proteins involved in AD that confirm previously reported candidate genes and prioritize new ones at GWAS loci. We developed highly accurate prediction models using prioritized proteins. Our findings offer insights into Alzheimer's disease biology that were missing when using plasma analyses, supporting the development of tissue-specific proteomics databases in neurologically-relevant tissues.

Background Non-syndromic orofacial clefts (NSOFCs) are the most prevalent craniofacial birth defects, affecting approximately 1 in 1000 live births worldwide. Despite previous genome-wide association studies (GWASs) identifying risk loci for NSOFCs, these variants explain only a small portion (20-30%) of the estimated heritability, and their functional mechanisms remain largely unknown. Therefore, we meta-analyzed suggestive genome-wide signals and integrated epigenetics data to discover and functionally characterize novel loci for NSOFCs. **Methods** We genotyped 158 single nucleotide variations (SNVs) with suggestive associations (E-05 ≤ P > E-08) from the African NSOFCs GWAS in an independent cohort of 824 cases and 1038 controls from Nigeria, Ghana, and Ethiopia. This was followed by performing allelic association adjusting for sex and the top principal components (PCs). Subsequently, we meta-analyzed the results with the discovery GWAS results. For non-coding significant SNVs, we constructed a haplotype block around the SNVs and overlayed it on chromatin mark datasets from human craniofacial tissues to predict the impact of the SNV(s) on regulatory regions. Further, we performed a dual luciferase reporter assay to test the allele-specific effect of the predicted regulatory variant(s) on enhancer activity.
Results and Discussions We found significant associations for SNVs in the 8q24 region with nonsyndromic cleft lip/palate, as well as associations with the 9q22, chr10q24 [*OPALIN*], and 2q22 regions with non-syndromic cleft palate (NSCP). Chromatin mark datasets from developing human craniofacial tissues showed that the SNVs at 8q24 and 9q22 were in haplotype blocks within, annotated craniofacial enhancers predicted to regulate the expression of the *MYC* and *PTCH1* genes; respectively. Evidence from dual luciferase reporter assay in relevant cell lines further supported the regulatory function of the SNV at 9q22 on enhancer activity. The 8q24 region is a widely studied cleft candidate region, and deletion of this region has been reported to cause NSOFCs in mice. The *PTCH1* functions in the hedgehog signaling pathway, and variants in this gene cause nevoid basal carcinoma syndrome, a syndromic form of OFCs. Additionally, the *PTCH1* gene is expressed in mesenchyme and subclusters of ectoderm during facial development. **Conclusions** Our study highlights the utility of epigenetic data in unraveling the functional mechanism underlying GWAS associations. Further, our result suggests that non-coding variants in regulatory regions near the *PTCH1* gene increase the risk for NSCP.

Hosp., London, United Kingdom, [6]Univ. of Bristol, Bristol, United Kingdom, [7]Univ. of Manchester, Manchester, United Kingdom, [8]Univ. of Oxford, Oxford, United Kingdom, [9]Newcastle Univ., Newcastle, United Kingdom, [10]Natl. Inst. on Aging, Bethesda, MD, [11]NIH, Bethesda, MD, [12]Univ. of Sydney, Sydney, Australia, [13]Univ. of New South Wales, Sydney, Australia, [14]UCL Great Ormond Street Inst. of Child Hlth., London, United Kingdom

Early-onset parkinsonism (EOP) can be monogenic. However, emerging studies indicate that rare and common variants, individually or jointly, together with known mutations, can influence age at onset, suggesting a more complex genetic aetiology of EOP. Here, we aimed to integrate clinical, pathological, genetic, and transcriptomic data from clinically diagnosed EOP cases to determine putative causal variants and genes as well as likely pathogenic biological pathways. We define early onset by motor age-at-onset below 50 years old following the recommendations from the International Parkinson and Movement Disorder Society Task Force. We evaluated 182 EOP cases with summary clinicopathological data, including 116 clinically diagnosed Parkinson's disease cases (PD), 8 postencephalitic parkinsonism cases (PEP), 11 progressive supranuclear palsy (PSP) cases, and 47 multiple system atrophy cases (MSA) from brain bank cases. We studied the genetic features using the Illumina Neurobooster array (NBA) and whole genome sequencing with 150 base-pair paired-end sequencing with 30x coverage generated in the Global Parkinson's Genetic Program (gp2.org). 33% of cases had mutations in defined Parkinsonism genes and further evaluation of this dataset is underway. We investigated the gene expression profiles of 56 early-onset PD cases compared to 269 late-onset PD cases and 242 controls with blood-derived RNA available samples at baseline from the Parkinson's Disease Biomarkers Program (PDBP). We accessed data from the AMP-PD portal and used the DESeq2 package to run differential gene expression analysis and clusterProfiler package for the functional enrichment analysis. We identified 216 up-regulated genes and 27 down-regulated when comparing EOPD cases to LOPD and 1088 genes up-regulated and 273 down-regulated when comparing EOPD cases against controls. In addition, we observed significantly enriched terms related to the regulation of RNA metabolic processes and the suppression of mitochondrial transport. These results suggest different gene expression profiles for early-onset PD cases. We are correlating the results of the gene expression data with the genetic analysis of the brain bank data, and further brain RNA analysis is underway. This work highlights an integration of clinicopathological data and multi-omic strategies in understanding the pathogenesis of EOP.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1164 Integrative analysis of multi-omics data identifies *PSMB9* as a gene responsible for TNF inhibitor response in patients with rheumatoid arthritis.

Authors:

Y. Kim[1], S. Lee[2], J. Lee[2], H-H. Won[1]; [1]Samsung Advanced Inst. for Hlth.Sci. & Technology (SAIHST) , Sungkyunkwan Univ., Seoul, Korea, Republic of, [2]Dept. of Med., Samsung Med. Ctr., Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of

Rheumatoid arthritis (RA) is an inflammatory disease characterized by joint inflammation and pain. Tumor necrosis factor (TNF) causes the inflammation related to RA. TNF inhibitors (TNFi) are used to treat RA patients by effectively blocking the activity of TNF. However, each RA patient can have different response to TNFi treatment. To detect genetic biomarkers of TNFi response and understand the underlying mechanism, we investigated expression quantitative trait loci (eQTLs) using the INTERVAL database, influencing to gene expression involved in TNFi response. We identified 31,873 *cis*-eQTLs for 29 differentially expressed genes (DEGs) in TNFi responders compared to non-responders. We tested associations of the 31,873 variants with TNFi response in 2,712 RA patients of European ancestry. We identified two variants, rs3793127 and rs1391373 that were significantly associated with TNFi response (p = 9.23E-05 and p = 0.000241) and with expression levels of *PSMB9* (p = 0.00131 and p = 3.74E-08). The up-regulation of *PSMB9* was observed in responders ($p < 0.05$, Mann and Whitney's test) after three months of TNFi treatment. Furthermore, single-cell RNA analysis showed that *PSMB9* was abundantly expressed in subsets of B cells and $CD8^+$ T cells, characterized by plasmablasts and $GZMK^+$, respectively. They might play a significant role in antibody response and cytokine activation. This study may help elucidate the molecular mechanism for the response to TNFi treatment.

Hosp. and Univ. of Oulu, Oulu, Finland, Oulu, Finland, [7]Analytic and Translational Genetics Unit, Dept. of Med., Massachusetts Gen. Hosp., Boston, MA

Genetic discoveries in schizophrenia (SZ) and other neurodevelopmental disorders have highlighted transcriptional regulation as one key point of convergence. Biological modeling of these genetic high-risk variants in human induced pluripotent stem cell (hiPSC) -derived neuronal models can help elucidate how transcriptional misregulation leads to impaired neuronal function. With whole exome sequencing, we have discovered deleterious variants in the transcriptional regulator *INTS6* gene in a family with 6 patients with intellectual disability (ID) and one with SZ from the Northern Finnish Intellectual Disability study (NFID). Intriguingly, in the Schizophrenia Exome Sequencing Meta-Analysis (SCHEMA) consortium, 3 additional patients and no controls were reported with deleterious variants of *INTS6* (OR=16.1, p=0.0092). *INTS6* encodes for a subunit of the integrator complex, which is involved in regulating transcription and processing of RNA polymerase II transcribed 3' small nuclear RNAs (snRNAs). Transcription initiation and attenuation are crucial for neuron function and development. We hypothesise that *INTS6* haploinsufficiency leads to reduced integrator complex function and therefore to alternative splicing and gene expression dysregulation in neurons. To study *INTS6*, we reprogrammed hiPSC lines from 6 cases, 6 non-carrier family members and 6 controls to discover functional consequences of the mutation in a patient-relevant genetic background. The variant carriers had reduced INTS6 peptide levels consistent with a loss of function effect. We will present results from transcriptional profiling of the differentiated neurons with RNA sequencing from cases and controls to illuminate the influence of *INTS6* in transcription, mRNA processing, and neuronal function. For validation of causality, we have generated CRISPR Cas9-edited isogenic rescue and knock-in neurons. Our study highlights the utility of patient-specific neuronal models in illuminating biological mechanisms associated with genetic risk variants in SZ and ID.

PB1166 Interrogation of functional variants in five COPD GWAS loci by massively parallel reporter assays

Authors:

A. Zhou[1], L. Gong[1], F. Guo[1], D. Qiao[2], V. Malik[3], y. yu[1], C. Benway[4], J. Liu[1], R. Chase[1], M. Cho[5], E. Silverman[6]; [1]channing lab, Brigham and Women's Hosp., Boston, MA, [2]Brigham and Women s Hosp., Needham Heights, MA, [3]Brigham and Women s Hosp., Boston, MA, [4]Boston Children s Hosp., Boston, MA, [5]Brigham and Women s Hosp., Duxbury, MA, [6]Brigham & Women's Hosp., Boston, MA

Most human complex disease-associated genetic variants identified from genome-wide association studies (GWAS) are in non-coding regions of the genome, indicative of potential undiscovered gene regulatory function. Integrative and high-throughput methods have been developed to identify functional variants associated with disease susceptibility by regulating causal gene transcription. We applied massively parallel reporter assays (MPRA) to identify functional variants in five COPD GWAS loci in three lung-relevant cell types: epithelial cells (16HBE), fibroblasts (MRC5), and endothelial cells (HUVEC). Among 1120 fine-mapped SNPs in five COPD GWAS regions included in the MPRA screening, we identified 25 SNPs with potential allele-specific effects on transcriptional activity. Four of these variants were confirmed by luminescence reporter assays in 16HBE and/or MRC5 cells demonstrating allele-specific enhancer activity. We further performed CRISPRi-based genome editing with targeted deletion of the genomic regions spanning potential functional variants in human bronchial epithelial cells (16HBE), followed by RNA-sequencing and qPCR validation. Two genes (*RUVBL1* and *RAB7A*) related to the WNT pathway, known to be important for lung repair regeneration and regulated by the previously identified COPD GWAS gene *FAM13A*, were identified as plausibletarget genes of potential functional COPD GWAS SNPs. In summary, through unbiased screening with MPRA in three cell types in combination with confirmatory reporter assays and CRISPR-based genome editing, we not only identified and validated top functional genetic variants associated with COPD but also pinpointed key target genes possibly implicated in COPD genetic susceptibility for future in depth mechanistic studies.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1167 Investigating ancestry-dependent cis-regulatory elements in *TOMM40* that modulate *APOE*-ε4 expression in Alzheimer's disease patient-derived microglia

Authors:

B. DeRosa[1], A. Ramirez[1], K. Nuytemans[1,2], L. Coombs[1], O. Oron[1], M. Vasquez[1], S. Simon[1], D. Van Booven[1], F. Rajabli[1,2], K. Celis[1], P. Whitehead[1], L. D. Adams[1], T. D. Starks[3], P. Mena[1], S. Tejada[1], G. Byrd[3], A. Griswold[1,2], L. Wang[1,2], J. Young[1,2], M. Pericak-Vance[1,2], D. Dykxhoorn[1,2], J. Vance[1,2]; [1]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Dr. John T. Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [3]Maya Angelou Ctr. for Hlth.Equity, Wake Forest Univ., Winston-Salem, NC

The strongest genetic risk factor for developing late onset Alzheimer's disease (AD) and sporadic early onset AD is the ε4 variant of the Apolipoprotein E gene (*APOE*). However, the risk conveyed by carrying *APOE*-ε4 varies between ancestral populations, with those of African ancestry showing lower ε4 risk compared to those of European ancestry. Furthermore, recent studies have shown that the variability in *APOE*-ε4 risk in admixed populations can be attributed to ancestry-dependent genetic variation in the region surrounding *APOE* (local ancestry; LA). *TOMM40*, a gene found immediately upstream of *APOE*, contains two intronic single nucleotide polymorphisms (SNPs), namely rs2075650 and rs59007384, with significant frequency differences between the African and the European *APOE*-ε4 haplotypes. Using massively parallel reporter assays (MPRAs) and chromatin structure analysis (Capture-C analyses), we previously observed higher enhancer activity of the intronic regions of *TOMM40* containing rs2075650 and rs59007384 in the European haplotype. To investigate the regulatory role of rs2075650 and rs59007384 in mediating ancestry-dependent *APOE*-ε4 expression, we used CRISPR/Cas9 to delete a 500 bp intronic region surrounding each SNP in induced pluripotent stem cell (iPSC) lines derived from African and European AD patients with an ε4/ε4 genotype. The isogenic sets of African and European iPSC lines (unedited and with deleted intronic regions) were validated for pluripotency, genomic stability, and the lack of off-target genome-editing resulting from the CRISPR-based gene correction. Ongoing studies in microglia generated from these lines will broaden our understanding of the contribution of these *TOMM40* regions in regulating the expression of *APOE*-ε4 in the context of African and European ancestral genetic backgrounds. The generation of isogenic sets of African and European iPSC lines with rs2075650 and rs59007384 reference and alternative alleles will help to comprehensively examine whether these *TOMM40* SNPs are the driving factors for the observed difference in ancestry-dependent enhancer activity.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1168 Investigating the interplay between variant pathogenicity and frequencies across populations

Authors:

R. Estanboulieh, A. K. Manrai; Harvard Med. Sch., Boston, MA

In order to provide clinical-grade variant pathogenicity classifications, genetic testing laboratories employ guidelines that combine several criteria and heuristics including knowledge about implicated molecular pathways, protein biochemistry, case-control cohorts, and population allele frequencies. Current guidelines generally classify variants with minor allele frequency (MAF) greater than 5% in any of the 5 continental populations as benign, but there have been limited systematic investigations of how to precisely tune this threshold to balance inclusion of pathogenic and exclusion of benign variants. Previous work has proposed frequency bounds for dominant and recessive Mendelian disorders that account for estimates of variant penetrance, disease prevalence, and other factors. If the Poisson-based filtering allele frequency of a variant exceeds that bound, it is automatically classified as likely benign. In this study, we investigate multiple definitions of a variant's filtering allele frequency on pathogenicity prediction, as well as their robustness to smaller data from understudied or admixed populations. These definitions include Poisson-based estimates in addition to other estimates that aggregate frequencies across populations motivated by information theory. We explore the performance of this method on a wide range of simple and complex genetic diseases, using high-confidence ClinVar variants as a gold standard, and validate our findings against individual-level genetic and clinical data from the UK Biobank. With the latter, we also study whether it is useful to account for the ancestry of an individual, such as in the case of context- or ancestry-dependent pathogenicity. Our analysis reveals that frequency bounding, while capturing most pathogenic variants, can still be sensitive to frequency estimates from understudied populations. In summary, this work contributes to the practical challenge of classifying variants by furthering our understanding of the interplay between a variant's pathogenicity and its frequency across different populations.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1169 IPSC-derived cerebral organoids as a neurological model of pediatric DPD deficiency.

Authors:

B. Bembenek, K. J. Bouchonville, R. E. Schmidt, S. M. Offer; Mayo Clinic, Rochester, MN

Dihydropyrimidine dehydrogenase (DPD) deficiency is caused by inactivating genetic variations in the *DPYD* gene, resulting in a metabolic disorder that has been correlated with neurologic and developmental conditions that arise during childhood. Case studies have reported associations between DPD deficiency and neurological symptoms, including epileptic seizures, microcephaly, delayed motor skill development, and autism spectrum-associated behaviors. The goal of this study was to characterize the cellular and molecular changes that are caused by DPD deficiency using patient- and control-derived cerebral organoids that were differentiated from human induced pluripotent stem cells (iPSC). Patient iPSC lines were obtained from affected individuals with three different genotypes associated with full or partial DPD deficiency; control lines were from unaffected individuals. Differential gene expression analysis with DESeq2 was performed comparing iPSCs, embryoid bodies, and mature organoids by patient phenotype and genotype. Overall, dysregulation of genes related to synaptic function, neurotransmitter signaling, cell-type markers, and neurological structural components was observed at all stages of development between cases and controls. To further investigate dysregulation at a single cell level, single cell RNA sequencing was performed on mature organoids, and immunofluorescence and functional analyses were performed to mechanistically investigate observed gene expression changes. Based on our results, we hypothesize that the upregulation of glutamate receptors results from a reduction of β-alanine availability via DPD deficiency, leading to reduced modulation of glutamatergic signaling, which provides a potential explanation for the epileptic-type seizures that have been reported in patients. This excitotoxic signaling is also hypothesized to inhibit synaptic development and promote demyelination through excessive superoxide production, which may be associated with delayed neurological development. Collectively, our data provide key insight into the etiology of this condition.

PB1170 Iterative improvement of deep learning models using synthetic regulatory genomics

Authors:

A. Ribeiro dos Santos, G. Ellis, H. J. Ashe, R. Ordoñez, M. T. Maurano; NYU Sch. of Med., New York, NY

Generative deep learning models can accurately reconstruct genome-wide epigenetic tracks from the reference genome sequence alone. But it is unclear what predictive power they have on sequence diverging from the reference, such as disease- and trait-associated variants. We previously characterized dozens of deletions, inversions, and rearrangements of DNase I hypersensitive sites (DHSs) at the Sox2 Locus Control Region (LCR) in mouse embryonic stem cells (mESC). Here, we use the state-of-the-art model Enformer to predict DNA accessibility across these engineered sequences when delivered in place of the Sox2 LCR. Overall, we observe good correlation between accessibility predicted by Enformer and experimentally measured Sox2 expression. But model performance was better for deletions or inversions spanning multiple DHSs than for smaller deletions of individual transcription factor recognition sequences. Predictive power was particularly poor for rearrangements affecting DHS order. To explore model performance on sequences diverging even further from the reference, we designed and delivered composite enhancer payloads containing Sox2 DHSs paired with DHSs from other mESC super-enhancers. We found that their activity in vivo significantly diverged from predictions in silico. Our results suggest that current deep learning models perform poorly when presented with novel sequence diverging in certain critical features from their training set. This suggests an iterative approach incorporating profiling of synthetic constructs can improve model generalizability, and ultimately enable functional classification of regulatory variants identified by population studies.

Mexicans, a population characterized by genetic admixture, are critically underrepresented in omics studies of obesity, despite their increased susceptibility and prevalence of obesity and cardiometabolic disease. To address this health disparity and bridge the knowledge gap, we profiled subcutaneous adipose tissue, a key fat depot, at the single cell level in 48 Mexicans (17% male). Our cohort comprised individuals with varying body mass index (BMI) (33% classified as overweight and 37.5% as obese), with a high proportion of Admixed American (AMR) ancestry (mean=67.1%), which serves as a proxy of the Native American ancestry. We first performed adipose single-nucleus RNA sequencing and careful quality control to create the largest to date Mexican single-cell subcutaneous adipose reference with 126,123 nuclei profiled. Focusing on adipocytes, a central adipose cell-type, we used Milo to identify 1,961, 84, 235, and 231 subcellular neighborhoods of transcriptionally similar cells that show differential abundance (DA) and 654 (225), 109 (10), 1,580 (54), and 378 (9) genes (adipocyte markers) in these neighborhoods that are differentially expressed (DE) by sex, AMR ancestry, BMI, and AMR ancestry-by-BMI interaction (FDR<5%), respectively, thus discovering functional subtypes within Mexican adipocytes. Intriguingly, in the neighborhoods with lower global AMR ancestry, we observed higher (p=0.036) average *cis*-regional (±500kb) local AMR ancestry in the downregulated vs upregulated adipocyte marker genes, thus showing influences of local ancestry in these DE genes. To test for genetic regulation of the DE and adipocyte expressed genes, we performed a *cis*-eQTL mapping in the adipocyte pseudobulk expression data, adjusting for ancestry. At FDR<5% and MAF>10%, we identified 35,617 eQTL SNPs, regulating 830 genes, including 4.05%, 3.44%, 5.81%, and 2.75% of the DE genes in AMR ancestry, AMR-by-BMI interacting, sex, and BMI-associated neighborhoods. We also found significant eQTL SNPs for 67 (8.7%) adipocyte marker genes, including key mitochondria and adipose function genes, *ETFDH*, *MGST1*, and *AQP7*. Of these *cis*-eQTLs, 24.2% were not reported in bulk adipose tissue in GTEx. Collectively, our study represents the first endeavor to examine Mexican subcutaneous adipose tissue at the single cell level, revealing distinct subpopulations of adipocytes influenced by sex, AMR ancestry, BMI, and interactions between AMR ancestry and BMI. Furthermore, we discovered *cis*-eQTLs regulating the DE genes at the cell-type level. Taken together, our study suggests that Native American ancestry transcriptionally influences the high obesity rates in Mexicans.

PB1172 Large-scale testing of AGXT missense variant effects.

Authors:

A. De Souza[1,2], N. Kishore[3,2], Z. Dai[1,2], J. Weile[4,2], W. van Loggerenberg[3,2], R. Li[2], A. Rayhan[2], C. L. Tucker[5], M. Gebbia[3,2], A. G. Cote[3,2], F. P. Roth[3,2]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Lunenfeld-Tanenbaum Res. Inst., Sinai Hlth., Toronto, ON, Canada, [3]Donnelly Ctr., Univ. of Toronto, Toronto, ON, Canada, [4]Donnelly Ctr., Univ. of Toronto, Ontario, Canada, Toronto, ON, Canada, [5]Dept. of Pharmacology, Univ. of Colorado Sch. of Med., Aurora, CO

Variants in the AGXT gene, encoding the liver enzyme alanine:glyoxylate aminotransferase (AGT), can cause kidney stones and other symptoms of Primary Hyperoxaluria Type 1 (PH1). Over 27% of clinically-observed AGXT missense variants are deemed variants of uncertain significance. Saccharomyces cerevisiae lacking key genes in glycine metabolism (SHM1, SHM2, GLY1, and AGX1) cannot grow in ethanol media without human AGXT or supplemented glycine. First, we validated this functional assay for assessing variants in the context of both the reference allele and the common minor allele Pro11Leu and Ile340Met (global minor allele frequency 10%), which sensitizes AGT to the effects of other mutations. Tests of variants in both the major and minor alleles backgrounds are useful in exploring the effects of genetic interactions on protein fitness. Next, we attempted to measure the functional impact of all possible amino acid substitutions in AGT using large-scale mutagenesis, experimental evolution of a lab population of yeast cells expressing these variants, and determination of variant frequencies before and after selection. This yielded functional scores for 6758 (86%) of 7820 possible amino acid changes, collectively representing a missense variant effect map for AGT. The map recapitulates known biochemical features of AGT and successfully separates pathogenic from benign variants. Thus, our map for AGXT/AGT represents a resource for discovering new sequence/structure/function relationships and potentially expanding the fraction of kidney stone patients who can obtain a definitive genetic diagnosis and thereby benefit from already-approved PH1 therapies.

PB1173 Large-scale trans-eQTL meta-analysis in lymphoblastoid cell lines reveals functional consequences of GWAS variants.

Authors:

K. Freimann[1,2], A. Brümmer[3,4], E. Holzinger[5], J. Maranville[6], N. Nakic[7], H. Ongen[7], L. Stefanucci[8], M. Turchin[6], G. Trynka[9], S. Bergmann[3,4,10], K. Alasoo[1,2]; [1]Univ. of Tartu, Tartu, Estonia, [2]Open Targets, South Building, Wellcome Genome Campus, Cambridge, United Kingdom, [3]Dept. of Computational Biology, Univ. of Lausanne, Lausanne, Switzerland, [4]Swiss Inst. of Bioinformatics, Lausanne, Switzerland, [5]BMS, Cambridge, MA, [6]Bristol Myers Squibb, Cambridge, MA, [7]GSK, Brentford, United Kingdom, [8]Wellcome Trust Sanger Inst., Hinxton, United Kingdom, [9]Wellcome Sanger Inst., Hinxton, United Kingdom, [10]Dept. of Integrative BioMed. Sci., Univ. of Cape Town, Cape Town, South Africa

Genome-wide association studies (GWAS) have provided valuable insights into the genetic basis of complex traits and diseases. However, the interpretation of GWAS findings can be challenging, particularly when the functions of associated genes are unknown. To unravel the molecular and regulatory consequences of GWAS variants, trans-eQTL studies have emerged as a promising approach. Unfortunately, most existing eQTL studies lack the statistical power to detect robust associations. In this study, we conducted a large-scale trans-eQTL meta-analysis using data from lymphoblastoid cell lines (LCLs) from over 3700 samples collected across nine cohorts. Our study is the largest of its kind in a single homogenous human cell type. This helps us to avoid the confounding effects associated with cell type composition in bulk tissues such as whole blood. We detected ten loci where the same genetic variant was associated with five or more target genes at a conservative p-value threshold ($p < 1e-11$). Three of these loci near CIITA, SP140 and USP18 also overlapped GWAS loci for several autoimmune diseases. A trans-eQTL variant near the USP18 gene was associated with both increased risk for systemic lupus erythematosus (SLE) and increased expression of up to 40 interferon-inducible genes. USP18 encodes a ubiquitin-specific peptidase that is a known negative regulator of interferon signalling, suggesting that the trans-eQTL variant likely impairs the ability of USP18 to effectively limit the interferon response. This observation is consistent with existing literature on rare diseases, where the dysfunction of USP18 is linked to the development of severe autoimmune disorders. We find that trans-eQTL analysis in a purified cell type is a powerful approach to interpret GWAS associations, but very large sample sizes are likely required for this to be practical. Furthermore, technical confounders such as mis-mapping RNA sequencing reads need to be carefully considered to avoid false positive associations.

PB1174 Leveraging AlphaFold2 for the classification of genetic Variants of Uncertain Significance

Authors:

H. Murali[1,2], E. C. Liao[1], K. Wang[1,2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania, Philadelphia, PA

Introduction: Next-generation sequencing has revolutionized genetic testing in the clinic, revealing numerous rare disease-associate variants. However, the sheer volume of data poses new challenges in determining the clinical significance of variants, often resulting in their classification as Variants of Uncertain Significance (VUS). Current *in silico* variant pathogenicity prediction tools rely on evolutionary conservation, phylogeny, and ensemble methods, but overlook variant impact on 3D protein structure and related features. The emergence of AlphaFold2 has transformed the field of protein structure determination, so we aim to use insights from structural biology to tackle the "VUS classification challenge". **Objectives:** This study outlines a method that leverages AlphaFold2 and genetic variant databases to enhance VUS reclassification. We used the gene *IRF6* as a case study, since rescue experiments in *irf6*$^{-/-}$ zebrafish have validated several mutations as deleterious or benign. New variants continue to emerge and present new opportunities for prediction and functional validation. We aim to evaluate the accuracy of computational tools in predicting the pathogenicity of missense mutations. Key questions regarding consensus among tools, correlations between residue position and pathogenicity, distribution of predictions for each tool, and comparison with functional assays are addressed. **Methods:** We compared results from over 30 pathogenicity prediction tools on 37 *IRF6* variants, using ANNOVAR for inter-tool comparisons and experimental results for tool-experiment comparisons. As IRF6 lacks an experiment-derived structure, we used predicted structures from AlphaFold2 to explore correlations between mutation clustering and pathogenicity within its protein structure. **Results and Conclusion:** Among the analyzed variants, 19 of 37 were unanimously predicted as deleterious by computational tools. Comparing *in silico* predictions with experimental findings, 12 variants predicted as pathogenic were experimentally determined as benign. Mapping variants to the protein revealed deleterious mutation clusters around the protein binding domain, underscoring its significance. N-terminal variants showed contrasting results, with most being benign despite being predicted as deleterious by some tools. In general, these tools favor labeling variants as pathogenic, highlighting the need for improvement in current predictive tools. Incorporating protein structural features and analyzing mutation neighborhoods may enhance classification and provide meaningful insights into pathogenicity predictions.

PB1175 Leveraging cell type-specific epigenomic data to dissect adult-onset and childhood-onset asthma GWAS loci.

Authors:

X. Zhong[1], C. Billstrand[1], N. Sakabe[1], I. Aneas[1], J. Gu[1], I. Salamone[1], W. Wentworth-Sheilds[1], R. Mitchell[1], A. I. Sperling[2], N. Schoettler[1], M. A. Nóbrega[1], X. He[1], C. Ober[1]; [1]Univ. of Chicago, Chicago, IL, [2]Univ. of Virginia, Charlottesville, VA

Asthma is a heterogenous disorder with age of onset being an important discriminating factor in differentiating asthma subtypes. GWAS of adult-onset asthma (AOA) and childhood-onset asthma (COA) have mapped more than 60 independent risk loci, yet the biological mechanisms that contribute to asthma at most risk loci remain unknown. Recent advances in epigenome profiling provides unprecedented opportunity to functionally characterize non-coding GWAS variants across trait-relevant cell types. Here, we applied a computational pipeline that integrates open chromatin regions (OCRs) and chromatin interactions in blood and lung cell types to dissect AOA and COA GWAS loci. We used a Bayesian hierarchical model (TORUS) to estimate the genome-wide enrichment of asthma risk variants in OCRs and performed functionally-informed fine-mapping with sum of single effects (SuSiE) regression, assigning higher prior causal probability to SNPs overlapping with highly-enriched OCRs. Across 52 fine-mapped independent LD blocks, we found 76 credible sets, 25 of which contained a SNP with high posterior inclusion probability (PIP), i.e., ≥ 0.8. Leveraging OCRs in blood and lung cell types, we further identified 21 candidate *cis*-regulatory elements harboring asthma risk variants with moderate to high PIPs. Using luciferase assays in a human bronchial epithelial cell (BEC) line (16HBE14o-), we validated allele-specific enhancer activity for two putative enhancer sequences, one on chromosome 19 which looped to the promoter of *CEBPA*, an enhancer-binding protein involved in airway inflammation, by PCHi-C in freshly isolated BECs. The second validated allele-specific enhancer resided in a gene-dense locus at 5q31.1 and interacted with the promoters of multiple genes by PCHi-C in primary blood cells. Further studies of these and other candidate *cis*-regulatory elements are currently underway. Taken together, our study revealed intricate regulatory landscapes underlying many asthma risk loci and demonstrated the utility of integrating epigenomic annotations in post-GWAS variant-to-function studies.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1176 Leveraging plasma proteomics and supervised machine learning to interpret complex-trait genetics

Authors:

J. Irudayanathan[1], C. Benner[1], X. Xie[2], R. Pendergrass[1], A. Mahajan[1], M. McCarthy[1]; [1]Genentech Inc., South San Francisco, CA, [2]Genentech Inc, South San Francisco, CA

Genome-wide association studies (GWAS) have identified thousands of variants that are associated with complex traits and diseases. Prioritizing trait-relevant cis-genes that are downstream effectors of non-coding variants remains challenging. Here we introduce a supervised machine learning model designed to prioritize cis-genes given a GWAS variant, by training on a truth set derived from cis-acting protein quantitative loci (pQTL). Specifically, cis-pQTL identified in the discovery cohort of the UK Biobank Pharma Proteomics Project (UKB-PPP) consortium (n=35571; 2941 proteins assayed) were fine-mapped to resolve credible sets of causal variants with SuSie and FINEMAP. This resulted in 4589 variant-gene pairs mapping to 1400 unique autosomal proteins (credible sets with at least one variant satisfying PIP > 0.7). Variant-gene pairs were annotated with 10626 features derived from the Enformer predicted variant effects and genomic tracks. Linear genomic distance between the transcriptional start site (TSS) of the gene and the variant as well as the number of genes within 1MB of the signal were included as additional features. We utilized the extreme gradient boosted tree algorithm and trained the model using 3616 of the cis-pQTLs: we then evaluated model performance using withheld data.We consistently achieved auROC ~ 0.8 for correct prediction of the associated protein in withheld data. As expected, given that almost 60% of the cis-pQTLs in the training set mapped to the nearest gene, linear distance to TSS scored consistently as an important feature. To assess whether the model might be overfitted to selecting the nearest gene, we tested model performance in the subset of cis-pQTL signals (n=2579 variant-gene pairs) where the cognate protein-coding gene is not the nearest gene to the variant, and observed only a modest drop in accuracy (auROC ~ 0.74) in this subset.To assess if the cis-pQTL predictor model would generalize to prioritize genes driving phenotypes in disease-based GWAS settings, we utilized a compendium of 841 paired noncoding-coding signals derived from analyses in UK Biobank. These were instances where a regulatory variant associated with a given trait was co-located with, but independent of, a coding burden signal for the same trait. The model achieved auROC ~ 0.71 in the validation data set.Using this modeling framework, we were able to demonstrate the transferability of cis-pQTL predictions to the challenging task of predicting effector genes at complex-trait GWAS loci. Ongoing analyses seek to explore the value of integrating these predictions with those from other orthogonal methods.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1177 Limited overlap of eQTLs and GWAS hits due to systematic differences in discovery

Authors:

H. Mostafavi, J. Spence, S. Naqvi, J. Pritchard; Stanford Univ., Stanford, CA

Most signals in genome-wide association studies (GWAS) of complex traits point to noncoding genetic variants with putative gene regulatory effects. However, currently identified expression quantitative trait loci (eQTLs) explain only a small fraction of GWAS signals. By analyzing GWAS hits for complex traits in the UK Biobank, and cis-eQTLs from the GTEx consortium, we show that these assays systematically discover different types of genes and variants: eQTLs cluster strongly near transcription start sites, while GWAS hits do not. Genes near GWAS hits are enriched in numerous functional annotations, are under strong selective constraint and have a complex regulatory landscape across different tissue/cell types, while genes near eQTLs are depleted of most functional annotations, show relaxed constraint, and have simpler regulatory landscapes. We describe a model to understand these observations, including how natural selection on complex traits hinders discovery of functionally-relevant eQTLs. Our results imply that GWAS and eQTL studies are systematically biased toward different types of variants, and support the use of complementary functional approaches alongside the next generation of eQTL studies.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1178 Local Admixture Mapping of Proteins in African Americans

Authors:

D. Cruz[1], L. Raffield[2], S. Deng[1], J. Wilson[1], R. Gerszten[1]; [1]Beth Israel Deaconess Med. Ctr., Boston, MA, [2]UNC - Chapel Hill, Chapel Hill, NC

Introduction: There is increasing evidence that protein levels in African Americans (AA) are influenced by population differentiated genetic variation. We investigated how local genetic ancestry may be associated with levels of circulating plasma proteins using proteomic profiling in the Jackson Heart Study, an AA cohort, in an attempt to identify additional genetic determinants of protein levels. **Methods**: We performed admixture mapping using local ancestry estimates (probabilities of whether an individual has 0, 1 or 2 alleles of African ancestry at each site in the genome from RFMix, based on similarity to 1000G reference panel) from TOPMed sequencing data for autosomal SNPs. Associations were then tested for 1,300 proteins measured using the SOMAscan proteomic platform. Each local ancestry regression model was adjusted for age, sex, and estimated global ancestry. We used a previously established significance threshold for local African ancestry analysis, $p<2.1X10^{-5}$. We further adjusted findings for previously reported GWAS variants in conditional analysis. **Results**: There were 58 local admixture mapping signals for 55 proteins (three proteins had two signals each). Twenty-nine protein signals survived conditional analysis, proteins of note include Apolipoprotein L1 (whose cognate gene contains known major risk variants for chronic kidney disease in AA) and Apolipoprotein A-1 (a component of high-density lipoprotein cholesterol). **Conclusion**: We present local admixture mapping results providing further evidence that population differentiated genetic variants influence circulating levels of plasma proteins. For a large proportion of our findings, admixture associations were not attenuated by conditioning on previously reported SNPs from GWAS studies. These analyses suggest that admixture mapping may identify association signals that are missed by GWAS, and may help to elucidate population differences affecting key biologic pathways.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1179 Long-read proteogenomics to connect disease-associated sQTLs to the protein isoform effectors of disease

Authors:

G. Sheynkman[1], A. Abood[2], M. Murali[1], C. Farber[1]; [1]Univ. of Virginia, Charlottesville, VA, [2]Univ. of Virginia, Raleigh, NC

A major fraction of loci identified by genome-wide association studies (GWASs) lead to alterations in alternative splicing, but interpretation of how such alterations impact proteins is hindered by the technical limitations of short-read RNA-seq, which cannot directly link splicing events to full-length transcript or protein isoforms. Long-read RNA-seq represents a powerful tool to define and quantify transcript isoforms, and recently, infer protein isoform existence. Here we present an approach that integrates information from GWAS, splicing QTL (sQTL), and PacBio long-read RNA-seq in a disease-relevant model to infer the effects of sQTLs on the ultimate protein isoform products they encode. We demonstrate the utility of our approach using bone mineral density (BMD) GWAS data, as well as other complex diseases such as Coronary Artery Disease (CAD) and Idiopathic Pulmonary Fibrosis (IPF). For BMD, we identified 1,863 sQTLs from the Genotype-Tissue Expression (GTEx) project in 732 protein-coding genes which colocalized with BMD associations (H4PP $\geq$ 0.75). We generated deep coverage PacBio long-read RNA-seq data (N=~22 million full-length reads) on human osteoblasts, identifying 68,326 protein-coding isoforms, of which 17,375 (25%) were novel. By casting the colocalized sQTLs directly onto protein isoforms, we connected 809 sQTLs to 2,029 protein isoforms from 441 genes. Overall, we found that 74 sQTLs influenced isoforms likely impacted by nonsense mediated decay (NMD) and 190 that potentially resulted in the expression of new protein isoforms. We will highlight several examples in which functional validation points to distinct isoform-level (not gene-level) effects, including TPM2. This long read RNA-seq and proteogenomics integrative approach will be described for various use cases. We expect our approach to be widely generalizable across diverse clinical traits and accelerate system-scale analyses of protein isoform activities modulated by GWAS loci.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1180 Loss of an oligodendrocyte specific silencer element drives the cell specific overexpression of lamin B1 in Autosomal Dominant Leukodystrophy

Authors:

B. Nmezi, Q. Padiath; Univ. of Pittsburgh, Pittsburgh, PA

The importance of non-coding regulatory elements in disease causation is only now being studied in depth. This is especially true of genomic silencers of which there have been almost no cases that have been directly shown to cause disease. We have identified a novel cell type specific silencer element that plays a role in the fatal neurological disorder, Autosomal Dominant Leukodystrophy (ADLD). ADLD is characterized by extensive CNS demyelination and most cases are caused by tandem genomic duplications involving the *LMNB1* gene, while a small subset are caused by genomic deletions upstream of the gene. How mutations involving a widely expressed gene such as *LMNB1* cause such a specific demyelinating disorder is unknown. Leveraging data from recently-identified families that carry *LMNB1* gene duplications without exhibiting demyelination, ADLD patient tissues, and CRISPR-modified cell lines and mouse models, we have identified a novel silencer element that is lost in ADLD patients that specifically targets *LMNB1* overexpression to oligodendrocytes. This element consists of CTCF binding sites that mediate three-dimensional chromatin folding involving the *LMNB1* promoter and the recruitment of the PRC2 repressor complex. The loss of *LMNB1*'s silencer element in ADLD identifies a novel role for silencer elements in tissue specificity and disease causation.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1181 Loss-of-function variants in *CUL3* cause a syndromic neurodevelopmental disorder

Authors:

T. Wang[1], P. Blackburn[2], F. Ebstein[3,4], T-C. Hsieh[5], M. Motta[6], F. Radio[6], J. Herkert[7], T. Rinne[8], I. Thiffault[9], M. Rapp[10], M. Alders[11], S. Maas[11], B. Gerard[12], T. Smol[13], C. Vincent-Delorme[14], B. Cogné[15], B. Keren[16], A. Ziegler[17], L. Hasadsri[18], P. Pichurin[18], E. Klee[18], K. Grand[19], P. Sanchez-Lara[19], E. Krüger[3], S. Bézieau[4], H. klinkhammer[20], P. Krawitz[20], E. Eichler[21], M. Tartaglia[6], S. Küry[22]; [1]Peking Univ. Hlth.Sci. Ctr., Beijing, China, [2]St. Jude Children's Res. Hosp., Memphis, TN, [3]Univ. Med. Greifswald, Greifswald, Germany, [4]Nantes Université, Nantes, France, [5]Univ. Hosp. of Bonn, Bonn, Germany, [6]Ospedale Pediatrico Bambino Gesù, Rome, Italy, [7]Univ. of Groningen, Groningen, Netherlands, [8]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [9]Children s Mercy, Kansas City, MO, [10]Children's Hosp. Colorado, Aurora, CO, [11]Amsterdam Univ. Med. Ctr., Amsterdam, Netherlands, [12]Ctr. Hosp.ier Univ.ire de Strasbourg, Strasbourg, France, [13]CHU Lille, Lille, France, [14]CH Arras, Arras, Cedex, France, [15]CHU NANTES, Nantes, France, [16]Sorbonne Université, Paris, France, [17]Univ. Hosp. of Angers, Angers, France, [18]Mayo Clinic, Rochester, MN, [19]Cedars-Sinai Med. Ctr., Los Angeles, CA, [20]Univ. of Bonn, Bonn, Germany, [21]Univ of Washington, Seattle, WA, [22]CHU de Nantes, Nantes, France

Purpose: *De novo* variants in *CUL3* (Cullin-3 ubiquitin ligase) have been strongly associated with neurodevelopmental disorders (NDDs), but no large case series have been reported so far. Here we aimed to collect sporadic cases carrying rare variants in *CUL3*, describe the genotype-phenotype correlation, and investigate the underlying pathogenic mechanism. **Methods:** Genetic data and detailed clinical records were collected via multi-center collaboration. Dysmorphic facial features were analyzed using GestaltMatcher. Variant effects on CUL3 protein stability were assessed using patient-derived T-cells. **Results:** We assembled a cohort of 35 individuals with heterozygous *CUL3* variants presenting a syndromic NDD characterized by intellectual disability with or without autistic features. Of these, 33 have loss-of-function (LoF) and two have missense variants. *CUL3* LoF variants in patients may affect protein stability leading to perturbations in protein homeostasis, as evidenced by decreased ubiquitin-protein conjugates in vitro. Specifically, we show that cyclin E1 (CCNE1) and 4E-BP1 (EIF4EBP1), two prominent substrates of CUL3, fail to be targeted for proteasomal degradation in patient-derived cells. **Conclusion:** Our study further refines the clinical and mutational spectrum of *CUL3*- associated NDDs, expands the spectrum of cullin RING E3 ligase-associated neuropsychiatric disorders, and suggests haploinsufficiency via LoF variants is the predominant pathogenic mechanism. **Keywords** Cullin-3 ubiquitin ligase, ubiquitination, dystonia, neurodevelopmental disorder

PB1182 Macula transcriptome and eQTL analyses identify regional specificity and susceptibility to age related macular degeneration

Authors:

J. Advani[1], J. M. Rouhana[2,3], A. R. Hamel[2,3], P. A. Mehta[2,3], M. A. English[1], M. Kwicklis[1], D. A. Ferrington[4], A. V. Segrè[2,3], A. Swaroop[1]; [1]Neurobiology, Neurodegeneration and Repair Lab., Natl. Eye Inst., NIH, Bethesda, MD, [2]Ocular Genomics Inst., Dept. of Ophthalmology, Massachusetts Eye and Ear, Harvard Med. Sch., Boston, MA, [3]The Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Dept. of Ophthalmology and Visual NeuroSci.s, Univ. of Minnesota, Minneapolis, MN

Age-related macular degeneration (AMD) is a multifactorial progressive neurodegenerative disease and a major cause of blindness among the elderly. Previous genome-wide association studies (GWAS) have identified genetic variants at 63 loci linked to AMD susceptibility loci. Our previous eQTL and TWAS analyses of peripheral retina have uncovered a number of target genes in AMD GWAS loci. However, functional consequences of the disease are largely manifested in the macula, which is the central region of the retina associated with high visual acuity. We therefore carried out RNAseq analysis of macula punches from 185 postmortem donor eyes with different AMD (Minnesota Grading System or MGS) grades and generated a reference transcriptome from controls (MGS1 n=60). We identified 12,975 protein coding genes and 955 non-coding genes in the reference transcriptome and 52 (MGS 1 vs MGS4), 24 (MGS 2 vs MGS4) and 135 (MGS3 vs MGS4) differentially expressed genes across different MGS grades in macula with (FDR &lt 0.1). Gene ontology and pathway analysis of reference macula transcriptome showed enrichment of axonogenesis, proteasome, regulation of autophagy and mitochondria related genes. Applying FastQTL to expression and imputed genotype data, we identified 7,085 expression quantitative trait loci (eQTLs) in cis (&lt 1 Mb) (FDR &lt 0.05). Gene ontology analysis of eGenes identified genes involved in vacuolar lumen, secretory vesicle, and mitochondrial matrix. We also compared eQTLs and eGenes identified in peripheral retina and macula and found 897 eQTLs and 5,037 eGenes to be common. Colocalization analyses with eCAVIAR between eQTL and AMD GWAS loci identified target genes at 6 AMD loci. Our data describes relationship between genetic regulation and expression in the macula, and association of eQTLs with AMD. We highlight the importance of examining target tissues/cell types relevant to complex diseases such as AMD. Future work will examine mQTLs and eQTMs in the macula using DNA methylation in control and AMD patients and include colocalization analyses and other methods to help identify additional causal genes and pathways underlying AMD pathology.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1183 Mapping genetic contributions to individual- and cell type-specific brain oxidative stress responses

Authors:

B. Umans, O. Allen, Y. Gilad; Univ. of Chicago, Chicago, IL

Oxidative stress is a key feature of several diseases that affect the human brain, including Parkinson's Disease and hypoxia arising from apneas and respiratory infection. Observations from other tissues suggest that inter-individual differences in response to changing oxygen availability are genetically regulated and, moreover, that oxygen stress responses differ across cell types. However, the cell type-specific factors governing the brain's response to oxidative stress remain unclear, and the extent to which these differences contribute to disease susceptibility is unknown.
To understand how human brain cells vary in their responses to oxidative stress, we collected single-cell transcriptome data from a panel of dorsal brain organoids derived from 21 human iPSC lines, which were acutely exposed to elevated or reduced oxygen for 24 hours. Organoids from all individuals gave rise to a developmental spectrum of cell types, including subtypes of radial glia, intermediate progenitors, excitatory and inhibitory neurons, and early glia. In our dataset of over 185,000 cells, we conservatively identified 12 principal cell types and fit a linear model in each to identify differentially expressed genes, finding a range of sensitivities to oxidative stress across cell types. To explore the basis of this sensitivity, we mapped the spatial positions of organoid cell types using a panel of antibody markers. While organoids show stereotyped architectures on a local scale, spatial position correlated poorly with oxidative stress sensitivity, suggesting instead that cell-intrinsic features govern the selective vulnerability of developing cortical neurons.
We also assessed the contribution of germline genetic variation to oxidative stress responses in each cell type. Using existing whole genome sequencing data from the individuals in our brain organoid panel, we mapped expression quantitative trait loci (eQTLs) in steady-state, low-oxygen, and high-oxygen conditions. Despite limited power, our preliminary analysis identified hundreds of eQTL genes across cell types and oxygen conditions, with substantial shared effects across cell types and conditions. Future studies will explore the impact of gene regulatory differences on brain development in the context of other environmental perturbations and aim to connect *in vitro* eQTLs to additional developmental and functional phenotypes.

PB1184 Mapping the landscape of lineage-specific dynamic regulation of gene expression using single-cell transcriptomics and application to genetics of complex disease

Authors:

H. Abe[1], P. Lin[1], D. Zhou[2], D. Ruderfer[1,2], E. Gamazon[1,2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Genetics Inst., Nashville, TN

Transcriptome wide association studies (TWAS) have become a widely-used approach to investigate the association between genetically regulated expression and complex traits. Though this approach has elucidated the functional interpretation for disease associations at tissue level, its application at the single-cell level remains to be investigated. Single-cell transcriptome data can provide valuable insights into the context specificity of the effect of genetic variation on various cellular processes involved in human biology and disease. Here, we present sc-TWAS, an approach for developing in silico cell type specific and cell-state adjusted prediction models of gene expression. By integrating individual level genotype data and single cell transcriptomic measurements from the HipSci consortium, we used a machine learning approach to train TWAS models in 8 dopaminergic neuronal cell types that are in the process of specializing from iPSCs across 3 time points. Using S-prediXcan, we then apply our gene expression prediction models to the latest GWAS summary data of neurodevelopmental disorders such as Schizophrenia (SCZ) obtained from Psychiatric Genomic Consortium (PGC). Our results show that sc-TWAS can detect known and novel genes associated with disease traits such as SCZ and enables insights into context-dependent disease mechanisms. We show that some SCZ associated genes have improved prediction performance R^2 for specific cell type and differentiation time point models. We further provide a resource from a phenome-wide application of our cell type specific and cell-state adjusted models to more than 4000 phenotypes from the UK Biobank. PheWAS on the cell type specific SCZ associated genes using this resource, showed the enrichment of blood cellular traits such as leukocyte and erythrocyte count ($-\log10p > 50$). Finally, using the longitudinal predicted expression data, we perform transcription factor motif enrichment analysis to identify genes that are co-regulated with each of significantly associated SCZ genes. The results from this analysis point to a wider network of disease relevant genes and transcription factor regulators. Overall, this work demonstrates the utility of incorporating cell type specificity and dynamics of genetic regulation in gene expression prediction and association to disease.

PB1185 Massively Parallel Reporter Assay Reveals Promoter Position-Dependent and Tissue-Specific Effects in Islet TSSs

Authors:

M. Bose[1], A. Tovar[1], A. Varshney[2], Y. Kyono[1], J. Kitzman[1], S. Parker[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan, Canonsburg, PA

Massively parallel reporter assays (MPRA) are a high-throughput method to assess activity of candidate cis-regulatory sequences, and can be used to detect allelic differences at disease-associated variants. Previously published MPRA studies have screened functional SNPs associated with various traits and conditions, including type 2 diabetes. Here, we used an MPRA library to quantify activity of 1,305 pancreatic islet-derived TSSs generated from CAP analysis of gene expression (CAGE) profiling. We cloned oligos upstream or downstream of a reporter gene along with either the human insulin (INS) promoter or a synthetic housekeeping promoter (SCP1). We used generalized linear models (GLM) to predict position-specific oligo activity from tissue-specific chromatin state regulatory annotations. Overlap with islet promoters ($\beta = 9.20$, $p < 0.01$) and positive strandedness ($\beta = 11.91$, $p < 0.001$) both predicted significantly higher activity for oligos cloned in the upstream position. We also used Lasso regression to predict position-specific oligo activity based on enrichment of transcription factor motifs (TFMs). Oligos that displayed preferential activity upstream of the reporter gene were enriched for TFMs such as FOXJ2, and BHLHE22, and E2F. These significant differences were not observed for oligos that had higher activity when cloned downstream of the promoter and reporter gene. Currently, we are experimentally validating observed strandedness effects with a follow-up MPRA library. We designed 20 oligos representing the extremes of strandedness (i.e., oligos with strongest effects of strandedness) which we cloned with the same promoters along with promoters for other metabolic cell types including liver (APOA2), adipose (ADIPOQ), and skeletal muscle (MYBPC2). Together, these results support use of MPRA strategies that account for positional and promoter context-dependent factors when assaying candidate regulatory elements in pursuit of understanding complex genetic diseases.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1186 Massively parallel reporter assays identify functional enhancer variants at QT interval GWAS loci.

Authors:

A. Kapoor[1], D. Lee[2], A. Chakravarti[3]; [1]UTHlth.Houston, Houston, TX, [2]Harvard Med. Sch. & Boston Children s Hosp., Boston, MA, [3]NYU Sch. of Med., New York, NY

Following a *cis*-regulatory mechanistic hypothesis for GWAS signals in the noncoding genome, we utilized massively parallel reporter assays (MPRA) to identify enhancer variants among 1,018 candidate noncoding variants across the 35 QT interval GWAS loci from the QTIGC study. 200-base long oligos with a 20-base 5′ flank, variant-centered 129-base sequence, 18-base spacer with SbfI and EcoRI sites for subsequent cloning of a minimal promoter-driven *eGFP* reporter cassette, 13-base unique barcode and a 20-base 3′ flank were designed. Each allele/variant was linked to 50 different barcodes for a total of 101,800 unique oligos. We used two different vector backbones in our episomal MPRA: pLS-mP, a lentiviral MPRA vector, propagated in E. coli Stable cells (pLS-mP/S), and pGL4.23, a classical enhancer assay vector, modified for MPRA and propagated in E. coli Stable (pGL4.23/S) or in DH10β (pGL4.23/D) cells. Mouse HL1 cardiomyocyte cells were transfected with the final MPRA plasmid libraries in 10 replicates, and paired-end sequencing of barcodes was performed in input plasmid DNA (3 replicates) and HL1 derived cDNA samples (10 replicates). Read counts for each barcode from input plasmid DNA were aggregated across the three replicates and normalized to total DNA reads. Read counts for each barcode from cDNA in each replicate were normalized to total cDNA reads. Reporter activity for each barcode in each replicate was assessed as $\log_2$ of the ratio of normalized read counts from cDNA to input plasmid DNA. Test element-level reporter activity was estimated as average of reporter activities across all corresponding barcodes and replicates. Of the 1,018 variants, both alleles at 1,014 (99.6%), 729 (71.6%) and 896 (88.0%) variants were successfully propagated in pLS-mP/S, pGL4.23/S and pGL4.23/D experiments, respectively, with failed elements being enriched for short C-rich sequences. Overall, the dynamic range of reporter expression in pLS-mP backbone was relatively limited, a likely outcome of the 5’ LTR promoter interfering with the minimal promoter downstream of the test elements, and was not used to identify enhancers. Among the shared variants (n=729) across the two pGL4.23-based experiments, the correlation was high (r=0.98), highlighting robust reporter activity measurements. Using a >10% increase in cDNA reads count over input plasmid (for either ref. or alt. test element) to define enhancers, 177 enhancer elements were identified of which 106 showed significant allelic difference by t-test at false discovery rate of <0.01. These enhancer variants map to 22 GWAS loci, and are being evaluated for causality by explaining target gene expression variation.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1187 Massively parallel reporter assays of enhancer variants at selected QT interval GWAS loci.

Authors:

L. Gunamalai[1], D. Lee[2], A. Kapoor[1]; [1]UTHlth.Houston, Houston, TX, [2]Harvard Med. Sch. & Boston Children s Hosp., Boston, MA

Electrocardiographic QT interval, a measure of ventricular de- and re-polarization, is a moderately heritable quantitative trait of clinical relevance as prolongation or shortening of the QT interval is associated with an increased risk of cardiac arrhythmias and sudden cardiac death. Genome-wide association studies (GWAS) have identified tens of trait associated loci, however, the identities of the causal variants and their molecular mechanisms underlying these common noncoding variants-based associations remain largely unknown. Following a *cis*-regulatory mechanistic hypothesis for GWAS signals in the noncoding genome, we used massively parallel reporter assays (MPRA) to identify enhancer variants at 12 selected QT interval GWAS loci. These 12 selected loci encompass genes implicated in Mendelian disorders of abnormal QT interval (long- and short-QT syndromes) and/or genes known to effect cardiomyocyte action potential duration or excitation-contraction coupling. Using a recently published QT interval GWAS meta-analysis, we identified all variants (n=15,455) that are within ± 500 kb of the lead variant and are either genome-wide significant ($P<5\times10^{-8}$) or in moderate-to-high linkage disequilibrium ($r^2>0.3$) with a genome-wide significant variant. Next, we used variant overlap with publicly available open chromatin regions identified in human cardiac left ventricle by DNase-seq or in human ventricular cardiomyocytes by single cell ATAC-seq (extended 300 bp on either side of peak summits) to filter 1,198 candidate variants. Of these, nine variants were filtered out as either being INDELs >20 bases or either allele along with its flanking sequence matching restriction enzyme sites used in cloning. MPRA oligos (300 base long) were designed to test both alleles at each of the remaining 1,189 variants in three different 229-base long flanking sequence contexts (left-shifted, center and right shifted) for a total of 7,134 unique test elements, with each element linked to 20 unique barcodes for a total of 142,680 oligos across two equally-sized pools. Once cloned in a MPRA-modified pGL4.23 backbone along with a minimal reporter-driven reporter gene, the two MPRA libraries will be transfected in mouse cardiomyocyte HL1 cells in 10 replicate transfections. Barcode sequencing from input plasmid DNA and HL1-derived RNA (cDNA) samples will be followed to assess enhancer activities and allelic differences. We expect our MPRA-based screen to identify multiple *cis*-regulatory enhancer variants that collectively regulate target gene expression, thereby underlying trait association.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1188 Maternal genetic variation shapes human milk and the infant gut microbiome

Authors:

K. Johnson[1], T. Heisel[1], E. Isganaitis[2], M. Rudolph[3], D. Fields[3], C. Gale[1], F. Albert[1], E. Demerath[1], R. Blekhman[4]; [1]Univ. of Minnesota, Minneapolis, MN, [2]Joslin Diabetes Ctr., Harvard Med. Sch., Boston, MA, [3]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, [4]Univ. of Chicago, Chicago, IL

Human milk is a complex mix of nutritional and bioactive components that provide complete nutrition for the infant. However, we lack a systematic understanding of the genomic factors shaping milk composition, and how milk variation influences infant health. Here, we generated multi-omic profiles of 242 exclusively breastfeeding mother-infant pairs, including maternal genotypes, milk transcriptome, milk metabolome, and infant fecal metagenome, to identify connections between human milk variation and infant development.

We identified cis-eQTLs for 2,690 genes expressed in human milk (FDR<5%), 487 of which were specific to the lactating mammary gland (i.e. did not colocalize with GTEx eQTLs). Genes with milk-specific eQTLs were enriched for genes in dairy cattle milk trait QTL (odds ratio=2.1, $P=1.7x10^{-3}$). Motivated by the protective role of lactation duration against breast cancer, we identified 8 milk eQTLs colocalized with breast cancer GWAS loci, including a milk-specific eQTL for *LMX1B* with a GWAS locus previously lacking a functional annotation (H4 posterior probability=0.99).

Leveraging our multi-omic study design, we identified 67 milk eQTL variant-metabolite associations mediated by milk gene expression (FDR<5%), including known examples like *FUT2* and fucose ($B=0.88$, $P=5.9x10^{-21}$). The *SORT1* locus, which was a milk eQTL, was associated with multiple metabolites including gamma-glutamylglutamine ($B=0.63$, $P=3.3x10^{-7}$). Expression of creatine transporter *SLC16A12* was associated with decreased milk creatine ($B=-2.4$, $P=1.3x10^{-7}$). As milk metabolites can promote or inhibit bacteria in the infant gut, we tested if eQTLs that influenced milk metabolites were also associated with infant gut microbe abundances. Three eQTLs associated with an infant gut microbe (FDR<5%); e.g., the variant associated with increased *SLC16A12* expression and decreased milk creatine was correlated with higher levels of an unnamed *Streptococcus sp.* in infant feces ($B=0.46$, $P=3.5x10^{-5}$).In sum, our results reveal new insights into how human milk variation can impact maternal and infant health, highlighting a need for further work on this biological system heretofore neglected by the field of human genetics.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1189 Measuring (almost) all possible *STK11/LKB1* missense variants in monogenic disease and cancer

Authors:

D. Zimmerman, A. Cote, W. Loggerenberg, M. Gebbia, J. Weile, N. Kishore, F. Roth; Univ. of Toronto, Toronto, ON, Canada

Germline loss of the Serine/Threonine Kinase 11 (*STK11/LKB1*) tumor suppressor leads to Peutz-Jeghers Syndrome (PJS), a rare monogenic disease conferring gastrointestinal complications and an increased lifetime cancer risk. Somatic loss of *STK11* variants are found in up to 30% of lung cancers, 20% of cervical, and several other tissue types at lower frequencies. Early genetic diagnosis of PJS helps establish life-long disease management, allowing for proactive screening and early interventions. Despite this and the American College of Medical Genetics (ACMG) inclusion of *STK11* as one of their 73 clinically actionable genes, over 85% of *STK11* germline clinical missense variants are currently classified as Variants of Uncertain Significance (VUS). To provide evidence to improve variant interpretation, we applied a Multiplexed Assay of Variant Effect (MAVE), based on *en masse* expression in mammalian cells and ensuing growth advantage of dysfunctional coding variants, to characterize variant functions for >70% of possible *STK11* missense variants. The resulting variant effect map shows strong agreement with known structural and biochemical properties, and performs well in separating pathogenic or benign annotations. Thus, we provide a resource for sequence-structure-function insights in STK11, and provide evidence for both known and yet-to-be-observed clinical STK11 variants.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1190 Mediation of *APOE* Associations with Cognition through ATN

Authors:

J-W. Jang; Kangwon Natl. Univ. Hosp., Chuncheon, Korea, Republic of

Mediation of APOE Associations with Cognition through ATNBackground: The e+4 allele of the apolipoprotein E (APOE) gene is a significant genetic risk factor for age-related cognitive decline. However, the precise causal relationship between e+4 alleles and cognition remains poorly understood. This study aimed to investigate the involvement of Amyloid/Tau/Neurodegeneration (ATN) in the associations between APOE and cognition.Methods: Multiple linear regression analyses were performed on a sample of 1158 subjects (mean age of 73.3 years; 45.0% female; 46.2% APOE e+4 allele carriers). Causal mediation analyses, using 5,000 bootstrapped iterations, were conducted to examine the mediation effects.Results: The APOE e+4 allele showed a negative association with cognition ($P < 0.05$) and ATN (all $P < 0.05$). The impact of the APOE genotype on cognition was partially mediated by ATN (all $P < 0.05$).Conclusion: ATN plays a partial mediating role in the potential links between the APOE genotype and cognition. Overall, the APOE e+4 allele may contribute to dysregulation of the ATN cascade, which subsequently leads to cognitive impairment.

PB1191 METTL23 mutation alters histone H3R17 methylation in inherited normal tension glaucoma

Authors:

T. Iwata[1], Y. Pan[1], A. Suga[2], I. Kimura[3], C. Kimura[4], Y. Minegishi[5], M. Nakayama[1], K. Yoshitake[1], D. Iejima[1], N. Minematsu[1], M. Yamamoto[6], F. Mabuchi[7], M. Takamoto[8], Y. Shiga[9], M. Araie[8], K. Kashiwagi[7], M. Aihara[8], T. Nakazawa[9]; [1]Nat Hosp. Organization Tokyo Med. Ctr., Meguro-ku, Japan, [2]Natl. Hosp. Organization Tokyo Med. Ctr., Tokyo, Japan, [3]Tokai Univ. Hachioji Hosp., Hachioji, Japan, [4]Kimura Eye Clinic, Iwaki, Japan, [5]Japanese Fndn. for Cancer Res., Toyoshima-ku, Japan, [6]JAC Ltd., Chiyodaku-ku, Japan, [7]Univ. of Yamanashi, Yamanashi, Japan, [8]Univ. of Tokyo, Bunkyo-ku, Japan, [9]Tohoku Univ. Graduate Sch. of Med., Sendai, Japan

Normal-tension glaucoma (NTG) is a heterogeneous disease characterized by retinal ganglion cell (RGC) death leading to cupping of the optic nerve head and visual field loss at normal intraocular pressure (IOP). The pathogenesis of NTG remains unclear. Here, we describe a single nucleotide mutation in exon 2 of the methyltransferase like 23 *(METTL23)* gene identified in a three-generation Japanese NTG family. We assessed its effects on expression, localization, and methylation by splicing using three transfected cell lines, patient-derived induced pluripotent stem cells (iPSCs), and *METTL23* c.A83G knock-in mice. We also determined whether *METTL23* defects cause RGC degeneration and optic nerve head fiber loss, the typical human NTG phenotype, in vivo*;* and explored the role of METTL23 in methylation in vitro and in vivo. This mutation caused *METTL23* mRNA aberrant splicing, which abolished normal protein production and altered subcellular localization. *Mettl23* knock-in (*Mettl23*$^{+/G}$ & *Mettl23*$^{G/G}$) and knockout (*Mettl23*$^{+/-}$ & *Mettl23*$^{-/-}$) mice developed a glaucoma phenotype without elevated IOP. METTL23 is a histone arginine methyltransferase expressed in murine and macaque RGCs. However, the novel mutation reduced Mettl23 expression in RGCs of *Mettl23*$^{G/G}$ mice, which recapitulated both clinical and biological phenotypes. Moreover, our findings demonstrated that Mettl23 catalyzed the dimethylation of H3R17 in the retina, and was required for the transcription of *pS2*, an estrogen receptor α target gene that was critical to RGC homeostasis through the negative regulation of NF-κB-mediated TNF-α/IL-1β feedback. This study showed for the first time that alterration of epigentics in the retina can devolp NTG. Our findings suggest an etiologic role of METTL23 in NTG with tissue-specific pathology.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1192 Microbiome and host genetic effects on gene regulation in Inflammatory Bowel Disease.

Authors:

S. Nirmalan[1], R. Blekhman[2], R. Pique-Regi[1], F. Luca[1]; [1]Wayne State Univ., Detroit, MI, [2]Univ. of Chicago, Chicago, MN

Inflammatory Bowel Disease (IBD) leads to chronic inflammation and scarring of the digestive tract. The gut microbiome is altered in IBD and many genetic risk variants associated with IBD are in genes that function in host response to microbes. Both host genetic variants and the gut microbiome regulate host gene expression in the colon; however, it is still unknown whether interactions between host genetics and the microbiome (GxM) regulate host gene expression in the gut in IBD. Identifying these GxM that modify genetic risk for IBD is imperative for understanding its pathogenesis. Here, we used data from the Human Microbiome Project to perform interaction eQTL mapping to identify GxM in IBD. Our sample consisted of host genotype, and paired host gene expression and mucosal gut microbiome (16S rRNA) data from rectum biopsies for 86 individuals (64 patients with IBD and 22 controls). We identified 3298 genes with eQTLs (eGenes, FDR = 10%). These eGenes are enriched in both the GTEx sigmoid colon (OR = 2.5, p < 2.2 * 10^-16) and transverse colon (OR = 3.7, p < 2.2 * 10^-16) eQTL datasets. We integrated the microbiome data with the eQTLs to identify GxM. We tested for interaction with the relative abundance of each microbe and found 37 interactions for 28 genes and 20 microbial taxa (FDR = 10%). We also tested for interaction with the presence/absence of a microbe and found 15 additional GxM (12 genes and 10 taxa; FDR = 10%). Six genes harbor multiple GxM and 8 microbes interact with multiple genes. For example, the abundance of the Blautia genus, an anaerobic microbe with anti-inflammatory activity, interacts with 7 eQTLs in genes involved in cell signaling and inflammatory response. The expression of 13 GxM genes is associated with IBD risk in PhenomeXcan. For example, increased expression of LAMTOR is associated with increased risk of IBD. We found that increased abundance of Blautia is associated with decreased expression of LAMTOR in individuals with the alternative allele, potentially decreasing IBD risk. Our results show the first evidence of genetic effects on gene expression that are modulated by the microbiome composition in IBD, and provide insight into how IBD risk could be decreased by targeting specific microbial taxa depending on host genotype.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1193 Mitochondrial DNA haplogroup K is protective of Autism Spectrum Disorder risk in populations of European ancestry.

Authors:

T. Wang, X. Chang, K. Ostberg, H. Qu, Y. Liu, J. Glessner, H. Hakonarson; Children's Hosp. of Philadelphia, Philadelphia, PA

Cumulative evidence indicates a critical role of mitochondrial function in Autism Spectrum Disorder (ASD) and implies that ASD risk may be linked to mitochondrial dysfunction due to variations in mitochondrial DNA (mtDNA). Although a few studies have explored the association between mtDNA variations and ASD, the role of mtDNA in ASD is still unclear. Here, we aimed to investigate whether mitochondrial DNA haplogroups are associated with the risk of ASD. Two European cohorts and an Ashkenazi Jewish (AJ) cohort were analyzed, with a total of 2,062 ASD patients compared with 4,632 healthy controls. DNA samples were genotyped using Illumina HumanHap550/610 and Illumina 1M arrays, inclusive of mitochondrial markers. Mitochondrial DNA (mtDNA) haplogroups were identified from genotyping data using HaploGrep2. A mitochondrial genome imputation pipeline was established to detect mtDNA variants. We conducted a case-control study to investigate potential associations of mtDNA haplogroups and variants with the susceptibility of ASD. We observed that the ancient adaptive mtDNA haplogroup K was significantly associated with decreased risk of ASD in the two European cohorts, which had a total of 2,006 cases and 4,435 controls (odds ratio 0.64, $P=1.79\times10^{-5}$), and we replicated this association in the Ashkenazi Jewish (AJ) cohort of 56 cases and 197 controls (odds ratio 0.35, $P=9.46\times10^{-3}$). Moreover, we demonstrated that mtDNA variants rs28358571, rs28358584 and rs28358280 are significantly associated with ASD risk. Additionally, expression quantitative trait loci (eQTL) analysis indicated that the rs28358584 and rs28358280 genotypes are associated with expression levels of nearby genes in brain tissues, suggesting that these mtDNA variants may confer risk to ASD via regulation of mitochondrial gene expression. In conclusion, this study sheds light on the role of mitochondria in ASD and provides new insights into the genetic mechanism underlying ASD via the potential involvement of mtDNA encoded proteins in the development of ASD.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1194 Molecular and cellular characterization of a lymphatic anomaly-associated mutation in *TEK*

Authors:

M. March[1], D. Li[2], S. Sheppard[3], L. Matsuoka[4], M. E. Matos[1], C. Kao[1], H. Hakonarson[2]; [1]Children s Hosp. of Philadelphia, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]NICHD/NIH, Rockville, MD, [4]Children S Hosp. of Philadelphia, Philadelphia, PA

As part of our ongoing efforts to characterize putatively causative variants that we have uncovered in a growing number of patients with arterial, venous, or lymphatic malformations (collectively referred to as cardiovascular anomalies or CVAs), we have identified a variant in the *TEK* gene (p.R915C) in a patient with a venous malformation. In order to characterize the effects of this variant in a relevant cell system, we expressed the variant and wild-type *TEK* in primary human dermal lymphatic endothelial cells, a cell system we have used to great effect to determine pathogenicity of variants and to characterize the response of variant-expressing cells to potential treatments. Cells expressing p.R915C *TEK* displayed increased activity in a spheroid sprouting assay (used to measure lymphangiogenesis potential *in vitro*) and displayed increases in phosphorylation in both ERK and AKT, indicating activation of both MAP kinase and PI-3 kinase signaling pathways. Treatment of cells with inhibitors of MEK (for MAPK signaling) and PIK3CA (for PI-3 kinase signaling) partially reversed the observed phenotypes, while treatment with rebastinib, a broadly active compound that possesses inhibitor activity towards Tie2 (the protein encoded by the *TEK* gene) completely reversed the observed changes in cell behavior. Taken together, these results suggest that directly targeting the Tie2 protein itself would be most beneficial in patients carrying *TEK* variants, as activation of Tie2 stimulates multiple downstream pathways.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1195 Molecular characterization of *PDGFRB* p.Asn666 variants

Authors:

T. Gladkauskas, O. Bruland, R. Mehrasa, E. Rødahl, C. Bredrup; Univ. of Bergen, BERGEN, Norway

Several gain-of-function substitutions at p.Asn666 platelet-derived growth factor receptor beta (PDGFRB) have been identified, namely p.Asn666Tyr, p.Asn666Ser, p.Asn666His, and p.Asn666Lys. The *PDGFRB* p.Asn666Lys variant is specifically associated with somatic infantile myofibromatosis, with the presence of this variant observed solely in a single case of gingival myofibroma. In contrast, the *PDGFRB* p.Asn666Ser variant is linked to Penttinen premature aging syndrome, characterized by premature aging, lipodystrophy, acro-osteolysis, chronic ulcers, and corneal vascularization. Additionally, the *PDGFRB* p.Asn666Tyr variant is associated with Ocular-pterygium digital keloid dysplasia, a condition marked by corneal vascularization and keloid formation on fingers/toes in otherwise healthy individuals. Lastly, the *PDGFRB* p.Asn666His variant has been identified in a single patient presenting with hemangioma, sagittal craniosynostosis, intracranial cyst, brachydactyly, and acro-osteolysis. The objective of this study was to investigate the underlying molecular mechanisms that contribute to the distinct phenotypes observed in these four p.Asn666 *PDGFRB* variants. Using ELISA and immunoblot analyses of transduced immortalized fibroblasts expressing wild-type PDGFRβ and these four variants, we observed constitutive activation of PDGFRβ across all substitutions. Importantly, we found that each variant displayed a unique pattern of phosphorylated tyrosine residues in PDGFRβ, leading to variant-specific upregulation of downstream signaling proteins including, p-AKT, p-STAT1, p-MAPK3/ERK1, and p-PLCγ1. In conclusion, our study provides evidence that the four described variants at the p.Asn666 position of PDGFRβ exhibit unique phosphorylation patterns in specific tyrosine residues of PDGFRβ and downstream signaling proteins. This could contribute to the distinctly different clinical conditions caused by these variants.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1196 Molecular tools for determination of post-trauma injury complications

Authors:

D. McDaniel, S. B. Robertson, B. Williams, G. A. Timberlake, L. S. McDaniel; Univ Mississippi Med Ctr, Jackson, MS

Background: An assessment of applying transcript level of genes with influential variability and differential expression analysis are powerful tools for sepsis biomarker determination during post trauma injury complication. Clinical characteristics associated with sepsis in combination with molecular markers are study tools to derive informative gene subsets for early determination of disease. Sepsis is a life-threatening response of the immune system to trauma induced complications which can potentially lead to tissue damage, organ failure, and death. Numerous risk factors in the context of inflammatory parameters such as cytokines and Toll-like receptor genes contribute to an early inflammatory response to the pathogen or damage associated molecular patterns (DAMPs) associated with trauma injury. Methods: A panel of candidate risk factors associated with the innate immune response genes were evaluated using blood from trauma patients within the first 72 hours upon the admission to SICU. Leukocytes including monocytes, macrophages and neutrophils for mRNA transcript analysis of cytokines, and the TLR-signaling pathway genes were tested. The expression was confirmed by quantitative PCR and plasma specimen from patients by ELISA. Results: The study confirms an early upregulation of the innate immune response through monocytes/macrophages, extends to neutrophil functional dynamics. TLR-2 and TLR-4 transcripts were significantly increased comparing day 1 vs. day 3 in patients who later developed sepsis. The IRAK-1, a major mediator of the TLR-signaling pathway was reversibility increased (2.0- fold) in patients with sepsis vs. no sepsis. TOLIP gene, a Toll-like receptor inhibitory protein, also known as Cox-2 gene was increased 4-fold in patients with no sepsis. The CD86 an HLA-Class II receptor molecule on monocytes and macrophages significantly increased in patients who later developed sepsis. Conclusions: Trauma causes changes in macrophage and monocyte activation. This data support correlation between TLR-2 and TLR-4 signaling molecules with the expression of pro-inflammatory cytokines in trauma induced sepsis. The performance of gene selection model is likely to be improved by extending to a broader dataset.

PB1197 *MTOR* variants increase the risk of developing thoracic aortic disease

Authors:

D. Guo[1], X. Duan[1], Z. Zhou[1], P. Gu[1], Y. Yu[1], I. Marin[1], M. Bamshad[2], D. Milewicz[1]; [1]UT McGovern Med. Sch. at Houston, Houston, TX, [2]UUniv. of Washington, Seattle, WA

Normal 0 false false false false EN-US ZH-CN X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin-top:0in; mso-para-margin-right:0in; mso-para-margin-bottom:8.0pt; mso-para-margin-left:0in; line-height:107%; mso-pagination:widow-orphan; font-size:11.0pt; font-family:"Calibri",sans-serif; mso-ascii-font-family:Calibri; mso-ascii-theme-font:minor-latin; mso-hansi-font-family:Calibri; mso-hansi-theme-font:minor-latin; mso-bidi-font-family:"Times New Roman"; mso-bidi-theme-font:minor-bidi;} To identify new genes for heritable thoracic aortic disease (HTAD), we developed a machine learning method to prioritize human genes based on established HTAD genes, protein-protein interaction, and mutational constraints, and *MTOR* emerged as a candidate gene (missense z-score = 7.0). *MTOR* rare variants (minor allele frequency ≤ 0.0001) predicted to be damaging were identified in exome data from 392 affected HTAD probands, 58 probands from trios, and 524 individuals with early-onset sporadic aortic dissections (< 60 years old; ESTAD). Eleven *MTOR* rare variants were identified and half the variants were located at the FAT or kinase domain of mTOR, which is location of gain-of-function *MTOR* mutations in cancer. Kinase function of mTOR was assessed for *MTOR* p.Arg1616His, p.Asn2292Ser, and p.Asp2520Val (located in kinase or FAT domains) by co-transfecting Flag-tagged *MTOR* constructs, with wildtype, an activating variant, or three exome variants, and a downstream protein phosphorylated by mTOR (HA-tagged 4EBP1) into HEK293T cells. Immunoblot analyses revealed that the *MTOR* variants p.Asn2292Ser and p.Asp2520Val significantly increased the phosphorylation of 4EBP1 when compared to wild-type mTOR, and to a similar levels as gain-of-function variants in cancer. To confirm a role of mTOR signaling in TAD, mTOR signaling was assessed in a mouse model of thoracic aortic dissection (mice exposed to beta-aminopropionitrile (BAPN)). Immunoblot analyses revealed increased levels of mTOR ($p<0.001$) and p70S6K ($p<0.05$) phosphorylation in the proximal aortas of BAPN-treated mice compared to control mice. Importantly, an mTOR inhibitor, rapamycin, prevented dissection deaths in this mouse model ($p <0.0001$). These data support that activating rare variants in *MTOR* predispose to TAD, and increased mTOR signaling contributes to the molecular pathogenesis of thoracic aortic disease.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1198 Multi-ancestry Whole-exome Sequencing Study of Alcohol Use Disorder in Two Cohorts

Authors:

L. Wang; Yale Univ., New Haven, CT

Background/Hypothesis: Alcohol use disorder (AUD) is a leading cause of death and disability worldwide. There has been substantial progress in genetic studies of AUD and problematic drinking. However, the SNP-based heritability attributable to common variants is low compared to expectations based on genetic epidemiology. Whole-exome sequencing (WES) is a powerful tool for identifying disease-associated variants, especially rare variants that may convey high odds risk ratios, but there is a lack of WES studies of AUD. Methods: WES datasets with 4,530 subjects from the Yale-Penn cohort and 413,476 samples from the UK Biobank were investigated to identify associated variants. DSM-IV alcohol dependence (AD) was diagnosed using the Semi-Structured Assessment for Drug Dependence and Alcoholism in the Yale-Penn cohort. AUD phenotype definition for the UK Biobank cohort was based on ICD-10 criteria. After quality control procedures, 1,668 European ancestry (EUR, 1,409 cases and 259 controls) and 1,547 African ancestry (AFR, 1,156 cases and 391 controls) participants from Yale-Penn were retained for subsequent analysis. WES data from 406,195 EUR samples (9,767 cases and 396,428 controls) and 7,281 AFR samples (111 cases and 7,170 controls) from the UK Biobank were also analyzed. Single-variant analyses and gene-based tests were conducted, followed by within-ancestry meta-analyses and cross-ancestry meta-analyses integrating both Yale-Penn and UK Biobank datasets. Enrichment of deleterious protein-truncating variants and other downstream analyses were also performed to investigate the contributions of coding variants. Results: Cross-ancestry meta-analysis integrating the Yale-Penn and the UK Biobank datasets identified the well-known functional variant rs1229984 in *ADH1B* associated with AUD (p=1.73e-31). Three other common variants—rs2298753, rs33988198 and rs17526590—in high linkage disequilibrium in the *ADH1C* gene were also significant after correcting for multiple testing. All these three noncoding variants are independent signals from rs1229984 and are also captured as significant signals in our previous problematic alcohol use genome-wide association study. Conclusions: Our study confirmed the association between rs1229984 and AUD and provided evidence for the exome-wide significant associations in the *ADH1C* gene with AUD. Recruitment of additional AUD subjects is needed to provide sufficient statistical power to identify rare coding variants that could account for missing heritability in the analysis of common variations.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1199 Multimodal analysis of RNA sequencing data powers genomic discovery.

Authors:

D. Munro[1,2,3], N. Ehsan[2], R. Vogel[1,2,3], M. Esmaeili-Fard[3], A. Gusev[4,5], A. A. Palmer[1], P. Mohammadi[3,6,2]; [1]Univ. of California San Diego, La Jolla, CA, [2]Scripps Res., La Jolla, CA, [3]Seattle Children's Res. Inst., Seattle, WA, [4]Dana-Farber Cancer Inst., Boston, MA, [5]Harvard Med. Sch., Boston, MA, [6]Univ. of Washington, Seattle, WA

Transcriptome data has been shown to identify the biological mechanisms driving genome-wide association study (GWAS) signals in populations. While RNA sequencing (RNA-seq) can reveal many aspects of transcriptome regulation, due to the practical complexity of extracting a diverse array of RNA phenotypes and applying them to downstream analyses, transcriptomic studies are often limited to one or two forms of RNA phenotypes, primarily total gene expression.

Here, we present Pantry (Pan-transcriptome phenotyping), a framework to generate diverse RNA phenotypes from RNA-seq data and perform downstream integrative analyses with GWAS data. Pantry generates six categories of transcriptional phenotypes (gene expression, isoform ratios, splice junction usage, alternative TSS/polyA, and mRNA stability) and applies them to molecular quantitative trait locus (QTL) mapping and transcriptome-wide association study (TWAS).

Using GEUVADIS data we mapped between 4,098 (alternative TSS) and 14,145 (gene expression) independent cis-QTLs per RNA phenotype category. We also demonstrate Pantry's utility with generalized TWAS using six categories of transcriptional phenotypes from GEUVADIS data and 114 GWAS traits. We found 10,845 significant hits across 80 traits involving 4,796 unique RNA phenotypes for 2,064 genes. Notably, of the 4,794 unique trait-gene associations mapped, 49.8% involved only non-expression RNA phenotypes, which would not have been identified in standard TWAS using only gene expression. This approach also allows for more fine-grained identification of regulatory mechanisms underlying GWAS signal in a large fraction of previously associated gene-trait pairs. Finally, we provide statistical analysis of the informational overlap across RNA phenotypes to help identify biologically independent signals. We provide the Pantry code, RNA phenotypes from all GEUVADIS and GTEx samples, and downstream QTL and TWAS results on the web.

PB1200 Multiome single-nuclear profiling of chromatin accessibility and gene expression in human liver samples: insights into cell-type-specific regulation.

Authors:

A. Alkhawaja[1], K. W. Currin[1], H. J. Perrin[1], S. Vadlamudi[1], A. S. Etheridge[1,2], G. H. Cannon[3], C. W. Anderson[3], A. H. Moxley[1], E. G. Schuetz[4], F. Innocenti[2,5], A. C. Iuga[6], T. S. Furey[1], K. L. Mohlke[1]; [1]Dept. of Genetics, Univ. of North Carolina, Chapel Hill, NC, [2]Eshelman Sch. of Pharmacy, Univ. of North Carolina, Chapel Hill, NC, [3]Advanced Analytics Core, Univ. of North Carolina, Chapel Hill, NC, [4]Dept. of Pharmaceutical Sci., St. Jude Children's Res. Hosp., Memphis, TN, [5]Lineberger Comprehensive Cancer Ctr., Univ. of North Carolina, Chapel Hill, NC, [6]Dept. of Pathology and Lab. Med., Univ. of North Carolina, Chapel Hill, NC

Disruption of metabolic regulation in liver can lead to impaired glucose and lipid accumulation, inflammation, and development of liver steatosis, fibrosis, and hepatitis. While previous studies using bulk tissue sequencing methods identified genetic variants associated with gene regulation in liver tissue, cell-type-specific effects remain understudied. Identifying genetic variants that affect gene regulation within distinct liver cell types may provide valuable insights into how the different liver functions are regulated at the molecular level. We jointly profiled single nucleus chromatin accessibility (snATAC-seq) and gene expression (snRNA-seq) in 40 human liver samples using the 10X Genomics multiome platform. These samples were obtained from 35 white and 5 black donors (25 males/15 females), aged 13 to 75 years old with body mass index values of 16 to 42 kg/m^2. Histopathological examination of 38 of the 40 liver samples revealed varying degrees of steatosis and fibrosis, including 7 samples that exhibited both conditions. After quality control, we identified 69,216 nuclei from 39 samples, representing 7 cell types based on canonical cell markers. Similar to published liver single cell studies, most nuclei were from hepatocytes (68%), while B-cells were the least abundant (1.4%). Unlike non-parenchymal cells, hepatocytes clustered by donor, suggesting a substantial influence of donor-specific genetic or environmental factors on hepatocytes. Of the 151,296 accessible chromatin regions (peaks) identified across all cell types, 97% overlapped peaks from bulk liver ATAC-seq from a superset of 138 individuals. We identified 50,641 peaks that were more accessible in one cell type relative to all others (DESeq2, FDR<5%), including 33,046 peaks more accessible in non-hepatocyte cell types. GWAS heritability enrichment in upregulated peaks identified contributions of distinct cell types to different traits, including enrichment of alanine aminotransferase and apolipoprotein B levels in hepatocytes, gamma-glutamyl transferase levels in cholangiocytes, and blood pressure in mesenchymal cells. We are currently identifying cell type expression quantitative trait loci (eQTL) and chromatin accessibility QTL (caQTL) and will colocalize QTL signals with GWAS loci for liver disease-relevant traits. In addition, cell type differential chromatin accessibility and gene expression in healthy vs steatosis/fibrosis samples will be investigated. These integrative analyses should provide insights into the role of liver cell type gene regulation in disease-relevant traits and identify potential targets for therapeutic interventions.

PB1201 Multiple sequence modifications result in loss of chitinolytic activity in YKL-40.

Authors:

K. Suzuki[1], K. Okawa[1], M. Ohkura[1], T. Kanaizumi[1], E. Tabata[1,2], F. Oyama[1]; [1]Kogakuin Univ, Tokyo, Japan, [2]Res. Fellow of Japan Society for the Promotion of Sci. (PD), Tokyo, Japan

Human YKL-40 (CHI3L1, HC GP-39), a chitinase-like protein (CLP) family member, shares structural similarities with the active chitinase CHIT1 but lacks chitinolytic activity. Elevated expression of YKL-40 has been observed in asthma, chronic obstructive pulmonary disease (COPD), inflammatory bowel disease (IBD), alcoholic cirrhosis, Alzheimer's disease, and cancer, making it a potential diagnostic marker. Understanding the biochemical properties of YKL-40 is crucial for unraveling disease mechanisms and developing effective treatments. While amino acid substitutions in the catalytic motif have been proposed as the cause of YKL-40 inactivation, our attempts to activate YKL-40 through specific substitutions (A138D and L140E) in the catalytic motif did not yield the desired results. This result suggests that the loss of chitinolytic activity in YKL-40 cannot be solely attributed to these amino acids. To identify the regions responsible for YKL-40 inactivation, we generated chimeric proteins by combining segments of MT-YKL-40 and CHIT1. Incorporating certain exons of YKL-40 into CHIT1 led to enzyme inactivation while introducing corresponding CHIT1 exons into MT-YKL-40 activated the protein. Furthermore, WT- and MT-YKL-40, along with the chimeric proteins, exhibited chitin recognition and binding, indicating that YKL-40 retains its chitinase framework but has selectively lost chitinolytic activity. Our findings suggest that the loss of enzymatic activity in YKL-40 results from extensive sequence modifications throughout the molecule rather than isolated amino acid mutations.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1202 Multi-signal eQTL power in the context of missing colocalization.

Authors:

J. Rosen[1], S. M. Brotman[1], K. A. Broadaway[1], K. L. Mohlke[1], M. I. Love[1,2]; [1]Dept. of Genetics, Univ. of North Carolina, Chapel Hill, NC, [2]Dept. of Biostatistics, Univ. of North Carolina, Chapel Hill, NC

One method to implicate genes at genome-wide association study (GWAS) signals is colocalization with gene expression quantitative trail loci (eQTL) signals; however, the modest number of GWAS-eQTL colocalizations observed to date has led to speculation that these two categories of signals are fundamentally different. To identify factors that may contribute to this colocalization gap, we investigated statistical power in eQTL studies, specifically considering that better powered eQTL studies exhibit more allelic heterogeneity, detected as multiple conditionally distinct signals per gene. We fit several parametric models to the empirical distribution of effect sizes of conditionally distinct signals observed in an eQTL study of ~2,200 individuals, demonstrating that the optimal fit is achieved using a log normal distribution. We utilize a model for estimating the power to detect eQTL signals as a function of effect size, sample size, and minor allele frequency (MAF) and propose a method to estimate the percentage of all eQTL signals detected as a function of sample size. We assessed how well this method could predict the relative number of primary eQTL signals identified in dorsolateral prefrontal cortex samples from CommonMind and BrainSeq as reported in the eQTL Catalogue, observing agreement between the predicted and observed number within 2%. We then determined the sample sizes needed to detect 80% of all eQTL signals in a hypothetical study across a range of minor allele frequencies. Identifying eQTL with MAF of 25, 10, 5, and 1% required sample sizes of ~5,000, 10,500, 19,800, and 95,000 individuals, respectively. Current sample sizes may be sufficient to saturate detection of genes with at least one eQTL but are insufficient to saturate detection of all eQTL signals. We then estimated the percentage of all eQTL signals detectable in studies of comparable size to the Genotype-Tissue Expression project (GTEx). At MAF of 25, 10, 5, and 1%, studies with a sample size of 700 would detect 29, 14, 6.5, and <1% of the theoretical total of all QTL signals, respectively. These results demonstrate that typical eQTL studies are only well-powered to detect large eQTL effect sizes and remain underpowered to detect most eQTL signals. Finally, we explored the relationships between signal distance to transcription start site (TSS) and signal strength and, in conjunction with the power analyses, interpreted these results in the context of eQTL colocalization with GWAS signals, ultimately concluding that insufficient power contributes substantially to missing colocalization.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1203 Nanoparticle enrichment mass-spectrometry proteomics identifies protein-altering variants for precise pQTL mapping

Authors:

S. Batzoglou; Seer, Inc, Redwood City, CA

Genome-wide association studies (GWAS) with proteomics generate hypotheses on protein function and offer genetic evidence for drug target prioritization. Although most protein quantitative loci (pQTLs) have so far been identified by high-throughput affinity proteomics platforms, these methods have some limitations, such as uncertainty about target identity, non-specific binding of aptamers, and inability to handle epitope-modifying variants that affect affinity binding. Mass spectrometry (MS) proteomics has the potential to overcome these challenges and broaden the scope of pQTL studies. Here, we employ the recently developed MS-based Proteograph™ workflow (Seer, Inc.) to quantify over 18,000 unique peptides from almost 3,000 proteins in more than 320 blood samples from a multi-ethnic cohort. We implement a bottom-up MS-proteomics approach for the detection and quantification of blood-circulating proteins in the presence of protein altering variants (PAVs). We identify 184 PAVs located in 137 genes that are significantly associated with their corresponding variant peptides in MS data (MS-PAVs). Half of these MS-PAVs (94) overlap with cis-pQTLs previously identified by affinity proteomics pQTL studies, thus confirming the target specificity of the affinity binders. An additional 54 MS-PAVs overlap with trans-pQTLs (and not cis-pQTLs) in affinity proteomics studies, thus identifying the putatively causal cis-encoded protein and providing experimental evidence for its presence in blood. The remaining 36 MS-PAVs have not been previously reported and include proteins that may be inaccessible to affinity proteomics, such as a variant in the incretin pro-peptide (GIP) that associates with type 2 diabetes and cardiovascular disease. Overall, our study introduces a novel approach for analyzing MS-based proteomics data within the GWAS context, provides new insights relevant to genetics-based drug discovery, and highlights the potential of MS-proteomics technologies when applied at population scale.
Highlights (1) This is the first pQTL study that uses the Proteograph™ (Seer Inc.) mass spectrometry-based proteomics workflow. (2) We introduce a novel bottom-up proteomics approach that accounts for protein altering variants in the detection of pQTLs. (3) We confirm the target and potential epitope effects of affinity binders for cis-pQTLs from affinity proteomics studies. (4) We establish putatively causal proteins for known affinity proteomics trans-pQTLs and confirm their presence in blood. (5) We identify novel protein altering variants in proteins of clinical relevance that may not be accessible to affinity proteomics.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1204 Natural variation in splicing is widespread across humans and can be used to interpret variants in complex traits

Authors:

H. Jacobs[1], B. Gorissen[1], B. Neale[2], H. Finucane[2], K. Karczewski[3], C. Burge[1]; [1]MIT, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Broad Inst., Medford, MA

A fundamental goal of human genetics is to characterize how genomic variants impact human phenotypes. Studies of quantitative trait loci, including those of expression (eQTLs) and splicing (sQTLs), have been successful in identifying the molecular mechanisms of some complex trait-associated variants. However, these studies explain a small fraction of known GWAS loci. In particular, sQTL studies are primarily powered to detect highly expressed known splicing events. A full understanding of splicing variation across humans might enhance GWAS interpretation by providing additional functional support for associated variants.

To explore natural variation in splicing, we use the GTEx project data to quantify population variation of percent spliced in (PSI) for thousands of exons in 49 different tissues. We discover ~70k "naturally-varying" splice events, 80% of which are not found in the GENCODE reference annotations. Non-reference splice sites have the canonical GT/AG structure and high splice site motif scores (median MaxEntScan = 7.85 versus ~8-9 for known splice sites). Many of these splice sites are found in multiple individuals, providing support for true splicing events missing in the reference dataset, and not just sequencing noise.

We implemented empirical bayes to quantify the fraction of individuals in a tissue in which an exon is included at a potentially biologically relevant level (PSI > 5%), calling this fraction exon frequency (EF). Interestingly, many splicing events have low exon frequency ("low EF"), meaning they exist only in a small subset of individuals, and are completely absent in others. Most low EF splicing events are missing from reference annotations, likely because they are only present in a subset of the population and in specific tissues. We highlight reasonably common (MAF 12-15%) genetic variants in genes ASGR1 and ECRG4 that are both sQTLs in GTEx and associated with traits in the UK BioBank actually increase splicing of an unannotated, natural-varying splicing event. Interestingly, splicing of those exons ranges between 0-20% across all individuals. This demonstrates the need to reliably detect splicing events with lower PSI values to aid in the interpretation of complex traits.

Besides genetic variants that explain low EF splicing, we also provide examples of trans-acting factors, such as age, that increase the number of low EF splicing events. Finally, we found that genetic variants associated with low EF splicing events are depleted in GTEx sQTL discovery, suggesting that these are identifying independent signals. We are currently performing a systematic detection of variants that impact low EF splicing events.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1205 Naturally occurring compounds block an exonic splicing silencer and partially rescue normal gene expression in a genotype of choroideremia.

Authors:

I. MacDonald, A. Radziwon; Univ Alberta, Edmonton, AB, Canada

In two unrelated families, an unusual synonymous change in the CHM gene, c.1359CtoT, p.(S453S) causes choroideremia, an X-linked retinal dystrophy. This non-canonical splice variant results in skipping of exon 11 in roughly 99.5% of total transcripts. In-silico analysis predicted the involvement of the known repressor hnRNPA1.Methods: Bibliographic search identified several compounds that could potentially inhibit hnRNPA1's repressor activity to promote exon 11 inclusion, restoring a normal transcript. Patient cells were treated with these and full-length CHM expression quantified by qPCR.Results: In-vitro screening showed that quercetin and shikonin significantly increased the inclusion of exon 11. Quercetin is a flavonoid polyphenol commonly found in fruit, while shikonin is a natural product isolated from purple gromwell root used in traditional Chinese medicine.Conclusions: These pre-clinical results may provide a lead to a potential treatment for this particular CHM variant. Encouragingly, shikonin was able to produce a statistically significant difference even at 50 nM, suggesting that an effective concentration may be achievable through oral supplementation. While this is the first reported instance in CHM where the creation of a putative hnRNPA1 recognition motif is the molecular mechanism, this class of mutation has been identified in numerous other genetic disorders. Once identified, these cases may be amenable to a similar treatment.
Two brothers with this variant presented with disparate phenotypes: typical disease progression in one and the other virtually unaffected. The aberrant transcript predominated in both, and qPCR found no statistically significant difference between them in two assayed cell types. Retinal pigment epithelium has not been examined. These results likely indicate that the observed residual 0.5% CHM expression relative to normal is very near the sufficiency threshold. The differences in the phenotypes may relate to the critical amount of protein that must be produced to maintain normal retinal function. As such, a modest increase in normal transcript may have dramatic effect on disease progression.
A clinical trial of shikonin supplementation could be planned, comparing the natural history of disease before and after treatment.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1206 Navigating the health landscape of sex chromosome trisomies using phenome-wide associations of medical records from three international cohorts

Authors:

D. Lapato[1], S. Davis[2], A. Liu[3], C. Teerlink[4], A. Gentry[1], E. Lancaster[1], M. Singh[1], C. Chris[5], G. Genovese[6], B. Gorman[7], T. Bigdeli[5], J. Lynch[8], J. Ross[9], A. Ganna[3], R. Hauger[10,11], R. E. Peterson[5]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]Univ. of Colorado Sch. of Med., Aurora, CO, [3]Inst. for Molecular Med. Finland, Helsinki, Finland, [4]Veterans Admin. Informatics and Computing Infrastructure, Salt Lake City, UT, [5]SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY, [6]Broad Inst. of Harvard and MIT, Boston, MA, [7]VA Boston Hlth.care System, Boston, MA, [8]Salt Lake City VA Med. Ctr., Salt Lake City, UT, [9]Nemours Children's Hlth., Wilmington, DE, [10]Univ. of California San Diego, San Diego, CA, [11]VA San Diego Hlth.care System, San Diego, CA

Sex chromosome trisomies (SCT) involve the gain of chromosome X or Y, resulting in Klinefelter syndrome (KS; 47, XXY), Jacob syndrome (JS; 47, XYY), or Triple X syndrome (TX; 47, XXX). SCTs are among the most prevalent chromosomal abnormalities observed in liveborn humans and affect ~1 in every 500-1000 males and ~1 in 1000 females born each year. SCTs have been associated with medical and neuropsychiatric comorbidities, including learning disorders, metabolic syndromes, and atypical sexual development and fertility. Because the majority of SCT research has focused on clinically ascertained cases, the full spectrum of health risks and comorbidities for individuals with a SCT is unknown due to biased sampling. This study sought to identify a broader array of health outcomes associated with SCT by applying a hypothesis-free reverse genetics approach to paired genotype measures and health records from three international cohorts.

A phenome-wide association study (PheWAS) meta-analysis was conducted using data from the Million Veteran Program (MVP), FinnGen Research Project, and UK Biobank (UKB). Individuals with SCTs were identified using standard genotype microarray quality control assessments that estimate chromosomal sex. ICD9/10 codes were mapped to phecodes, and the relative prevalence of phecodes was compared between SCT cases and controls matched 1:5 (cases:controls) for age, sex, and race within each dataset. Logistic regression was run with SCT as the predictor, age at enrollment, race, and the first ten genetic principal components as covariates, and phecodes as the binary outcome. P-values were corrected using FDR Benjamini Hochberg procedures. Random effects meta-analysis was applied given the expected heterogeneity across biobanks.

N=2758 individuals across the three biobanks were predicted to carry a SCT based on genotypic data. The SCTs identified were KS (n=1320), JS (n=1096), and TX (n=342). In total, over 90,000 ICD codes were mapped onto 1875 unique phecodes. Significant phecodes reflected a multi-system array of comorbidities, including dermatological (e.g., skin ulcers, cellulitis), circulatory (e.g., chronic venous insufficiency), metabolic (e.g., Type 2 diabetes mellitus), immune/autoimmune (e.g., arthritis), and musculoskeletal (e.g., osteoporosis) conditions.

These results align with published epidemiological studies and suggest that SCTs may have a wider range of comorbidities than previously reported. Additional work will be needed to determine the etiopathogenesis of those conditions. Robust, generalizable knowledge about the comorbidities of SCTs will be invaluable for providing informed health care.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1207 Neuronal transcription of autism gene *PTCHD1* is regulated by a conserved downstream enhancer sequence

Authors:

S. Pastore, T. Muhammad, P. Frankland, P. Hamel, J. Vincent; Univ. of Toronto, Toronto, ON, Canada

Introduction: *Patched domain-containing 1* (*PTCHD1*) is a susceptibility gene for autism and intellectual disability (ID) encoded at Xp22.11. Research has suggested that alterations in the dosage of *PTCHD1* may contribute to the pathoetiologies of these disorders. Despite this, there is a paucity of data to illuminate the mechanisms that regulate *PTCHD1* expression. This study sought to characterize the *Ptchd1* promoter in a mouse neuronal model, and identify distal cis-regulatory elements that may affect its transcription. **Methods:** To characterize the *Ptchd1* promoter, mouse embryonal carcinoma (P19) lines stably-expressing reporter constructs with promoter truncations were generated. Stable lines were promoted towards the neuronal lineage, and luciferase activity was evaluated. Putative transcription factor binding sites (TFBSs) were inferred within the promoter using the SwissRegulon database. In parallel, analyses of publicly-available DNase I-seq. datasets were conducted to describe the chromatin landscape surrounding *Ptchd1*. Specifically, comparisons were performed between mouse neonatal forebrain and liver tissues, which display high and low relative levels of *Ptchd1* expression, respectively. Next, the Wellington algorithm from the pyDNase package was utilized to identify DNase footprints within accessible regions, followed by motif discovery using HOMER. Lastly, CRISPR-Cas9 was employed to delete candidate regulatory regions in P19 lines, followed by differentiation, RNA isolation, and RT-qPCR to assess *Ptchd1* expression. **Results:** The 276 bp genomic region spanning -422 to -147 relative to the transcription start site appears to be critical for the expression of *Ptchd1*, and also contains evolutionarily-conserved TFBSs for the transcription factor Sp1, as well as for the chromatin-remodeling protein CHD1. An enhancer-containing genomic region located downstream of the *Ptchd1* coding sequence was accessible to DNase I in the forebrain, but inaccessible in the liver. This region included a DNase footprint with a putative binding site for the transcriptional activator-repressor YY1. Deletion of this entire downstream open chromatin region attenuated *Ptchd1* expression in neurons by over 64%. **Conclusion:** This study described segments of the *Ptchd1* promoter, and detected conserved TFBSs that may mediate its expression. In addition, an enhancer-containing putative downstream regulatory region was ascertained, deletion of which diminished *Ptchd1* expression in neurons. Collectively, these data clarify the *PTCHD1* promoter and provide context regarding structural variations that may have neurodevelopmental consequences.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1208 New insights into biotinidase deficiency in a large carrier screening cohort.

Authors:

E. Kramer Dugan[1], Y. Wang[1], M. Hajjar[1], B. Prigmore[1], V. Souter[1], P. Benn[2], B. Wolf[3]; [1]Natera, Inc., Austin, TX, [2]Univ. of Connecticut Hlth.Ctr., Farmington, CT, [3]Ann and Robert H. Lurie Children's Hosp. of Chicago, Chicago, IL

Introduction: Biotinidase deficiency (BD) is a treatable, autosomal recessively inherited disorder with a reported prevalence of approximately 1 in 60,000 for profound and partial enzyme deficiency. BD is a core disorder included in newborn screening in the US. While newborn screening will likely detect all cases of profound BD, it may fail to detect all cases of partial deficiency because of enzymatic cut-offs. The objective of this study was to determine the variants in the *BTD* gene, and the carrier frequency ascertained in a reproductive carrier screening cohort. Methods: This retrospective study included female individuals, aged 18-55 years who had reproductive carrier screening with a 274-gene panel between Jan 2020 and Sep 2022. Carrier frequencies for pathogenic/likely pathogenic (P/LP) variants were evaluated for the entire cohort and stratified by self-reported race/ethnicity. In addition, carrier frequencies were calculated for D444H with or without other variants, because D444H is usually associated with partial BD but can cause profound BD if in allelic combination with A171T (and a small number of other variants). Results: The overall frequency of P/LP *BTD* variants in the study population was 5,620/91,637 (6.1%) including 5,092/91,637 (5.6%), which were D444H variants. The frequency of D444H was higher in those self-identifying as White (7.9%) compared to other racial/ethnic groups, with the lowest frequency (1.5%) in the Black group. After excluding D444H (alone or in combination with another variant), the frequency of all other P/LP variants combined was 508/91,637 (0.6%) with a lower frequency in the Asian group (0.3%) compared to White (0.6%). The most common combination of variants was homozygosity for D444H in 88 individuals (0.10%), followed by D444H/A171T found in 53 individuals (0.06%). Excluding these combinations, we identified 19 individuals with two or more pathogenic variants (0.02%), 16 of whom had at least one copy of D444H. These could be indicative of an affected individual (variants in trans) or a complex carrier state (in cis), and where additional variant phase testing was indicated.Conclusion: Reproductive carrier screening that includes evaluation of *BTD* identifies a high frequency of variants, but only a small proportion have the potential of resulting in a child with profound BD. Accurate counseling about the D444H variant is important for patient understanding of the disease variability. Benefits of prenatal screening include identification of potentially affected pregnancies and subsequent neonatal surveillance.

PB1209 New T2T CHM13 genome emphasizes the importance of proper genomic structure and indicates dramatic gene movements. Genomics: #ItsComplicated

Authors:

M. Wadsworth[1,2], M. Page[1,2], B. Aguzzoli Heberle[1,2], J. Miller[1,3,4,5], M. Ebbert[1,2,6]; [1]Sanders-Brown Ctr. on Aging, Univ. of Kentucky Coll. of Med., Lexington, KY, [2]Dept. of NeuroSci., Univ. of Kentucky Coll. of Med., Lexington, KY, [3]Dept. of Pathology and Lab. Med., Univ. of Kentucky, Lexington, KY, [4]Dept. of Microbiol., Immunology, and Molecular Genetics, Univ. of Kentucky, Lexington, KY, [5]Div. of BioMed. Informatics, Dept. of Internal Med., Univ. of Kentucky, Lexington, KY, [6]Div. of BioMed. Informatics, Internal Med., Univ. of Kentucky Coll. of Med., Lexington, KY

Background:
Having a correct genome structure and annotation is critical to truly understand human health and disease for many reasons, including establishing which genomic variations are “normal” or “healthy”. The first complete telomere-to-telomere genome assembly, CHM13, provides us a second de novo human reference genome to compare genome structure and annotations, and provides invaluable insight into the previously incomplete regions of the genome. Here, we perform a systematic comparison of the regions common to both the HG38 and T2T CHM13 reference genomes to assess structural and annotation differences between the two references and found significant variation. Our results highlight: (1) how difficult it is to generate an accurate genome annotation, and (2) how essential a high-quality pan-genome with proper annotations will be to fully understanding human health and disease.
Methods:
We performed systematic comparisons between the structures and annotations for both the HG38 and T2T CHM13 reference genomes using genomic arithmetic (bedtools), sequence identity comparisons (BLAT), and camouflage assessment based on our previous work (genes that cannot be adequately assembled or aligned with short reads).
Results:
Between the HG38 and CHM13 references, we identified four major classes of annotation differences, totaling 1193 genes that change chromosomes entirely and/or are duplicated in new regions of the genome; the four classes include: (1) 68 single-copy non-syntenic genes (change chromosomes, entirely); (2) 24 non-syntenic duplications (change chromosomes & duplicated); (3) 476 non-syntenic and syntenic duplications (remain on original chromosome & duplicated); and (4) 625 syntenic duplications (remain on original chromosome & duplicated on same chromosome). As expected, ~70% overlap camouflaged regions, leaving them unrepresented in short-read sequencing data. One region (~5852 nucleotides) includes five genes whose sequences, according to HG38, are duplicated on chr1 from the mitochondria, but are entirely absent from chr1 in CHM13 (confirmed in population data). We also identified 281 genes that are uniquely annotated in HG38.
Conclusion:
While the CHM13 reference genome finally “completes” the human genome, it also demonstrates how far we have to go. We highlight major structural changes between the two genomes, some of which we validated as legitimate population differences rather than being corrections to HG38. A high-quality pan-genome with accurate annotations will simply be the beginning of fully understanding genomic variations, as we ultimately need to construct each individual’s genome structure.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1210 N-of-1 personalized medicine: Identification of a putative small fiber peripheral polyneuropathy-causing mutation in the glycolytic intermediate enzyme,*PHGDH*.

Authors:

M. Glanz[1], J. McCarthy[2], T. Bowers[3], S. Hofherr[2], E. Frise[2], M. Reese[2], M. E. Merritt[1], E. T. Wang[1]; [1]Univ. of Florida, Gainesville, FL, [2]Fabric Genomics, Oakland, CA, [3]Broad Inst., Kingston, MA

Millions of Americans are impacted by peripheral neuropathies, a heterogenous class of neurological diseases characterized by debilitating neuropathic pain and sensory loss. One-third of peripheral neuropathies are idiopathic; therefore, limited understanding of underlying mechanisms makes diagnosing and treating these diseases extraordinarily challenging. Here, we describe the characterization of a candidate gene, phosphoglycerate dehydrogenase (*PHGDH*), for a small fiber peripheral polyneuropathy in a presumed n-of-1 patient. Whole genome paired-end Illumina sequencing was performed using 10X Genomics library preparation. Genomic analysis was conducted with Fabric Genomics GEM, a proprietary, cutting-edge Artificial Intelligence driven algorithm that integrates multiple genomic and clinical datasets to produce a ranked list of candidate casual variants with >95% sensitivity, including candidate genes of uncertain significance. In this n-of-1 proband, we identified two allelic mutations in *PHGDH*: 1468G>A and 792+6T>G. Two children of the proband carry a single 1468G>A variant, while a third child and the proband's mother carry a single 792+6T>G variant. The 1468G>A variant reduces the catalytic activity of *PHGDH*, while the effect of 792+6T>G was unknown. Mini-gene splicing assays revealed that this latter mutation results in exon 7 skipping, potentially through weakening of the 5' splice site. Analysis of patient fibroblasts detected a reduction in *PHGDH* transcript and protein levels. To explore strategies for abrogating *PHGDH* exon 7 skipping and restore optimal enzyme levels, we performed a high-throughput point mutagenesis screen of *PHGDH*exon 7 and flanking introns. This approach identified putative exon 7 regulatory splice sites which may serve as therapeutic targets. Given the prominent sensory nerve clinical phenotype, we developed a new clinical diagnostic method characterizing specific nerve fiber subtype innervation patterns *in situ* from 3 mm patient skin punch biopsies. This technique enables accurate identification of distal nerve fiber degeneration patterns, thus providing an unprecedented phenotypic analysis of nerve fiber death. Our work reveals novel functional roles for *PHGDH* mutants and their causal candidacy for a rare form of neuropathy. Collectively, our approach lays groundwork for new phenotypic diagnostics and RNA-targeting therapeutic development for polyneuropathies.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1211 Non-syndromic congenital sideroblastic anemia: Phenotype and genotype of nine Indian patients.

Authors:

R. DONGERDIYE[1], P. Kedar[2]; [1]ICMR-Natl. Inst. of Immunohaematology, Mumbai, Maharashtra, India, [2]Natl. Inst. of Immunohematology (ICMR), MUMBAI, India

Congenital Sideroblastic Anemia (CSA) are a group of inherited and acquired bone marrow failure disorder defined by pathological iron accumulation in the erythroid precursors or mitochondria. CSA is caused by mutations in genes involved in the heme biosynthesis, iron -sulfur [Fe-S] cluster biosynthesis, and mitochondrial protein synthesis. The most prevalent form of CSA is X-linked SA (XLSA), caused by mutation in erythroid-specific **δ**;- aminolevulinate synthase (*ALAS2*), which is the first enzyme of heme synthesis pathway in erythroid cells. Other lesser- known genes responsible for causing CSA are *SLC25A38, HSPA9, SLC19A2, TRNT1, ABCB7* and few more. Here, we describe nine cases of CSA confirmed by genomic sequencing. The detailed clinical examination revealed microcytic anemia (in 7 of 9 cases), presence of ring sideroblasts (in 7 of 9 cases), dyserythropoiesis (in 2 of 9 cases), and iron accumulation in bone marrow in all the cases. Presently, only two patients are responding well to pyridoxine while others are on blood transfusion support. Here, we report two patients with XLSA, inheriting two hemizygous varinats in gene *ALAS2*: c.844G>T, p. (Ala282Ser) and c.508C>T, p. (Arg170Cys). We have also identified two homozygous mutations in gene *SLC25A38*: c.569C>G, p. (Pro190Arg); c.400C>T, p. (Arg134Cys) and two heterozygous variants in *HSPA9* gene: c.976G>T p. (Asp326Tyr), c.1388C>T p. (Thr463Ile). The latter is co-inherited with a frameshift mutation (c.137_138delCA, p. (Pro46Glnfs*8)) caused by a 2 base deletion in the *ALAS2* gene.The functional consequences of these variants were assessed using bioinformatics tools and their effect on the protein structure was investigated using PyMoL. In view of the results obtained in this study, we suggest bone marrow examination combined with genetic sequencing offers reliable and confirmed diagnosis to the CSA patients. Also, congenital sideroblastic anemia due to mutation in *SLC25A38* is prevalent than *ALAS2* in India. In conclusion, this study demonstrates the seven mutations in three distinct genes that causes non-syndromic CSA in the Indian population.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1212 Novel and known minor alleles of *CNTNAP2* gene variants are associated with comorbidity of intellectual disability and epilepsy phenotypes: A case-control association study.

Authors:

B. Mudassir, Z. Agha; COMSATS Univ., Islamabad, Pakistan

Neurodevelopmental disorders are heterogeneous due to underlying multiple shared genetic pathways and risk factors. Intellectual disability, epilepsy and autism spectrum disorder phenotypes overlap which indicates the diverse effects of common genes. Recent studies suggested the probable contribution of *CNTNAP2* gene polymorphisms to the comorbidity of these neurological conditions. This study was conducted to investigate the role of *CNTNAP2* polymorphisms rs147815978 (G>T) and rs2710102 (A>G) as a risk factor for comorbidity of intellectual disability and epilepsy in a group of 345 individuals including 170 patients and 175 healthy controls recruited from various ethnic groups of Pakistani population. Our case-control study group was genotyped by tetra primer ARMS-PCR technique and results were analysed to know the effects of *CNTNAP2* rs 147815978 (G>T) and rs2710102 (A>G) polymorphisms in the group. The frequency of risk allele T (rs147815978) and risk allele G (rs2710102) for homozygous recessive genotypes (TT/GG) in our study group was 36.47% while odds ratios for risk allele T (rs147815978) was 5.45 (3.90-7.61:95%CI, P=0.000) and that for risk allele G (rs2710102) was 2.39 (1.76-3.24: 95%CI, P=0.0001). Homozygous recessive genotypes (TT/GG) appeared only in cases and not in control group which indicated these as suspected risk genotypes and the significant association ($p<0.05\%$) of *CNTNAP2* gene polymorphisms rs147815978 (G>T) and rs2710102 (A>G) with co-occurrence of intellectual disability and epilepsy phenotypes in our study group which is in HWE ($\chi^2=174$, $P<0.0001$). Logistic regression analysis shows additive ($p<0.0001$) and multiplicative ($p<0.001$) models which confirms significant association of both the polymorphisms in our data, which are closely located on same haplotype (D'=-0.168). We propose that *CNTNAP2* rs 147815978 (G>T) and rs2710102 (A>G) polymorphisms are possible risk loci for overlapping neurodevelopmental disorders in Pakistani population. We propose the role of a previously reported SNP rs2710102 (A>G) with a novel SNP rs147815978 (G>T) for *CNTNAP2* gene association with neurodevelopmental disorders in our data. Our study has expanded the knowledge of *CNTNAP2* gene polymorphisms as probable biomarkers for susceptibility of co-occurrence of intellectual disability and epilepsy phenotypes in Pakistani population. We hope that our study will open new horizons of *CNTNAP2* gene variants research to cure the neurological conditions in Pakistani population where consanguinity is a tradition and prevalence of neurodevelopmental disorders has increased from 1 to 2 percent during last five years.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1213 Novel disease associations identified in pediatric restrictive cardiomyopathy by genomic and transcriptomic analysis.

Authors:

M. Padua[1], A. Phatak[1], A. Haaning[1], C. C. Sucharov[2], S. D. Miyamoto[3], Y. Liu[1], S. M. Ware[4]; [1]Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [3]Dept. of Pediatrics, Colorado Fetal Care Ctr., Children's Hosp. Colorado, Sch. of Med., Aurora, CO, [4]Indiana Univ., Indianapolis, IN

Restrictive cardiomyopathy (RCM) in children is a rare myocardial disorder characterized by normal chamber size and thickness with impaired ventricular filling due to diastolic dysfunction. It is associated with high morbidity and mortality and there is no effective medical therapy. Pathogenic variants in sarcomeric genes can cause RCM, but the underlying etiology is frequently unknown. To investigate causation and pathogenesis of RCM, we performed exome, mRNA- and small RNA-sequencing (RNA-seq) analyses using explanted left ventricular heart tissue from pediatric RCM transplant subjects (n=14) and compared them to pediatric controls (n=4). From exome data, known pathogenic variants were identified in *BAG3* and *FLNC* as well as novel variants, which were absent from population databases, including a *FLNC* in-frame duplication variant (*c.6527_6547dup*; p.Arg2176_Ser2182dup), and a heterozygous splice acceptor variant in *TNNI3* (rs397516340) ascertained as likely pathogenic per the American College of Medical Genetics and Genomics guidelines. This splice acceptor variant generated an exon-fusion between *TNNI3* exon 7 and the neighbor gene *TNNT1* exon 10, causing a decrease in *TNNI3* expression as assessed by qPCR. Variants of uncertain significance in known cardiomyopathy genes were also identified by exome sequencing. From RNA-seq analysis, 1931 genes were differentially expressed (upregulated n=825; downregulated n=1106). Among them, *MYH6*, which has been previously implicated in other cardiomyopathies, was downregulated in RCM, as well as *HOPX*, a gene involved in cardiac development. In addition, numerous long non-coding RNA (lncRNAs) were differentially expressed between the RCM and control group. *BANCR*, a lncRNA involved in heart development that is highly expressed in other cardiomyopathies, was significantly upregulated in RCM cases versus controls. Other lncRNAs such as *TMC6* (*TNRC6C-AS1*), *CRMA* (*C20orf166-AS1*) and *HAND2-AS1* were also upregulated, suggesting an important role for epigenetic regulation of RCM. Finally, small RNA-seq showed a few microRNA differentially expressed between the two groups. Notably, microRNA-150, which is often downregulated in cardiovascular disease and is associated with heart failure prognosis, was significantly downregulated in RCM. These novel findings on the genetic landscape and its regulation in pediatric RCM provide an opportunity for important investigation and development of therapeutics.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1214 Novel *MARVELD2* Frameshift Variant Associated with Post-lingual Autosomal Recessive Non-Syndromic Hearing Impairment

Authors:

E. ABOAGYE[1,2], S. Adadey[3], E. Wonkam-Tingang[1], K. K. Esoh[1], L. Xhanka[1], T. Kubheka[1], L. De Souza Rios[1], L. Amenga-Etego[2], I. Schrauwen[4], S. Mowla[1], G. Awandare[2], S. M. Leal[4], A. Wonkam[5,1]; [1]Univ. of Cape Town, Cape Town, South Africa, [2]Univ. of Ghana, Legon-Accra, Ghana, [3]NIH, Bethesda, MD, [4]Columbia Univ., New York, NY, [5]Dept. of Genetic Med., JHU, Baltimore, MD

Background: Studies of multiplex and simplex congenital hearing impairment (HI) cohorts in Ghana have implicated a *GJB2*-p.Arg143Trp founder variant as the predominant (16% - 42%) cause of the condition. Though most heritable HI cases have monogenic etiology, there is still high genetic and allelic heterogeneity, and many causative variants have been reported in only specific populations. In addition, analysis of known HI genes fails to identify the causative anomaly in 30% of new cases. **Methods**: We analyzed whole - exome sequenced data of a consanguineous multiplex family with variable late age of onset non-syndromic hearing impairment (NSHI), negative for the common *GJB2* pathogenic variant. Bi-directional Sanger validation was performed for genotype-phenotype segregation analysis. *In-silico* variant effect prediction tools were used to investigate the elucidated whole-exome variant pathogenicity. Homology modeling was used to predict the mutant protein structure. The variant was screened in 46 ethnic representative hearing controls and 151 unrelated simplex probands to validate pathogenicity. **Results**: Homozygous MARVEL domain containing 2 (*MARVELD2)*: c.1058dupT-p.Val354SerTer5 frameshift variant on exon 2 was present in all the affected kindreds. The bi-allelic novel *MARVELD2* (*MIM 610572*) variant co-segregated with varied age of onset and degree of post-lingual phenotype. The putative novel variant was absent in the 46 hearing controls and 151 unrelated simplex cohort. The variant was also absent in databases, including heredity hearing loss homepage (HHL), online Mendelian inheritance in man (OMIM), Genome Aggregation Database (gnomAD), dbSNP, ClinVar, and ClinGen. The elucidated *MARVELD2*: c.1058dupT-p.Val354SerfsTer5 thymine duplication was predicted to truncate the encoded protein (C-terminal occluding_ELL domain). We found strong evidence to suggest this variant is associated with the intra-family variability of bilateral autosomal recessive non-syndromic hearing impairment (ARNSHI). Review of the gene identified twelve isolated *MARVELD2* pathogenic variants reports in seven countries, and knockout/knockdown *MARVELD2* gene mice that showed progressive HI. **Conclusion**: We have shown that this novel variant segregate with bilateral ARNSHI, thus expanding pathogenic spectrum of *MARVELD2* and refining HI genotype - phenotype gene curation. Cell-based characterization of mutant MARVELD2 expression, cellular transport, morphology, and tight junction architecture investigations are needed to confirm our prediction on the pathobiology of occludin_ELL domain truncation.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1216 Personal transcriptome variation is poorly explained by current genomic deep learning models.

Authors:

R. Shuai, C. Huang, P. Baokar, R. Chung, R. Rastogi, P. Kathail, N. Ioannidis; Univ. of California, Berkeley, Berkeley, CA

Genomic deep learning models can predict genome-wide epigenetic features and gene expression levels directly from DNA sequence. While current models perform well at predicting gene expression levels across genes in different cell types from the reference genome, their ability to explain expression variation between individuals due to cis-regulatory genetic variants remains largely unexplored. Here we evaluate four state-of-the-art models—Enformer, Basenji2, ExPecto, and Xpresso—on paired whole genome sequencing and RNA-sequencing data (n=421) measured on lymphoblastoid cell lines (LCLs) from the Geuvadis Consortium. We focus on the 3,259 genes for which the Geuvadis analysis of expression quantitative trait loci (eQTLs) identified at least one statistically significant genetic association. **First, we validate that these models explain a significant fraction of expression variation across genes using the reference genome** by comparing expression predictions on the reference genome to the median expression level measured for each gene over all individuals in the Geuvadis dataset. Across genes, we find Spearman rank correlations between predicted and observed expression levels of 0.57 for Enformer, 0.52 for Basenji2, 0.54 for ExPecto, and 0.33 for Xpresso. **Next, we show that these models struggle to explain variation in expression across individuals.** We construct personal input sequences for each individual by inserting their single nucleotide variants (SNVs) into the reference sequence around each gene transcription start site (TSS). Using each individual's personal input sequences, we predict expression levels of the aforementioned 3,259 genes and find that although the correlation between predicted and observed expression computed across genes (*cross-gene correlation*) for each individual is similar to the reference genome performance of the corresponding model, the distribution of *cross-individual* correlations for each gene is centered close to zero for all models. We find that although genes with strong eQTLs tend to have larger magnitude cross-individual correlations, the models often predict incorrect directions of genetic effect (negative correlation) for these genes. Furthermore, we find that the four tested models are more consistent with one another in the *magnitude* of their cross-individual correlation for a given gene than in the *direction* of that correlation. **These results suggest that current genomic deep learning models can recognize the presence of causal regulatory variation but struggle with understanding the direction of effect of such variation on gene expression.**

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1217 Pharmacogenomics in a dish: Lithium and valproic acid molecular response QTLs in human neural progenitor cells

Authors:

B. Le[1], J. M. Valone[2], N. Matoba[3], J. Mory[1], M. Love[4], J. L. Stein[5]; [1]UNC, Durham, NC, [2]UNC Chapel Hill, Raleigh, NC, [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [4]UNC-Chapel Hill, Chapel Hill, NC, [5]UNC Chapel Hill, Chapel Hill, NC

Lithium (Li) and valproic Acid (VPA) are widely used first-line treatments for BD, but clinical responses are highly variable and mechanisms driving their effects are largely unknown. Fetal VPA exposure can impair neurodevelopment and increase risk for ASD. Genetic influences on clinical responses in patient populations are beginning to be characterized, but are limited by low power, difficulty in isolating specific effects due to the prevalence of polypharmacy, and uncontrolled compliance, duration, and dose across participants. Here we present a "pharmacogenomics in a dish" approach to understand how genetic variation impacts response to these compounds. We describe the effects of Li and VPA on gene regulation, and how these changes are tuned by common genetic variation within primary human neural progenitor cells (hNPCs). Our experiment measured chromatin accessibility via ATAC-seq and gene expression via RNA-seq in 78 genotyped hNPC lines after 48 hour exposure to approximately clinically-relevant concentrations of either 1.5mM LiCl, 1mM VPA, or vehicle. Over 10,000 and 45,000 regulatory elements showed significant changes in chromatin accessibility in response to Li or VPA, respectively (FDR &lt 0.1, |logFoldChange| &gt 0.25). Many transcription factor binding site (TFBS) motifs, such as RFX, were enriched within regulatory regions opened by Li treatment. While Li is known to inhibit GSK3B, a critical component of the canonical Wnt pathway, TCF/Lef TFBS motifs were not enriched in peaks opening or closing due to Li stimulation. We detected 493 and 7,700 differentially expressed genes in response to Li or VPA treatments, respectively (FDR &lt 0.1, |logFoldChange| &gt 0.25). Cellular proliferation genes were upregulated by Li and downregulated by VPA, consistent with proliferation assays conducted in the same samples. We measured the effects of common genetic variants by mapping chromatin accessibility and gene expression quantitative trait loci (caQTLs and eQTLs, respectively). 20,762 and 4239 chromatin accessibility peaks were altered by caQTLs specifically during Li or VPA respectively - an up to 80% increase in discovery compared to the 25,710 caPeaks detected under vehicle conditions. 464 and 447 unique eGenes were regulated by eQTLs specifically during Li or VPA exposure respectively - a 50% increase in discovery compared to the 883 eGenes detected under vehicle conditions (FDR &lt 0.1). These context-specific QTLs reveal novel genetic influences on gene regulation previously undetected by QTL approaches in unstimulated bulk post-mortem tissue and facilitate pharmacogenomic interpretations of Li and VPA treatments.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1218 Phenomic environment-wide association study to evaluate the complexity of the exposome

Authors:

N. Palmiero[1], T. Gonzalez Zarzar[2], K. Passero[3], J. McGuigan[4], J. Zhou[5], D. Crawford[6], M. Aguilar[3], A. Ludman[3], M. Hall[3]; [1]Penn State Univ., State College, PA, [2]Pennsylvania State Univ., State College, PA, [3]The Pennsylvania State Univ., State College, PA, [4]Pennsylvania State Univ., University Park, PA, [5]The Pennsylvania State Univ., University Park, PA, [6]Case Western Reserve Univ., Cleveland, OH

Phenome-wide association studies (PheWAS) that identify genomic-based interrelationships between phenotypes have not been applied to exposome research. Here, in a phenomic environment-wide association study (PheEWAS), we interrogated the relationship between the phenome and the exposome. Using National Health and Nutrition Examination Survey (NHANES) data with a discovery subset and a replication subset, we performed linear regression for 326 exposure predictors and 55 phenotypes, adjusting for age, sex, socioeconomic status, body mass index, self-reported race/ethnicity, and data release cycle year. We found associations between alpha-tocopherol (vitamin E) with triglycerides, retinol with triglycerides, gamma-tocopherol with triglycerides, retinol with uric acid, and retinol with blood urea nitrogen. A race/ethnicity-stratified PheEWAS to determine whether exposure-phenotype relationships varied by race/ethnicity identified 106 significant associations and 11 unique race/ethnicity-specific associations, indicating the importance of studying race/ethnicity effects across all groups. These results provide new information on the complexity of the exposome at the level of the phenome.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1219 † Polymorphic short tandem repeats contribute to complex traits via multiple mechanisms.

Authors:

J. Margoliash, Y. Li, X. Zhang, A. Goren, M. Gymrek; Univ. of California San Diego, San Diego, CA

Short tandem repeats (STRs), genomic regions each consisting of a sequence of 1-6 base pairs repeated in succession, represent one of the largest sources of human genetic variation. Polymorphism in the number of repeats at thousands of STR loci has been associated with gene regulation. However, many STR effects are not captured well by standard genome-wide association studies (GWAS) or downstream analyses that are mostly based on single nucleotide polymorphisms (SNPs). To study the involvement of STRs in complex traits, we imputed genotypes for 445,720 autosomal STRs into SNP data from 408,153 UK Biobank participants and tested for association with 44 blood and serum biomarker phenotypes. We used two fine-mapping methods, SuSiE and FINEMAP, to identify GWAS signals putatively caused by STRs and estimate that STRs drive 5.2-9.7% of GWAS signals for these traits. By comparison, we demonstrate that STRs account for approximately 7.5% of allelic variation and 18.5% of base pair variation amongst the variants present in our fine-mapping analyses. Overall, we identify 118 high-confidence STR-trait associations that pass all of our fine-mapping tests. We hypothesize that STRs impact complex traits through a variety of mechanisms. The majority of STRs identified are non-coding, and we hypothesized they could play regulatory roles. Using data from GTEx, we find 17 of our set of high-confidence STRs are significantly associated with gene expression after multiple hypothesis correction, and 31 are significantly associated with changes in the DNA methylation level of nearby CpG sites. Additionally, we find two trait-associated repeats in protein-coding regions. Using AlphaFold, we suggest that one of these, a poly-serine repeat in E2F4, influences red blood cell counts by modulating the intermolecular distance of the binding between E2F4 and the protein RBL2. This binding protects E2F4 from ubiquitination and subsequent degradation. As a result, perturbing this binding can effect the stability of E2F4 and hinder E2F4s's role in cell proliferation. Together, our results suggest polymorphic tandem repeats make widespread contributions to complex traits through a variety of mechanisms. Our results provide impetus to further study these and other potential mechanisms to better understand the way STR polymorphism can contribute to complex traits and, in extreme cases, to diseases. We provide a set of stringently selected candidate causal STRs, and we demonstrate the need to routinely consider a more complete view of human genetic variation in GWAS.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1220 Population-scale single-cell transcriptomics of clonal haematopoiesis.

Authors:

Clonal haematopoiesis (CH) is an age-related process characterised by the acquisition of somatic mutations in haematopoietic stem cells, leading to their preferential expansion. CH has been implicated in a wide variety of adverse clinical outcomes, including higher risk of haematological cancers and cardiovascular disease, but the mechanisms remain unclear. In order to better understand the biological impact of CH, we investigated the transcriptional consequences of CH in blood on transcriptomes utilising the OneK1K cohort: a population-scale genomic cohort of 977 individuals (mean age 64 years) with orthogonal whole genome sequencing (WGS), genotyping array, and single-cell RNA sequencing (scRNA-seq) datasets derived from peripheral blood. Using both WGS and genotyping array data we generated somatic variant callsets encompassing single-nucleotide, small indel, and large mosaic chromosomal alterations (mCAs), with a detectable somatic driver variant detected in over 11% of individuals. Orthogonal scRNA-seq data was then used to measure the impact of CH-associated somatic variants and genes on relative proportions of blood leukocytes, as well as their transcriptional impact within specific cell types. Our study offers new insight into the transcriptional impact of CH-associated genes and variants, with implications for their therapeutic manipulation.

Heinzen[4]; [1]Nationwide Children s Hosp., Columbus, OH, [2]Nationwide Children's Hosp., Columbus, OH, [3]Nationwide Childrens Hosp., Columbus, OH, [4]UNC Chapel Hill, Chapel Hill, NC, [5]Columbia Univ., Bronx, NY, [6]McGovern Med. Sch., Houston, TX, [7]Boston Children's Hosp., Boston, MA

Somatic mosaicism is a known cause of neurological disorders, including developmental brain malformations and epilepsy. Brain mosaicism is traditionally attributed to post-zygotic genetic alterations arising in fetal development. Here we describe post-zygotic rescue of meiotic errors as an alternate origin of brain mosaicism in patients with focal epilepsy who have mosaic chromosome 1q copy number gains. Genomic analysis showed evidence of an extra parentally-derived chromosome 1q allele in the resected brain tissue from 5 of 6 patients. This copy number gain is observed only in patient brain tissue, but not in blood or buccal cells, and is strongly enriched in astrocytes. Astrocytes carrying chromosome 1q gains exhibit distinct gene expression signatures and hyaline inclusions, supporting a novel genetic association for astrocytic inclusions in epilepsy. Further, these data demonstrate an alternate mechanism of brain chromosomal mosaicism, with parentally derived copy number gain isolated to brain, reflecting rescue in other tissues during development.

PB1222 Predicting genetically regulated gene expression on the X chromosome

Authors:

X. Zhang[1], J. Below[2], A. Naj[3], B. Kunkle[4], E. Martin[5], W. Bush[1,6]; [1]Case Western Reserve Univ, Cleveland, OH, [2]Vanderbilt Univ Med Ctr., Nashville, TN, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Univ. of Miami, Miami, FL, [5]Univ. of Miami Miller Sch. of Med., Miami, FL, [6]Cleveland Inst. for Computational Biology, Cleveland, OH

Despite the potential importance of genetic variation on the X chromosome, it is often omitted in disease association studies. The exclusion of the X chromosome has also propagated into the post-GWAS era, as transcriptome-wide association studies (TWAS) also ignore the X due to the lack of adequate models of X chromosome gene expression. In this work, we trained elastic net penalized models in the brain cortex and whole blood using whole genome sequencing (WGS) and RNA-seq data. To make generalizable recommendations, we evaluated multiple modeling strategies in a homogeneous study population of 175 whole blood samples for 600 genes, and 126 brain cortex samples for 766 genes. SNPs (MAF>0.05) within the gene's two megabase flanking window were used to train the tissue-specific model of each gene. We tuned the shrinkage parameter and evaluated the model performance with nested cross-validation. Across different mixing parameters, sample sex, and tissue types, we trained 511 significant gene models in total, predicting the expression of 229 genes (98 genes in whole blood and 144 genes in brain cortex). The average model coefficient of determination (R^2) was 0.11 (range from 0.03 to 0.34). We tested a range of mixing parameters (0.05, 0.25, 0.5, 0.75, 0.95) for the elastic net regularization, and compared the sex-stratified and sex-combined modeling on the X chromosome. We further investigated genes escaping X chromosome inactivation to determine if their genetic regulation patterns were distinct. Based on our findings, sex-stratified elastic net models with a balanced penalty (50% LASSO and 50% ridge) are the most optimal approach to predict the expression levels of X chromosome genes, regardless of X chromosome inactivation status. The predictive capacity of the optimal models in whole blood and brain cortex was confirmed through validation using DGN and MayoRNAseq temporal cortex cohort data. The R^2 of tissue-specific prediction models ranges from 9.94×10^{-5} to 0.091. These models can be used in Transcriptome-wide Association Studies (TWAS) to identify putative causal X chromosome genes by integrating genotype, imputed gene expression, and phenotype information.

PB1223 Predicting mode of action of missense variants by graph representation of protein structural context

Authors:

G. Zhong, Y. Shen; Columbia Univ., New York, NY

Accurate prediction of functional impact of missense variants is fundamentally important for disease gene discovery, clinical genetic analysis, and protein engineering. Previous efforts have focused on predicting a binary pathogenicity classification, but the functional impact of missense variants is multi-dimensional. Different pathogenic missense variants in the same gene may act through different modes of action, such as gain or loss of functions or partial loss on one of the functions, and ultimately increase the risk of different conditions or diseases. The mechanisms of the functional impact depend on the functions of the encoded protein, therefore, predicting mode of action requires components that are tuned to the functions specific to each protein or protein families. In this work, we developed a new method, PreMode, that learns universal representation of coding sequence variants and used transfer learning to predict modes of action in each protein or protein family. PreMode learns a general representation of sequence variation within protein structural context using SE(3)-equivariant graph neural networks on AlphaFold2 predicted protein structures. We curated the largest set of mode-of-action-labeled missense variants (1772 Gain-of-function, 7426 Loss-of-function) from human genetics data and deep mutational scanning experiments. We first pre-train PreMode on large labeled pathogenic/benign variant databases, then performed transfer learning for an array of mode of action prediction tasks. PreMode outperformed previously published methods in most of the tasks, especially in ion channel genes with an area under the curve of 0.92. We applied PreMode to published de novo mutation data from individuals with neurodevelopmental disorders and found several high confidence gain-of-function variants. Furthermore, we showed the PreMode framework is not limited to individual missense variants in human proteins but can also model the combined effects of multiple variants in engineered proteins.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1224 Predicting the effects of genetic variants on chromatin accessibility with a deep learning approach

Authors:

J. Jaureguy; UCSD, Salk Institute for Biological Studies, CA

Genome-wide association studies (GWAS) have identified thousands of genetic variants associated with human traits and diseases. However, the majority of these variants lie within the non-coding portion of the genome and, we currently lack knowledge of the molecular function of the associated variants and of which of them are causal. Molecular quantitative trait locus (QTL) analysis can help determine variant function, by identifying variants associated with molecular traits such as chromatin accessibility (caQTLs) and gene expression (eQTLs). However, due to linkage disequilibrium, the identity of causal variants remains ambiguous. Furthermore both genome-wide association and QTL studies lack power to detect associations with rare genetic variants. Machine learning methods have recently emerged as an alternative method for determining variant function. These methods predict gene expression, chromatin accessibility, and transcription factor binding from DNA sequence alone. However, currently, machine learning models are trained on reference genome sequences and do not consider human genetic variation in training. We hypothesized that including genetic variation and allele-specific open chromatin (ASOC) in machine learning models could increase their ability to predict variant function. Here, we introduce a "variant aware" model that is able to predict the impact of both common and rare genetic variants on chromatin accessibility. We utilized transfer learning to incorporate genetic variation and allele-specific information into the training of a machine learning model. For training and testing my model, I selected a human macrophage dataset containing ATAC-seq data and genotype information for 23 unique donors under four treatment types. The variant aware model yielded a Spearman rank correlation (rho) of rho=0.29 for allelic imbalance predictions and rho=0.62 for ATAC-seq read depth predictions, which exceeded the performance of reference-trained models DeepSea (rho=0.26 for allelic imbalance; rho=0.43 for ATAC-seq read depth), and Basset (rho=0.11 for allelic imbalance; rho=0.34 ATAC-seq read depth). In summary, our machine learning model that leverages genetic variation and allele-specific information, more accurately predicts the effects of common genetic variants on chromatin accessibility, and we are in the process of predicting the effects of rare variants. These results indicate that variant aware machine learning models have great potential in improving predictions of common and rare genetic variants on molecular traits, especially rare genetic variants that cannot be assessed by QTL-based methods.

PB1225 Predicting the functional impact of compound heterozygous genotypes from a large scale variant effect map

Authors:

G. Cromie[1], M. Xie[1], K. Owens[2], M. Timour[1], M. Tang[1], J. N. Kutz[2], A. El-Hattab[3], R. McLaughlin[1], A. Dudley[1]; [1]Pacific Northwest Res. Inst., Seattle, WA, [2]Univ. of Washington, Seattle, WA, [3]Coll. of Med., Univ. of Sharjah, Sharjah, United Arab Emirates

Reduced activity of the enzymes encoded by *PHGDH*, *PSAT1*, and *PSPH* causes a set of ultrarare, autosomal recessive diseases known as serine biosynthesis defects. These diseases present in a broad phenotypic spectrum, with Neu-Laxova syndrome at the severe end, infantile serine biosynthesis defects, with severe neurological manifestations and growth deficiency, in the intermediate range, and in the form of childhood disease with intellectual disability at the mild end. However, L-serine supplementation, especially if started early, can ameliorate and in some cases even prevent symptoms. Therefore, knowledge of pathogenic variants can improve clinical outcomes. On this basis, we utilized a functional growth-based assay in haploid yeast cells to measure the impact of 1,914 SNV-accessible amino acid substitutions in PSAT. Our results agree well with existing clinical variant interpretations, evolutionary data and protein structure-function relationships, supporting the use of our data as functional evidence under the ACMG interpretation guidelines. Using existing variants with clinical classifications enabled us to define deleterious, non-deleterious and uncertain ranges of our growth assay and to then place 1634 (85%) of the tested amino acid substitutions in the informative deleterious or non-deleterious categories. In addition to assaying the functional impact of individual variants in yeast haploid cells, we also experimentally assayed pairwise combinations of *PSAT1* alleles that recapitulate human genotypes, including compound heterozygotes, in yeast diploids. Results from our diploid assay successfully distinguish the genotypes of affected individuals from those of healthy carriers and agree well with disease severity. Finally, we present a linear model that uses our individual allele measurements (from haploid cells) to accurately predict the behavior of allele pairs from our diploid assay. This model then allowed us to leverage our 1,914 individual allele measurements to predict the biallelic function of ~1.8 million allele combinations, each corresponding to a potential human *PSAT1* genotype. Taken together, our work provides an example of how large-scale functional assays in model systems can be powerfully applied to the study of ultrarare diseases.

PB1226 Predicting the pathogenicity of missense variants in AMPA receptors

Authors:

L. Montanucci[1], T. Brünger[2], N. Bhattarai[1], D. Lal[3]; [1]Cleveland Clinic, Cleveland, OH, [2]Cologne Ctr. for Genomics, Brühl, Germany, [3]Harvard Med. Sch. / Broad Inst., Boston, MA

Ionotropic glutamate receptors (iGluRs) are ligand-gated ion channels activated by the neurotransmitter glutamate. They mediate the majority of excitatory synaptic transmission throughout the central nervous system and are key players in synaptic plasticity, which underlie critical brain functions like learning and memory. iGLluRs comprise four sub-classes of receptors: NMDA receptors (encoded by the GRIN genes), AMPA receptors (encoded by the GRIA genes), kainate receptors (encoded by the GRIK genes) and delta receptors (encoded by the GRID genes).Genetic variants in the genes encoding for iGluRs are associated with severe neurological and neuropsychiatric disorders. Most clinically characterized genetic variants in iGluRs belong to the class of NMDA receptors, with about 400 clinically characterized variants from patients and 1,500 control variants from general population. Variants in AMPA receptors, instead, are characterized to a much lesser extent with only ~30 variants for which the clinical significance has been annotated and ~100 known control variants for general population. Therefore, computational methods able to predict the pathogenicity in AMPA receptors are crucial for genetic interpretation in clinical practice and inform precision therapies for patients with AMPA receptor variants.Taking advantage of the big number of well-characterized variants in NMDA receptors, we previously developed a pathogenicity predictor, specifically trained on NMDA receptors variants and based on variant proximity to ligands. We showed that proximity of the variant to ligands is key feature for predicting pathogenicity, outperforming existent predictors. Here, our goal is to transfer the predictive knowledge we gathered from well-characterized GRIN genes, to GRIA genes, by exploiting the high structural conservation between NMDA and AMPA receptors. We therefore adapted the pathogenicity predictor previously developed for NMDA receptor missense variants, to predict the pathogenicity of AMPA receptors missense variants.

PB1227 Prioritizing coronary artery disease risk variants in atherosclerosis using deep learning models of chromatin accessibility in mouse

Authors:

S. Kundu[1], R. Wirka[2], D. Li[1], J. Monteiro[1], D. Sharma[1], L. Sundaram[1], T. Quertermous[1], A. Kundaje[1]; [1]Stanford Univ., Stanford, CA, [2]Univ. of North Carolina, Chapel Hill, NC

Arterial smooth muscle cells (SMCs) respond to atherosclerotic lesions in coronary artery disease (CAD) by de-differentiating, proliferating, and migrating in a process known as phenotypic modulation. Recent work has revealed that these SMCs transform into fibroblast-like cells, known as fibromyocytes, which play a protective role by forming fibrous caps that cover these lesions and prevent adverse events, such as arterial thrombosis and myocardial infarction. Furthermore, genes at loci implicated in CAD risk through genome-wide association studies (GWAS), such as TCF21, ZEB2, and SMAD3, play a crucial role in the formation of these protective SMC-derived fibromyocytes. Although the transcriptomic changes underlying this phenotypic modulation of SMCs have recently been studied, the gene regulatory programs driving these transcriptomic changes remain poorly understood. Similarly, the causal variants modulating disease risk at hundreds of CAD GWAS loci remain unidentified.
In order to characterize the changes in the regulatory landscape during phenotypic modulation, we profiled the gene expression and chromatin accessibility of lineage-traced SMCs in aortic atherosclerotic tissue from mice at single cell resolution. We found a trajectory of cell states from quiescent SMCs to fibromyocytes and chondromyocytes, which are similar to endochondral bone-forming cells and are found at the end of the phenotypic modulation trajectory. To identify the transcription factors (TFs) regulating the genes expressed along this trajectory, we trained convolutional neural network models that can map regulatory DNA sequence to base resolution chromatin accessibility profiles in each cell state. Using model interpretation tools, we annotated the putative binding sites for each of these TFs along the trajectory and linked them to their target genes.
Finally, we used these cell-state specific models trained on mouse data to score the functional impact of all non-coding human variants associated with CAD risk. Strikingly, we found more than 500 variants with significant effects on predicted accessibility, spanning the entire phenotypic modulation trajectory. These variants disrupt motifs of key transcription factors, such as SRF, AP-1, MEF2, and ZEB, and have concordant scores from models trained on human cells with matching phenotype, highlighting the power of this approach to identify functional variants across species. Experimental validation of these prioritized variant effects in human coronary artery smooth muscle cells is underway.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1228 Promoter region functional polymorphism (30bpuVNTR) of monoamine oxidase A gene association with serum protein levels in psychiatric disorders

Authors:

A. Hashmi[1], R. Qamar[2], M. Azam[3]; [1]Comsats Univ. islamabad, Islamabad, Pakistan, [2]Sci. and Technology Sector, ICESCO, Rabat, Morocco, [3]COMSATS Univ. Islamabad, Islamabad, Pakistan

Background: Monoamine oxidase A (MAOA) is a mitochondrial outer membrane enzyme that has a role in the metabolism of different biogenic amines, including dopamine, serotonin and norepinephrine. The functional studies of the *MAOA* have revealed the effect of the variable number of tandem repeat sequences (VNTR) in the promoter region on the transcriptional activity of the *MAOA* that consequently affects the homeostasis of the biogenic amines which may be implicated in the aetiology of multiple psychiatric conditions and mood disorders. **Objective:** The current study was aimed to determine the effect of the promoter region 30 base pair (bp) VNTR of the *MAOA* (*MAOA*-30bp µVNTR) on its serum levels and association with major depressive disorder (MDD), bipolar disorder (BD) and schizophrenic (SHZ) patients of the Pakistani population. **Methodology:** A total of 1062 subjects [MDD *n*=416; BD *n*=200; SHZ *n*=97; and controls *n*=349], were genotyped for *MAOA*-30bp µVNTR through standard polymerase chain reaction (PCR) technique. Univariant followed by multivariant logistic regression analysis was applied to determine the genetic association. Serum MAOA levels were determined through enzyme-linked immunosorbent assay (ELISA) and the Mann-Whitney U test was applied. **Results:** Eight different repeats (R) alleles; 2R, 3R, 3.5R, 4R, 4.5R, 5R, 5.5R and 6R of 30bp *MAOA*-µVNTR were observed where 4.5R, 5.5R and 6R were the rare repeat alleles, found in the current Pakistani cohort with no significant association with the studied psychiatric conditions. However, compared to controls the total MAOA serum levels were found significantly elevated in SHZ (P=0.004). In sub-group analysis cases and controls were grouped with respect to alleles; low-activity alleles (MAOA-LA=2R, 3R, 5R), high-activity alleles (MAOA-HA=3.5R, 4R) and rare alleles (MAOA-R=4.5R, 5.5R, 6R). Significant elevated MAOA serum levels were observed in higher activity (CON-HA) and lower activity (CON-LA) alleles compared to rare alleles (CON-R), (P<0.03), within the control group. Whereas, in case-control analysis, significantly higher serum levels of MAOA were observed only in the rare allele groups of BD-R (P=0.008) and SHZ-R (P=0.05). **Conclusion:** This is the first report from the Pakistani population, giving us further insights into the complex nature of *MAOA* regulation and its association with different psychiatric conditions. Though the study focused only on the 30bp µVNTR element, the potential interactive contribution of other functional polymorphisms and the gene/environment cannot be ruled out to influence the expression of *MAOA* and its serum-based levels in different ethnicities.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1229 Promoter Usage Quantitative Trait Loci in Chronic Obstructive Pulmonary Disease

Authors:

A. Saferali, Z. Xu, R. Chase, M. Cho, P. Castaldi, C. Hersh; Brigham & Women's Hosp., Boston, MA

Rationale: Transcriptional quantitative trait locus study results can be integrated with genome wide association study (GWAS) data to provide insight into biological mechanisms involved in disease. We have previously identified multiple COPD GWAS loci which can be explained by splice QTLS (sQTLs), 3'UTR length QTLs (apaQTLs), and eQTLs, however, there remain several loci with unexplained functions. Here, we investigate SNPs that are associated with promoter activity (proQTLs) to identify novel functions for GWAS variants in chronic obstructive pulmonary disease (COPD). **Methods:** RNA sequencing data and whole genome sequencing data from lung tissue of 1241 subjects from the Lung Tissue Research Consortium (LTRC) was obtained through the NHLBI TOPMed project. ProActiv was used to quantify promoter activity (the amount of transcription initiated at each promoter), by quantifying the number of junctional reads aligning to the first set of introns belonging to a transcript corresponding to a given promoter. COPD and lung function associated SNPs for colocalization analysis were ascertained from a published GWAS (Sakornsakolpat et al., Nat Genet 2019;51:3). **Results:** We identified 23,007 active promoters from 16,337 unique genes. Activity of 7,328 promoters from 6,365 genes was associated with at least one SNP (proQTLs). ProQTLs were most commonly associated with the first promoter located in the gene (63.7%), while 17.8% were associated with the second. For the 7,086 unique lead proQTL-variants, the median distance from the transcript promoter was 19 bases upstream. In relation to the gene body, 53.7% of lead variants were intronic, followed by intergenic (27.1%), exonic (6.3%), and 5'UTR variants (3.8%). We found that 6,114 proQTL lead variants (86%) were also eQTL-variants at FDR<0.05 in LTRC lung tissue. Colocalization analysis revealed that out of the 82 loci associated with COPD, thirteen colocalized with proQTL data with a posterior probability > 0.8. Of these, the proQTL with the highest effect size was the association between rs11580609 with promoter activity of *Peroxiredoxin 1 (PRDCX1*) ($p=1.1x10^{-157,}$, $\beta=-1.7$). Specifically, rs11580609-G, which is associated with decreased risk of COPD ($p=1.24x10^{-7}$, $\beta=-0.05$) and increased lung function (FEV1/FVC; $p=6.1x10^{-11}$, Z=-6.5), is also associated with increased activity of a promoter located at GRCh38 chr1:45523047 (mean activity CC=3.6, GG=1.5). **Conclusions:** We identified 7,086 unique variants associated with promoter activity. A total of 13 COPD GWAS loci contain evidence of proQTLs, suggesting that analysis of promoter activity in lung tissue can provide novel insights into disease mechanisms.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1230 Quantitative evaluation of DNA damage and repair dynamics as predictors of clinical phenotypes in individuals with germline *PTEN* variants.

Authors:

R. Wei[1,2], M. Hitomi[1,3], T. Sadler[1], L. Yehia[1], J. Scott[3,2,4,5], C. Eng[1,5,6,7,8]; [1]Genomic Med. Inst., Lerner Res. Inst., Cleveland Clinic, Cleveland, OH, [2]Dept. of Nutrition and Systems Biology and Bioinformatics Program, Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [3]Translational Hematology & Oncology Res., Cleveland Clinic, Cleveland, OH, [4]Dept. of Radiation Oncology, Cleveland Clinic, Cleveland, OH, [5]Taussig Cancer Inst., Cleveland Clinic, Cleveland, OH, [6]Ctr. for Personalized Genetic Hlth.care, Med. Specialties Inst., Cleveland Clinic, Cleveland, OH, [7]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [8]Germline High Risk Cancer Focus Group, Case Comprehensive Cancer Ctr., Case Western Reserve Univ., Cleveland, OH

Persons with germline variants in the tumor suppressor gene phosphatase and tensin homolog, *PTEN*, have PTEN hamartoma tumor syndrome (PHTS). PHTS confers a high risk of malignancies, but up to 23% are diagnosed with autism spectrum disorder (ASD) and/or developmental delay (DD). Importantly, the accurate prediction of these two disparate phenotypes (cancer vs. ASD/DD) for PHTS at the individual versus cohort level remains elusive. Notably, PTEN is a guardian of genome integrity. However, integrative studies that quantify the DNA damage response (DDR) in individuals with PHTS in relation to phenotypes and genotypes have not been explored. In this study, we used 43 lymphoblastoid cell lines (LCLs) derived from individuals with PHTS to investigate the associations between DDR and *PTEN* genotypes and/or clinical phenotypes ASD/DD vs. cancer. We used the exponential decay model, which describes signal decrease at a rate proportional to its current value, to fit our quantified time-course γH2AX immunofluorescence signals induced by γ-irradiation of the LCLs. We found that *PTEN* nonsense variants (n=18) are associated with less DNA damage repairing ability/higher DNA damage levels after repair than *PTEN* missense variants (n=17, p=0.01). More specifically, PTEN p.Arg335Ter (n=5) showed higher DNA damage levels after repair than PTEN p.Arg173Cys (n=8, p=0.01). As related to PHTS phenotypes, those with neither ASD/DD nor cancer (n=8) showed higher DNA damage repairing half-life than those diagnosed with ASD/DD alone (n=17, p=0.049). We also applied the reaction-diffusion partial differential equation (PDE) mathematical model, a tumor cell growth model with a DNA damage term, to accurately describe the DDR process in the LCLs. The numerical results of the PDE reflecting DDR were visualized as heatmaps for each LCL, including DNA damage repair and cell growth capacity. By calculating the peak signal-to-noise ratio (PSNR) and structural similarity index measure (SSIM) for each heatmap, we found that LCLs with different *PTEN* genotypes have different DDR signatures. In order to better understand *PTEN* genotype-associated cellular phenotype and organismal phenotype-associated cellular phenotype, we used an integrated experimental and theoretical modeling approach to derive a signature of growth and repair. This integrative analysis of DDR dynamics will enable more precise prediction of clinical phenotypes (ASD/DD vs. cancer) at the individual level, thus enabling more precise medical management of individuals with PHTS.

PB1231 Quantitative trait loci mapping of circulating metabolites in cerebrospinal fluid reveals insights into biological mechanisms

Authors:

T. Boltz[1], L. Reus[2], M. Francia[1], M. Bot[1], N. Ramesh[1], W. M van der Flier[3], P. Visser[2], S. van der Lee[3], B. Tijms[2], L. Olde Loohuis[1], C. Teunissen[3], R. Ophoff[1]; [1]UCLA, Los Angeles, CA, [2]Alzheimer Ctr. Amsterdam, Amsterdam, Netherlands, [3]VU Univ. Med. Ctr., Amsterdam, Netherlands

The use of functional phenotypes within genome-wide association contexts has provided mechanistic insights into complex disease architectures, though these insights lag behind particularly for neuropsychiatric diseases. In this study, we use metabolomics to measure the levels of 5,543 CSF metabolite levels, both targeted and untargeted, in 977 Dutch individuals with cerebrospinal fluid (CSF) and genetic data. Individuals originated from two separate cohorts including the Utrecht cohort (n=490 cognitively healthy subjects) and the Amsterdam Dementia Cohort (n=487 subjects from a well-characterized memory clinic cohort). We performed genome-wide metabolite quantitative trait loci (mQTL) mapping on CSF metabolomics and found 126 Bonferroni-significant mQTLs, representing 65 unique CSF metabolite levels across 52 independent loci. By imputing the CSF levels of the significant metabolites into the GWAS of various brain-related diseases, we identified 40 significant metabolite-trait associations. Similarly, by imputing brain-derived gene expression into our CSF metabolomics data, we find colocalized gene-metabolite associations for over 90% of our genome-wide significant mQTL. These findings highlight new metabolic pathways that may be involved in the dysregulation of neurodegenerative and psychiatric disorders.

PB1232 Rare variant annotation tools: a practical guide for researchers.

Authors:

A. Ziegler, C. Riccio; MedizinCampus Davos, Davos, Switzerland

Due to the declining costs of sequencing, the feasibility of whole-genome sequencing on a large scale has increased, enabling rare variant association studies (RVAS) involving thousands of subjects. In contrast to common variant genome-wide association studies (GWAS), RVAS hold the promise of identifying high-impact variants. Nonetheless, the interpretation of RVAS findings poses a complex challenge because of the many different types of variations and the abundance of annotation tools. This presentation provides a practical guide to selecting the most appropriate tools for rare variant annotation. A systematic search was done in PubMed to identify tools that predict the effects of genetic variants. Tools that are disease-specific, cannot be installed locally, or were not recently updated were excluded from further consideration. The tools were evaluated based on criteria such as types of variants covered, predicted consequences, documentation, and redundancy with other databases. A total of 72 tools were identified and included in this review. These tools varied substantially in terms of annotation coverage, ranging from tools focusing on one functional element, e.g., enhancers to general variant annotation tools. The types of annotations provided include functional consequences in coding and non-coding regions, population frequencies, conservation scores, and pathogenicity scores. We assigned each tool with Sequence Ontology (SO) terms corresponding to the variants and effects covered by the tool. We provide a file that can be easily queried by researchers to select tools covering specific types of variants. Some tools offer focused annotation for specific variant types or molecular mechanisms, and general variant annotation tools provide broader coverage across variant types and consequences. Integration of multiple tools can enhance the accuracy of variant effect prediction, thus aiding the understanding of the biological basis of rare variant/disease associations. Researchers can use this guide to efficiently select appropriate tools for rare variant interpretation, which allows them to create experimentally testable hypotheses.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1233 Rare variant association analyses of plasma protein levels in a multi-ancestry cohort.

Authors:

C. Sarnowski[1], D. Dutta[2], J. Zhang[3], J. Ma[1], E. Boerwinkle[1], J. Coresh[3], B. Yu[1], N. Chatterjee[3]; [1]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Natl. Cancer Inst., Bethesda, MD, [3]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Background: Majority of protein quantitative trait loci (pQTL) studies to date have focused on local associations with common genetic variants (minor allele frequency [MAF] > 1%) primarily in participants of European descent. The effect of rare variants on both proximal (cis) and distal (trans) proteins could have notable impact on the genetic architecture of the proteome. Aim: We analyzed whole exome sequencing data from 5,281 European American (EA) and 1,797 African American (AA) participants in the Atherosclerosis Risk in Communities (ARIC) Study to evaluate the contribution of rare variants on 4,955 plasma proteins levels measured by SomaScan at visit 2. Methods: We evaluated gene-level association of rare (MAF ≤ 1%) loss of function (lof) variants with protein levels using variant-set mixed model association tests (SMMAT) or likelihood-based tests for quantitative traits (LRT-q), that model the effect of rare variants on either the mean or the overall distribution of protein levels respectively. We conducted analyses separately in EA and AA participants. Cis versus trans associations were defined based on a 5MB region around each protein transcription starting site. Gene results were filtered based on a cumulative minor allele count of at least 25. Threshold to define significance accounted for multiple testing ($P_{trans} \leq 6.5\times10^{-10}$; $P_{cis} \leq 9.9\times10^{-8}$). Results: The mean heritability of a protein attributed to cis-lof variants was slightly higher in AA (mean = 1.9% [0.01% - 7.9%]) compared to EA (mean = 1.3% [0.01% - 4.8%]). SMMAT detected 307 (EA) and 93 (AA) significant protein-gene associations. LRT-q identified large majority of the SMMAT signals (92.8% in EA & 79.5% in AA) along with large number of additional signals (1,076 in EA & 277 in AA). Across both methods, majority of the associations detected were in trans (76.1% in EA & 77.2% in AA). We detected with both methods a cis association of rare variants annotated to *C6* with C6 protein in both ancestries and trans-associations in EA participants of SPOCK1 protein (chr5) with rare variants annotated to *CRIPAK*-chr4 and *SLC17A9*-chr20. We also identified trans-associations in both ancestries of four proteins (PTGR2-chr14 [SMMAT], FARS2-chr6 [LRT-q], and VBP1-chrX & SUMF2-chr7 [LRT-q & SMMAT]) with rare variants annotated to *C6*-chr5. Cross-ancestry replication (P < 5% with same direction of effects) was observed for 32% (EA) and 25% (AA) of the significant genes, driven by MAF differences across ancestries. Conclusion: Our ancestrally diverse study can provide important insights into the overall contribution of rare variants in the genetic regulation of plasma proteins. PB1234 Rare variant dosage in sudden cardiac death-related genes increases risk of sudden cardiac death among hypertrophic cardiomyopathy patients.

Authors:

Q. Huang[1], C. Zhang[1], M. Lu[1], X. Bo[2], J. Wang[1], L. Song[1]; [1]State Key Lab. of Cardiovascular Disease, Fuwai Hosp., Natl. Ctr. for Cardiovascular D, Beijing, China, [2]Inst. of Hlth.Service and Transfusion Med., Beijing, China

Introduction: Incorporating genetic testing to refine the risk stratification of hypertrophic cardiomyopathy (HCM) patients for sudden cardiac death (SCD) remains essential and challenging. We evaluated the dosage effect of rare deleterious variants on the SCD outcome in HCM patients.
Methods and results: A total of 836 unrelated HCM patients were prospectively recruited with a median follow-up time of 5.20 years and 25 patients reaching SCD. Participants with available and quality control qualified whole exome sequencing were screened for rare deleterious variants in 43 curated SCD-related genes based on the disease they caused (inherited cardiomyopathies and hereditary arrythmias) and their encoded proteins' function (sarcomere, desmosome, ion channels). Rare variant dosage in SCD-related genes was a significant predictor of SCD (HR, 3.5; 95% CI, 1.2-10.1, P = 0.02). After adjusting for age, gender and clinical SCD risk factors recommended by 2020 American Heart Association (full model), rare variant dosage showed independent association with SCD (adjusted HR, 4.4; 95% CI, 1.1-18.6, P = 0.03). The C-index for full model is 0.80 (95% CI 0.670-0.890, P < 0.001).
Conclusion: Our study defined an SCD-related gene set and demonstrated in a large HCM cohort that rare variant dosage in this gene set is an independent predictor of SCD and may be integrated into future SCD prediction model for HCM patients.

PB1235 Rare variants affecting telomere length and disease identified through multi-omic modeling

Authors:

R. Keener[1], T. Li[2], F. Aguet[3], K. Ardlie[4], J. Rotter[5], S. Rich[6], A. Battle[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins Sch. of Med., Baltimore, MD, [3]Illumina, Inc., Foster City, CA, [4]Broad Inst., Cambridge, MA, [5]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [6]Univ. of Virginia, Scottsville, VA

Telomeres protect the ends of linear chromosomes and as humans age, telomere length (TL) decreases. When telomeres become critically short, a senescence or apoptosis signal prevents further telomere loss. Individuals with extremely short TL present with Short Telomere Syndromes (STS), including bone marrow failure and immunodeficiency, while individuals with extremely long TL are predisposed to cancer. To gain insight into TL genetic regulation, prior work from our group and others used genome-wide association studies to examine the role of common genetic variation in TL. This strategy identified novel genes involved in TL regulation, some of which we experimentally validated. However, this approach ignores the effects of rare variation, which can have larger effect sizes and uniquely impact genes under strong constraint.

Studies of rare variant effects on TL have improved our understanding of TL biology, but have largely required laborious STS patient pedigree studies. We leveraged TL estimates and rare variant data from the Trans-Omics for Precision Medicine (TOPMed) Program to broadly examine the impact of rare variation on TL. Previously we developed Watershed, a Bayesian hierarchical model, which uses whole genome sequencing with paired multi-omic data (expression, splicing, methylation, and/or protein levels) to prioritize rare variants causing significant disruption of molecular phenotypes. This multi-omic signature generates interpretable hypotheses for coding and non-coding rare variants, providing a posterior probability that the variant causes outlier status for each molecular signal, for example that splicing is disrupted but expression is not. We used data from 5,310 MESA individuals to train Watershed and observed that in 40/86 individuals with extremely short TL (<1% in TOPMed), Watershed prioritized rare variants in at least one gene from a panel of 16 STS genes. The variant with the largest posterior probability (0.984) was predicted to affect expression of *TPP1*, which encodes a protein critical for TL regulation. We will expand our analysis to another 103,812 TOPMed individuals and incorporate multi-omic data where available. Examination of highly weighted variants in individuals with extreme TL relative to average TL will potentially identify novel genes involved in TL regulation. In addition, we will examine the interplay between TL regulation and multi-omic signals over age (0-98 years old). Finally, we will apply our model to data from STS patients to improve their genetic diagnosis. Together this work has utility in improving STS patient diagnosis and furthering our understanding of the molecular mechanisms governing TL.

PB1236 Rare*Plasmodium falciparum*coronin gene mutations following ACT treatment of malaria in South WesternNigeria.

Authors:

O. Ajibaye[1,2], Y. A. Olukosi[1], E. Oriero[2], M. Oboh[3], B. Iwalokun[4], I. Nwankwo[5], O. V. Adaramoye[6], S. Chukwuemeka[1], A. Ngwa[7]; [1]Nigerian Inst. of Med. Res., Lagos, Nigeria, [2]Med. Res. Council, The Gambia, Banjul, Gambia, [3]Med. Res. Council, The Gambia, ?Banjul, Gambia, [4]Nigerian Insttute oof. Med. Res., Lagos, Nigeria, [5]Ctr. for Molecular Parasitology, Dept. of Microbiol. and Immunology, Drexel Univ. Coll. of Med.,, Philadelphia, PA, [6]Coll. of Med., Univ. of Lagos, Lagos, Nigeria, [7]Nigerian Inst. of Med. Res., Lagos, Gambia

Non-Pfkelch13 parasite protein variants have been implicated in artemisinin (ART) resistance, but not in Africa. Genetic markers underlying in vivo reduced ART efficacy among African P. falciparum populations are currently unclear. We investigated SNPs in Plasmodium falciparum actin-binding protein (Pfcoronin) and host *cyp2b6* associated with in vivo ART tolerance in Nigeria.Seven isolates showing parasitaemia after Day 3 in a 28-day therapeutic efficacy study of artemether-lumefantrine among 51 volunteers in Lagos, Nigeria were investigated. Molecular diagnosis was done by microscopy, conventional and real-time PCR amplification of Pf18S rRNA gene, var acidic terminal sequence, telomere-associated repetitive elements-2 and coupled conventional and real-time Pf18S rRNA PCR. Twelve neutral P. falciparum microsatellite loci genotyping were analyzed to confirm recrudescence in comparison with msp2 genotyping. We genotyped drug resistance targets (DHFR_51, DHFR_59, DHFR_108, DHFR_164, MDR1_86, MDR1_184, DHPS_581 and DHPS_613), *cyp2b6* and sequenced PfCoronin bi-directionally for presence and association of mutations with ART tolerance.Molecular techniques employed detected P. falciparum infections. One infecttion was recrudescent by microsatellites analysis out of the four identified as recrudescent infections by msp2 genotyping. Presence of the drug resistance-associated haplotypes, pfdhfr/pfdhps/pfmdr1 ($108_{T/N}/51_{I}/164_{L}/59_{R}/581_{G}/86_{Y}/184_{F}$) was observed in two samples. H_e, allelic diversity, for each microsatellite locus from pre- and post-drug administration, revealed no significant difference in the mean H_e ($P = 0.19$, Mann-Whitney test). Significant LD ($I_A^S = 0.2865$, $P=0.02$, Monte Carlo simulation) around the neutral microsatellite loci was observed. Three new Pfcoronin SNPs (V55L, L77I and D154Y) were found. and *cyp2b6* SNP implicated SNPs here reported may guide investigations on mechanisms of emerging African ART resistance.

PB1237 Recurrent and non-recurrent copy number variants in American Indian tribes with substance use disorders

Authors:

S. Majid, C. Hodgkinson, P-H. SHEN, C. Marietta, D. Sambo, D. GOLDMAN; NIAAA/NIH, ROCKVILLE, MD

Copy Number Variants (CNVs) are large structural variants that can alter function by several mechanisms, including gene deletion and duplication, and thereby may alter susceptibility to Substance Use Disorders (SUDs). CNVs have been implicated in several neuropsychiatric diseases including autism, schizophrenia, and Alzheimer's disease. The rarity or de novo nature of most CNVs impedes linkage to phenotypes; however even rare CNVs may be abundant in families and founder populations. Therefore, in this study, we identified recurrent CNVs (rCNVs) in American Indian tribes that are relatively low in genetic admixture but have high prevalence of SUD. CNVs were identified via Illumina SNP arrays in 400 Plains Indians and 320 Southwest Indians. All had been psychiatrically diagnosed via structured interviews (SADS-LA). Uniquely, we identified large (>200 kb) rCNVs that were abundant in both of two geographically separated American Indian tribes. A CNV at chromosome 6p21.33 was present in more than one in eight individuals in one of the populations and in more than one in four in the other, and multiple homozygotes were observed for that deletion. Haplotype and deletion breakpoint analyses showed that the recurrent CNVs derived from a common ancestor. Most individuals carried at least one rCNV, and CNV load ranged from 0 to 5. These rCNVs, including deletions and duplications encompassing various genes that may contribute to development of SUDs, are being evaluated for effect on transcriptome and linkage to behavior.

PB1238 Regulatory interactions of autism-associated neuronal enhancers implicate novel genes in autism etiology.

Authors:

B. Mifsud[1], D. Aljogol[1], S. Hussain[1], M. Kohailan[2], S. Salim[1], K. Fakhro[3], F. Mohammad[1]; [1]Hamad Bin Khalifa Univ., Doha, Qatar, [2]Sidra Med., Doha, Qatar, [3]Sidra Med. and Res. Ctr., Doha, Qatar, Qatar

Autism spectrum disorders (ASD) are highly heterogeneous neurodevelopmental disorders that are usually associated with secondary phenotypes including intellectual disability, posttraumatic stress disorder (PTSD), anxiety and epilepsy. Over 100 risk genes have been identified, yet they only explain a fraction of the cases. The majority of sporadic ASD are attributed to the presence of *de novo* variants, most of which are in the non-coding portion of the genome. Here, we analyze non-coding single-nucleotide autosomal *de novo* variants in 4,864 ASD cases and 3,865 controls to pinpoint regulatory elements contributing to the etiology of autism. We identified 18 ASD-associated *cis*-regulatory elements that interact with 95 genes, four of which (*EXOC3, EEF1A2, PXDN and CHRNB3)* have been previously reported. Thirty-eight known transcription factor binding sites (TFBSs) were altered at these *cis*-regulatory elements in at least three cases, including motifs for the ASD-associated THRA, EGR2, NR1D1 and VEZF1. Lost TFBSs were enriched for transcription factors (TFs) involved in nervous system development and immunity, whereas gained TFBSs were enriched for those involved in response to sensory cues, including sensory organ development. Pan-neuronal knockdown of two genes during development, one novel (*AHRR*) and one ASD-associated gene (*SLIT3*), resulted in abnormal response to stimulus, learning, social interactions and anxiety in *Drosophila*. In conclusion, *cis*-regulatory elements contribute to autism etiology. Incorporating chromosome conformation capture technologies is a more accurate approach to define target genes, as they recognize those that are in spatial proximity irrespective of their linear genomic position.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1239 † Response eQTLs in primary human chondrocytes identify novel putative osteoarthritis risk genes

Authors:

N. Kramer[1], E. Thulson[1], P. Coryell[1], S. D'Costa[1], K. L. Mohlke[1], B. O. Diekman[1,2], R. F. Loeser[1], D. H. Phanstiel[1]; [1]UNC, Chapel Hill, NC, [2]North Carolina State Univ., Raleigh, NC

Osteoarthritis (OA) is a complex degenerative disease of the joint, and genome-wide association studies (GWAS) have already identified over one hundred genetic loci associated with OA risk, but the putative genes and genetic mechanisms underlying OA are still unknown. Here we generate and use a well powered chondrocyte genomic dataset derived from the cartilage of 102 healthy donors in both a resting state and stimulated with fibronectin fragment (FN-f)-a known OA trigger-to characterize condition and sex-associated gene expression changes and to identify novel response expression QTLs (eQTLs). Condition-separated modeling of standard cis eQTLs identified 1517 significant control eGenes (FDR $p<0.05$, containing at least 1 eQTL) and 1482 significant FN-f eGenes, with 667 eGenes specific to control samples, 632 eGenes specific to FN-f samples, and 850 eGenes found in both conditions. To capture OA stimulus-specific eQTLs that may reflect conditionally regulated mechanisms, we specifically identified response eQTLs by testing for the interaction effect of donor genotype with condition either before or after FN-f treatment. Through this analysis, we identified 270 eGenes specific to resting chondrocytes and 353 eGenes specific to chondrocytes treated with FN-f. Notable FN-f response SNP-eGene pairs include rs12901081-G associated with higher SMAD3 expression (log2 allelic fold change 1.24), and rs8011143-C associated with lower ABHD4 expression (log2 allelic fold change -1.79). 177 genes differentially regulated by FN-f were also significant FN-f response eGenes, including the differentially downregulated response eGene DIO2, which has been cited as a potential OA susceptibility gene. Initial colocalization of FN-f response signals with various OA phenotype GWAS with coloc ($PP4>0.7$) after LD filtering ($r2 > 0.5$) revealed a robust colocalization of the response eQTL signal for SMAD3 with 7 OA GWAS phenotypes, prioritizing SMAD3 as a potential functional gene associated with OA progression. Sex-specific differential expression identified 259 genes in untreated samples and 84 genes after FN-f treatment, 48 of which were significant in both conditions (FDR $p<0.01$). One notable X-chromosome gene was KDM6A, which showed increased expression in females in both conditions and has previous associations with OA development. Taken together, the FN-f model system provides a controlled context to probe the stimulus-specific mechanisms of OA progression and discover novel molecular trait loci that are not detected as standard eQTLs, which will further prioritize candidate genes for future study and translation into OA treatments.

PB1240 Revealing the Extensive Allelic Heterogeneity and Impact of Mobile Elements Across 64 Diverse Human Haplotypes

Authors:

W. Zhou[1], B. Rodriguez-Martin[2], P. Balachandran[3], M. Loftus[4], P. A. Audano[5], Y. Gan[6], The Human Structural Variation Consortium, S. E. Devine[7], J. O. Korbel[8], R. E. Mills[9], M. K. Konkel[10], C. R. Beck[11]; [1]Univ. of Michigan Med. Sch., Ann Arbor, MI, [2]European Molecular Biology Lab., Heidelberg, Germany, [3]The Jackson Lab., Bar Harbor, ME, [4]Clemson Univ., Clemson, SC, [5]The Jackson Lab., Farmington, CT, [6]Harvard Univ., Cambridge, MA, [7]Univ. of Maryland Sch. of Med., Baltimore, MD, [8]European Molec Biology Lab, Heidelberg, Germany, [9]Univ Michigan Med Sch, Ann Arbor, MI, [10]Clemson Univ, Clemson, SC, [11]The Jackson Lab. and UConn Hlth., Farmington, CT

Mobile element insertions (MEIs) diversify human genomes through retrotransposition, polymorphism, and recombination. Polymorphic MEIs contribute to both inter- and intra-individual genetic variation, leading to ongoing mutagenesis. In this study, we conducted a thorough analysis of MEIs in 64 phased haplotypes from sequence-resolved assemblies representing individuals from diverse populations, enabling an exploration into highly repetitive regions of the genomes that pose challenges for traditional sequencing methodologies. We identified 9,600 non-redundant polymorphic MEIs, including 1,183 LINE-1s, 7,838 *Alu* elements, 534 SVAs, 24 HERV-Ks, and 21 processed pseudogenes comprising 7.4 Mbp of insertion sequences. 64% of these insertions fell within existing repetitive regions, where we observed nested 'repeats in repeats', i.e. *Alu* in *Alu* and LINE-1 in LINE-1, with these insertions concentrated within A-rich reference MEI regions. Additionally, we observed 2,639 alleles lacking a reference MEI.

Our 64 haplotype assemblies enabled the interrogation of allelic heterogeneity associated with each sequence-resolved MEI locus. For full-length LINE-1 sequences, we identified 198 active loci where the extent of allelic heterogeneity positively correlated with insertion allele frequency, age, and subfamily status. Notably, allelic differences frequently impact the coding and mobilization potential for LINE-1s, which includes hot (i.e. highly active) elements in cancer. For instance, we observed a subset of haplotypes with intact ORFs for a hot LINE-1 at 9q32, while other haplotypes, including the reference genome, harbored a common protein-truncating single nucleotide polymorphism at ORF2p. We further observed that the greatest variability in SVA length was due to allelic variation within the hexameric and variable number of tandem repeat regions.

Two homologous MEIs can act as substrates of ectopic DNA repair leading to different types of structural variants. We identified 1,833 deletions, 223 duplications, and 63 inversions mediated by two distinct mobile elements that affect nearly 12 Mbp; *Alu* elements drive 80% of these rearrangements. Breakpoint analysis of the mobile element-mediated rearrangements revealed that almost 75% were driven by homologous recombination.

In summary, our results provide a comprehensive understanding of mobile element-derived variation between genetically diverse individuals, highlighting extensive differences in transposon content, allelic heterogeneity, mobile element-driven rearrangements, and begin to elucidate the effects of these variants on human genomes.

PB1241 Role of genetic and environmental variation on gene expression in whole blood from ethnically diverse African populations

Authors:

C. Zhang[1], M. Hansen[1], Y. Feng[1], W. Beggs[1], S. Mpoloka[2], G. Mokone[3], T. Nyambo[4], G. Belay[5], C. Fokunang[6], A. K. Njamnshi[7], S. A. Tishkoff[1,8,9]; [1]Dept. of Genetics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [2]Biological Sci., Univ. of Botswana, Gaborone, Botswana, [3]Faculty of Med., Univ. of Botswana, Gaborone, Botswana, [4]Dept. of Biochemistry, Kampala Intl. Univ. in Tanzania, Dar es Salaam, Tanzania, United Republic of, [5]Dept. of Microbial Cellular and Molecular Biology, Addis Ababa Univ., Addis Ababa, Ethiopia, [6]Dept. of Pharmacotoxicology and Pharmacokinetics, Faculty of Med. and BioMed. Sci., The Univ. of Yaoundé I, Yaoundé, Cameroon, [7]Dept. of Neurology, Central Hosp. Yaoundé, Yaoundé, Cameroon, [8]Dept. of Biology, Univ. of Pennsylvania, Philadelphia, PA, [9]Ctr. for Global Genomics and Hlth.Equity, Univ. of Pennsylvania, Philadelphia, PA

We generated whole blood transcriptomes using RNA-seq from 517 individuals from 19 ethnically and geographically diverse African populations from Ethiopia, Tanzania, Botswana, and Cameroon. These populations have diverse ancestries, speak different languages (Niger-Congo, Afroasiatic, Nilosaharan, and Khoesan), and have diverse subsistence practices (e.g., hunting-gathering, pastoralism and farming). Furthermore, they inhabit extreme environments such as rainforests and high altitudes, and some experience a high burden of communicable or non-communicable diseases. We compare expression profiles and identify numerous differentially expressed genes (DEGs) among African ancestries, some of which are associated with ancestry specific traits. For instance, in rainforest hunter-gatherers from Cameroon who have shorter stature, DEGs are enriched for intrauterine growth retardation and bone development loci, and in the Fulani, who have high prevalence of diabetes in adults, DEGs are enriched for metabolic processes (e.g., insulin signaling pathway). We show that the rainforest environment, independent of genetic ancestry, is significantly associated with differential expression of approximately 700 genes, many of which play a role in immune function (e.g. genes related to antigen presentation and inflammation response). We find a substantial number of RNA-Seq reads in rainforest populations that are mapped to parasite genomes, suggesting a high burden of pathogens may shape the differential expression profiles within these populations. We identify several key transcription factors mediating expression changes in response to varying parasite loads. By integrating transcriptomic and WGS data, we fine-map cis-regulatory variants, many of which are novel. We further identify ancestry-biased eQTLs, some of which are common only in certain populations. We colocalize regulatory variants with GWAS associations for 34 human traits/diseases identified in both African and European populations. We identify novel eQTL-disease-colocalizations in African GWAS (e.g. an eQTL at *P4HA1*, which influences collagen synthesis, colocalized with an African height GWAS) that could not be colocalized with GTEx data. In summary, we generated an atlas of African transcriptomic diversity and identified eQTLs which may influence differences in phenotypes or disease susceptibility among ethnically diverse populations. Our study sheds light on the understanding of molecular links of genetic variants to human traits/diseases and advances precision medicine in African populations and globally. Funded by ADA 1-19-VSN-02, NIH 1R35GM134957, R01AR076241.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1242 Saturation mutagenesis data facilitate the interpretation of non-coding variants in an *IRF6* enhancer associated with nonsyndromic cleft-lip w/o cleft palate.

Authors:

R. Hollstein[1], F. Thieme[1], F. Lauber[1], A. Biedermann[1], J. Fazaal[1], M. Schubach[2], M. Kircher[3,2], K. Ludwig[1]; [1]Inst. of Human Genetics, Univ. of Bonn, Bonn, Germany, [2]Berlin Inst. of Hlth.at Charité – Univ.smedizin Berlin, Berlin, Germany, [3]Inst. of Human Genetics, Univ. Hosp. Schleswig Holstein, Lübeck, Germany

Nonsyndromic cleft lip with/without cleft palate (nsCL/P) is one of the most common birth defects. Its etiology is multifactorial with a strong genetic component. Several genes have been implicated in nsCL/P, e.g. because of their location near GWAS loci or by rare variants found in monogenic forms. However, these only partially explain its high heritability. The contribution of rare, noncoding variants has been rarely investigated, largely due to limitations in attributing pathogenic effects.

One of the best studied genes involved in nsCL/P is *IRF6*. Common and rare variants within the gene itself and an upstream enhancer (*MCS9.7*) are associated with different forms of orofacial clefting, including nsCL/P. Here, we combined two sequencing-based high-throughput methods to screen the *IRF6* enhancer *MCS9.7* for candidate variants across the entire allelic spectrum, including rare variants. We used molecular inversion probes (MIPs) to sequence 699 nsCL/P cases and 511 population controls of European descent. In total, we found 11 variants in cases: three common single nucleotide variants (SNV), two 4- and 9-bp indels, and six rare SNVs.

In parallel, we performed a massively parallel reporter assay (MPRA) to facilitate variant interpretation. We transfected HaCaT, GMSM-K and HEKT293T cells with a previously established saturation mutagenesis library of *MCS9.7* to analyse the effects of all possible single nucleotide exchanges within the *MCS9.7* sequence (362 bp). Fold-changes and p-values were calculated for each substitution, and these results were then integrated with the variants observed in nsCL/P cases.

One common SNV (rs76145088) and one rare variant (rs189972759) showed a significant decrease of enhancer activity that was specific to HaCaT cells ($0.05 > p$). Interestingly, the variant with the highest effect size (nominally significant, $0.05 > p > 1e\text{-}5$) in HaCaT and GMSM-K cells was recently associated with cleft palate only in a finnish cohort. Overall, five of six rare variants affected the enhancer activity at least in either HaCat or GMSM-K at nominal significance threshold. The two common variants had no effect ($p > 0.05$). In conclusion, our data suggest that the combination of MPRA data together with large-scale identification of individual variants might be a promising tool for the prioritization of causal non-coding variants. We have demonstrated this for orofacial clefting, but this approach might also be applicable to other human disorders with a suspected contribution of rare non-coding variants.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1243 Scalable count-based models improve power and robustness to detect eQTLs in large-scale single-cell data

Authors:

Z. Zhang[1], E. Kawaguchi[1], S. Gazal[2], N. Mancuso[3]; [1]Univ. of Southern California, Los Angeles, CA, [2]USC, Los Angeles, CA, [3]Univ. of Southern California, South Pasadena, CA

Expression quantitative trait (eQTL) analyses have identified numerous variants associated with gene expression levels from bulk mRNA; however, integrative efforts with genome-wide association studies (GWAS) explain little observed risk. This limited overlap can be partially explained by bulk eQTL reflecting a mixture of cell type-specific eQTLs. To this end, single-cell RNA-seq data when combined with genetics enables identifying cell type-specific eQTLs and improves our understanding of GWAS mechanisms. Current eQTL mapping approaches rely heavily on continuous assumptions after data normalization, which is not optimal for single-cell gene expression count data. While generalized linear models (GLM) provide a path towards modeling count data, they are computationally demanding, and do not scale to the millions of tests required for cell type-specific cis-eQTL testing.

To address this limitation, we propose jaxQTL, a flexible framework for single-cell eQTL mapping using highly scalable GLMs. To scale inference, jaxQTL leverages five optimizations. First, we use conjugate gradient at each step, which leverages efficient sparse matrix-vector numerical routines. Second, we fit separately a covariate-only "null model" to initialize variant-specific models and improve convergence. Third, we "short-circuit" inference if the variant effect-size does not deviate sufficiently from the null after a small number of iterations. Fourth, we employ a Beta-approximation of the null distribution to reduce the number of permutations necessary to compute empirical p-values. Lastly, we implemented our approach using the Python framework JAX, which provides an end-to-end differentiable framework, makes use of "just-in-time" compilation to leverage highly optimized Fortran/C++ numerical libraries, and enables GPU or TPU execution without any additional efforts from the user.

To benchmark jaxQTL, we performed cis-eQTL mapping for 135 genes with known cis-eQTLs in natural killer cells from N=981 individuals in Onek1k single-cell RNA-seq data. Using a Poisson model, jaxQTL has improved statistical power compared with the linear model for identifying 135 previously reported cis-eQTL (P=1.54E-4), while maintaining calibrated P-values under permutations. Importantly, jaxQTL is ~10x faster compared with a GLM implemented in off-the-shelf software, thus substantially reducing overhead required for computing cis-eQTL scans in single-cell data.

Taken together, jaxQTL provides a robust and scalable approach to identifying cis-eQTLs in single-cell data.

PB1244 sc-eQTGen: large scale federated cell-type specific eQTL mapping in PBMCs

Authors:

M. Bonder[1], D. Kaptijn[1], M. Korshevniuk[1], R. Oelen[2], sc-eQTLGen consortium, L. Franke[3], M. van der wijst[1]; [1]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [2]UMCG, Groningen, Netherlands, [3]Univ. Med. Ctr. Groningen, Groningen, Groningen, Netherlands

Background/Objectives: Over the last decade, single-cell RNA sequencing (scRNA-seq) has grown in popularity as a potent alternative to bulk RNA-seq, as scale, cost and sensitivity have significantly improved. These developments have now paved the way for the generation of large numbers of population-based scRNA-seq datasets that are a valuable resource for studying the effect of genetic variation (through expression quantitative trait locus (eQTL) mapping) on expression of individual cell types. To fully leverage these emerging data resources, we have founded the single-cell eQTLGen consortium (sc-eQTLGen).
Methods: We have developed a pipeline that harmonizes the preprocessing, QC, cell type annotation and eQTL mapping of peripheral blood mononuclear cell (PBMC) scRNA-seq data. Every cohort in the consortium has run these pipelines, and shared the non-privacy sensitive summary statistics, which we combine in a federated manner.
Results: Here, we present the results of the first data freeze in which we have meta-analyzed scRNA-seq-derived eQTL summary statistics of over 2,000 individuals for each of the major cell types in PBMCs. These results reveal the cell types in which eQTLs are to be identified. We show the cell type specificity of cis-eQTLs in PBMCs and the colocalization of cell type specific eQTL signals with disease.
Conclusion: Upcoming data freezes will further increase the sample size, cell type resolution, and number of donor characteristics under study, and will expand our analyses to other data modalities. Thereby, we expect that the sc-eQTLGen framework enables us and the community at large to gain a more complete understanding of gene expression and its regulation in health and disease.

PB1245 ScMetaBrain: Federated single-cell consortium for cell-type specific eQTL analysis of neurological disease variants.

Authors:

H-J. Westra[1], M. Vochteloo[1], R. Oelen[1], D. Neavin[2], R. Warmerdam[1], U. Vosa[3], M. Korshevniuk[1], D. Kaptijn[1], M. G. P. van der Wijst[1], M. Bonder[1], scEQTLgen Consortium, T. Esko[3], Y. Huang[4], H. Runz[4], D. Malhotra[4], J. Bryois[5], E. Tsai[4], L. Franke[1]; [1]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [2]Garvan-Weizmann Ctr. for Cellular Genomics, Darlinghurst, Australia, [3]Univ. of Tartu, Tartu, Estonia, [4]Biogen Inc., Cambridge, MA, [5]Roche Innovation Ctr., Basel, Switzerland

Recently we have completed large scale eQTL meta-analyses in blood (eQTLGen; Vosa *et al*. 2021) and brain (MetaBrain; de Klein *et al*. 2023), providing insight into the downstream effects of disease-associated genetic risk factors. Although having substantial sample sizes, these studies lack the cell type context that single-cell RNA sequencing (scRNA-seq) can provide. To pinpoint these cellular contexts and better interpret neurological diseases, we have initiated the scMetaBrain study, which aims to enable a federated scRNA-seq eQTL analysis in human brain.

To harmonize and compare with our single cell eQTL efforts in blood, we have adapted our recently developed pipeline (scEQTLGen, van der Wijst *et al*. 2020) to brain. This includes robust containerized pipelines that perform quality control, demultiplexing, cell type classification, and eQTL analysis per cell-type and dataset. By applying a meta-analysis of the summary statistics, we enable easy inclusion of new datasets without the need of sharing person-identifiable data.

As proof of concept, we have applied our pipeline to automatically analyze 35 samples from Mathys *et al*. 2019. Using the Bakken *et al*. 2021 dataset as reference, our approach automatically annotates five major brain cell types with high accuracy (97% true positive compared to manual assignment). Moreover, we are able to replicate the *cis*-eQTLs observed in a large brain single-cell eQTL study (n=192; Bryois *et al*. 2022) with high agreement (allelic concordance >0.89, R_b > 0.86 for excitatory neuron and oligodendrocytes), highlighting the validity of our methodology.

Here we introduce scMetaBrain, in which we aim to setup a single-cell brain consortium for the identification of downstream consequences of trait-related genetic variants in specific brain cell types. We envision that this consortium will enable a unique opportunity to disentangle tissue and cell type specific regulatory effects in the brain.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1246 Severe respiratory phenotype in *KCNH1*-related Temple Baraitser Syndrome

Authors:

E. Conner[1,2], I. Glass[1,2], C. Thompson[3], A. George[3], M. Chen[1,2], N. Natarajan[1,2], A. Bouldin[4], A. Scott[2], T. Wenger[1,2]; [1]Univ. of Washington, Seattle, WA, [2]Seattle Children's, Seattle, WA, [3]Northwestern Univ., Chicago, IL, [4]Swedish Med. Ctr., Seattle, WA

We describe two children with severe neurologic and respiratory presentations who were heterozygous for the same novel pathogenic activating variant in *KCNH1*. A 2-month old female infant was born by vaginal delivery (face presentation) at term following an uncomplicated pregnancy with normal birth indices. At delivery she had respiratory distress, central hypotonia and abnormal dystonic limb movements. Examination noted anonychia and hypoplasia of bilateral thumbs and halluces with the remaining digits having hypoplastic nails. Hyperekplexia was present and was partially responsive to clonazepam. Neurologic evaluation consisted of normal MRI, and EEGs without seizure activity. Nasoduodenal feeding was required due to aspiration. Rapid exome sequencing revealed a pathogenic variant in *KCNH1* (c.1478 C>T, p.T493I), not been previously reported. Though initially she had rare, self-resolving desaturations, clinical observation of her abnormal breathing pattern including tachypnea and apneic pauses prompted a polysomnogram. Her sleep study revealed severe sleep disordered breathing with apnea-hypopnea index of 70/hour (normal <15/hr) due to mixed (but predominantly central) apneas. Due to subsequent aspiration event and subsequently required frequent suctioning as well as high flow nasal cannula to treat desaturations and hypercapnia. She remains hospitalized awaiting repeat sleep study to determine the need for tracheostomy/ventilatory support. While pursuing potential targeted therapies, we learned that functional studies were in process for the T493I variant because of an additional previously unreported child who also had severe neurologic features and died at age 9 of respiratory failure. Functional studies of the variant supported gain of function. Specifically, the variant causes a large hyperpolarizing shift in the voltage-dependence of channel activation. Respiratory failure is an uncommon feature in *KCNH1*-related disorders. The combination of abnormal neurologic features and sleep study findings suggest the abnormal respiratory function is neurologically mediated. We hypothesize the T493I gain-of-function variant may be associated with more severe neurologic outcomes including neurologically-mediated respiratory failure. Moreover, it highlights the importance of pursuing polysomnography for clinically observed respiratory abnormalities rather than relying on oxygen desaturations alone in infants with *KCHN1*-related disorders.

Most eQTL studies have relatively modest sample sizes and focus on identifying one primary eQTL per gene, both of which limit power to detect the full range of regulatory variants. We expanded eQTL discovery for subcutaneous adipose tissue by analyzing 2,344 samples from five studies of primarily European ancestry. eQTL meta-analysis detected 34K conditionally distinct eQTL signals in 18K genes, which is 2.3-fold more signals and >1.6-fold more eQTL genes than detected by any of the five studies alone. Over half of eQTL genes had at least two eQTL signals. Compared to primary signals, non-primary signals had lower effect sizes and minor allele frequencies and corresponded to genes with higher heritability and lower tolerance for loss of function. Adipose eQTL variants for 1st-4th signals were enriched in adipose promoters and enhancers (P<3e-3), and 2nd, 3rd, and 4th signals showed successively less enrichment, particularly for promoters, indicating signals accounting for more gene expression variance are enriched in promoters. We compared adipose primary eQTL lead variants to blood eQTL lead variants from the eQTLGen study (n=31,684) and found that 45% of adipose primary eQTL were not detected as blood eQTL (P≤1e-6; r^2<0.2), highlighting the value of using diverse tissues. Next, we colocalized conditionally distinct eQTL and GWAS signals for 28 cardiometabolic disease (CMD) traits. We identified 3,605 colocalized GWAS-eQTL signal pairs for 1,861 eQTL genes (*coloc* PP4≥0.5; GWAS-eQTL r^2≥0.5). Compared to primary eQTL signals, non-primary signals identified 46% more eQTL-GWAS colocalizations and 488 (36%) additional candidate genes, suggesting that non-primary eQTL signals may explain some of the missing regulation of GWAS loci. Non-primary eQTL signals were slightly less likely than primary signals to colocalize with GWAS signals, even when accounting for eQTL strength. To determine if gene expression mediates variant effects on CMD traits, we used MRLocus to examine 26 genes with at least 2 nearly independent (r^2≤0.05; D'≤0.5) colocalized GWAS-eQTL signal pairs; 11 showed a consistent gene dosage effect on the GWAS trait (adjusted P≤0.1). Finally, 70% of GWAS-eQTL colocalized signals had a lead or proxy variant (r^2 ≥ 0.8) overlapping open chromatin in adipose tissue or adipocyte cells, indicating putative functional variants. In summary, this adipose eQTL analysis tripled the size of previous studies, furthered understanding of allelic heterogeneity in gene regulation, greatly expanded discovery of eQTL colocalized with CMD GWAS signals, and identified thousands of candidate genes that may point to new drug targets.

PB1248 Single Cell Multiomics Profiling of Visceral Adipose Tissue Reveals New Insights into the Genetic Regulation of Cardiometabolic Disease

Authors:

U. Arasu[1], I. Selvarajan[1], T. ÖRd[1], M. Taipale[1], A. Toropainen[1], M. Sukhatme[2], A. Kar[3], S. Lee[4], M. Alvarez[4], D. Kaminska[1,4], V. Männistö[1], J. Pihlajamäki[1,5], P. Pajukanta[6,7], M. Kaikkonen[1]; [1]Univ. of Eastern Finland, Kuopio, Finland, [2]UCLA, Pasadena, CA, [3]UCLA, Saratoga, CA, [4]UCLA, Los Angeles, CA, [5]Kuopio Univ. Hosp., Kuopio, Finland, [6]Univ California Los Angeles, Pacific Palisades, CA, [7]Inst. for Precision Hlth., Los Angeles, CA

We conducted the first single cell multiomics (RNA and ATAC) profiling of human visceral adipose tissue (VAT) obtained from seven individuals with obesity in the Kuopio Obesity Surgery (KOBS) cohort. After extensive quality control, 3200 nuclei showed clustering into five main cell types: adipocytes, adipose stem/progenitor cells (ASPC), endothelial cells, mesothelial cells, and macrophages. We performed a comprehensive analysis of the identified cell types to investigate their associated transcription factors using SCENIC. This analysis not only confirmed known drivers of cell identity but also revealed novel transcription factors that play a crucial role in shaping the identity of these cells.Building upon the established knowledge that common genetic variants associated with cardiometabolic diseases often reside in non-coding regions of the genome, we employed Linkage Disequilibrium Score Regression (LDSC) to examine the enrichment of cardiometabolic trait -associated SNPs within 1 kb of the peaks in adipocytes (50k peaks), ASPCs (63k), mesothelial cells (75k) and macrophages (42k). As an example of our preliminary findings, we demonstrate that adipocyte, ASPC, and macrophage peaks account for a significant proportion of per-SNP heritability for Non-Alcoholic Fatty Liver Disease (non-permuted p-values=0.004, 0.017, 0.048) and triglyceride levels (TG; non-permuted p-values=0.025, 0.031, 0.045). The significant enrichment of TG heritability within the peaks of these three cell types was further validated using publicly available single-nucleus ATAC-Seq data from 30 distinct adult human tissues and 222 unique cell types (catlas.org).In order to identify the potential susceptibility variants responsible for the enriched heritability observed in regulatory elements for cardiometabolic traits, we performed experimental fine-mapping using a massively parallel reporter assay in preadipocytes, adipocytes (control and TGFb conditions), and macrophages (control, IL1b and TGFb conditions). In total, we identified variants with allele-specific activity for hundreds of loci associated with cardiometabolic traits across different cell types and conditions. Notably, this analysis unveiled previously unrecognized common regulatory variants near *COBLL1* and *IRS1* genes.In conclusion, our work provides a comprehensive resource for the functional characterization of cell types, variants, and genes associated with cardiometabolic traits in VAT. Additionally, this advanced multiomics approach opens new avenues for the exploration of disease mechanisms in other complex disorders.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1249 Single-cell eQTL mapping identifies cell type- and disease-specific genetic control of COVID-19 severity.

Authors:

J. Astley[1], COMBAT Consortium, J. Knight[2], R. Edahiro[3], Y. Okada[4], Y. Luo[1], L. Jostins[5]; [1]Kennedy Inst. of Rheumatology, Univ. of Oxford, Oxford, United Kingdom, [2]Univ. of Oxford, Oxford, United Kingdom, [3]Osaka Univ., Ashiya, Japan, [4]Osaka Univ. / The Univ. Tokyo / RIKEN, Osaka, Japan, [5]Wellcome Trust Ctr. Human Genetics, Oxford, Oxfordshire, United Kingdom

The underlying mechanisms regulating immune response to Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) are not yet sufficiently characterized. Expression quantitative trait loci (eQTL) studies aid discovery of variants regulating gene expression, and differences in signal between cell types or disease severity contexts can be explored to gain insight into this process. We analysed transcriptomic and genetic data from 76 donors and ~$4.6x10^6$ cells of European ancestry: 8 healthy individuals, 16 diagnosed with sepsis at the time of sample collection, and 52 individuals diagnosed with Coronavirus disease (COVID-19) at 4 WHO-defined stages of severity. TensorQTL mapping software was used to perform a genome-wide search for conditionally independent cis-QTLs across 16 major peripheral blood mononuclear cell types, including T cells and monocytes. In total, 2163 cis-independent eQTL signals were found across 16 cell types; most frequently in CD4 cells (792) and classical monocytes (576), followed by CD8 (245) and natural killer (NK) cells (205). The strongest eQTL signal was found in classical monocytes (cMono) at the *RPS26* locus, regulated by variant rs10876864 ($P=1.46x10^{-25}$, $\beta=-1.34$). This relationship was observed in 8 other key cell types involved in immune response: increased dosage of the minor allele (A) was associated with decreased expression of *RPS26* in 3 sub types of mononuclear phagocytes (MNPs) - classical and non-classical monocytes (ncMono) and dendritic cells (DC) - as well as CD4, CD8 and other T cell groups. We report a context specific effect of this eQTL in 5 cell types including NK ($P=2.85x10^{-4}$, $\beta=46.1$), CD4, CD8 and DC. The signal we observed in cMono ($P=8.34x10^{-3}$, $\beta=9.65$) was also detected in monocytes by Edahiro et al (Nature Genetics 2022) in an independent study in a Japanese cohort ($P=3.52x10^{-2}$, $\beta=0.158$). Expression of *RPS26* decreases with increased COVID-19 severity in GG and heterozygous genotype samples, whereas the relationship is reversed with AA genotypes. This variant is in high linkage disequilibrium ($R^2=0.92$) with a variant associated with COVID-19 hospitalization (rs7297175) and is itself associated with several clinical phenotypes including Type 1 Diabetes. Our results emphasise the genetic contribution to individual immune response, in particular to SARS-CoV-2, and demonstrate the importance of expanding these studies to further our understanding of host defence mechanisms in the context of infectious disease.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1250 Single-cell eQTL mapping in healthy and Crohn's-afflicted terminal ileum offers novel insights into inflammatory bowel diseases

Authors:

T. Alegbe[1,2], M. Krzak[1], L. Taylor[3], M. Ghouraba[1], M. Strickland[1], M. Tutert[1], M. Ozols[1], J. Ostermayer[1], J. Skelton[4], G. Jones[5], C. Cotobal Martin[1], V. Iyer[1], M. Parkes[6,2], R. E. McIntyre[1], T. Raine[6,2], C. A. Anderson[1]; [1]Wellcome Sanger Inst., Hinxton, United Kingdom, [2]Univ. of Cambridge, Cambridge, United Kingdom, [3]NIH, Bethesda, MD, [4]Cancer Res. UK Cambridge Inst., Cambridge, United Kingdom, [5]Univ. of Edinburgh, Edinburgh, United Kingdom, [6]Addenbrooke's Hosp., Cambridge, United Kingdom

Inflammatory bowel diseases (IBD) are complex and highly polygenic diseases of the gastrointestinal tract. Genome-wide association studies (GWAS) have associated over 320 loci with IBD or the two most common subtypes: Crohn's disease (CD) and ulcerative colitis (UC). As with many other polygenic diseases, for the vast majority of loci it remains unclear which genes and cell types are impacted by disease-associated variants. Expression quantitative trait loci (eQTL) have been used to identify genes whose expression is perturbed by disease associated variants. However, the limited resolution afforded by bulk RNA sequencing, and a lack of context specificity, has hampered these efforts.

To tackle these issues and better understand IBD we generated single-cell RNA-sequencing data from terminal ileal biopsies of 158 healthy and 88 CD-afflicted individuals with the aim of mapping single-cell eQTLS (sc-eQTLs). Our expression dataset consisted of over 1 million single-cell transcriptomes, characterising 49 cell types across immune, epithelial, and mesenchymal populations. We performed pseudobulk eQTL mapping at a high and low cell type resolution finding over 7500 eGenes (FDR < 0.05), just under half of which were undetectable without cell type annotation.

We reproduced eQTL effects from GTEX terminal ileum, GTEX colon, and the database of immune cell eQTLs (DICE) whilst also finding novel eQTLs not present in the bulk datasets. Utilising our cohort's heterogeneity, we were able to map sc-eQTL interactions with disease status and inflammation degree finding 26 interaction sc-eQTL effects. Colocalisation analysis of our TI sc-eQTLs with CD, UC and IBD GWAS resulted in 22%, 20% and 17% of GWAS loci, respectively, colocalising (PP4 > 0.75), implicating the identified eGenes and gut cell types as likely drivers of inflammatory bowel diseases.

Our findings demonstrate the value of mapping eQTLs with tissue-derived disease state single-cell data. We are able to assign IBD-relevant sc-eQTLs known from prior bulk work to intestinal cell types but beyond that, by sampling from one of the most commonly inflamed sites in Crohn's disease, with a disease cohort and at single-cell resolution, we have uncovered novel sc-eQTLs. These sc-eQTLs may have been previously masked by other cell types, undetectable in healthy, uninflamed samples or not found outside of disease site cell types. By combining our sc-eQTLs with existing GWAS, we have discovered genes and cell types that play a causal role in complex disease which brings us a step closer to potential novel, genetically-motivated therapeutics. As our sample size grows we expect to derive more insight into the biology of IBD.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1251 Single-cell sQTL links cell type-specific regulation of splicing to complex diseases

Authors:

B. Liu[1], T. Chi[1], Y. Zhang[1], Y. Tong[1], W. Wang[1], K. Kock[2], Y. Okada[3], J. Shin[4], S. Prabhaker[4], Asian Immune Diversity Network; [1]Natl. Univ. of Singapore, Singapore, Singapore, [2]Brigham and Women s Hosp., Boston, MA, [3]Osaka Univ. / The Univ. Tokyo / RIKEN, Osaka, Japan, [4]Genome Inst. of Singapore, Singapore, Singapore

Alternative splicing is a fundamental mechanism that connects genetic variations to complex diseases. To identify genetic effects underlying complex diseases, it has become increasingly important to investigate the proper cell types and contexts. Leveraging the Asian Immune Diversity Atlas dataset, we provide a detailed dissection of the cell-type and context-specific genetic regulation of alternative splicing by single-cell RNA sequencing of ~1M peripheral blood mononuclear cells (PBMCs) from ~500 healthy donors of diverse Asian ancestries. We categorized PBMCs into 22 known cell types in the hematopoietic system and pinpointed two novel subtypes of $CD16^{+}$ monocytes based on *IFITM2* isoforms. We identified 13,460 independent cis-sQTLs with up to 16.1% of sGenes harboring more than one regulatory variant. Multivariate adaptive shrinkage modeling across all cell types revealed that 21.2% of sQTLs are shared across all cell types, while 7.5% are specific to a single cell type. We identified 865 dynamic introns as well as 107 dynamic sQTLs whose genetic effects change along the B cell developmental trajectory. Notably, we identified a dynamic intron usage for *PAX5*, a B-cell-specific transcription factor whose isoform-specific TF activity is in debate. Our data suggested that *PAX5A* upregulation and *PAX5B* downregulation promotes the differentiation of naïve B cells. Our analysis also identified 608 trans-sGenes, 393 (64.6%) of which only appears in a single cell type. In particular, we identified a trans-sQTL for *PTPRC*, a protein tyrosine kinase critical for T-cell development, that colocalizes with a cis-eQTL for *hnRNPLL*, a ribonucleoprotein known to bind to exon four to six of *PTPRC*. Notably, the genetic effects on *hnRNPLL* and *PTPRC* are dynamic across T-cell development, with two distinct lead sSNPs spaced more than 36kb apart and in low LD ($r^2 < 0.3$). Finally, we observed strong enrichment of sQTL effects in autoimmune and inflammatory GWAS loci. Up to 25% of GWAS loci colocalized with sQTLs in at least one cell type. Specifically, we observed a lead sSNP that disrupts the splice donor of exon 1B of *IRF5*, which leads to intron retention and non-sense mediated decay. Moreover, we observed a female-specific colocalization between *CLEC2D*, a natural killer surface receptor, with lymphocyte count. Whether *CLEC2D* is involved in sex biases in autoimmune disease risk requires further investigation. This work reveals several novel regulatory mechanisms through cell-type-specific and dynamic QTL mapping and uses them to explain mechanisms underlying autoimmune diseases.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1252 Skipping of COL4A4 exon 27 is associated with hematuria

Authors:

F. Lona Durazo[1,2], K. Omachi[3,4], D. Fermin[5], F. Eichinger[5], J. P. Troost[5], J. H. Miner[3], A. Paterson[6,7,8], M. Barua[8,9,10], S. Gagliano Taliun[11]; [1]Montréal Heart Inst., Montreal, QC, Canada, [2]Université de Montréal, Montréal, QC, Canada, [3]Washington Univ. Sch. of Med., St. Louis, MO, [4]Kumamoto Univ., Kumamoto, Japan, [5]Univ. of Michigan, Ann Arbor, MI, [6]Hosp for Sick Children, Toronto, ON, Canada, [7]Dalla Lana Sch. of Publ. Hlth., Toronto, ON, Canada, [8]Univ. of Toronto, Toronto, ON, Canada, [9]Univ. Hlth.Network, Toronto, ON, Canada, [10]Toronto Gen. Hosp. Res. Inst., Toronto, ON, Canada, [11]Montréal Heart Inst./Université de Montréal, Montreal, QC, Canada

Hematuria is a complex trait that is a result of many genetic and environmental factors. It is an important, yet understudied sign of chronic kidney disease and can be associated with kidney failure. A better understanding of the biological pathways involved in hematuria can ultimately facilitate novel treatment options to improve kidney outcomes of patients. Here, we combined genetic variant-trait association statistics from the UK Biobank with predicted gene expression and splicing from GTEx kidney cortex samples from individuals of European genetic ancestry (n = 65) in a transcriptome-wide association study (TWAS), to identify additional biological mechanisms influencing hematuria. Our TWAS identified significant associations for 5 genes in terms of expression and 3 significant splicing events. Notably, we identified an association between hematuria and the skipping of *COL4A4* exon 27, which is genetically predicted by intronic variant rs11898094 (minor allele frequency 13%). We found independent evidence supporting the existence of this skipping event in glomeruli-derived mRNA transcriptomics data (n = 245) from the NEPTUNE dataset. We then performed functional assays, which revealed that the transcript with exon 27 spliced out affects collagen IV trimer assembly and secretion (Student's *t*-test p-value < 0.005, compared to wild type), highlighting the potential impact of this splicing event on kidney biology. Altogether, our results highlight the value of investigating the role of non-coding sequence, an underexplored region, by integrating multiple data types to shed light on kidney traits and their underlying disease mechanisms.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1253 SNPred outperforms other ensemble-based SNV pathogenicity predictors and elucidates the challenges in performance evaluation of predictive models using ClinVar.

Authors:

I. Molotkov[1], M. Artomov[1,2]; [1]Nationwide Children's Hosp., Columbus, OH, [2]The Ohio State Univ. Coll. of Med., Columbus, OH

Accurate identification of pathogenic variants is crucial for the diagnosis, treatment, and prevention of genetic diseases. In this study, we introduce SNPred, an ensemble gradient boosting model for predicting the pathogenicity of nonsynonymous single nucleotide variants (SNVs). SNPred uses 40 variant pathogenicity predictors from dbNSFP database to create an aggregate pathogenicity score. The performance of SNPred was evaluated on seven distinct validation datasets derived from ClinVar and *BRCA1* Saturation Genome Editing (SGE) data. Across all validation scenarios, SNPred consistently outperformed other state-of-the-art tools, such as BayesDel, MetaRNN, and REVEL, particularly in the case of rare and cancer-related variants (ROC AUC of 0.99 for SNPred compared to 0.94-0.97 for the next four leading methods). We employed a novel approach to validation on a curated set of ClinVar variants that are inaccurately predicted by most pathogenicity prediction tools. In this challenging scenario, SNPred exhibited a remarkable ROC AUC of 0.99, surpassing the next four leading predictors by a margin of 0.05 to 0.08.

During the validation process, we discovered several challenges which are inherent to validation of SNP pathogenicity predictors on ClinVar and may lead to inaccurate performance estimations. Firstly, we sought to empirically examine the hypothesis that variants which are accurately classified using computational tools appear in ClinVar more frequently, making them overrepresented in the database. To that end, we considered a set of *BRCA1* variants from ClinVar and a non-intersecting set of *BRCA1* variants from an SGE study. We tested how 20 top-performing predictors would perform on these two datasets. Confirming our hypothesis, all 20 of the predictors classified ClinVar variants more accurately, with the mean difference in AUC ROC of 0.07. Secondly, we assumed that, as literature suggests, the misclassification rate in ClinVar is estimated to be at least 2%. As a result, we prove that the exceptionally high accuracy scores achieved by certain models on ClinVar are only attainable if the models overtrain by learning to misclassify variants that are already misclassified in ClinVar. These findings indicate that validation of any pathogenicity prediction algorithm using ClinVar data may result in inflated performance estimates.

In conclusion, we developed a new tool for SNV pathogenicity prediction that outperforms other ensemble models in various validation setting. Additionally, we highlighted potential sources of inflation in performance estimation when using ClinVar.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1254 Statistical Mechanics of coding variants quantitatively predicts gene influence in select populations, including Parkinson's Disease cohorts.

Authors:

O. Lichtarge[1], Y. Lagisetty[2], M. Samieinasab[1], C. Wang[1], F. Nazem[1], D. Marciano[1], P. Katsonis[1], J. Asmussen[1], J. Botas[1], M. Raveendran[3], A. Harris[1], J. Rogers[1], I. Al-Ramahi[1], K. Lee[4], J. Botas[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Univ. of Texas McGovern Med. school, Houston, TX, [3]BCM, Houston, TX, [4]Baylor Coll. Med., Houston, TX

Life is complex and seemingly difficult to describe with simple equations. Yet, this study shows that genetic information obeys statistical mechanics, leading to the powerful imputation of genes in complex diseases, such as Parkinson's.

A first step computes the energy of mutations in fitness landscapes with a modified evolutionary action equation. We may then calculate the energy distribution of coding variants in sequenced genomes and find it follows Boltzmann statistics, from genes to chromosomes and from individuals to populations of humans, macaques, and *E. coli*. These data suggest that statistical mechanics is a fundamental description of natural coding variants, across scales.

To rule out mere coincidence, we asked if statistical mechanics could predict a new genetic feature. We focused on the equipartion of energy, a central tenet of modern physics intrinsic to statistical mechanics, stating that systems in equilibrium distribute energy equally among their degrees of freedom. We found that for equipartition to hold, we must precisely define a new variable, w (normalized by gene length), corresponding to a gene's mutational influence (or *weight*) in the fitness landscape.

We found that the w value of each gene correlated with degree centrality in protein interaction networks (Spearman $\rho = 0.97$, $p < 10^{-60}$). Genes with top w values also interacted mutually ($p < 10^{-16}$); mediated essential biological processes; and were enriched for haplotype insufficiency ($p < 10^{-21}$) and disease associations ($p < 10^{-49}$) in humans. Similar findings held in macaques and *E. coli*, in which growth after gene knockdown correlated inversely with w ($R^2 = -0.72$, $p < 10^{-27}$). Thus, equipartition predicts gene weight and this weight agrees with observations on gene influence.

Strikingly, while most genes had equal w values upon comparing 1978 healthy subjects and 1826 Parkinson's Disease (PD, from AMP-PD) patients, a subset of genes had greater weight w either in patients or controls. Multiple tests link these genes to PD, including their ability to separate cases from controls in independent, held-out subjects ($AUC = 0.63$, $z = 6.2$). Thus, deviations in w between populations inform on disease associations.

To our knowledge, this work is the first to unify physics, genetics, and evolution into a computable, quantitative framework defining the mutational energy of coding variants and the weight (w) of genes. While future extension to non-coding variants is desirable, in practice, this paradigm shift to the physics of fitness landscapes already sheds light on influential genes in select sequenced populations, including cohorts harboring a complex disease, such as PD, or free from it.

PB1255 † Statistically and functionally fine-mapped blood mRNA and protein expression QTLs from 1,405 humans reveals their distinct regulation patterns and disease relevance

Authors:

Q. Wang[1,2], T. Hasegawa[3], H. Namkoong[4], S. Ryunosuke[5], R. Edahiro[2], K. Sonehara[1,2], H. Tanaka[4], S. Azekawa[4], S. Chubachi[4], Y. Takahashi[2], S. Sakaue[6], S. Namba[2], K. Yamamoto[2], Y. Shiraishi[7], K. Chiba[7], H. Tanaka[3], H. Makishima[5], Y. Nannya[5], Z. Zhang[5], R. Tsujikawa[5], R. Koike[3], T. Takano[8], M. Ishii[4], A. Kimura[3], F. Inoue[5], T. Kanai[4], K. Fukunaga[4], S. Ogawa[5], S. Imoto[1], S. Miyano[3], Y. Okada[1,2,9], Japan COVID-19 Task Force; [1]The Univ. of Tokyo, Tokyo, Japan, [2]Osaka Univ., Osaka, Japan, [3]Tokyo Med. and Dental Univ., Tokyo, Japan, [4]Keio Univ., Tokyo, Japan, [5]Kyoto Univ., Kyoto, Japan, [6]Harvard Med. Sch., Boston, MA, [7]Natl. Cancer Ctr. Res. Inst., Tokyo, Japan, [8]Kitasato Univ., Tokyo, Japan, [9]RIKEN, Yokohama, Japan

Studying genetic regulations of protein expression (protein expression QTL = pQTLs) offers deeper understanding of regulatory variants uncharacterized by studies of mRNA expression regulation (expression QTL = eQTLs) alone. Here we report on a comprehensive cis-e/pQTL statistical fine-mapping from 1,405 genotyped samples with blood mRNA and plasma protein expression (n=2,932 proteins from Olink explore 3072) information, as part of the Japan COVID-19 Task Force (JCTF).

Fine-mapped eQTLs (defined as posterior inclusion probability = PIP>0.9, n=3,464, nearly tripling the size of our previous release) were enriched for 932 variants validated with in-house massive parallel reporter assay (MPRA) using K562 and HepG2 (>2 fold enrichment compared to those with PIP<0.1; p=2.5e-6). Fine-mapped pQTLs (n=582) were enriched for missense variations on structured and extracellular domains (>2,000 fold enrichment compared to random, 2.5 and 1.4 fold within missense variations; p<1e-100). When focusing on trans-e and pQTL associations, our analysis revealed associations between class I HLA and KIR genes (KIRDL1 at mRNA and KIRDL3 at protein level; p=7.2e-9 and p=1.2e-25).

We found a limited level of colocalization between e/pQTLs (only 12% of the genes presented colocalization posterior probability = CLPP>0.1). Genes with mRNA specific-QTLs are relatively universally expressed (average 46 GTEx tissues versus 41 for protein specific-QTLs; p=6.3e-4), suggesting buffering of mRNA expression variation at post-transcriptional, multi-tissue levels. Protein specific-QTLs were more relevant to complex traits in biobank studies (7.6 versus 5.6 fold enrichment of trait-causal variants in Biobank Japan; p=2.7e-3). As examples of disease relevant genes with protein-specific regulation, we highlight *TNFRSF11A*, *APOE*, and *EFHD1*.

Utilizing COVID-19 severity information, we also show that condition-specific interaction eQTL (ieQTL) effects have limited penetrance to plasma protein levels, due to expression leakage from non-blood tissues: even for *CLEC4C*, where the ieQTL effect is the most significant (p=4.1e-32 for rs7302014), ipQTL effect does not reach significance (p=2.4e-7). Finally, highlighting the ABO gene as an example, we show that negative correlation between mRNA and protein expression can arise due to linkage disequilibrium (LD) between distinct nearby eQTLs and pQTLs.

Our results highlight the value of pQTL analysis for a finer understanding of gene expression regulations and identification of disease-associated loci. We also developed an interactive browser, planned for public release by the time of the conference.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1256 Strain-specific structural variants in mice impact CTCF-mediated transcriptional control.

Authors:

N. Moskwa[1], S. Syed[2], C. Lee[2]; [1]The Jackson Lab., Farmington, CT, [2]The Jackson Lab. for Genomic Med., Farmington, CT

Genomic variants are a major contributor to phenotypic diversity within a species. However, linking the functional relevance of noncoding genetic variants to specific phenotypes has been challenging due to the incomplete annotation of noncoding DNAs. Among the different type of genetic variants, structural variants (SVs) are widespread and affect more bases in the typical genome than single nucleotide variants. When SVs accumulate in noncoding regulatory regions, they have the potential to create population-enriched transcriptional profiles within a species.

In the cell, chromosomes are partitioned into topologically associating domains (TADs). TAD boundaries are enriched in CCCTC-binding factor (CTCF) sites. Interestingly, there are thousands of CTCF chromatin binding sites (CCBSs) riddling the noncoding genome that are not involved in TAD formation. In fact, approximately 40% of CCBSs are intronic. Intronic CCBSs are capable of mediating chromatin interactions that are implicated in gene regulation.

To better understand which SVs disrupt specific CTCF-mediated chromatin interactions and lead to phenotypic diversity, we have conducted an investigation using two phenotypically diverse inbred mouse strains: C57BL/6J (B6) and 129S1/SvImJ (129S). We have developed a strategy to identify noncoding genetic variants responsible for inter-strain phenotypic differences, with a particular focus on intronic SVs that disrupt CCBSs and chromatin contacts. We performed a comprehensive association study between B6 and 129S mouse embryonic stem cells (ESCs), integrating RNA-seq, chromatin organization, and long read whole genome sequencing data. We have identified a total of 4,168 B6-specific and 1,654 129S-specific CTCF-bound chromatin interactions overlapping SVs, which appear to result in the dysregulation of 1,053 genes (129S vs B6 ESCs comparison; padj<0.1 and |log2(fold change)| > 0.5). To test for the causality of intronic SVs that disrupt CCBSs in a strain-specific manner, we used CRISPR/Cas9 to introduce prioritized SVs into B6 ESCs and assessed gene expression, CTCF chromatin binding and genome interaction differences between control and SV-engineered ESCs. Our preliminary findings have identified SVs overlapping genes *Ireb2*, *Mtf1*, *Ccdc171*, *Mnd1*, and *Numbl* as possible contributors to phenotypic differences observed between the B6 and 129S ESCs. Our goal is to ultimately annotate all noncoding SVs in the mouse genome and understand the mechanisms by which noncoding SVs change cell type-specific transcriptomes, resulting in strain-specific phenotypes.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1257 Structural bioinformatics for deep variant phenotyping of SMARCA4.

Authors:

M. Zimmermann[1], N. Haque[1], B. Ratnasinghe[1], S. Jorge[1], Y-I. Chi[2], J. Wagenknecht[1], R. Urrutia[1]; [1]Med. Coll. of Wisconsin, Milwaukee, WI, [2]Med. Coll. of Wisconsin, Wauwatosa, WI

Protein-coding genetic alterations are frequently observed in Clinical Genetics, but the high yield of variants of uncertain significance remains a limitation in diagnostics and decision-making. Interpreting genetic variation is now a more pressing challenge than sequencing individuals. For genes with established roles in defining congenital syndromes, we have yet to uncover the underlying mechanisms for why some genetic variation is pathogenic, and others are not. For example, SMARCA4 mutations cause Coffin-Siris Syndrome, yet 338 missense variants have already been observed, 311 (92%) of which lack interpretation primarily due to their observation in single cases, plus 27 (likely)pathogenic. Thus, new approaches are needed to enhance the information available to each patient. We take a proteogenomic approach and use computational tools to calculate how genetic variants alter their encoded protein structures, dynamics, and effects on protein complexation. These tools are established in basic sciences but have yet to achieve systematic use in genomics. Further, the revolution in protein structure prediction driven by artificial intelligence algorithms empowers our approach and enables scalability of structural bioinformatics. Herein, we characterize a broad mutational landscape of SMARCA4 variations using not only genomic scores, but calculations derived from cryo-EM and protein structure, such as rigidity and flexibility analyses and active site rearrangements. Our goal is to interpret how mutations affect the enzyme functionally. Then, how SMARCA4 fits within its cognate chromatin remodeling complex, and how genetic variation in SMARCA4 may also change the complex. This scale in the number of mutations characterized and structural context is key for improving the interpretation of novel and ultra-rare genomic variants. The mechanistic readouts our approach generates will indicate specific testable hypotheses for functional genomics validation, including changes to protein stability, histone binding capacity, and helicase processivity. Our study is trailblazing and practical for enhancing the field. Similar approaches can be applied to help interpret human genetic variation underlying many congenital and malignant conditions, such as we demonstrate for Coffin-Siris Syndrome.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1258 Structural variants and heterochromatin link chromatin risk genes with neurodevelopment in autism spectrum disorder.

Authors:

M. Garvin[1], D. Kainer[2]; [1]Oak Ridge Natl. Lab., Oak Ridge, TN, [2]Univ. of Queensland, Brisbane, Australia

Autism spectrum disorder (ASD) is a highly heritable and highly heterogeneous neuropsychiatric condition whose cause is still unknown because there are no recurrent genes found among diagnosed individuals. One of the most common functional properties of the many reported risk-genes for autism is “chromatin modification” but it is not known how this biological process relates to neurodevelopment and autism. We recently reported frequent, recurrent genomic structural variants (SVs) in two cohorts of individuals with autism that were identified using Non-Mendelian inheritance (NMI) patterns in family trios. The genes harboring the SVs participate in neurodevelopment, glutamate signaling, and chromatin modification, confirming previous reports and providing greater detail for these processes in ASD. The majority of these ASD-associated SVs (ASD-SV) were found in non-coding regions of the genome and were enriched for expression quantitative trait loci (eQTL) suggesting that gene dysregulation results from these genomic disruptions rather than alteration of proteins. Here, we intersect the ASD-SV from our earlier work with different gene regulatory and epigenetic multi-omic layers to understand how they may function to produce autism. Our results indicate that the core of ASD resides in the dysregulation of a process called RNA-induced Initiation of Transcriptional gene Silencing (RITS) that is meant to maintain heterochromatin and produces SVs in the genes within these chromosomal regions, resulting in alterations in brain development. This finally links reported ASD-risk genes involved in chromatin remodeling with neurodevelopment. In addition, it may explain the role of de novo mutations in ASD and provide a framework for more accurate diagnostics and endophenotypes.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1259 Systematic analysis of mitochondrial carrier functional redundancy using complex genetic interaction analysis.

Authors:

B. Greco, K. Dadelahi, E. Kuzmin; Concordia Univ., Montreal, QC, Canada

Complex genetic interactions occur when a combination of mutations in more than two genes leads to an unexpected phenotype that deviates from a combined effect of individual mutations and lower order combinations. Due to the prevalence of complex genetic interactions, they are thought to have the potential to affect the biology of inheritance. In this work, we use the budding yeast model organism to investigate the complex genetic interactions involving a conserved eukaryotic gene family of mitochondrial carriers to understand how they buffer each other's loss and contribute to genomic robustness. Mitochondrial carriers regulate the transfer of metabolites across cytosol and mitochondrial matrix and thus play an important role in cellular metabolism and human disease. We used Synthetic Genetic Array (SGA) haploid selection method to construct 240 unique double mutant with 23 single mutant control query strains involving 23 yeast mitochondrial carrier orthologous genes that have been directly implicated in human diseases. We will interrogate them using trigenic-SGA to construct 1330 triple mutants and measure their trigenic interactions to understand how mutations in three genes combine to affect fitness. Trigenic-SGA involves crossing double mutant query strains to an array of single mutants and through an automated mating and meiotic recombination to select haploid triple mutants, measure their colony size and quantify their trigenic interactions. By integrating these data with genome-wide association studies (GWAS) and validations in human cells should enable us to gain insight into disease heritability related to mitochondrial carrier gene family. Ultimately, this work will shed light on the genotype-to-phenotype relationship and complex disease heritability.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1260 Systematic curation and validation of pathogenic and likely pathogenic 3’ and 5’ untranslated region variants using deep learning artificial intelligence models.

Authors:

E. Bohn, T. Lau, D. Merico, A. Celaj, A. Deshwar, S. Gandhi, B. Kanuparthi, T. Masud; Deep Genomics, Toronto, ON, Canada

Background: Variants in 5’ and 3’ untranslated regions (UTR) are implicated in disease. While predictive algorithms have been developed to assist in interpreting their pathogenicity, their utility is contingent on the quality of data used for training and validation. **Purpose**: We curated a high-confidence set of pathogenic and likely pathogenic (P/LP) variants in the 3’ and 5’ UTR and used publicly available deep learning artificial intelligence (DL-AI) models to validate these classifications. **Methods**: 3’ and 5’ UTR variants documented as P/LP were obtained from ClinVar. Evidence was curated for each variant to inform classification following American College of Medical Genetics and Genomics (ACMG) and Association for Molecular Pathology (AMP) guidelines, and recommendations for adaptation to non-coding contexts. DL-AI models (FramePool, Saluki, Enformer) trained on UTR-related mechanisms were applied for validation. Prediction scores were compared between P/LP variants acting through the mechanism for which the model was designed (model-matched), P/LP variants operating through a different or undetermined mechanism (model-mismatched), and putative benign variants. PhyloP was used to compare conservation scores between P/LP and putative benign variants. **Results**: Of 295 3’ and 188 5’ UTR variants identified through ClinVar, 26 and 68 were interpreted as P/LP, respectively. Mechanistic information was available for 22 3’UTR variants, the most frequent being modulating a microRNA binding site (n = 7), impacting the polyadenylation signal (n = 10), and impacting mRNA stability (n = 3). 5’ UTR variants operated at both the level of transcription and translation. Common mechanisms included altering promoter activity (n = 14), impacting an upstream open reading frame (n = 10), and introducing a novel upstream start codon (n = 13). A significant difference in prediction scores was obtained with all DL-AI models when comparing model-matched P/LP variants, to both model-mismatched P/LP and putative benign variants, which was also supported by our internally developed proprietary predictors. PhyloP conservation scores were significantly higher among P/LP compared to putative benign variants for both the 3’ and 5’ UTR. **Conclusions**: We present a high-confidence set of P/LP 3’ and 5’ UTR variants spanning a range of mechanisms. DL-AI models substantiate these interpretations, with a distinction in scores supporting the relevance of mechanism-informed use. These datasets will support further development of AI algorithms designed to predict the impact of 3’ and 5' UTR variants which may be implicated in disease.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1261 Targeted CRISPRa/CRISPRi screen confirms functional SNPs and identifies novel target genes at multiple RCC susceptibility loci.

Authors:

T. Winter[1], T. Myers[1], L. Colli[2], L. Jessop[1], J. Choi[1], M. J. Machiela[1], M. P. Purdue[1], K. Brown[1], S. Chanock[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]Ribeirao Preto Med. Sch. - Univ. of Sao Paulo, Sao Paulo, Brazil

Genome wide association studies (GWAS) have identified 13 renal cell carcinoma (RCC) risk regions as well as additional loci with nominal significance. Detailed investigation of how each susceptibility region functions can reveal the underlying biological bases of RCC susceptibility. To date, most characterized GWAS regions function through altered regulation of one or more genes in a critical pathway in RCC, as shown with regions 8q24, 11q13, 12p12.1 and 14q24. Disease risk alleles have been mapped to enhancers which loop to the promoters of target genes and regulate their expression. To identify such interactions between functional SNPs and target genes, we evaluated a set of variants based on a Massively Parallel Reporter Assay (MPRA), eQTL analysis, capture Hi-C, and an arrayed CRISPRa/CRISPRi screen in the same two cell lines as the MPRA. The MPRA identified 196 SNPs across 19 regions with significant allele-specific effects, indicating cis-regulatory activity. Of these, 39 SNPs displayed chromosome loops allowing physical interaction with the promoter of a nearby gene, as well as a significant cis-eQTL with the same gene. In this way, 24 putative target genes of 39 SNPs across 10 RCC risk loci were nominated. To confirm the presence of a cis-regulatory relationship between these SNPs and putative target genes, we performed an arrayed CRISPRa/CRISPRi screen in ACHN (RCC) and HEK293T (embryonic renal) cells covering each of the 10 regions, 39 SNPs, and 24 candidate target genes. Cis-regulatory relationships were assessed by TaqMan qPCR for the 24 putative target genes. For CRISPR inhibition, ACHN and HEK293T cells were stably transduced with inactive cas9 fused to the ZIM3 repressor domain and for CRISPR activation, fused to the VP64 activator domain. Initial results of the screen have identified multiple novel cancer relevant target genes of renal cell carcinoma predisposition, including *ABL2* at 1q25 and *MAP2K1* at 15q22. Further functional investigation of these regions is underway to characterize these SNP-gene relationships and elucidate their role in RCC risk.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1262 Telomere-to-telomere, pangenomic references improve eQTL power and enable the detection of sex-specific eQTLs in the developing human brain.

Authors:

J. Lalli[1], J-Y. An[2], N. Sestan[3], S. Sanders[4], D. Werling[1]; [1]Univ. of Wisconsin-Madison, Madison, WI, [2]Korea Univ., Seoul, Korea, Republic of, [3]Yale Univ., New Haven, CT, [4]Oxford Univ., Oxford, United Kingdom

Autism spectrum disorder (ASD) is 4X more prevalent in males, and sex-specific differences in gene regulation likely contribute to this imbalance. Expression QTL (eQTL) studies are a well established method of determining the effect of naturally occurring genetic variants on nearby gene regulation. However, past studies have found sex-specific eQTLs difficult to detect using standard association methods.
The subtle effects of common variants on gene expression can be hidden by technical noise. One source of noise, especially in ancestrally diverse cohorts, is reference error. In regions of high homology (eg., pseudogenes, or tandem repeats), small differences between a reference sequence and a patient genome can result in variant calling errors and gene expression variability that is poorly captured by current methods.
Working with our previously published BrainVar cohort of bulk RNA and DNA from the pre-frontal cortex of 87 human fetuses, we measured the role of reference error in the detection of sex-specific eQTLs by extending the Nextflow RNAseq and Sarek WGS pipelines to align reads to either the GRCh38, T2T, or human pangenome references. These references have been shown to reduce mismapping during alignment, especially in regions of high homology. Implementing this pipeline required producing a lifted over GATK resource bundle and phased 1000 Genomes variant panel in T2T coordinates.
Aligning WGS reads to the T2T genome reference resulted in increased autosomal depth (30.3X -> 32.1X) and coverage (94.1% -> 99.4%). Pangenomic alignment also improved autosomal depth (31.6X), with reduced variability of coverage. More RNAseq reads aligned to the Refseq v110-T2T annotation than the GRCh38 annotation. Analysis of the resulting data showed that the T2T annotation in an over 20% increase in the number of sex-differential eGenes discovered, while the number of pseudogenic eGenes declined. Gene ontology analysis of the T2T alignment data revealed that genes regulated in a sex-specific manner were associated with impaired language skills and neurodevelopmental delay, and were associated with the transcription factor SP1, a transcription factor known to complex with estrogen receptor. These results were not observed in GRCh38 aligned data.
To our knowledge, this work is the first comparative study to assess how the T2T and/or pangenome reference affects eQTL association studies. We believe this work demonstrates the need for geneticists to make use of these new resources to address reference error. All resources and pipelines are available for general use on Github.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1264 The challenges of variant classification - a snapshot of reality through proficiency testing

Authors:

S. Deans[1], D. Cregeen[1], F. Khawaja[1], M. Sales[1], M. Tabiner[2], R. Treacy[1]; [1]GenQA/UK NEQAS, Edinburgh, United Kingdom, [2]GenQA, Oxford, United Kingdom

Background/Objectives: Clinical genomic testing requires the classification of the pathogenicity of sequence variants, and the assessment of their clinical impact. As more guidance is generated to aid this work, there is a challenge to standardise approaches across variant types and in different clinical settings. GenQA has globally delivered laboratory proficiency testing (PT)/external quality assessments (EQAs) for variant interpretation since 2013 and has adapted this approach to provide a mechanism for individuals to demonstrate their competency, and to support the education of the scientific and clinical workforce.
Methods: Modules for classification of single nucleotide variants (SNVs) and copy number variants (CNVs) were provided online through the Genomics Individual Education (GENie) platform. Individual participants were provided with details of the variants and the clinical setting and were expected to classify them along with documenting the evidence used to obtain the classification. Real time assessment was applied through the platform and participants received a summary of their performance and the expected classification detailing the evidence applied.
Results: As a pilot, individuals completed the classification of three SNVs and/or three CNVs during a weeklong exercise. Following the successful delivery of this individual educational module, ongoing accessible assessments for either germline SNVs or CNVs were delivered whereby a random set of six variants were provided for classification each time a participant accessed GENie. These were generated from a vast bank of variants and included prenatal, postnatal, diagnostic, and predictive clinical scenarios. The range of variant classifications from the pilot and GENie modules will be presented.
Conclusion: Accuracy of variant classification is essential to ensure patients receive the correct results and clinical management. This assessment demonstrated variability in the use and application of the guidelines, and the continued need for PT/EQA to educate and promote standardisation.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1265 The contribution of deleterious variants affecting PAM amidating activity on insulin response, incretin levels and diabetes risk.

Authors:

A. Giontella[1], M. Åkerlund[1], L. Lotta[2], A. Baras[2], J. Overton[2], P. Kaufmann[3], Y. Ilina[3], O. Melander[4]; [1]Lund Univ., Malmö, Sweden, [2]Regeneron Genetics Ctr., Tarrytown, NY, [3]PAM Theragnostics GmbH, Hennigsdorf, Germany, [4]Malmo Univ Hosp, Malmo, Sweden

Background: Peptidylglycine-α-amidating monooxygenase (PAM) is the only known enzyme responsible for the amidation process of bioactive peptides, an essential step for their biological activation.PAM is a key enzyme for the endocrine system, and perturbation in its activity has been reported to be associated with insulin secretion, diabetes, and cardiovascular diseases, with a mechanism that remains unclear. **Aim:** This work aimed to investigate at the population level the effect of coding variants that affect PAM amidating activity (PAM-AMA) on hormonal regulation of insulin secretion, using data from the Malmö Diet and Cancer (MDC, n∼27,000), the Malmö Preventive Project (MPP, n∼3,600), and the UK Biobank (UKB, n∼500,000). **Methods:** Exome-wide association analysis was used to identify deleterious coding variants associated with PAM-AMA, which was assessed with a validated assay in ∼ 8,000 from MDC and MPP. The variants, aggregated in a weighted score, were tested for their association with fasting and after oral glucose tolerance test (OGTT) insulin and incretin levels (GIP, GLP-1) in the MDC, at fasting and after. Additionally, the association with glycemic traits (glucose level and HbA1c) and diabetes risk, was evaluated in all the three cohorts. **Results:** Two missense aminoacidic substitutions in *PAM* gene, Ser539Trp (MAF: 0.7%) and Asp563Gly (MAF: 5%), resulted as the lead variants of the association, which independently contribute to a decrease of 2.33 (p: $2.5E^{-140}$) and 0.98 (p: $1.12E^{-225}$) SD units of PAM-AMA, respectively.The score showed a strong association with lower insulin level at 30 min after OGGT (-0.07 [-0.10;-0.03]; p: $5.0E^{-4}$ for each SD increase of the score). A suggestive inverse association was found with fasting GLP-1 (-0.03 [-0.07,-0.001]; p: 0.05), while no association was reported for GIP.In addition, the score was associated with increased glucose level (0.007 [0.005,0.010]; p:$2.2E^{-5}$), HbA1c (0.012 [0.009,0.015]; p: 3.8^{E-14}), and with increased diabetic risk (OR [95%CI] 1.07 [1.06,1.08]; p: $8.08E^{-41}$). **Conclusion:** This study represents the largest population-based study reporting the role of the measured PAM amidating activity on insulin response, and diabetes risk. Individuals who carry PAM-AMA deleterious missense mutations, exhibit a lower insulin response, higher glycemic traits, and an overall higher diabetes risk. These findings highlight the importance of early identification of PAM LoFs carriers, as they could benefit from targeted anti-diabetic treatments.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1266 The contribution of short tandem repeats to splicing variation in humans

Authors:

Y. Li[1], J. Margoliash[2], A. Goren[3], M. Gymrek[4]; [1]Univ. of California San Diego, San Diego, CA, [2]Univ. of California, San Diego, La Jolla, CA, [3]UCSD, San Diego, CA, [4]Univ California San Diego, La Jolla, CA

Short tandem repeats (STRs) are consecutively repeated sequences of 1-6 base pairs that constitute a significant source of human genetic variation. Multiple recent studies have revealed a broad contribution of STRs to gene regulation and complex traits. In addition to regulating gene expression, STRs have also been implicated in multiple splicing-related processes, including forming binding sites for splicing factors such as hnRNP-L. However, their contribution to splicing variation in humans has not been explored genome-wide. Here, we leveraged whole-genome sequencing and expression data from the Genotype-Tissue Expression (GTEx) Project to comprehensively assess the impact of STRs on splicing in humans. Using the tool HipSTR, we conducted multi-sample genotyping of 1.6 million STRs across 652 individuals. We examined associations between the repeat length of STRs and the percent spliced-in (PSI) values of exons within 100kb of these STRs while controlling for population structure, sex, and PEER factors. We tested 269,298 unique STR-exon pairs and discovered 46,958 significant associations (termed SpliceSTRs) at a false discovery rate of 10%. We applied the FINEMAP algorithm to conduct fine-mapping of the SpliceSTR associations against nearby SNPs. This yielded 5,393 unique spliceSTRs, termed FM-spliceSTRs, with a posterior inclusion probability of at least 50%. As an orthogonal validation, ANOVA analysis has shown that 45.3% FM-spliceSTRs explain exon splicing beyond the best SNPs. Compared to all the analyzed repeat units, we found significant enrichment of FM-spliceSTRs in specific repeat units, including AAAG/AAGG, GT/CG, ATCC, and AAAAC ($p<0.05$). FM-spliceSTRs close to splicing sites may directly modulate the splicing process. In one example, a GT dinucleotide repeat, positioned 17 base pairs downstream from the donor site of exon 2 of TMEM263 is negatively associated with the splicing of that exon. This finding is further supported by the predictions obtained from spliceAI, which show a correlation between the length of the STRs and the predicted donor site score. Overall, our study unveils the widespread impact of STRs on alternative splicing and identifies a set of highly credible FM-spliceSTRs. These findings provide valuable insight into the pathomechanism of genetic diseases.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1267 The crossroads of fine-mapping, single-cell multiome and immunophenotyping to inform on the molecular drivers of diseases in FinnGen

Authors:

M. Kanai[1], T. M. Delorey[1], C. B. Porter[1], K. Nanki[1], H. Hwang[1], I. Teixeira-Soldano[1], J. Karjalainen[2], R. S. Rodosthenous[2], J. Halonen[3], J. Honkanen[3], J. Juvila[3], D. Chafamo[1], T. Yoshida[1], M. Arvas[3], M. Kurki[2], M. P. Reeve[1], W. Zhou[1], FinnGen, J. Partanen[3], A. Palotie[2], D. B. Graham[1], M. J. Daly[1], R. J. Xavier[1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Univ. of Helsinki, Helsinki, Finland, [3]Finnish Red Cross Blood Service, Helsinki, Finland

Despite recent success in identifying causal variants of complex traits, translating their functional effects into mechanistic insights requires substantial efforts. In particular, population isolates such as those in Finland have excelled in uncovering novel causal variants but lagged in characterizing their functional effects due to the lack of samples carrying such high-impact, population-enriched variants.

To address this issue, we present a single-nuclei multiome atlas of gene expression and chromatin accessibility in peripheral blood mononuclear cells (PBMC) from Finnish blood donors. In collaboration with the Finnish Red Cross Blood Service, we collected 960 PBMC samples from the FinnGen participants, prioritizing carriers of Finnish-enriched variants. We utilized the 10x multiome to jointly profile gene expression and chromatin accessibility within the same nuclei, and the FACS immunophenotyping to quantify frequencies of immune cell types.

Here, we initially analyzed 192 samples for a pilot analysis. This pilot atlas comprises 1.4 million single nuclei of PBMCs. Using pseudobulk approach, we identified 8,629 unique eGenes (FDR < 5%) for at least one cell type. We found 8,805 unique *cis*-eQTL variants with > 2x Finnish enrichment, including 370 variants that belong to 95% credible sets (CS) in disease GWAS of FinnGen. For example, we found a 114x Finnish-enriched (MAF = 4.2%) inflammatory bowel disease (IBD) risk variant rs748670681 (*TNRC18* intron; OR = 2.2) showed significant *cis*-eQTL associations in CD4/8 T cells ($P = 1.0 \times 10^{-24}$; $\beta = -1.7$).

Leveraging the single-nuclei multiome, we constructed cell-type-specific enhancer-gene maps using SCENT (Sakaue et al, *medRxiv*). We identified 17,700 unique chromatin accessibility peaks significantly associated with *cis*-gene expression within the same nuclei for at least one cell type. Of these, 1,276 peaks overlap with GWAS fine-mapped variants in 95% CS, including rs748670681 that overlaps with CD4/8 T cell specific chromatin accessibility peak that positively regulates *TNRC18* expression.

Finally, we leverage the atlas to investigate the underlying molecular drivers of diseases in FinnGen. We annotate each disease GWAS loci whether they mediate chromatin accessibility and/or gene expression in *cis* and *trans*, and quantify disease heritability mediated via molecular traits. For example, we are able to dissect the molecular role of rs748670681 into its *cis*-eQTL effect and colocalization with TNRC18-regulatory peak while lacking caQTL effect with the colocalizing peak itself. Our findings underscore the potential of a biobank-scale atlas for characterizing Finnish-enriched variants.

PB1268 The global transcriptomic response to genetic perturbations

Authors:

A. Nadig[1], E. Robinson[2], L. O'Connor[1]; [1]Broad Inst., Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA

Pooled perturbational screens with gene expression profiling provide a compelling opportunity to study thousands of genetic perturbations at once. As in GWAS, many genuine nonzero associations may not reach statistical significance, making them invisible to downstream analyses. A lack of methods to model these effects leaves open fundamental questions: (1) which perturbations cause the greatest transcriptomic change?, (2) what is the transcriptome-wide relationship between effects of different perturbations?, and (3) what proportion of effects are captured by significant differentially expressed genes? We present Transcriptome-wide Analysis of Differential Expression (TRADE), a suite of statistical tools for modeling distributions of differential expression effects from large-scale perturbational screens or any other differential expression experiment. TRADE fits a flexible mixture model to observed effects and standard errors to estimate the distribution of true differential expression effects. Applying these methods to a genome-wide CRISPRi screen of expressed genes in a K562 cell line, we find that, unexpectedly, most genetic perturbations have nonzero effects on a large swath of the transcriptome, with the median genetic perturbation affecting approximately a third of expressed genes. Very few of these effects are statistically significant individually, and significant effects capture only ~30% of the transcriptome-wide signal at current sample sizes, suggesting that significant gene lists are an incomplete summary of differential expression effects. Genes that are depleted of loss-of-function variants in the human population are also depleted of differential expression in response to most perturbations, implying that regulatory robustness parallels mutational constraint. Analyzing transcriptomic data from experiments that titrate mRNA and protein levels, we estimate dose-response curves for global transcriptomic effect, and find that transcriptome-wide effects are generally buffered against dosage changes: many critical genes have negligible transcriptome-wide effects at 50% dosage but large effects at lower dosage. We estimate the correlation of transcriptome-wide perturbational effects between cell types, and find that the median correlation of differential expression effects between K562 and RPE1 cells is 0.41, compared with a correlation of 0.93 for replicate experiments in the same cell type, suggesting substantial cell-type differences in gene regulatory networks. Our findings provide foundational insights into genome regulation and the interpretation of disease-associated genetic variation.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1269 The nonalcoholic fatty liver disease promoting allele *GCKR(P446L)* promotes both lipid and glycogen accumulation in a human liver cell line.

Authors:

Y. Chen[1], B. Saini[1], J. Chen[2], B. Halligan[1], E. K. Speliotes[1], the GOLD consortium; [1]Univ. of Michigan, Ann Arbor, MI, [2]Northwestern Univ., Evanston, IL

Background: Nonalcoholic fatty liver disease (NAFLD) is a prevalent disease that affects about 30% of the US population. NAFLD is genetically influenced, and human genome wide association studies have identified a genetic variant in *GCKR(P446L)* that promotes the disease. *GCKR* encodes the glucokinase regulatory protein (GKRP) which is a negative regulator of glucokinase (GCK). Here we examine how *GCKR(P446L)* may promote liver disease. **Material and Methods:** Using lentiviral integration, we created stable human Huh-7 liver cell lines with wildtype and mutant P446L GCKR overexpressed or knocked down using shRNAs. We measured intracellular triglyceride and glycogen levels and GYS2, GCK, GKRP, FASN and ACC protein levels using Western blot analysis under various glucose concentrations and incubation durations. **Results:** *GCKR(P446L)* increased triglyceride and glycogen accumulation compared with *GCKR(WT)* overexpressed or control Huh-7 cells across different doses of glucose (0, 2, 5 and 25mM) after 8 hours of incubation ($p<0.0001$). The most significant difference in both lipid and glycogen accumulation between WT and P446L occurred at 2 mM glucose. We also found that overexpression of wild-type *GCKR* can significantly decreased glycogen content compared with control Huh-7 cells only at high glucose (25 mM) condition ($p<0.010$). Knockdown of *GCKR* also significantly increased cellular glycogen compared with non-target control Huh-7 cells at low concentrations of glucose (2 and 5 mM) after 8 hours of incubation. Western blot results showed that GCKR (P446L) variant significantly increased the protein level of glycogen synthase GYS2 about 2- and 3- fold as well as Fatty Acid Synthase (FASN) and Acetyl- CoA Carboxylase (ACC) and glucokinase (GCK) compared to cells expressing vector and GCKR(WT) at 2- and 5- mM glucose condition. Knockdown GCKR expression significantly increased GYS2 protein ~2 fold compared with non-target Huh-7 cells in 2 mM glucose ($p<0.0001$). **Conclusion:** Here we show that *GCKR (P446L)* increased both triglyceride and glycogen accumulation compared with *GCKR (WT)* in Huh-7 cells suggesting a cell autonomous effect on these endpoints. Overexpression of *GCKR (P446L)* mimics *GCKR* knockdown suggesting that the P446L mutation is a loss of function change. At least one-way *GCKR (P446L)* increases TG and glycogen synthesis in liver may be by increasing ACC and FASN levels to increase de novo lipogenesis and by up-regulating glycogen synthase GYS2 levels respectively. Further studies will determine how increased triglyceride and glycogen synthesis lead to the liver disease in patients carrying the *GCKR (P446L)* allele.

PB1270 The outcome of next-generation sequencing in clinical diagnosis: Experience of Kuwait Medical Genetic Center

Authors:

L. Bastaki[1], R. M. Elshafie[1,2], M. Marafie[1], B. Albash[1], A. Alwadaani[1], S. BAHZAD[1], H. Alrohaif[1], S. Alkanderi[1], A. Alshammari[1], F. Mohammed[1], L. Aljeryan[1], M. Al-Ali[1], M. Al Ben Ali[1], N. M. Ali[1], D. Ibrahim[1], A. H. Aboelanine[1], S. Omar[1], S. Gouda[1], D. Marafi[1,3], H. Alsharhan[1,3], T. M. Kamal[1], L. AlDakheel[1], F. Alali[1], A. Kenawy[1], A. Alaqeel[1], A. Elmonairy[1], A. A. Ahmed[1], H. I. Albastawisy[1], A. Elshafey[1]; [1]Kuwait Med. Genetic Ctr., Ministry of Hlth., Sulaibikhat 80901, Kuwait, [2]Corresponding author, Kuwait city, Kuwait, [3]Dept. of Pediatrics, Faculty of Med., Kuwait Univ.., P.O. Box 24923, 13110 Safat, Kuwait

Introduction: Next-generation sequencing (NGS) techniques have facilitated human genome sequencing. The implementation of NGS in clinical practice has tremendously improved the diagnostic yield of rare disorders. Kuwait is an Arab Gulf country with a mixed population of native Kuwaitis, Arab and non-Arab residents. Before 2018, the Kuwait Medical Genetic Center (KMGC) at the Kuwait Ministry of Health offered a limited menu of genes for Sanger sequencing. In 2019, a collaborative effort was undertaken to develop a broad-based NGS sequencing menu serving the needs of clinicians all over Kuwait hospitals. This paper aims to share the experience of Kuwait Medical Genetic Center in the use of next-generation sequencing (NGS) gene panels and whole exome sequencing in the diagnosis of rare genetic disorders. To the best of our knowledge, no comprehensive data on the spectrum of variants associated with rare disorders in the Kuwait population has been published before. Methods and Subjects: This study is a retrospective review of 3857 sequencing tests, including both whole EXOME and NGS targeted panels, which have been performed at KMGC from February 2019 to May 2023. All patients had been referred to our laboratory for diagnostic testing, through clinical examination, and appropriate investigations. This study was approved by the Institutional Review Board of Kuwait Medical Genetic Center.

Results and Discussion: The data analysis results of this study have been tabulated, analyzed, and compared with that from other centers. Overall, across the 3857 tests, a definitive result was provided in 24.26%, a possible/probable result was provided in 22.66%, and a negative result was provided in 53%.

Conclusion: To the best of our knowledge, this is the first comprehensive report of this number of NGS tests in Kuwait. Our experience with 3857 sequencing tests suggests that analysis of similarly affected sibs with heterogeneous disorders reduces reporting of unnecessary variants of uncertain significance and facilitates the identification of candidate genes.

PB1271 The small RNA transcriptome and its genetic regulation across human tissues

Authors:

P. Stojanov[1], T. Coorens[1], J. Fernandez del Castillo[1], S. Steelman[1], S. Young[1], C. Nussbaum[1], K. Ardlie[1], G. Getz[2], F. Aguet[3]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Broad Inst. at MIT and Harvard, Cambridge, MA, [3]Illumina, Foster City, CA

Population-based analyses mapping associations between genotypes and gene expression have identified expression quantitative trait loci (eQTLs) for almost all genes, enabling the identification of molecular mechanisms underlying genetic associations with complex traits and diseases. However, only a minority of complex trait associations have been linked to QTLs, partly due to limited power to detect regulatory effects in the relevant cell type, context, or molecular phenotype. Notably, standard RNA-sequencing protocols exclude small RNAs and preclude the study of thousands of small noncoding RNAs with essential roles in the post-transcriptional regulation of gene expression. Here, we present the characterization of small RNAs across 16,814 samples, 47 tissue sites and 978 donors in the GTEx Project, including microRNAs (miRNAs), Piwi-interacting RNAs (piRNAs), transfer RNAs, small nuclear RNAs, small nucleolar RNAs, Y RNAs, and others. We used personal transcriptomes and reference databases for alignment and applied stringent quality controls to minimize artifacts related to short sequences (~20-30nt), resulting in the quantification of 41,458 small RNAs. We used supervised classification to identify putative novel RNAs not present in references, and detected 57 novel high-confidence miRNAs. We observed strong tissue specificity for miRNAs, with other small RNAs showing homogenous expression across tissues. Small RNA expression is highly correlated with surrounding mRNAs or lncRNAs, suggesting shared transcriptional regulation. We mapped QTLs in cis and trans, identifying 100s to 1000s of cis-eQTLs for each RNA species. In line with tissue specificity of miRNA expression, miRNA cis-eQTLs also show a higher degree of tissue specificity than mRNA cis-eQTLs. For miRNAs and their predicted target genes, we used colocalization and mediation analyses to study how cis-regulatory effects on miRNA expression propagate to their target genes, in turn modulating their expression, and show how these effects link to complex trait associations.
In summary, we provide the largest resource of small RNA diversity and their eQTLs across human tissues. We demonstrate the importance of characterizing the full spectrum of small RNAs that play critical roles in the regulation of gene expression, including in development and disease.

PB1272 The ulcerative colitis risk variant of adenylyl cyclase 7 has reduced cAMP signaling and promotes immune activation

Authors:

C. Cardinale[1], A. Strong[1], V. J. Watts[2], H. Hakonarson[1]; [1]Childrens Hosp. of Philadelphia, Philadelphia, PA, [2]Purdue Univ., West Lafayette, IN

Ulcerative colitis (UC) is an inflammatory condition of the large intestine. Genome-wide association studies identified a specific polymorphism in the adenylyl cyclase 7 gene (*ADCY7*; p.Asp439Glu) that confers a two-fold increased risk of UC, second in effect size only to the human leukocyte antigen (HLA) locus. The mechanism by which the p.Asp439Glu variant modulates disease risk is unknown. We now demonstrate that this variant has normal membrane localization in U-2 osteosarcoma cells, but impaired protein expression. Cyclic AMP production and CREB activation are also diminished ~40% by the risk variant. ADCY7 knockdown by siRNA, as a model for the risk variant in human primary CD4+ T cells, inhibits prostaglandin E2-mediated downregulation of proliferation, CD69 marker expression, and cytokine production. Our data suggest that the p.Asp439Glu variant confers increased risk of UC by inhibiting ADCY7-mediated cAMP production, thereby enhancing T cell activity. A direct-acting ADCY7 agonist may be a novel therapy for UC.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1273 Tissue-specific mtDNA regulation of gene expression

Authors:

X. Giannoulis[1,2], S. Wengert[1], N. Cai[1,2]; [1]Helmholtz Pioneer Campus, Helmholtz Zentrum München, Neuherberg, Germany, Germany, [2]Sch. of Med., Technical Univ. of Munich (TUM), Munich, Germany, Germany

The mitochondrial DNA (mtDNA) encodes essential components of the oxidative phosphorylation pathway and RNAs that form parts of their translational machinery. However, gene regulatory effects of mtDNA and mtDNA-encoded genes have not been comprehensively explored. Using data from the GTEx consortium in 48 tissues from 684 individuals of European ancestry, we perform cis- and trans-eQTL analysis to investigate mtDNA-based gene regulation. First, we identify 309 significant mtDNA-cis-eQTLs (FDR 5%) for mtDNA-encoded genes across 38 out of 48 tissues tested, of which 108 are independent. Second, we identify 260 genome-wide significant associations (P<5x10-8) between nuclear DNA (nucDNA) SNPs and mtDNA gene expression (mtDNA-trans-eQTL), involving 210 unique nuclear loci. Of these, 150 are cis-eQTLs for nucDNA encoded genes (nuc-eGenes), and through mediation analysis, we find 117 of these nuc-eGenes mediate the mtDNA-trans-eQTL effects of their cis-eQTLs. For the rest, mtDNA-trans-eQTL effects are independent of their cis-eQTLs effects. Third, we find 108 mtDNA SNP associations with 68 nucDNA encoded genes (nucDNA-trans-eQTL) after controlling for the number of tissues and genes tested (P<1.25x10-9), across 25 out of the 48 tissues tested. Of these nucDNA-trans-eQTLs, 21 are cis-eQTLs for mtDNA encoded genes (mt-eGenes), and mediation analysis shows 20 of them mediate the nucDNA-trans-eQTLs effects of their cis-eQTLs. This demonstrates the potential existence of feedback-mediated co-regulation between mtDNA and nucDNA gene expression. Indeed, we find that nucDNA-eGenes with nucDNA-trans-eQTLs show significant enrichment in 75 pathways (72 of which are brain-specific), with top enrichments in RNA polymerase II activity, Biocarta-curated mitochondria pathways, and DNA-binding transcription factor activity. We also find that mtDNA-trans-eQTLs (across all tissues) overlap genes with significant GWAS hits on phenotypes such as height, BMI and metabolic syndrome, demonstrating the organismal relevance of these findings. Overall, our analysis builds the first comprehensive multi-tissue map of mtDNA and nucDNA cross-talk on gene expression regulation, a first step towards understanding the role of tissue-specific mito-nuclear interactions in health and disease.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1274 Topic modeling uncovers cell states and context-specific genetic regulation in embryoid bodies

Authors:

M. Li[1], J. M. Popp[1], K. Rhodes[2], K. A. Barr[2], R. Jangi[1], B. J. Strober[3], K. Tayeb[2], Y. Gilad[2], A. Battle[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Univ. of Chicago, Chicago, IL, [3]Harvard Sch. of Publ. Hlth., Boston, MA

Regulatory effects on gene expression often vary across cellular contexts such as cell types, states, and environments. However, discovery of context-specific regulatory effects is limited by our ability to efficiently assay diverse contexts of interest, such as those arising during cellular differentiation, as well as our ability to resolve the many biological processes which may be simultaneously active. Indeed, some interesting or disease-relevant cell states may not be known *a priori*. To address these challenges, we employed a unique experimental framework, embryoid bodies (EBs), in combination with topic modeling, an unsupervised machine learning method, to identify gene expression patterns reflective of diverse cell types and states. These EBs were derived from 53 individuals and are asynchronously differentiating cellular aggregates that give rise to numerous cell types. We collected single-cell RNA-sequencing data of these EBs that represent over 900,000 cells ranging from pluripotent stem cells to states resembling numerous differentiated fetal cell types. To model the complex, interwoven biological processes arising within this model system without attempting to define them *a priori*, we applied FastTopics, a tool for non-negative matrix factorization of count data, which learns patterns or "topics" in gene expression and models each cell as a weighted combination of these topics in a continuous and unbiased manner. We then characterized each topic using gene set enrichment analysis (GSEA) with the top differentially expressed genes. Our approach identified topics that represent both cell-type specific biological processes, such as glial cell differentiation, and processes shared across many cell types, such as mitosis. Finally, we applied CellRegMap using our learned topics to identify genotype-context interactions (GxC). Using this approach, we identified hundreds of eQTLs with evidence for GxC effects that are driven by multiple cellular contexts reflected by our topics. This study describes a flexible approach to identify latent cellular contexts in a uniquely broad *in vitro* model of cellular differentiation, and provides insights into regulatory changes governing diverse cell states.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1275 Trajectory inference of multiple cellular lineages in embryoid bodies.

Authors:

R. Jangi[1], J. M. Popp[1], K. Rhodes[2], K. A. Barr[2], M. Li[1], B. Strober[3], K. Tayeb[2], Y. Gilad[2], A. Battle[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Univ. of Chicago, Chicago, IL, [3]Harvard Sch. of Publ. Hlth., Brookline, MA

Experimental methods for studying cellular differentiation are rapidly advancing to the point where in vitro systems are capable of generating multiple cell types in a single framework. However, early and intermediate stages of differentiation for many cell types have remained understudied in human genomics due to limited analytic pipelines for singular trajectories generated from a multi-lineage system. Entire trajectories can reveal patterns of gene expression and regulation that are transient during early stages of differentiation, but have phenotypic consequences in later stages. With distinct trajectories, we can capture temporally dynamic genetic regulation of gene expression (dynamic expression quantitative trait loci or dynamic-eQTLs) specific to each lineage. To study these effects, computational methods to infer distinct trajectories from multi-lineage systems are needed.To capture diverse trajectories, we used embryoid bodies (EBs), three-dimensional cellular aggregates of pluripotent stem cells that differentiate into various cell types. As differentiation occurs at different speeds for these cells, we can characterize multiple developmental states and dynamic regulatory processes at a high resolution. We collected single-cell RNA sequencing data from human EBs across 53 donors, representing over 900,000 cells, and confirmed the presence of all 3 germ layers in EBs with canonical marker gene expression. We first verified the presence of multiple stages of differentiation based on marker gene expression established by previous work. We then developed a pipeline for identifying trajectories of interest based on scDRS, a method that generates cell-level scores by testing for enrichment of trajectory-relevant gene expression compared to mean and variance matched control gene expression. We applied this approach to a trajectory from each germ layer. We began with cardiomyocytes, a previously characterized cell type in a directed differentiation system, identifying cells along the cardiomyocyte trajectory.We mapped dynamic-eQTLs along this lineage and identified 303 significant dynamic-eQTLs, including regulatory effects that were replicated in a previous study and novel regulatory effects. We also identified a neuron trajectory, and characterized 574 dynamic effects. Finally, we identified a hepatoblast trajectory with downstream analysis in progress. We will expand this pipeline to identify trajectories for more cell types and identify novel dynamic-eQTLs. This work will capture transient regulatory effects in diverse developmental cellular trajectories to characterize the differentiation landscape.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1276 Transcriptome wide Association Study of Activated Monocytes Identifies NETO2 and CRISPLD2 as Potential Alzheimer's disease Resilience Genes

Authors:

Y. Mustafa[1], W. Bush[2], T. Hohman[3], L. Dumitrescu[4], L. Main[5], J. Haines[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ, Cleveland, OH, [3]Vanderbilt Univ Med Ctr., Nashville, TN, [4]Vanderbilt Univ. Med. Ctr., Nashville, TN, [5]Case Western Reserve Univ., Lakewood, OH

Alzheimer's disease (AD) is a highly heritable neurodegenerative disease of aging and the most common cause of dementia. A potential paradox of AD pathogenesis is that the hallmark protein aggregations consistent with AD pathology are commonplace in the elderly, yet only some manifest clinical symptoms. This fact, along with the limited clinical benefit seen from drugs which target these aggregations suggest that mechanisms of AD-resilience are a potential avenue for identifying new therapeutic targets. GWAS of AD have been extremely successful in identifying AD-risk loci, and have provided substantial evidence that innate immune cells, particularly myeloid cells, have a substantial role in AD development but are unexplored with respect to AD-resilience. We hypothesized that genetic variants influence the function and response of monocytes through changes in gene expression, contributing to differences in AD-resilience outcomes. To test this hypothesis, we performed a transcriptome-wide association study (TWAS) of monocytes in four activation states. Monocyte genetic and expression data (Fairfax et al. 2014) were processed and used to build elastic net-regression models of monocyte genetically-regulated expression in the naive state, 2- and 24-hours following LPS stimulation, and 24-hours following IFN-$\boldsymbol{\gamma}$; stimulation. These conditions are intended to simulate monocyte response to innate and adaptive immune challenges. Weights for eQTL effects were subsequently used by S-PrediXcan against summary statistics of an AD case-only meta-analysis of global resilience to AD (Dumitrescu et al. 2020). Using TWAS, we identified two genes with Bonferroni-significant association to AD-resilience (among cases only): NETO2 (LPS24h, $P < 5.0x10\text{-}7$) and CRISPLD2 (IFN24h, $P < 6.0x10\text{-}6$), each in a different context of inflammation. Both results suggest that genetic predisposition to lower expression of these genes in monocytes during inflammation is associated with increased global resilience to AD. We also validate our findings in a cohort of Indiana and Ohio Amish using a different but related "cognitive preservation" phenotype, with the NETO2 association replicating in this population with a consistent direction of effect ($P < 8.0x10\text{-}4$). Lastly, a colocalization analysis using SuSie demonstrated that TWAS-significant regions had a distinct eQTL structure that is not present in other cell types including microglia, neurons, endothelial cells, and oligodendrocytes--suggesting that this association is monocyte-specific. The association of these genes suggest a possible role of monocyte-driven pathogenic inflammation in AD.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1277 Transferrin isoform analysis as a functional test for genetic variation in *PMM2*

Authors:

M. Schultz, K. Liedtke, C. Turgeon, A. White, G. pino, D. Peck, A. Studinski, P. L. Hall, D. Matern; Mayo Clinic, Rochester, MN

Introduction: Clinical testing of transferrin glycosylation is a standard screening test for patients with suspicion of an inborn error of N-linked glycosylation. The role of this test is expanding to include characterization of genetic variants detected in molecular testing. Individuals with the most common CDG, PMM2-CDG (70% of CDG cases), exhibit an abnormal transferrin profile; however, there are a few reports of false negative results. A better understanding of transferrin clinical sensitivity informs its value as a diagnostic test, functional evaluation for novel variants, and method to exclude potentially undetected variants. We present our experience with transferrin isoform analysis for PMM2-CDG to better understand its clinical sensitivity in the most common CDG type.
Methods: This cohort was ascertained by follow up of clinical results or by reported diagnosis. Clinical transferrin testing is performed by intact protein profiling by mass spectrometry. We make an implicit assumption that the laboratory would be contacted if a patient was diagnosed with PMM2-CDG after receiving negative transferrin results.
Results: We reviewed diagnostic testing results from individuals with PMM2-CDG (n=89). The transferrin profile was abnormal or indeterminate in 85/89 cases (clinical sensitivity = 95.5%). Two of the results were indeterminate and four were true false negatives by the assay's established cutoff. Closer examination of these individuals revealed known pathogenic variants, notably 3 individuals harboring c.722G>C, p.C241S, two with a splicing alteration c.178G>T, p.V60L, and one with a promoter alteration, c.-167G>T. In cases with a single pathogenic variant (n=18), none had positive transferrin results and were resolved as confirmed carriers.
Conclusions: These data demonstrate that transferrin analysis has >95% clinical sensitivity for PMM2-CDG and is a reliable functional test for genotypes of uncertain significance and to exclude the possibility of undetected second variants in *PMM2*. Three pathogenic variants observed in multiple cases with normal or indeterminate transferrin isoform profiles highlight an important limitation of the test which can be addressed by prior knowledge of their genotype-phenotype correlation. Provided there are no other clinically relevant molecular findings in the N-glycosylation pathway, positive transferrin results could be considered PS3 criteria for functional evidence in variant classification (for a VUS in trans with a P/LP variant) and consistent with a diagnosis of PMM2-CDG.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1278 treX-QTL: A mixture-model for identification and characterization of trans-eQTLs

Authors:

C. Wu[1], T. Xu[1], D. Munro[1,2], P. Mohammadi[1,2], A. Palmer[1], A. Goren[1], M. Gymrek[1]; [1]Univ. of California, San Diego, San Diego, CA, [2]Univ. of Washington, Seattle, WA

Studies of expression quantitative trait loci (eQTLs) aim to discover genetic variants that explain variation in gene expression, and may be linked to complex traits or diseases. While thousands of cis-eQTLs have been identified, robust detection of trans-eQTL effects is challenging mainly due to insufficient statistical power. Thus, biological mechanisms and characteristics of trans-eQTLs remain largely unknown.

We introduce treX-QTL, a novel trans-eQTL detection method that improves statistical power over methods that test gene-by-variant pairs separately by jointly modeling effects of an individual variant across all genes. treX-QTL uses a biologically plausible mixture model of effect sizes that enables inference of the number of target genes of a variant. To benchmark and evaluate effects of trans-eQTLs detectable by our method, we developed a simulation framework that models parameters including effect sizes, number of target genes of trans-eQTLs, and effects of covariates. Using our simulation framework we show that widely used correction techniques such as PCA or PEER remove effects of true trans-eQTLs along with technical variation.

We tested treX-QTL with a publicly available yeast expression dataset of 1,012 meiotic segregants. We identify 367 unique variants acting as trans-eQTLs at FDR 5% and replicate 3 hotspots of trans-eQTLs, mostly found in transcription factors, which treX-QTL predicted to affect over half of expressed genes. Next, we applied treX-QTL to a RatGTEx brain dataset that consists of 340 rats. We identified dozens of novel trans-eQTLs with target genes throughout the genome. To identify candidate genes driving these signals, we performed motif analysis of the promoters of target genes. For one chr7 trans-eQTL hotspot overlapping the key neuronal transcription factor Neurod4, we found target genes were enriched for Neurod motifs (p=1e-11), supporting it as the causal gene.

Finally, we applied treX-QTL to expression data for 52 tissues in humans from the GTEx cohort. While this analysis did not return strong trans-eQTL candidates, our power analyses suggest the GTEx dataset is still substantially underpowered to detect even moderately strong trans-eQTLs. Overall, our framework provides an important resource for future trans-eQTL studies involving humans and other complex organisms.

The treX-QTL package and simulation framework can be found online.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1279 Uncovering sources of human gene expression variation in a globally diverse cohort

Authors:

D. Taylor, M. Tassia, R. McCoy; Johns Hopkins Univ., Baltimore, MD

Gene expression variation accounts for a large proportion of phenotypic variation within and between species and is a major contributor to human traits and diseases. Previous large-scale studies of human gene expression have been invaluable for revealing mechanisms of genome function but have largely focused on individuals of European ancestries. This bias diminishes the generalizability of results to understudied populations and limits broader understanding of the diversity and evolution of gene expression across populations. To address these challenges, we performed RNA sequencing of lymphoblastoid cell lines derived from 731 globally-diverse individuals from the 1000 Genomes Project. Quantification of gene expression levels and alternative splicing revealed that the vast majority of gene expression variance (92%) and splicing variance (95%) is partitioned within as opposed to between populations-mirroring patterns of human genetic diversity. Additionally, gene expression variance within populations decreases with migratory distance from Africa, consistent with the serial founder effects during historical human expansion across the globe. Interestingly, gene expression variance was also lower for genes under stronger evolutionary constraint, supporting a model of stabilizing selection shaping expression variability. Using existing high-coverage whole-genome sequencing data from the same individuals, we leveraged the global diversity of our dataset to identify cis-eQTLs and cis-sQTLs in >15,000 and >7,000 genes, respectively. In addition to replicating the results of previous large-scale e/sQTL studies, we also identified novel associations, including many variants specific to Asian or Admixed American samples which were under-represented or absent in previous molecular association studies. Interestingly, we observed that genes with population-stratified expression are more likely to have population-stratified eQTLs, thereby explaining observed differential expression between populations. Taking advantage of the diverse history of recombination events in our sample, we performed fine-mapping to identify candidate causal expression and splice-altering variants, revealing evidence of widespread allelic heterogeneity (nearly 4,000 genes with >1 independent eQTL [40% of genes with finemapped eQTLs]) and strong enrichment within annotated regulatory elements. Together, our study reveals key sources of gene expression variation and its evolution across diverse human populations and provides a powerful resource for the field of human functional genomics.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1280 Uncovering the brain-specific genetic regulation of splicing by mapping splicing quantitative trait loci in 13,061 post-mortem brain RNA-seq samples.

Authors:

A. Real[1], K. BP[2], B. Z. Muller[2], W. H. Cuddleston[2], J. Humphrey[2], T. Raj[2], D. A. Knowles[1,3]; [1]New York Genome Ctr., New York City, NY, [2]Icahn Sch. of Med. at Mount Sinai, New York City, NY, [3]Columbia Univ., New York City, NY

Alternative splicing enables genes to generate diverse transcript isoforms and multiple proteins with altered structural or functional properties, by selecting different combinations of exons. It is tightly regulated in a cell- and tissue-specific manner. In the brain, splicing contributes to neuronal diversity and plasticity across brain regions and its dysregulation is linked to neurological disorders, yet the underlying mechanisms remain unclear. We investigated splicing landscapes in the brain to understand their genetic regulation across tissues and involvement in neurodevelopmental and neurodegenerative processes. Our "BigBrain" resource harmonized 13,061 unique RNA-sequencing samples from 12 published datasets across 7 brain regions to allow meta-analyses of multiple brain regions and ancestry-specific cohorts for cis- and trans- expression and splicing quantitative trait loci (eQTL and sQTL). To detect splicing patterns between samples from different brain cohorts, we used the LeafCutter algorithm to cluster splicing junctions in a cohort- and tissue-aware approach. Initial meta-analysis mapped 58,735 cis-sQTLs for 28,957 genes (FDR 5%) in 4,342 individuals. However, principal component analysis identified cohorts and brain regions as key drivers of gene expression and splicing differences across the BigBrain tissues. To account for this variation systematically across all BigBrain cohorts and achieve optimal data harmonization, we compare batch correction and meta-analysis approaches, holding out one cohort to evaluate sQTL replication rate. Specifically, we compare 1) global batch correction across all datasets vs per tissue-cohort correction, and 2) fixed-effect, random-effect, and multivariate adaptive shrinkage-based meta-analysis vs mega-analysis across cohort-tissue pairs. Mega-analysis combines raw data from multiple studies, potentially resulting in a larger sample size and increased statistical power compared to meta-analysis, enabling more precise estimates and improved detection of subtle splicing effects. It allows exploration of subgroup effects and interactions not possible in a meta-analysis providing a comprehensive and robust approach to synthesizing data, yielding more reliable and generalizable results. Finally, we perform colocalization analysis to enhance the interpretation of neurological GWAS loci. Harmonizing published transcriptomics datasets into the BigBrain project will shed light on multiple aspects of gene expression, alternative splicing, and its genetic regulation, enhancing our understanding of splicing genetic regulation in different brain regions.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1281 Uncovering the role of actin cytoskeletal dynamics in seizures caused by *TIAM1* loss

Authors:

S. Lu[1], M. Ma[1], F. A. Blanco[1], M. Gu[1], D. Dutta[1], Y. Huang[1], X. Pan[1], H. Li[1], W. K. Chung[2], K. F. Tolias[1], H. J. Bellen[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Columbia Univ., New York, NY

Epilepsy, defined by recurrent seizures, is one of the most common neurological diseases affecting 50 million people worldwide. People with epilepsy often have comorbid conditions including learning and memory defects, anxiety and depression. The mechanism underlying epilepsy remains elusive. Since hyper-excitability of neuronal synaptic transmission can cause seizures, much work has focused on synaptic transmission defects in the pathogenesis of epilepsy. However, little attention has been given to the role of actin cytoskeleton in epileptogenesis. Actin cytoskeletal dynamics are essential for the physiological properties of neurons, and growing evidence has indicated that altered cytoskeletal dynamics may contribute to epilepsy in general. Aberrant expression levels of various actin cytoskeletal proteins are known to be involved in epilepsy. Moreover, mutations in actin-associated proteins, including Filamin A (OMIM: 300049), PAK1 (OMIM: 618158), alpha-II spectrin (OMIM: 613477), and DIAPH1 (OMIM: 616632), cause epilepsy. Recently, we have identified various proteins that are associated with seizures in humans, and these proteins are involved in the regulation of actin dynamics. Among them, bi-allelic loss-of-function (LoF) variants in *TIAM Rac1 associated GEF 1* (*TIAM1*) cause a neurodevelopmental disorder with language delay and seizures (NEDLDS, OMIM: 619908). TIAM1 is a Rac1-specific guanine nucleotide exchange factor (GEF), activating signaling pathways that regulate actin cytoskeleton organization within neurons. *TIAM1* and its fly ortholog, *still life* (*sif*), are enriched in the central nervous system (CNS). Loss of *sif* in flies leads to reduced survival and severe seizure-like behaviors. Especially, we found that *sif* is mainly expressed in neurons rather than glia in the fly CNS, and the seizure-like behaviors associated with *sif* LoF are mainly caused by neuronal loss of *sif*. Notably, *sif* loss in excitatory neurons, specifically glutamatergic neurons, causes seizure-like behaviors. Interestingly, *sif* loss in glutamatergic neurons resulted in significant mitochondrial accumulation in axons and increased mitochondria in synaptic terminals. These findings suggest that *TIAM1*/*sif* loss may cause mitochondrial trafficking defects by disrupting actin cytoskeletal dynamics, thus leading to aberrant neuronal excitability and the occurrence of seizures in NEDLDS patients. Further investigations into the molecular mechanisms may provide valuable insights into novel therapeutic strategies for the treatment of epilepsy.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1282 Understanding the role of Hippo effectors Yap1 and Wwtr1 in optic fissure fusion.

Authors:

U. NEELATHI, D. Sanchez-Mendoza, B. Brooks; NIH, Bethesda, MD

The developing eye forms an optic fissure (OF) on its ventral side, the edges of which fuse to form a continuous layer of retinal pigment epithelium (RPE) and neural retina (NR). Failure of the OF to close causes uveal coloboma, which can affect iris, ciliary body, retina, choroid and optic nerve. It is genetic disorder which accounts for 10% cases of childhood blindness. Several genes and genetic pathways are linked to coloboma. Mutations in YAP1, an effector of Hippo signaling downstream of *FAT1* (another coloboma-associated gene), have been described in patients with syndromic and non-syndromic coloboma. WWTR1 (TAZ) is another effector of Hippo signaling and together with *YAP1* serves as a transcriptional coactivator via *TEAD* transcription factors. These observations prompted us to further study the role of Hippo signaling in OF fusion in a zebrafish model. *yap1* and *wwtr1* are expressed in RPE, OF and periocular mesenchyme (POM). *wwtr1* mutants exhibit grossly normal eye development without coloboma. *yap1* homozygous mutants have variable phenotype from bilateral coloboma to unilateral coloboma and/or microphthalmia. The double homozygous mutants have developmental arrest at approximately 16hpf, making it difficult to study OF fusion. Compared to *yap1-/-* mutants, *yap1-/-; wwtr1+/-* embryos have a higher penetrance of coloboma and pigmentation defects. In yap1-/-; wwtr1+/- mutants, expression of *aldh1a2* (dorsal), *vax2* (ventral), *foxG1a* (nasal) and *foxD1* (temporal) does not change compared to WT embryos, indicating the coloboma in these mutants is not due to defective optic cup morphogenesis. The OF lips appose but do not fuse in these mutants, as seen by the retention of laminin (basement membrane) at 48hpf and 72hpf. While characterizing the OF edges in these mutants by *ntn1a* expression, we have observed that there is a tissue between the OF edges. This was also confirmed by *dct* expression, where we can see the melanosomes being excluded at and around OF edges. The tissue between the OF was not optic stalk (OS) in origin as we did not see any upregulation of *fgf8* transcript. Expression of RPE markers *mitfA* and *tfec* is down regulated in and around the OF edges. Upregulation of early NR maker *pax6* at 24hpf and expression of late NR markers *Alcama and Huc/D,* which mark the retinal ganglion cells and amacrine cells respectively, in between the OF edges at 72hf, imply that the tissue in between the OF is NR in origin. Our observations imply that in *yap1-/-; wwtr1+/-* mutants the OF fails to fuse due to formation of NR in between the OF edges. We are investigating whether *yap1* and *wwtr1* directly regulate the expression of these RPE genes resulting in NR formation between the OF lips.

Unique genetic architecture of CSF and brain metabolites pinpoints the novel targets for the traits of human wellness

Background Perturbation in brain metabolism has been identified as an essential part of neurodegeneration and other brain-related disorders. Many metabolites and human traits harbor genetic components. Several studies have identified plasma and urine metabolites contributing to various traits and disorders based on genetic evidence. To study neurological traits, brain and cerebrospinal fluid (CSF) are tissues more relevant than plasma or urine. However, no study has thoroughly examined the genetic regulators of brain and CSF metabolite levels that could be used to identify causal metabolites of neurological disorders. The genetic architecture of metabolite levels in central nervous system can be different from those in circulating tissues due to blood-brain barrier and the metabolism of brain cells. We, therefore, pursued a large-scale brain and CSF metabolite genome-wide association studies (MGWAS) to identify metabolites contributing to 27 brain-related traits or disorders.

Methods We measured 440 metabolites in 2311 CSF samples (Knight ADRC, DIAN, ADNI, Barcelona-1, Fundació ACE) and 962 metabolites in 1016 brain samples (Knight ADRC, ROSMAP, MAYO). We identified MQTL and performed metabolome-wide association study (MWAS) to identify metabolites associated with traits. Mendelian randomization (MR) and colocalization were performed for causality and shared genetic regulations between metabolite abundance and 27 human wellness traits.

Results We identified 219 independent associations (59.8% novel) for 144 CSF metabolites and 36 independent associations (55.6% novel) for 34 brain metabolites. Most of the novel signals (97.7% and 70.0% in CSF and brain) were tissue specific. The nominated functional genes for 42.9% of CSF associations and 34.4% of brain associations encoded cis-acting proteins to the associated metabolites. By integrating MWAS-FUSION, MR, and colocalization, we identified eight metabolites to be causal for eight brain-related human wellness traits (11 relationships). We found that low mannose level was causal to bipolar disorder and as dietary supplement it may provide therapeutic benefits. Low galactosylglycerol level was found causal to Parkinson's disease.

Conclusion We conducted the first large-scale CSF and brain genome-wide association study. Our findings expand the knowledge of MQTL in central nervous system, provide insights into human wellness, and successfully demonstrates the utility of combined statistical approaches to inform interventions.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1284 Unraveling Functional Effects of Curly Su Mutations in Drosophila Melanogaster: Computational Mutagenesis and Genetics Insights

Authors:

S. Teng, A. Sobitan; Howard Univ., Washington DC, DC

The Curly Su protein (dMPO), a homolog of human myeloperoxidase (hMPO), plays a crucial role in wing development in Drosophila melanogaster. Through its generation of reactive oxygen species (ROS), dMPO contributes to diverse cellular and physiological processes. Given the similarity between the sequences of dMPO and hMPO, dMPO presents an exceptional opportunity for experimental validation in studies related to development and immunity. In this study, we employed saturated computational mutagenesis to investigate the effects of specific mutations on both dMPO and hMPO. By analyzing predicted folding energy changes, we identified target mutations, with G378W emerging as the most destabilizing mutation for dMPO. To validate the impact of these mutations, including G378W and Deletion 305-687, we generated transgenic fruit flies using genome editing techniques. Our observations revealed that G378W influenced wing phenotypes and the overall lifespan of the samples during husbandry. To gain further insights, we performed transcriptome analysis using RNAseq on both transgenic and wild-type samples. By comparing differentially expressed genes (DEGs) between treatment groups, we conducted gene ontology analysis to elucidate the functional attributes of down-regulated and up-regulated genes. The combined use of computational tools and genetics experiments allowed for rapid discovery of the novel functional effects of missense mutations in target proteins. This integrated approach provides valuable insights into the intricate relationships between genetic alterations and phenotypic outcomes.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1285 Unraveling the role of MPDZ SNP rs139926461 in osteoblast function and bone mineral density (BMD) using prime editing.

Authors:

A. Buo, K. Perumal, L. Dillard, C. Farber; Univ. of Virginia, Charlottesville, VA

BACKGROUND: Osteoporosis, defined by low bone mass and increased fracture risk, burdens 200+ million globally and incurs over $50 billion in healthcare costs due to fragility fractures. Research efforts have increasingly focused on elucidating the genetic underpinnings of bone health, with gene-editing methods offering potential to validate causal genetic variations. Despite this potential, these methods are underutilized in bone research.
The Multiple PDZ Domain Crumbs Cell Polarity Complex Component (*MPDZ*) has emerged as a candidate gene of interest due to compelling genetic evidence implicating its role as the causal driver of the bone mineral density (BMD) association at chromosome 9p23. Our prior research corroborated its role in regulating bone mass accrual in mice. However, the causal variant influencing *MPDZ* function is still unidentified, justifying gene editing of candidate variants.
METHODS: We used Prime Editing, a precise CRISPR-based DNA editing tool, to edit a BMD-associated *MPDZ* SNP, rs139926461. This SNP, an expression quantitative trait locus for *MPDZ* that is linked with BMD, is located in the *MPDZ* promoter. The C allele of rs139926461 is associated with lower MPDZ expression in comparison to the reference T allele. We changed the T to a C, hypothesizing that this substitution affects *MPDZ* transcription. Human fetal osteoblasts (hFOBs), which are homozygous for the T allele, were transfected with plasmids designed to direct the desired prime edited-mediated substitution. Cells were sorted for GFP to enrich the population of potentially edited cells.
RESULTS: Targeted sequencing of the *MPDZ* promoter region revealed that 20% of the DNA reads from these cells were successfully edited from T to C at rs139926461. Single-cell clonal populations were obtained and RNA was extracted from five clones for allele-specific expression analysis. Among these, only one clone, 3A11, showed a notable deviation in the C-to-T ratio at a separate heterozygous exonic SNP, rs34605667. In contrast to the approximate 50:50 C-to-T balance seen in other clones, the 3A11 clone showed a 36:64 C-to-T distribution, suggesting a distinct allelic imbalance. Sanger sequencing of this clone confirmed a heterozygous T-to-C edit at rs139926461, linking the observed allelic imbalance to the presence of the C at this SNP.
SUMMARY: These results provide evidence that the rs139926461 C allele impacts *MPDZ* gene transcription, thereby accounting for part of the BMD-associated osteoporosis risk. Further, this marks the first successful use of prime editing in bone cells, offering a promising approach for future exploration of osteoblast function and skeletal phenotypes.

Genome-wide association studies (GWAS) have identified independent signals at 5p15.33 across numerous cancers, with protective alleles for one cancer often conferring risk for another. Many of these associations are thought to act via allele-specific alterations in the *cis*-regulation of target genes. eQTL and TWAS in multiple tissue types implicate two plausible target genes: *TERT* and *CLPTM1L*. However, the mechanisms linking cancer susceptibility alleles to their presumed target genes, as well as the divergent directions of association across different cancers, remain elusive. With this in mind, we employed a comprehensive approach integrating statistical fine-mapping of GWAS summary statistics with massively parallel reporter assays (MPRA) and a densely tiled CRISPRi screen implemented across eight cell lines, representing four distinct cancers associated with 5p15.33 alleles - melanoma, lung, pancreatic, and bladder cancer.

Integrative screening identified up to 30 variants across multiple signals in the locus with putative allele-specific transcriptional activity. Furthermore, a variable number tandem repeat (VNTR) in intron 9 of CLPTM1L emerged as a potent transcriptional enhancer in CRISPRi screening. Leveraging PacBio sequencing, VNTR alleles of European ancestry samples from the 1000 Genomes Project were genotyped and found to be highly polymorphic, with longer VNTRs linked to the haplotype tagged by rs31490-A (risk increasing for melanoma and pancreatic cancer, protective for lung cancer). Subsequent imputation into a pancreatic cancer GWAS of 9,040 cases and 12,496 controls revealed an association between longer VNTRs and risk of pancreatic cancer (OR for VNTR in the 75th percentile = 1.17, 95% CI = 1.13-1.22, P = 2.21x10-12). This association of the lead SNP rs31490 is no longer genome-wide significant upon conditioning on the VNTR genotype (P= 2.20x10-5), suggesting that these VNTR alleles merit consideration as part of the credible variant set within this multi-cancer-associated haplotype.

Initial observations suggest VNTR-mediated *cis*-regulation of *TERT* in pancreatic cancer cell lines. Ongoing experiments in relevant cell lines utilize luciferase reporter systems and DNA-protein binding assays with the aim of not only deciphering how longer VNTRs differentially exert their transcriptional effects compared to shorter alleles but also characterizing the divergent directions of effect between different cancer types. These findings underscore the proposition that cancer susceptibility at the 5p15.33 locus may be mediated by both SNPs and an uncharted class of variants, yet to be characterized in the post-GWAS landscape.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1287 Unravelling the Genetic and Phenotypic Heterogeneity of Red Cell Membranopathies in Indian Population Using Next Generation Sequencing.

Authors:

T. MORE[1], P. Kedar[2]; [1]INDIAN COUNCIL OF Med. RESEARCH-Natl. Inst. OF IMMUNOHAEMATOLOGY, MUMBAI, India, [2]Natl. Inst. of Immunohematology (ICMR), MUMBAI, India

Red cell membranopathies refers to genetically and phenotypically heterogenous disorders due to defects in red cell membrane and skeletal proteins. Red cell membranopathy is a common cause of hemolytic anemia varying from mild to severe hemolysis due to defects in red cell membrane protein genes. Causative genes implicated in RBC membranopathies are numerous, making a gene-by-gene approach time consuming, expensive and labor intensive. Use of Next Generation Sequencing (NGS) targeted sequencing panel can expedite the molecular diagnosis after routine laboratory tests. This study reports the genetic and phenotypic heterogeneity of 124 Indian patients with red cell membranopathies using targeted next-generation sequencing and studied the correlation between the identified variants with their corresponding phenotypic features. We diagnosed 104 Hereditary Spherocytosis (HS) patients harbouring 39 *ANK1*, 47 *SPTB*, 6 *SLC4A1* AND 7 *SPTA1* variants. A total of 74 novel and 25 reported variants has been detected causing HS. Also, we identified 7 patients of Hereditary Xerocytosis (HX) harbouring 4 novel and 4 reported *PIEZO1* variants. Eight patients of Hereditary Elliptocytosis (HE) and 5 patients of Hereditary Pyropoikilocytosis (HPP) were diagnosed harbouring 9 novel and 4 reported *SPTA1* variants. All of the detected variants have damaging effect on the protein stability and function, as shown by the *in silico* analysis. The possible effect of the detected variants on the protein structure was studied using the HOPE software and DynaMut tools. This report mainly illustrates the molecular heterogeneity of red cell membranopathies in Indian patients. Comprehensive genetic and phenotypic evaluation assists in implementing the knowledge of genetic patterns and spectrum of variants, providing a molecular support for diagnosis of red cell membranopathies. Our experience demonstrates the high diagnostic yield of NGS for molecular diagnosis of RBC membrane disorders associated with defects in large genes. Timely detection of the disorder not only offers therapeutic benefits for patients but is likely to help in genetic counselling and future antenatal diagnosis, if required.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1288 Unveiling the Functional Relevance of Protein Coding Short Tandem Repeats in APOB and E2F4 through Structural Modeling and Analysis

Authors:

X. Zhang, J. Margoliash, M. Gymrek; Univ. of California San Diego, La Jolla, CA

Short Tandem Repeats (STRs) are repetitive DNA sequences found throughout the human genome and are of significant interest due to their potential role in biological processes and diseases. We previously performed an STR-based genome wide association study (GWAS) in the UK Biobank and identified more than 90 polymorphic STRs whose repeat lengths are thought to be causally associated with blood and serum biomarkers in humans. While the majority of trait-associated STRs are non-coding, two high-impact protein-coding STRs were identified: an imperfect poly-leucine repeat in APOB associated with LDL cholesterol and a poly-serine repeat in E2F4 associated with multiple traits including red blood cell count. Fully exploring the structural consequences and functional implications of protein-coding STR variants has been challenging due to the repetitive nature of the RNA and proteins they encode. Here we explored using AlphaFold to generate structural models for variant alleles in these regions, allowing us to investigate their potential functional implications. For the APOB repeat, consistent with previous studies, our structural simulations indicate that the STR mutation affects the signal peptide region, potentially impacting protein secretion efficiency. We hypothesize that this locus primarily affects APOB protein levels by modulating its secretion rather than inducing structural changes. On the other hand, AlphaFold simulation suggests the poly-serine region in E2F4 lies in a flexible region. Modifying the poly-serine copy number did not directly affect the predicted E2F4 structure. However, when analyzing the complex formed between E2F4 and P130, a factor from the pRB family that acts as an inhibitor and stabilizes E2F4, we found that the shorter variant binds more tightly to the P130 co-factor. Knockdown/knockout of E2F4 has been reported to significantly affect cell proliferation. Our simulation suggests the longer variant reduced stability due to ineffective P130 binding, potentially leading to increased degradation susceptibility, consistent with the direction of effect observed in GWAS. In future studies, we will profile protein expression in cells containing variable poly-serine copy numbers to validate this finding. Overall, our analysis highlights how genetic variation in protein-coding STRs may affect protein structure and functional domains. While the accuracy of AlphaFold in SNP analysis is debated due to the minor impact of single point mutations on overall protein structure, our results suggest it may provide meaningful biological insights into potential function of trait-associated STRs.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1289 Using CRISPR in the embryonic mouse brain to model patient variants in *MAP1B* associated with periventricular nodular heterotopia

Authors:

C. Kittock[1,2], L-J. Pilaz[1,2]; [1]Univ. of South Dakota, Sioux Falls, SD, [2]Sanford Res., Sioux Falls, SD

Recently, frameshift truncating and nonsense variants in *MAP1B* have been associated with periventricular nodular heterotopia (PVNH). PVNH is a neuronal migration disorder thought to arise from abnormal neuronal migration during embryonic development of the cerebral cortex. *MAP1B* encodes MAP1B, known for its role in regulating both microtubule and actin networks during embryonic brain development. However, the mechanism by which variants in *MAP1B* lead to PVNH is unknown. To study PVNH *in vivo*, we use Breasi-CRISPR, a method we developed to efficiently edit the genome of neural progenitor cells in the embryonic mouse cortex. By using Breasi-CRISPR to introduce *MAP1B*-associated PVNH patient variants and epitope tags in the endogenous *MAP1B* locus, we can directly model *MAP1B*-associated PVNH. Introduction of a *MAP1B*-associated PVNH variant via Breasi-CRISPR results in abnormal neuronal accumulation in the embryonic mouse cortex, thus partially recapitulating the patient phenotype. Live imaging in brain slices revealed that these neurons migrated slower and traveled shorter distances than wild type neurons. *MAP1B*-associated PVNH variants demonstrated robust protein expression via immunofluorescence and Western blotting. This suggests that *MAP1B* variants escape nonsense-mediated decay and that the truncated protein is stable. Due to the expression of truncated MAP1B, we hypothesized that the pathogenic mechanism underlying PVNH could be the truncated protein acting as a dominant negative. However, overexpression of the same *MAP1B*-associated PVNH variant did not recapitulate the migration delay seen when this same variant was introduced via Breasi-CRISPR. In conclusion, these data indicate that introduction of a *MAP1B*-associated PVNH variant in the endogenous *MAP1B* locus results in a neuronal migration delay in the embryonic mouse brain, but a dominant negative mechanism is unlikely to underlie this phenotype. Further experiments will test other potential mechanisms such as loss of certain *MAP1B* domains and/or haploinsufficiency. Altogether, these studies use cutting-edge tools to model PVNH *in vivo* in order to contribute to our understanding of neuronal migration disorders, the molecular mechanism underlying normal MAP1B function, and our general understanding of cortical development.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1290 Using signatures of natural selection to inform functional significance of GWAS variants in Inflammatory Bowel Disease

Authors:

V. Gartner[1], N. Nishiyama[2], M. R. Schaner[1], K. Clough[1], S. Z. Sheikh[1], T. S. Furey[3]; [1]Univ. of North Carolina, Chapel Hill, Chapel Hill, NC, [2]UNC Chapel Hill, Chapel Hill, NC, [3]Univ North Carolina, Chapel Hill, Chapel Hill, NC

Inflammatory Bowel Disease (IBD), which includes Crohn's disease (CD) and ulcerative colitis (UC) as the two main disease subtypes, is a chronic disease of the gastrointestinal tract characterized by an inappropriate immune response to the enteric microbiota in genetically susceptible individuals. Genome Wide Association Studies (GWAS) have identified over 250 IBD risk loci, the majority of which are in non-coding regions of the genome and whose functional mechanisms contributing to disease are poorly understood. Colocalizing GWAS loci with expression and chromatin accessibility quantitative trait loci (eQTL and caQTL) can help identify putative causal variants and link risk loci with measurable phenotypes at the molecular level, but still leaves a gap in our understanding of the functional significance of these risk loci and association with disease phenotypes. Previous studies have linked adaptations in the immune system in defense of environmental pathogens with an increased risk of autoimmunity. Thus, for immune-related complex diseases such as IBD, the functional significance of disease risk loci may be related to an adaptive response to new pathogens that have acted as selective pressures in shaping population allele frequency. Towards this end, previous studies have shown that genomic signatures of natural selection can be used to identify causal SNPs within risk loci and help prioritize autoimmune disease risk variants. In this study, we sought to further test this hypothesis by investigating evolutionary pressures on candidate causal IBD variants and their associated target genes identified by colocalizing IBD GWAS variants with eQTL and caQTL results from colon tissue collected from 96 well-phenotyped IBD patients (90 CD and 6 UC) and 50 non-IBD patients. We are assessing signatures of selection of variants associated with IBD subtypes (CD and UC), as well as within clinical phenotypic sub-groups of these subtypes, to characterize subtype-specific disease pathways, assist with fine-mapping of GWAS loci, and prioritize candidate variants for functional follow-up studies. These results build on previous efforts to use human-specific signals of natural selection to understand the genetic basis of autoimmune and complex diseases to better inform effective diagnosis of IBD subtypes and potential treatments based on critical subtype-specific biological pathways.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1291 Validating clinical interpretations of familial hypercholesterolemia variants using East Asian Biobank data

Authors:

M. Hwang[1,2], B-J. Kim[1], H-H. Won[2], Y. Kim[1]; [1]Korea NIH, Cheongju-si, Korea, Republic of, [2]Sungkyunkwan Univ, Seoul, Korea, Republic of

Key databases used for clinical interpretation include HGMD and ClinVar, which organize genetic variant information based on expert analysis, algorithmic predictions, and biological functions. Clinical interpretation of genetic variants is crucial for understanding their implications in disease. Despite the significance of these resources, inconsistencies among experts and limitations in precise functional predictions underscore the need for enhanced accuracy of variant interpretation. In recent years, large-scale biobanks have been established worldwide, including Korea Biobank, BioBank Japan, UK Biobank, Kadoorie Biobank, TOPMed, and others. These biobanks play a crucial role in researching disease-associated genetic variants and may provide an invaluable opportunity to validate the clinical interpretations through disease association analyses involving hundreds of thousands of participants. With a focus on familial hypercholesterolemia (FH), this study aims to validate the clinical interpretation of genetic variants registered in ClinVar. To achieve this goal, genetic variants and low-density lipoprotein (LDL) phenotypes from approximately 126,000 Korean participants were analyzed along with genome-wide association summary statistics for LDL from BioBank Japan, proposing a reclassification method based on the association results. The validation and reclassification process involved defining outliers in the genetic effect distribution from association results and reclassifying clinical interpretation of variants based on empirical effect size distribution considering allele frequency of the variants. Through this process, we validated one pathogenic variant and 66 benign variants classified according to ClinVar interpretation. Additionally, conflicts arising from 12 variants of uncertain significance (VUS) were resolved by reclassifying five pathogenic variants and seven benign variants. Notably, the reclassified pathogenic variants exhibited a higher prevalence of heart-related disease, including coronary artery disease and congestive heart failure, in comparison to the benign variants. Overall, this study emphasizes the pivotal role of large-scale biobanks in advancing our understanding of disease-associated genetic variants and improving the accuracy of clinical interpretations. The validation and reclassification of FH-related variants serve as a valuable step towards enhancing our knowledge and clinical practice in the field of precision medicine.

PB1292 Variants in the SOX9 transactivation middle domain induce axial skeleton dysplasia and scoliosis

Authors:

L. Wang[1], Z. Liu[2], S. Zhao[3], K. Xu[1], C. Qiu[4], Z. Zhao[1], G. Li[5], J. Cai[1], Q. Li[1], Z. Wu[6], R. Gray[2], N. Wu[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]The Univ. of Texas at Austin, Austin, TX, [3]Baylor Coll. of Med., Houston, TX, [4]Shandong Univ., Jinan, China, [5]Peking Union Med. Coll. Hosp. Chinese Academy of Med. Sci., beijing, China, [6]Peking Union Med. Coll. Hosp., Chinese Academy of Med. Sci., Beijing, China

SOX9 is an essential transcriptional regulator of cartilage development and homeostasis. In humans, dysregulation of *SOX9* is associated with a wide spectrum of skeletal disorders, including campomelic and acampomelic dysplasia, and scoliosis. The mechanism of how *SOX9* variants contribute to the spectrum of axial skeletal disorders is not well understood. Here, we report four novel pathogenic variants of *SOX9* identified in a large cohort of patients with congenital vertebral malformations. Three of these heterozygous variants are in the HMG and DIM domains, and for the first time, we report a pathogenic variant within the transactivation middle (TAM) domain of *SOX9*. Probands with these variants exhibit variable skeletal dysplasia, ranging from isolated vertebral malformation to acampomelic dysplasia. We also generated a *Sox9* hypomorphic mutant mouse model bearing a microdeletion within the TAM domain ($Sox9^{Asp272del}$). We demonstrated that disturbance of the TAM domain with missense mutation or microdeletion results in reduced protein stability but does not affect the transcriptional activity of SOX9. Homozygous $Sox9^{Asp272del}$ mice exhibited axial skeletal dysplasia including kinked tails, ribcage anomalies, and scoliosis, recapitulating phenotypes observed in human, while heterozygous mutants display a milder phenotype. Analysis of primary chondrocytes and the intervertebral discs in $Sox9^{Asp272del}$ mutant mice revealed dysregulation of a panel of genes with major contributions of the extracellular matrix, angiogenesis, and ossification-related processes. In summary, our work identified the first pathologic variant of *SOX9* within the TAM domain and demonstrated that this variant is associated with reduced SOX9 protein stability. Our finding suggests that reduced SOX9 stability caused by variants in the TAM domain may be responsible for the milder forms of axial skeleton dysplasia in humans.

PB1293 Variant-to-function translation of obesity-associated loci through multi-omics data integration

Authors:

V. Diez-Obrero[1], R. A. J. Smit[1,2], M. Guindo-Martinez[1,2], R. J. F. Loos[1,2]; [1]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Copenhagen, Denmark, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Introduction: Genome-wide association studies (GWAS) have identified hundreds of loci associated with body mass index (BMI). However, the variant-to-function translation of only a handful of these loci has been successful. Here, we aim to identify candidate effector genes within BMI-associated loci, and reveal their molecular effects, to ultimately provide new biological insights into obesity pathogenesis.
Methods: We integrated GWAS summary statistics of BMI reported by the GIANT Consortium (Yengo et al, 2018) with multi-omics quantitative trait loci (QTLs), including plasma-derived gene expression, protein, and metabolite QTLs (e/p/metabQTLs), and brain and adipose tissue-derived eQTLs from different studies. We performed colocalization analyses to detect shared genetic signals between BMI and -omic traits. We used cis-e/pQTLs to identify candidate effector genes within loci, and trans-e/p/metabQTLs to pinpoint the molecular effects of cis-colocalizing loci. We implemented a two-sample Mendelian Randomization approach to assess the causal relationship between -omic traits and BMI.
Results: Cis-e/pQTLs of 916 genes colocalized at 259 of the 536 BMI-associated loci. The integration of multiple QTL datasets from different tissues maximized the power for discovery. In 18 of the 259 loci, the same genes colocalized both at the gene expression- and protein-level (e.g., TTC12 and LYZ). Trans-e/pQTLs and/or metabolite-QTLs colocalizing in 181 of the 259 cis-colocalizing loci pointed to molecular mechanisms. For example, we found that genetic variants in GIPR that are associated with higher BMI and cardiovascular disease, also associate with higher protein levels of GIP, lower protein levels of SCGB3A1, QPCTL, and MSMB, and lower levels of X-12818 metabolite in plasma. Furthermore, the protein levels in plasma of 62 genes, such as SNX1 and PRKCB, are causally associated with BMI, which may provide new biomarkers of obesity risk.
Conclusion: Integrating multi-omics data with GWAS results successfully provided new molecular insights into the variant-to-function translation of BMI-associated loci.

Session Title: Molecular Effects of Genetic Variation Poster Session I

PB1294 Vitamin D binding protein gene polymorphisms of the rs7041 and rs4588 minor allele are associated with HIV and tuberculosis co-infection.

Authors:

E. Acen; MAKERERE Univ., PHYSIOLOGY RESEARCH LABORATORY KAMPALA UGANDA, Uganda

Vitamin D binding protein gene polymorphisms of the rs7041 and rs4588 minor allele are associated with HIV and tuberculosis co-infection. Background: Studies show that the D binding protein (DBP) gene located at 4q12-q13 is highly polymorphic with over 120 variants (Bikle & Schwartz, 2019). These genetic variants affect the distribution of vitamin D in the circulatory system, leading to vitamin D deficiency and compromised immunity (Alhomsi et al., 2020). The two extensively studied non-synonymous DBP single nucleotide polymorphisms (SNPs) rs7041 and rs4588 occur in different populations (Santos et al., 2017). The wild-type Gc1F genotype is predominantly found in the African population, with a low frequency of Gc2 and Gc1S genotypes, and it is associated with low vitamin D levels in whites. According to previous research minor alleles exhibit tendencies of being risk alleles of disease. The aim of this study was to explore the DBP gene polymorphism and the risk of disease among TB patients and household contacts with and without HIV infection. Methods: This was across-sectional study with 53 active tuberculosis patients attending Kiruddu Referral Hospital, 23 latent tuberculosis individuals, and 27 individuals without tuberculosis infection from the KTB cohort. These were aged between 12 to 65 years. DNA extraction and PCR were performed and a product of 498 bp was obtained. We genotyped the DBP gene by Sanger sequencing and the single nucleotide polymorphisms were identified using the BioEdit tool. Results: The study frequency distributions of the DBP genotypes were reported as 97% Gc1F, 2% Gc2 and 1% Gc1S and Hardy-Weinberg equilibrium analysis was in equilibrium, D'= 0. Majority were female 63 (61.2 %) and of these 19 (18.4%) were HIV positive. The 2% of the participants had the Gc2 genotype and had HIV and TB co infection Conclusion: The DBP Gc1F genotype was predominantly found in the study population with the minor alleles associated with active and latent TB states. Additionally the Gc2 minor allele was associated with HIV and active TB confection in the Ugandan population.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1295 Whole exome sequencing data reveals candidate loci for Type 1 diabetes in Kuwaiti-Arab families

Authors:

R. Nizam[1], P. Hebbar[2], S. John[3], D. Antony[1], M. Dashti[4], A. Channanath[1], A. Shaltout[1], H. Alkandari[1], H. Koistinen[5], J. Tuomilehto[6], O. Alsmadi[7], T. Thanaraj[1], F. Al-Mulla[8]; [1]Dasman Diabetes Inst., Kuwait, Kuwait, [2]Dasman Diabetes Inst., Shark, Kuwait, [3]Dasman Diabetes Inst., 15462, Dasman, Kuwait, [4]Dasman Diabetes Inst., Al Kuwayt, Kuwait, [5]Univ. of Helsinki and Helsinki Univ. Hosp., Helsinki, Finland, [6]Finnish Inst. for Hlth.and Welfare, Helsinki, Finland, Finland, Finland, [7]King Hussein Cancer Ctr., Amman, Jordan, [8]Dasman Diabetes Inst., Kuwait City, Kuwait

Prevalence of Type 1 diabetes (T1D) has been remarkably high in Kuwait and in the Middle Eastern region. International Diabetes Federation (2021) ranks Kuwait as third among countries with high prevalence of T1D. Consanguineous marriages are common in Kuwait (50-70%) leading to an excessive burden of recessive alleles. Despite this, limited studies have explored the genetic epidemiology of T1D from Kuwait. In the present study, we aim to identify genomic loci linked to T1D in Kuwaiti-Arab families which were previously unreported. Data and samples used in this study were obtained from the Childhood-Onset Diabetes eRegistry (CODeR), Kuwait. Linkage analysis was carried out on whole exome sequencing data from 18 unrelated T1D families consisting of 37 T1D cases and 49 unaffected first-degree relatives. Parametric two-point linkage analysis based on both recessive/dominant inheritance model was performed with PSEUDOMARKER 2.0 using default parameters. We identified three potential genomic regions linked to T1D in Kuwaiti-Arab families and these include chromosome 6p22.2 (LOD =3.72), 3p25.3 (LOD=3.010) and 4q31.3 (3.186) which showed evidence of significant linkage under a recessive mode of inheritance ($P \leq 2.2\times10^{-5}$). Fine mapping of these regions revealed candidate genes associated with uric acid metabolism. Supportive quantitative trait loci (QTL) data from GTEX and NephQTL indicates the likelihood for shortlisted genes to be a potential marker for nephropathy in T1D. In the first of its kind study from the region, our study highlights candidate loci linked to T1D in Kuwaiti-Arab families and their prospective role in disease etiology by regulating the expression of genes implicated in uric acid and metabolic events, as evidenced by publicly available QTL data.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1296 Identification of suicide risk loci in eQTLs by whole-genome sequencing analysis.

Authors:

S. Han[1], E. Diblasi[1], E. Monson[1], A. Shabalin[1], D. Chen[1], A. Fraser[2], Z. Yu[2], M. Staley[3], W. Callor[3], E. Christensen[3], D. Crockett[4], Q. Li[5], V. Willour[6], E. Ferris[7], A. Bakian[1], B. Keeshin[1], A. Docherty[1], K. Eilbeck[1], H. Coon[1]; [1]Univ. of Utah Sch. of Med., Salt Lake City, UT, [2]Univ. of Utah Huntsman Cancer Inst., Salt Lake City, UT, [3]Utah Dept. of Hlth.and Human Services, Salt Lake City, UT, [4]Intermountain Hlth.care, Salt Lake City, UT, [5]Janssen R&D, LLC, Titusville, NJ, [6]Univ Iowa, Iowa City, IA, [7]Univ. of Utah Sch. of Med., Satl Lake City, UT

Recent large-scale genome-wide association studies (GWAS) have started to identify potential genetic risk loci associated with risk of suicide; however, a large portion of suicide-associated genetic factors affecting gene expression remain elusive. Dysregulated gene expression, not assessed by GWAS, may play a significant role in increasing the risk of suicide death. We performed the first comprehensive genomic association analysis prioritizing brain expression quantitative trait loci (eQTLs) within regulatory regions in suicide deaths from the Utah Suicide Genetic Risk Study (USGRS). 440,324 brain-regulatory eQTLs were obtained by integrating brain eQTLs, histone modification ChIP-seq, ATAC-seq, DNase-seq, and Hi-C results from publicly available data. Subsequent genomic analyses were conducted in whole-genome sequencing (WGS) data from 986 suicide deaths of non-Finnish European (NFE) ancestry and 415 ancestrally matched controls. Additional independent USGRS suicide deaths with genotyping array data (n=4,657) and controls from the Genome Aggregation Database were explored for WGS result replication. One significant eQTL locus, rs926308 (p=3.24e-06), was identified. The rs926308-*T* is associated with lower expression of *RFPL3S*, a gene important for neocortex development and implicated in arousal. Gene-based analyses performed using *Sherlock* Bayesian statistical integrative analysis also detected 20 genes with expression changes that may contribute to suicide risk. From analyzing publicly available transcriptomic data, nine of these genes have previous evidence of differential expression in psychiatric disorders that may be associated with suicide, including schizophrenia and autism (*ZNF501*, *CNN3*, *IGF1R*, *KLHL36*, *NBL1*, *PDCD6IP*, *SNX19*, *TBCA*, and *ARSA*). In summary, our study identified one risk locus and nine genes associated with suicide risk via gene expression, providing new insight into possible genetic and molecular mechanisms leading to suicide.

Ctr., Cleveland, OH, [7]Dept. of Psychiatry, Case Western Reserve Univ., Cleveland, OH, [8]Geriatric Psychiatry, GRECC, Louis Stokes Cleveland VA Med. Ctr., Cleveland, OH, [9]Inst. for Transformative Molecular Med., Sch. of Med., Case Western Reserve Univ., Cleveland, OH, [10]Dept. of NeuroSci., Case Western Reserve Univ., Sch. of Med., Cleveland, OH, [11]Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [12]Nash Dept. of NeuroSci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [13]Ronald M. Loeb Ctr. for Alzheimer's Disease, Icahn Sch. of Med. at Mount Sinai, New York, NY

Transposable element (TE) dysregulation of quantitative trait loci (QTL) has not been well-characterized in human brains. Here, we leveraged large-scale RNA-sequencing (RNA-seq), whole-genome sequencing (WGS), and various QTL data (xQTL) from three brain biobanks to comprehensively characterize TE activation across diverse pathobiology of Alzheimer's disease (AD), including Tau and amyloid beta, APOE genotypes, and sex differences, using AI\ML and translational bioinformatics approaches. To identify genetic control of expressed TEs, we integrated expressed TEs with matched whole-genome sequencing (WGS) data and identified 38,398 genome-wide significant TE expression quantitative trait loci (teQTLs) in human brains. Compared with traditional various quantitative trait loci (xQTLs), we found that most teQTLs regulate distinct genes. We then used colocalization analysis to integrate six AD GWAS summary statistical datasets (278,950 cases versus 1,780,303 controls) with xQTLs, including teQTLs, gene expression QTLs (eQTLs), DNA methylation QTLs (meQTLs), and H3K27 histone acetylation QTLs (haQTLs), for identifying likely causal TEs involved in AD. This identified new AD risk genes, including complement C1q tumor necrosis factor-related protein 4 (*C1QTNF4*) and farnesyl-diphosphate farnesyltransferase 1 (*FDFT1*). A TE from Plat_L3 subfamily (chr11: 47605296-47605575) suppressed expression of *C1QTNF4* (its nearest gene) via long-range enhancer-promoter chromatin interaction in neurons. We identified that a TE from AluJb subfamily (chr8: 11840915-11841089) increased expression of *FDFT1* (its nearest gene) via microglia-specific long-range chromatin looping. Expression perturbation of *FDFT1* and *C1QTNF4* were significantly correlated with Braak staging score of AD patients. We further identified that individuals with AD risk allele APOE4 displayed elevated expression of AluJb and *FDFT1* in patient induced pluripotent stem cells (iPSC)-derived microglia and superior frontal gyrus (SFG) microglia compared to APOE3 individuals. These findings demonstrate widespread TE dysregulation in human aging brains and teQTLs offer a useful QTL analytic approach to identify AD risk genes and other complex diseases if broadly applied.

Session Title: Molecular Effects of Genetic Variation Poster Session II

PB1298 Wnt activity reveals context-specific genetic effects on gene regulation in neural progenitors.

Authors:

J. Valone, N. Matoba, B. D. Le, J. Wolter, J. Mory, D. Liang, N. Aygun, K. A. Broadaway, M. L. Bond, K. L. Mohlke, M. J. Zylka, M. I. Love, J. L. Stein; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Common genetic variation has previously been associated with brain-relevant traits and risk for neuropsychiatric disorders; however, these loci are mostly found in non-coding regions without clear mechanisms of action. Regulatory mechanisms of non-coding loci are inferred by mapping the effects of genetic variation on regulatory element activity, marked by accessible chromatin peaks (chromatin accessibility quantitative trait loci or caQTL), or gene expression (eQTL). Studies in bulk post-mortem tissue have explained mechanisms for a subset of brain-trait associated loci through colocalization of causal variants, yet many brain-trait associated variants remain unexplained. This “missing regulation” may be due to variants impacting regulatory mechanisms only in specific contexts or under certain stimuli (response-QTLs). We hypothesized that stimulation of a developmental signaling pathway in a homogeneous neural cell type would reveal previously undetected functions of genetic variation.
We evaluated context-specific effects of genetic variation in a population of primary human neural progenitor cells (hNPCs; nmax= 82), a developmental cell type with regulatory elements enriched for genetic association signals in multiple-brain related traits and neuropsychiatric disorders. We measured chromatin accessibility via ATAC-seq and gene expression via RNA-seq in hNPCs following stimulation of the canonical Wnt pathway, which is known to impact neural progenitor proliferation, cortical patterning, and has previous associations with neuropsychiatric disorders.
Wnt-responsive regulatory elements (WREs) were enriched for variants associated with brain structure and neuropsychiatric disorders. Over 43,000 caQTLs regulating over 36,000 unique caPeaks were identified alongside over 3,000 unique eQTL-eGene pairs. Stimulation of the Wnt pathway increased the detection of genetically influenced REs/genes by 66.2%/52.7%, and led to the identification of 397 REs primed for effects on gene expression. Genetically influenced REs were enriched in regions under positive selection along the human lineage, including a previously validated enhancer of the Wnt receptor gene FZD8. We also found over 1,800 response-caQTLs and 102 response-eQTLs, where a significant genotype-by-condition interaction was detected. Context-specific molecular quantitative trait loci increased brain-trait colocalizations by up to 70%.
Our results characterize context-specific genetic effects in hNPCs that provide novel insights into neurodevelopmental gene regulatory mechanisms underlying brain trait-associated loci.

Session Title: Molecular Effects of Genetic Variation Poster Session III

PB1299 α-Synuclein pathology in *Drosophila melanogaster* is exacerbated by haploinsufficiency of *Rop*: Connecting STXBP1 encephalopathy with α-synucleinopathies.

Authors:

T. Matsuoka[1], H. Yoshida[2], T. Kasai[3], T. Tozawa[1], T. Chiyonobu[1,4]; [1]Dept. of Pediatrics, Graduate Sch. of Med. Sci., Kyoto Prefectural Univ. of Med., Kyoto, Japan, [2]Dept. of Applied Biology, Kyoto Inst. of Technology, Kyoto, Japan, [3]Dept. of Neurology, Graduate Sch. of Med. Sci., Kyoto Prefectural Univ. of Med., Kyoto, Japan, [4]Dept. of Molecular Diagnostics and Therapeutics, Graduate Sch. of Med. Sci., Kyoto Prefectural Univ. of Med., Kyoyo, Japan

STXBP1 haploinsufficiency causes STXBP1 encephalopathy (STXBP1-E), which encompasses neurological disturbances including epilepsy, neurodevelopmental disorders, and movement disorders. STXBP1 (also called Munc18-1) is involved in SNARE complex formation and contributes to synaptic vesicle exocytosis. A recent in vitro study proposed the role of STXBP1 as a molecular chaperone for α-synuclein, a key molecule in the pathogenesis of neurodegenerative disorders including Parkinson's disease. Patients with STXBP1-E have been reported to exhibit extrapyramidal symptoms, but no studies to date have shown α-synuclein pathology in model organisms or patients with STXBP1-E. Here, we report that haploinsufficiency of *Rop*, the *STXBP1* homolog in *Drosophila*, exacerbates α-synuclein pathology. Homozygosity for null variants of *Rop* is lethal at the embryonic stage, whereas flies that are heterozygous for null variants survive to adulthood, although their protein expression is about 20% lower than that of the wild type. In this *Drosophila* model of STXBP1-E, the volume of transgenic human α-synuclein in the 1% Triton-soluble fraction was significantly reduced compared to the control, while that in the 1% Triton-insoluble fraction was significantly increased, indicating that *Rop* haploinsufficiency aggravates α-synuclein aggregation. The α-synuclein-transgenic STXBP1-E model also showed a significant decrease in the number of dopamine neurons compared to control flies, and adults displayed reduced motor function. This model also displayed worsening compound eye degeneration. These results indicate that α-synuclein neurotoxicity is exacerbated in STXBP1-E model flies. We also showed that feeding trehalose to STXBP1-E model flies significantly reduced the 1% Triton-insoluble fraction of α-synuclein and restored adult locomotor function. This study is the first to demonstrate a molecular interaction between STXBP1 and α-synuclein using a model organism. This study contributes to understanding the mechanisms of neurodegeneration in patients with STXBP1-E and provides new insights into the pathogenesis of α-synucleinopathies.

PB1301 2-Sample Mendelian Randomization Reveal Widespread Lipidomic Dysregulation Underpinning Severe Obesity in Self-identified Mexican Americans

Authors:

M. Yaser[1], M. Graff[2], H-H. Chen[3], P. Sharma[4], J. E. Curran[5], P. J. meikle[6], W. Zhu[7], H. Highland[8], K. Young[2], L. Petty[9], A. Gutierrez[10], M. Lee[11], J. McCormick[11], S. P. Fisher-Hoch[12], J. E. Below[13], K. E. North[2]; [1]Univ. of North Carolina Chapel Hill, Chapel Hill, NC, [2]Univ North Carolina, Chapel Hill, NC, [3]Vanderbilt Unviersity, Nashville, TN, [4]Univ. of North Carolina, Chapel Hill, NC, [5]Univ. of Texas Rio Grande Valley, Brownsville, TX, [6]Univ. of North Carolina Chapel Hill, Baker Heart and Diabetes Institute, Australia, [7]Vanderbilt Univ., Nashville, TN, [8]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [9]Vanderbilt Univ. Med. Ctr., Nashville, TN, [10]UT Hlth.Houston, Houston, TX, [11]UTH SPH Brownsville, Brownsville, TX, [12]UT SPH Brownsville, Brownsville, TX, [13]Univ. of Vanderbilt Med. Ctr., Nashville, TN

Background Severe obesity (SevO), a Body Mass Index (BMI) of ≥40 kg/m^2, is the fastest-growing metabolic disorder in the U.S. While lipids are significantly associated with SevO, the nature of the association between the heterogenous lipid species has not been queried, particularly in high-risk populations. We conducted a two-sample Mendelian Randomization (2SMR) to characterize the lipid species that underpin the risk of SevO in self-identified Mexican Americans, a population that has a SevO prevalence twice that of non-Hispanic Whites. **Methods** We conducted a phenotypic association analysis between the lipids and SevO in individuals from the Cameron County Hispanic Cohort (CCHC). We performed genome-wide associations (GWAS) for lipid species nominally ($p<0.05$) associated with SevO in 2,096 individuals from the CCHC. We also utilized a multi-population SevO-GWAS, comprised of 32,358 cases and 45,806 controls for our outcome. We extracted the associated genetic variants from the respective species' GWAS results, considering only variants surpassing a significance threshold of 5×10^{-6}. We then matched these variants' summary statistics to their corresponding pairs in the SevO GWAS. Subsequently, for each species, we ran a 2SMR using MR Egger to account for pleiotropy. To further assess clinical significance, we queried the instrumental variables from significant lipid species in the GWAS catalog. **Results** Analyses revealed that 34 classes (597 species) showed an association with SevO, out of 49 lipid classes (830 species). 2SMR identified 41 lipid species with potentially causal associations with SevO. Among these, 29 demonstrated a protective effect against SevO, including 3 ceramides, 3 trihexosylceramides (Hex3Cer), 6 lysophosphatidylcholines (LPC), 7 phosphocholines (PC), 2 sphingomyelins (SM), 1 lysophosphatidylethanolamine (LPE), 1 dimethyl-cholesteryl ester (dimethyl-CE), and 1 phosphatidylinositol (PI). On the other hand, 18 lipid species were identified as risk-increasing for SevO, including 3 diglycerols (DG), 12 triglycerols (TG), 1 sphingomyelin (SM), 1 phosphatidylinositol (PI), and 1 phosphocholine (PC). Genetic instruments associated with protective species were associated with polyunsaturated fatty acids, immunity cells, and coagulation. In contrast, the genetic instruments associated with the risk-increasing species were frequently linked to cholesterols, liver diseases, and cardiovascular diseases (CVD). **Conclusion** Our results support an important role of dysregulation of species of lipids in the pathogenesis of SevO. Such findings are important as they may inform novel targets and interventions for SevO.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1302 3D genomic features across over 50 diverse cell types reveal insights into the common and differing genomic architectures of sixteen autoimmune disorders

Authors:

K. Trang, M. C. Pahl, J. A. Pippin, P. K. Sharma, Z. Thompson, S. F. Grant, A. D. Wells; Ctr. for Spatial and Functional Genomics, The Children's Hosp. of Philadelphia, Philadelphia, PA

The risks for many autoimmune disorders are polygenic with a degree of overlap in susceptibility loci, suggesting a shared molecular etiology across diseases. Genome-wide association studies (GWAS) has shown genetic intercorrelation between such diseases, including ankylosing spondylitis (AS), Grave's disease, Hashimoto's thyroiditis, celiac disease, Crohn's disease, inflammatory bowel disease, ulcerative colitis, atopic eczema, juvenile idiopathic arthritis (JIA), multiple sclerosis, psoriasis, rheumatoid arthritis, systemic lupus erythematosus, type I diabetes mellitus, and vitiligo. However, remains uncovered the degree to which these diseases share underlying causal variants, corresponding effector genes, and cellular context. Leveraging our existing 3D genomic datasets consisting of high-resolution promoter-focused Capture-C/Hi-C, ATAC-seq, and RNA-seq across over 50 diverse human cell types enabled us to contrast the causal variants and the corresponding effector genes for these diseases. These include various innate and adaptive immune cells whose functions play crucial roles in the development and progression of autoimmune diseases, plus non-immune cell types spanning metabolic, neuronal, and pluripotential stem cell lineages. Using stratified LD regression, we calculated the proportion of genome-wide SNP heritability attributable to our derived cell type-specific features via the integration of the most recent GWAS summary statistics for these diseases. These analyses revealed a statistically significant enrichment (P<0.05) for 13 diseases across all immune cell types. Interestingly, Grave's disease also showed enrichment in several metabolic, neural, and stem cell types. AS, JIA and psoriasis were exceptions, with such enrichments limited to distinct subsets of T cell and plasmacytoid dendritic cells. Subsequent application of our chromatin contact-based ‘variant-to-gene’ mapping of these loci in these cell types identified “hub” genes including members of the NF−kappa B binding and integrin binding pathways that appeared in almost every cell type for all disorders, supporting the notion that mediation of cell-cell and cell-extracellular matrix adhesion plays crucial roles in autoimmune etiology. Other immune functional pathways and biological processes were uniquely associated with a given cell type or with a specific disorder. In conclusion, our comprehensive appraisal of 3D genomic datasets in a large panel of different cell types drives greater genomic understanding of both the similarities and the differences across autoimmune disease pathogenesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1303 3D modelling predicts reduced stability and protein binding for a biallelic missense variant in the Sonic Hedgehog gene in autism spectrum disorder

Authors:

T. Muhammad[1], A. Rabia[2], R. Harripaul[1], A. Mikhailov[3], M. Carter[4], S. Mahmood[2], S. Maqbool[5], J. Vincent[3], M. Ayub[6]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Univ. of Hlth.Sci., Lahore, Pakistan, Lahore, Pakistan, [3]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, [4]Dept. of Genetics, Children's Hosp. of Eastern Ontario,, Ottawa, ON, Canada, [5]Children's Hosp. & The Inst. of Child Hlth., Lahore, Pakistan, Lahore, Pakistan, [6]Dept. of Psychiatry, Queens Univ. Kingston,, Kengston, ON, Canada

Background: Dissecting the genetics of autism spectrum disorders (ASD) has indicated the importance of *de novo* variants in single genes as well as copy number variants involving one or more genes. Recently, studies have shown the importance of biallelic pathogenic variants in genes with autosomal recessive (AR) inheritance, particularly in populations in which consanguineous marriages are common. However, it is also noteworthy that biallelic variants may have quite different phenotypic and clinical consequences to heterozygous variants in the same gene.**Objectives:** The goal was to explore the phenotype/genotype relationship for a rare biallelic missense mutation in *Sonic Hedgehog*, though clinical assessments of the patient, and molecular genetic and *in silico* analyses to examine the underline genetic and proteomic alterations.**Methods:** Clinical assessments were performed for developmental, medical and family history, current functioning, problematic behaviors, psychiatric symptoms and ASD using ADI-R as framework. Biometrics and dysmorphology were assessed. Genetic analysis were carried out by microarray genotyping and whole exome sequencing. Functional predictions for deleteriousness using various well known prediction tools. For *in silico* analysis, molecular docking MD simulations were performed using MOE and Desmond.**Results:** Here we report on a proband with ASD, who inherited a biallelic missense variant in the gene encoding the developmental morphogen, Sonic Hedgehog (*SHH*; NM_000193.4: c.206A>T: p. Asn69Ile). Heterozygous missense or loss-of-function variants in *SHH* have previously been reported in association with the autosomal dominant (AD) forebrain and midface developmental disorder, holoprosencephaly-3 (HPE3; MIM 142945). Here we describe the clinical features identified with this biallelic missense variant of a conserved amino acid residue, for comparison and contrast with the features of HPE3 and related phenotypes. We also demonstrate a predicted reduction in stability of the mutant SHH protein, also impacting its binding with hedgehog interacting protein (HHIP).
Conclusion: Here, we report on a family with a biallelic missense mutation in SHH, with ASD but no sign of HPE, and present supporting evidence for the pathogenicity of the mutation from 3D-modelling analysis that predicts reduced functionality and/or stability of SHH.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1304 A comparison of the obesity-associated transcriptome in skeletal muscle of African Americans and Europeans

Authors:

S. Das[1], S. S. Das[2]; [1]Wake Forest Univ. Sch. of Med., Winston-salem, NC, [2]The Sch. of Biotechnology at Atkins, Atkins Academic and Technology High, Winston-salem, NC

Obesity is a common disease with a higher prevalence among African Americans. Obesity alters cellular function in many tissues, including skeletal muscle, and is a risk factor for many life-threatening diseases, including cardiovascular disease and diabetes. Utilizing publicly available summary statistics data from transcriptome-wide analyses on skeletal muscle tissues from well-powered human cohorts, in this study, we compared genes and biological pathways affected by obesity in European and African ancestry populations. Results from the linear regression analysis on the FUSION (European, N= 301) and AAGMEx (African American, N=256) cohorts identified 2569 body mass index (BMI)-associated transcripts ($q<0.05$), of which 970 genes (at $p<0.05$) are associated in both cohorts, and the majority showed the same direction of effect on BMI. Biological pathway analyses, including over-representation and gene-set enrichment analyses, identified enrichment of protein synthesis pathways (e.g., ribosomal function) and the ceramide signaling pathway in both cohorts among BMI-associated down- and up-regulated transcripts, respectively. A comparison using the IPA-tool suggested activation of inflammation pathways only in Europeans with obesity. Interestingly, these analyses suggested repression of the mitochondrial oxidative phosphorylation pathway in Europeans but showed its activation in African Americans. Integration of SNP-to-Gene analyses-predicted target gene-lists for obesity-associated genetic variants (GWAS-identified SNPs) and BMI-associated transcripts suggested that these SNPs might cause obesity by altering the expression of critical target genes (e.g., *GRB14*) in the muscle. This study provides replication of obesity-associated transcripts and biological pathways in skeletal muscle across ethnicities, but also identifies obesity-associated processes unique in either African or European ancestry populations.

PB1305 A contextual genome-wide perspective on physical activity and its relationship to health and illness

Authors:

M. Galimberti[1,2], D. F. Levey[1,2], J. D. Deak[1,2], K. Adhikari[1,2], C. Overstreet[1,2], H. Zhou[1,2], N. J. Lake[1], K. Harrington[3,4], M. Lek[1], J. Gaziano[4,5,6], M. B. Stein[7,8], J. Gelernter[1,2]; [1]Yale Univ. Sch. of Med., New Haven, CT, [2]VA Connecticut Hlth.care System, West Haven, CT, [3]Boston Univ. Sch. of Med., Boston, MA, [4]VA Boston Hlth.care System, Boston, MA, [5]Brigham and Women's Hosp., Boston, MA, [6]Harvard Med. Sch., Boston, MA, [7]Univ. of California San Diego, La Jolla, CA, [8]VA San Diego Hlth.care System, San Diego, CA

Physical activity (PA) is beneficial for health and can be useful for prevention against numerous diseases. Here, we considered PA from a genome-wide perspective, identifying risk variants and genes, and studying its relationship with other traits of interest.

Using data from the Million Veteran Program (MVP), we created a quantitative physical activity rank (PAR) score, combining different PA intensities -- vigorous, moderate, and light - by summing their frequencies. For PAR phenotype during leisure time, we conducted GWAS analyses for European (EUR) (n=189,812; heritability (h^2)= 0.083±0.005), African (AFR) (n=27,044; h^2= 0.034±0.017), and Latin-American (AMR) (n=10,263; h^2= 0.083±0.036) ancestries. We also completed GWAS in MVP for different contexts of vigorous activity - leisure (V-Leisure), work (V-Work), home (V-Home) - in EUR. We ran a meta-analysis including MVP PAR EUR data and UK Biobank (UKB) summary statistics (only EUR available) on strenuous sport and other exercises (124,842 cases, 225,650 controls; h^2= 0.061±0.003). These two traits had high genetic correlation (rg=0.76±0.03) and the meta-analysis had h^2= 0.060±0.003. A cross-ancestry meta-analysis included UKB and MVP data for EUR, AFR, and AMR ancestry. The EUR and cross-ancestry meta-analyses identified 67 and 70 independent SNPs, respectively. In both cases the strongest association was on chromosome 3 at *CADM2**rs62253088 (EUR *p*-value=2.0×10^{-21}; cross-ancestry *p*-value=6.1×10^{-20}). Genetic correlations and Mendelian Randomization (MR) analyses between the PAR traits and other health outcomes confirmed the protective effects of PA on cardiovascular and respiratory system diseases, metabolic traits, aging, osteoarthritis, and gastroesophageal reflux disease. A multivariable MR analysis evaluated the possibility of body mass index as a confounder confirmed a protective role of PAR versus hospitalization caused by COVID19 (β=-0.067±0.016; *p*-value=2.8×10^{-5}). There were strong genetic differences between the vigorous activity traits. We calculated genetic correlations between V-Leisure, V-Work, and V-Home with previously analyzed traits of interest. We observed 15 traits with significant statistical differences between V-Leisure and V-Work, 12 between V-Leisure and V-Home, and 3 between V-Home and V-Work. Income, leisure screen time, and educational attainment showed significant statistical differences for all three pairs of traits. In conclusion, we provide new insights into the biology of PA, showing genetic differences and advantages according to the context, and the health benefits of PA genetic liability in protecting against several diseases.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1306 A genetic analysis of familial aggregation in inflammatory bowel disease multiplex families.

Authors:

I. Cleynen[1], D. Jans[1], H-S. Lee[2], M. Ferrante[3], S. Vermeire[3]; [1]KU Leuven, Leuven, Belgium, [2]Dept. of Biochemistry and Molecular Biology, Seoul, Korea, Republic of, [3]UZ Leuven, Leuven, Belgium

Inflammatory bowel disease (IBD), encompassing Crohn's disease (CD) and ulcerative colitis (UC), is characterized by chronic inflammation of the gut. In some families, a remarkably high prevalence of disease is seen. Here, we aim to determine the role of the known IBD risk loci in familial aggregation of disease, as well as to study if there are common variants specific to familial IBD. We used a single-centre dataset of imputed immunochip genotypes of 53 IBD families that have at least three affected first-degree relatives (157 CD, 31 UC, 129 unaffected first-degree relatives, 9 healthy spouses) and a sporadic dataset for comparison (1684 CD, 908 UC, 869 controls). For each individual, a polygenic risk score (PRS) was calculated with PRSice based on the IBD summary statistics of de Lange et al (2017), a p-value threshold ≤ 0.01 and MAF ≥ 0.01. As a group, unaffected first-degree relatives have a lower PRS than affected relatives (p=6.27e-4, β(se)=-0.56(0.14)), but still higher than unrelated controls (p=6.74e-4, β(se)=0.44(0.11)). Twenty-four families have a familial PRS - ie the mean PRS of all relatives in a family - that is higher than the mean PRS of sporadic cases; while seven families have a familial PRS that is lower than the mean PRS of unrelated controls (low PRS families). Although in most families the affected members have a higher mean PRS than the unaffected members, this relationship is sometimes reversed, especially in the low PRS families. Family-based association analysis with SAIGE found nine variants to be associated (p<1e-4) with familial IBD. Two independently associated variants, rs2241130 (p=1.19 e-5, β(se)=1.21(0.28)) and rs144641193 (p=8.23e-5, β(se)=1.29(0.33)), reside in a known IBD locus (*IL1RL1-IL18RAP*). Some other variants were also located in genes previously implicated in IBD, either through GWAS [rs72781786 in *PRKCQ* (p=2.93e-5, β(se)=-0.95(0.23))], or functional studies [rs2242601 in *EPHA1* (p=1.43e-5, β(se)=0.70(0.16)) and rs2272766 in *CTSB* (p=5.98e-5, β(se)=0.65(0.16))]. One of the four new loci is rs10772102 (p=6.41e-5, β(se)=-0.64(0.16)), located between *CLECL1*, that mediates immune cell-cell interactions, and *CD69*, that plays a role in T-cell differentiation. Our analysis indicates that common IBD risk variants play an important role in familial aggregation of disease in many multiplex families. Some families however have a very low polygenic risk, indicating shared environmental factors might be relatively more important, or genetic factors not captured by the score, e.g. rare variants, may have contributed. Also, a few loci are specifically implicated in familial IBD, some related to the immune system.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1307 A genome-wide interaction study identified genetic variants modifying the associations of fish oil supplementation with circulating polyunsaturated fatty acids.

Authors:

S. Ihejirika, A. Chiang, A. Singh, K. Ye; Univ. of Georgia, Athens, GA

Fish oil supplements (FOS) are a readily available source of omega-3 polyunsaturated fatty acids (PUFAs), an essential component of human diet. Omega-3 and omega-6 PUFAs have been linked to reduced risks and improved prognosis of a variety of chronic diseases. Previous observational association studies and randomized controlled trials indicate the presence of varying individual responses when administered dietary PUFAs or supplements. Genetic factors may be partially responsible for these varying responses. Here, we performed a genome-wide interaction study to identify genetic variants that modify the associations of fish oil supplementation with circulating PUFAs. We examined 14 phenotypes, including the absolute circulating levels of total PUFAs, omega-3 PUFAs, omega-6 PUFAs, linoleic acid (LA), docosahexaenoic acid (DHA), their relative percentages in total fatty acids, and their ratios. In a cohort of unrelated European-ancestry individuals from the UK Biobank, 113003 individuals took fish oil supplements and 243632 did not, based on the initial recruitment assessment. We identified three interaction loci reaching the genome-wide significance of $P < 5 \times 10\text{-}8$. One locus was identified for the omega-6:omega-3 ratio surrounding the *FADS1-FADS2-FADS3* gene cluster. The minor allele of the top variant (rs174535; T>C, minor allele frequency, MAF = 0.35) is associated with a stronger increase of the omega-6:omega-3 ratio in individuals that take fish oil supplements than those that do not. *FADS1* and *FADS2* are known to be involved in the biosynthesis of long-chain PUFAs. The second locus was for LA% and mapped to the *SLC35F4* gene. The minor allele of the lead variant (rs117393536; C>T; MAF = 0.038) is associated with higher LA% in participants with fish oil supplementation, but with lower LA% in those without. The third significant locus was for total PUFA levels and around the *PLVAP* gene. The minor allele of the top SNP (rs7258084, (G>A; MAF = 0.16) is associated with higher total PUFAs in those taking fish oil supplements, but with lower total PUFAs in those not taking the supplements. Additionally, we will apply the GCTA-GREML to estimate the proportion of phenotypic variance explained by genome-wide interactions with fish oil supplementation. These findings highlight the importance of gene-environment interaction studies to identify more variants explaining the missing heritability and to develop genome-informed personalized nutrition.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1308 A genome-wide meta-analysis connects iron homeostasis to metabolic disease through poly-unsaturated fatty acid synthesis.

Authors:

S. Praggastis[1], A. Gilly[2], B. Crowell[1], L. Ivanova[1], Regeneron Genetics Center, GHS-RGC DiscovEHR Collaboration, Mayo Clinic Project Generation, Penn Medicine BioBank, A. N. Economides[1], S. Hatsell[1], H. E. Lob[1], J. Bovijn[3], L. A. Lotta[4], T. De[5]; [1]Regeneron Pharmaceuticals, Tarrytown, NY, [2]Regeneron Genetics Ctr., Regeneron Pharmaceuticals, Tarrytown, NY, [3]Regeneron Genetics Ctr., Oxford, United Kingdom, [4]Regeneron Genetics Ctr., Tarrytown, NY, [5]Regeneron Genetics Ctr., Arlington Heights, IL

Individuals with genetic iron overload diseases have a higher incidence of type 2 diabetes. In individuals without clinically apparent iron overload serum levels of the iron biomarkers ferritin and transferrin positively correlate with type 2 diabetes. The molecular mechanisms connecting iron and metabolic dysfunction remain unknown. The goal of this study was to identify genetic variations that connect iron homeostasis with metabolism. We performed a large-scale genome-wide association study (GWAS) meta-analysis of iron, glucose-related biomarkers (N = 480,389), and type 2 diabetes (58,379 cases, 530,072 controls) in UKB, GHS, MALMO, UPENN, and SINAI cohorts.. We identified a variant, rs174560, in the *FADS1/FADS2* locus associated with both reduced iron levels and reduced glucose levels (Total Iron Binding Capacity, beta (95%CI) = 0.044 SD (0.035, 0.052), $p = 2.0 \times 10^{-23}$, Glucose, beta (95%CI) = -0.023 SD (-0.027, -0.018), $p = 7.5 \times 10^{-27}$). This variant is a multi-tissue expression quantitative trait locus (eQTL) resulting in reduced expression of *FADS1*, in high linkage disequilibrium with another *FADS1* variant associated with reduced iron in a previous iron GWAS. *FADS1* plays a critical role in long chain polyunsaturated fatty acid (PUFA) synthesis, hepatic depletion of this gene improves glucose clearance and limits adipose tissue expansion *in vivo*. *In vitro FADS1* expression is induced by iron supplementation. Variants in the *FADS1* locus have been strongly associated with blood glucose levels in previous GWAS, the mechanism underlying this association is unclear. Using CRISPR/Cas9 and siRNA technologies, we investigated this connection by targeting *FADS1* expression in the liver of C57Bl/6 mice. Specific reduction of *FADS1* impaired PUFA synthesis, reduced serum iron, and elevated *Hamp* expression confirming *FADS1* involvement in iron homeostasis. Additionally, reducing *FADS1* expression in $HFE^{-/-}$ mice, a genetic model of iron overload, significantly reduced serum aspartate aminotransferase levels (AST). High circulating AST levels are commonly used to diagnose liver damage or disease. This improvement in AST levels indicates reducing *FADS1* expression may be protective against liver damage. Future studies will investigate the molecular connection between *FADS1* and *Hamp* gene expression, as well as glucose metabolism.

Sch. of Med., Boston, MA, [2]Univ. of Washington Sch. of Med., Seattle, WA, [3]Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Univ. of Miami Sch. of Med., Miami, FL, [5]Indiana Univ. Sch. of Med., Indianapolis, IN, [6]Univ. of Washington Sch. of Publ. Hlth., Seattle, WA, [7]Rush Univ. Med. Ctr., Chicago, IL, [8]Univ. of Pennsylvania Sch. of Med., Philadelphia, PA, [9]Columbia Univ. Sch. of Med., New York, NY, [10]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [11]Boston Univ. Sch. of Publ. Hlth., Boston, MA

Background: More than 75 common variant loci account for only a portion of the heritability for Alzheimer's disease (AD). A more complete understanding of the genetic basis of AD can be deduced by exploring associations with AD-related endophenotypes. **Methods:** We conducted genome-wide scans for cognitive domain performance using harmonized and co-calibrated scores derived by confirmatory factor analyses for executive function, language, and memory. We analyzed 103,796 longitudinal observations from 23,066 members of community-based (FHS, ACT, and ROSMAP) and clinic-based (ADRC and ADNI) cohorts using generalized linear mixed models including terms for SNP, age, SNP×age interaction, sex, education, and five ancestry principal components. Significance was determined based on a joint test of the SNP's main effect and interaction with age. Results across datasets were combined using inverse-variance meta-analysis. Genome-wide tests of pleiotropy for each domain pair as the outcome were performed using PLACO software. **Results:** Individual domain and pleiotropy analyses revealed genome-wide significant (GWS) associations with five established loci for AD and AD-related disorders (*BIN1*, *CR1*, *GRN*, *MS4A6A*, and *APOE*) and eight novel loci. *ULK2* was associated with executive function in the community-based cohorts (rs157405, $P=2.19\times10^{-9}$). GWS associations for language were identified with *CDK14* in the clinic-based cohorts (rs705353, $P=1.73\times10^{-8}$) and *LINC02712* in the total sample (rs145012974, $P=3.66\times10^{-8}$). *GRN* (rs5848, $P=4.21\times10^{-8}$) and *PURG* (rs117523305, $P=1.73\times10^{-8}$) were associated with memory in the total and community-based cohorts, respectively. GWS pleiotropy was observed for language and memory with *LOC107984373* (rs73005629, $P=3.12\times10^{-8}$) in the clinic-based cohorts, and with *NCALD* (rs56162098, $P=1.23\times10^{-9}$) and *PTPRD* (rs145989094, $P=8.34\times10^{-9}$) in the community-based cohorts. GWS pleiotropy was also found for executive function and memory with *OSGIN1* (rs12447050, $P=4.09\times10^{-8}$) and *PTPRD* (rs145989094, $P=3.85\times10^{-8}$) in the community-based cohorts. Functional studies have previously linked AD to *ULK2*, *NCALD*, and *PTPRD*. **Conclusion:** Our results provide some insight into biological pathways underlying processes leading to domain-specific cognitive impairment and AD, as well as a conduit toward a syndrome-specific precision medicine approach to AD. Increasing the number of participants with harmonized cognitive domain scores will enhance the discovery of additional genetic factors of cognitive decline leading to AD and related dementias.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1310 A haploblock involving dozens of variable and/or differentially expressed proteins contributes to the large effect of HLA-B57 in HIV-1 control

Authors:

S. Le Clerc[1], M. Rahmouni[1], L. De Marco[1], J-l. Spadoni[1], M. Tison[1], R. Medina-Santos[1], T. Labib[1], J. Noirel[1], J. Fellay[2], P. McLaren[3], J-F. Zagury[1]; [1]CNAM, Paris, France, [2]EPFL & CHUV, Lausanne, Switzerland, [3]Publ. Hlth.Agency of Canada, Winnipeg, MB, Canada

We have conducted a Genome-Wide Association Study (GWAS) to compare a cohort of 543 HIV Elite Controllers (ECs, maintaining a viral load below 1000 copies/ml), with 3272 uninfected control subjects of European descent. By leveraging the latest database, we performed imputation of 35552 Single Nucleotide Polymorphisms (SNPs) within the Major Histocompatibility Complex (MHC) region and identified 2626 significant signals ($p<5.10\text{-}8$). Importantly, we confirmed the presence of well-established MHC signals, including rs2395029, a marker of *HLA-B*57:01*, and rs4418214, associated with the *MICA* gene.In our search for genetic markers associated with super elite control (defined as viral load below 100 copies/ml) in a subset of 217 subjects, we found a large ancestral haploblock within the MHC region, present in all individuals carrying the HLA-B*57:01 allele. This haploblock spans a length of 1.9 MB (1894493 pb) and consists of 379 SNPs exhibiting high linkage disequilibrium (LD). It encompasses a significant portion of the MHC region and is associated with damaging variations in proteins such as NOTCH4 or DXO. Moreover, according to GTEx, this haploblock is associated with differential mRNA expression patterns for several genes such as *MICB*, *HLA-B*, *ZBTB12*, *ZFP57*, *HLA-S*, which could potentially contribute to the control of HIV-1 replication. We extended our investigation to two cohorts of seropositive African-American subjects and examined the SNP rs1131446, in high LD with rs2395029 in Europeans, which tags *HLA-B*57:03* in African populations and is associated with the control of viral load. We found that this SNP together with 43 SNPs in LD form a small haploblock spanning 128 kb in African Americans. The GTEx mRNA expression profile associated with this haploblock in PBMCs from African subjects was highly similar to that observed in Europeans. These findings suggest a potential common mechanism underlying the massive effect of the *HLA-B*57:01/B*57:03* alleles for the control of HIV-1 replication. Overall, our study not only revealed a novel haploblock and molecular mechanisms involved in HIV-1 control but also highlighted the interplay of various factors, including direct anti-HIV-1 activity, and innate/adaptive responses, that could contribute to the elite control phenotype.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1311 A haplotype based extreme phenotype GWAS to functional investigation revealed the function of *CNTNAP5* in glaucomatous neurodegeneration

Authors:

S. Chakraborty, S. Saha Roy, J. Sarma, S. Das, S. Bagchi, S. Saha, S. Bhattacharjee, M. Acharya; Natl. Inst. of BioMed. Genomics, Kalyani, India

Primary angle closure glaucoma is one of the main leading causes of blindness (PACG). As per clinical reports, in India, ~30% of people show a narrow iridocorneal angle (<15°), but out of these only 0.5-1% people develop PACG. In order to rule out anatomical heterogeneity and age as a confounder, we conducted a haplotype based GWAS, where we compared early-onset PACG patients with progressive angle closure (PACG: age <50 years) to older anatomically predisposed (narrow angle <15°) non-glaucomatous individuals (PACS: age >60 years). In our discovery GWAS, we identified 13 SNPs of *CNTNAP5* that were associated with PACG. Subsequent conditional analyses prioritize SNP rs780010 of *CNTNAP5*, where G allele, was significantly (P=0.0024) associated with higher cup-to-disc ratio, which is a clinical parameter directly correlated with glaucomatous neurodegeneration. We further validated rs780010, in a separate replication cohort and observed a significant association (odds ratio=2.307, P=0.012). Integrative bioinformatic analysis showed that the associated intronic region of *CNTNAP5* shows higher transcriptional regulation activity with active enhancer marks. For functional follow-up of risk allele of rs780010 in *CNTNAP5*, we performed a dual-luciferase assay in HEK293T cells and we observed that G allele showed higher luciference activity. As per genome-wide expression data CNTNAP5 is highly expressed in retinal neurones. In order to determine the function of *CNTNAP5* in ocular development and the morphology of the retinal nerve in zebrafish, we thus used morpholino to knockdown *CNTNAP5* in zebrafish. Immunofluorescence (IF) analyses using acetylated tubulin antibody showed significant eye size reductions and retinal nerve thinning in zebrafish morphants (*CNTNAP5*-MO) compared to 5bp-mismatch morpholino injected control fish. Moreover, in spontaneous movement behavioural analysis, *CNTNAP5*-MO zebrafish have a significantly lower average total distance moved when light was on compared to 5bp-mismatch controls whereas no significant difference in movement was observed when light was off, might indicates peripheral vision loss. Additionally, colocalization IF using cleaved-caspase3 and NeuN antibody showed significant neurodegeneration *CNTNAP5*-MO zebrafish. Therefore, our GWAS results not only indicate a genomic association of the *CNTNAP5* with PACG but also imply that it might play in glaucomatous neurodegeneration. Further, post-GWAS functionalization led us to believe that *CNTNAP5* is an important player for neurodegeneration that further leads to retinal nerve thinning, thereby increasing the risk of PACG-associated vision loss.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1312 A key neuroendocrine stress response gene linked with post traumatic stress disorder is rapidly evolving in humans.

Authors:

J. Pecon-Slattery[1,2], D. O'Rourke[1]; [1]Cornerstone Genomics INC, Frederick, MD, [2]Colorado State Univ., Fort Collins, CO

We investigate the evolution of human exome variation within the Primate Order. Our project focused on identification of those genes that rapidly evolve only in humans compared to our extended family of the Primate Order. We queried the CodeXome® database created from exome data sequenced from 55 of 77 exotic genera within Primates, rooted by Scandentia, and anchored to human exome build HG38 coordinates. Our search identified those genes with the highest number of human-specific mutations relative to the rest of the primate phylogeny. Our results included *ADCYAP1*, adenylate cyclase activating polypeptide 1, a gene that encodes a neuropeptide linked with adrenal stress response. We found this gene to have a unique pattern of evolution within the exome and provide detailed insights on rates of mutation, patterns of selection and potential impact in mediating neuroendocrine stress response in primates. This study represents the first comprehensive comparative evidence for how the gene evolves, and baselines natural variation for interpreting potential variants liked with PTSD.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1313 A Large Meta-Analysis Identifies Genes Associated with Anterior Uveitis

Authors:

S. Gelfman[1], A. Moscati[2], S. Huergo[3], R. Wang[4], V. Rajagopal[1], N. Parikshak[4], V. Kumar[1], E. Chen[5], M. Leblanc[6], R. Hazlewood[1], J. Freudenberg[7], B. Cooper[2], A. Ligocki[2], C. Coppola[4]; [1]Regeneron Genetic Ctr., Tarryttown, NY, [2]Regeneron Pharmaceuticals, Tarrytown, NY, [3]Regeneron Pharmaceuticals, Tarryttown, NY, [4]Regeneron Genetics Ctr., Tarrytown, NY, [5]Regeneron, North Brunswick, NJ, [6]Regeneron, Bronx, NY, [7]Regeneron, Tarrytown, NY, [8]Malmo Univ Hosp, Malmo, Sweden

Anterior Uveitis (AU) is the inflammation of the anterior part of the eye, the iris and ciliary body, and accounts for ~80% of Non-Infectious Uveitis. AU is a shared complication of Human Leukocyte Antigen (HLA) class-I-opathies including Ankylosing Spondylitis and Psoriatic Arthritis, and is strongly associated with HLA-B*27 (~20-50% of AU cases are HLA-B*27 positive). We performed the largest AU exome sequencing and meta-analysis to date, including eight independent cohorts consisting of 3,850 ICD defined cases and 916,549 controls. We identified common genome-wide significant loci in *HLA-B* (OR=3.37, p=1.03e-196) and *ERAP1* (OR=0.86, p=1.1e-08). In addition, we found *IPMK* (OR=9.4, p=4.42e-09) and *IDO2* (OR=3.61, p=6.16e-08) as genome-wide significant risk-associated genes based on the burden of rare coding variants. We further divided the cohort into HLA-B*27 positive and HLA-B*27 negative individuals and deciphered the genetic risks for AU in each subgroup.
The *ERAP1* haplotype was strongly protective only for B*27-positive AU (OR=0.73, p=5.2e-10), raising *ERAP1*'s therapeutic potential in the management of AU. Genetic factors affecting the risk for B*27-negative AU also became evident: a novel genome-wide significant common signal near HLA-DPB1 (rs3117230, OR=1.26, p=2.7e-08), *IPMK* and *IDO2* as novel risk genes for B*27-negative AU specifically, and several additional candidate risk genes, including *ADGFR5*, *STXBP2*, and *ACHE*. Taken together, using the largest cohort of AU to date, we deciphered the underlying genetics of B*27-positive and B*27-negative AU and identified novel rare and common genetic signals for both sub-types of disease.

Most genomic therapeutic targets for Alzheimer disease (AD) focus on previously discovered genetic risk variants. However, protective loci against disease formation are alternative targets for pharmaceutical development. To investigate factors driving cognitive preservation, we examined genetic variation in older cognitively unimpaired individuals at high risk for developing AD, defined as having a first degree relative with dementia. Cognitive status was determined as either cognitively impaired (CI) or cognitively unimpaired (CU) using multiple neurocognitive assessments and confirmed by a clinical adjudication board. We performed genome-wide linkage (GWLS) and association (GWAS) studies in the Midwestern Amish, a closed founder population. 946 study individuals were connected into a 14-generation all-connecting pedigree of 8,222 individuals. This pedigree was used to correct our GWAS for relatedness and generate sub-pedigrees for GWLS. The GWAS was performed using the GENESIS R package for autosomes, and XWAS for the X chromosome. 11 single nucleotide polymorphisms (SNPs) were suggestive (p-value<$1x10^{-4}$) in our association analyses, but no SNP reached genome-wide significance. The GWLS were performed using MERLIN for autosomes and MINX for the X chromosome. These were performed using dominant and recessive parametric models and nonparametric models, repeated in both two-point and multipoint analyses resulting in 106 significant (HLOD>3.3) SNPs. We identified the sub-pedigrees driving these significant results for several loci. Most of these locus-specific sub-pedigrees could be combined into larger pedigrees for localized Markov chain Monte Carlo (MCMC) linkage analyses. The chromosome 2p11.2-13.1 region significant in multiple of our linkage analyses retained robust results (LOD=4.87). This region was not seen as suggestive in our GWAS. After further investigation, a biallelic SNP, rs1402906, defined a binding site for the transcription factor (TF) POU1F1a in this region. The segregating minor allele destroys the binding for POU1F1a. This TF regulates a nearby gene, *LRRTM1*, located in an intronic region of the *CTNNA2* gene, which was detected in previous analyses as a risk locus for AD in a subset of this Amish population. Additionally, shared promoters of *LRRTM1* and *CTNNA2* within our significant linkage region regulate alternative isoforms of *CTNNA2* involved in synapse formation and turnover, highlighting this locus as potentially important in the etiology of AD.

Introduction: We constructed and evaluated prediction models for incident hypertension using gene-based polygenic risk scores (PRS) and lifestyle variables.
Methods: We used a gradient boosting trees algorithm (LightGBM) machine learning framework to estimate the probability of incident hypertension, 3-6 years after baseline examination. The data included 12,334 unrelated TOPMed individuals of diverse race/ethnicities, free of hypertension at baseline. We identified genes associated with systolic and diastolic blood pressure (SBP, DBP) by location of associated SNPs (p-value < 5x10-8) from regions identified in multiple multi-ethnic GWAS studies (UKBB+ICBP, MVP, and BBJ). We used PRS-CS to construct PRSs localized to the gene regions. We also included lifestyle factors (smoking status, sleep duration), covariates (age, sex, BMI) and time between the baseline clinic visit to the next exam. We trained four LightGBM models: all models included age, sex, and BMI at baseline. Each of the models did not use one type of variable: 1) used lifestyle measures (smoking status, sleep duration) but did not use PRSs; 2) used PRSs and smoking status but not sleep duration; 3) used PRSs and sleep duration but not smoking status; a final model 4) used lifestyle measures and PRSs. There were N=9,867 individuals in the training dataset, and N=2,467 individuals in the test dataset, in which model performance was assessed. The primary prediction performance metrics was the F1 score, which optimizes both the precision and recall of a prediction model. We evaluated model performance by strata of individuals.
Results: We constructed 231 gene-based SBP and DBP PRSs. Model performance increased with addition of measures, with gene-based PRS having the largest contribution to prediction accuracy: in the combined testing dataset, model 1) without PRSs had F1 score of 2%, model 2) without sleep duration had F1 score of 15%, model 3) without smoking status had F1 score of 13%, while model 4) including all these measures had F1 score of 48%. Model performance varied by strata, with, for model 4), the highest performance being in obese individuals (BMI>30; test dataset N=527; F1 score = 59%), and the lowest performance being in individuals defined with healthy weight (BMI<25; test dataset N=1,010; F1 score = 40%).
Conclusion: Including both lifestyle and genetic measures improves prediction of hypertension development.

Unit, Entebbe, Uganda, [13]Dept. of Non-Communicable Disease Epidemiology, London Sch. of Hygiene and Tropical Med., London, United Kingdom

Background: Observational studies have shown associations between haematological traits and type-2 diabetes mellitus (T2D), however, these findings are limited by cofounders. Our study utilizes Mendelian randomization (MR) approach which addresses the above limitation, to investigate the effect of haematological traits like white blood cell (WBC) count, haemoglobin (Hb) levels, and red blood cell (RBC) count on T2D in African ancestry individuals. **Method:** The participating cohort includes participants of African ancestry in the Blood Cell consortium (n = 15,171) and the Million Veteran Program dataset (n = 53, 445). We applied a univariable, bidirectional, and multivariable 2-sample MR to estimate the causal relationship between 15 haematological traits and T2D using GWAS summary statistics. Genetic instruments for haematological traits and T2D were selected and these included only the variants that attained a genome-wide significant level of $P \leq 5 \times 10^{-8}$. The inverse-variance weighted MR approach was used to estimate causal effects in the main analysis, in addition to sensitivity analyses that are robust to pleiotropic variants. **Results:** In the main inverse-variance weighted (IVW) MR estimates, genetically determined mean corpuscular hemoglobin concentration (MCHC), mean corpuscular hemoglobin (MCH) and mean corpuscular volume (MCV) levels were associated with decreased risk of T2D with an OR_{IVW} of 0.867 per g/dL difference in MCHC levels (95% CI: 0.803-0.937; $P_{IVW} = 0.00028$), OR_{IVW} of 0.888 per pg difference in MCH levels (95% CI: 0.835-0.943; $P_{IVW} = 0.00012$) and OR_{IVW} of 0.911 per fL difference in MCV levels (95% CI: 0.856-0.969; $P_{IVW} = 0.0313$) respectively. While genetically high levels of RBC were significantly associated with an increased risk of T2D with OR_{IVW} of 1.105 per 10^{12}/L difference in RBC levels (95% CI: 1.027-1.189; $P_{IVW} = 0.0076$). For WBC traits, there was evidence of protective effects of total WBC count (WBC) [OR= 0.941 (CI: 0.909-0.974, P= 0.0006] and neutrophil count (NEU) [OR= 0.940 (CI: 0.917-0.965, P= .95E-06] on T2D. In the reverse analysis, genetically determined T2D was associated with lower levels of RBC distribution width (RDW) and elevated levels of lymphocyte count (LYM). The multivariable analysis showed that genetically predicted MCH, MCHC, RDW, MCV, and lower levels of WBC were significantly associated with a decreased risk of T2D. **Conclusion:** These findings suggest that haematological traits play a role in the development of T2D. However, further research is needed to validate and explore the biological pathways involved in these associations.

PB1317 A Multi-Ancestry Meta-Analysis of GWAS for Mitral Valve Prolapse Identifies 34 Novel Genomic Regions

Authors:

A. Small[1], A. Georges[2], J. Lee[3], C. Roselli[4], D. Milan[5], P. T. Ellinor[6], Y. Sun[7], K. Cho[8], P. Wilson[7], A. Ganna[9], G. Peloso[10], N. Bouatia-Naji[11], P. Natarajan[12]; [1]Brigham and Women's Hosp., Boston, MA, [2]Université de Paris, Inserm U970, Paris, France, [3]Broad Inst. of MIT and Harvard, Finnish Inst. for Molecular Med., Cambridge, MA, [4]Broad Inst., Cambridge, MA, [5]Leducq Fndn., Boston, MA, [6]Massachusetts Gen. Hosp. / The Broad Inst., Boston, MA, [7]Emory Univ., Atlanta, GA, [8]VA Boston Hlth.care System, Boston, MA, [9]Helsinki Inst. of Life Sci. HiLIFE, Helsinki, Finland, [10]Boston Univ., Boston, MA, [11]INSERM, Paris, France, [12]Broad Inst. of Harvard and MIT, Cambridge, MA

Introduction: Mitral valve prolapse (MVP) is a common pathology of the mitral valve characterized by thick, redundant mitral valve leaflet tissue. MVP manifests clinically as mitral regurgitation, and carries significant morbidity including valve replacement, heart failure, and sudden cardiac death. The genetics of MVP are only partially understood.
Methods: We performed a meta-analysis of genome-wide association studies (GWAS) for MVP incorporating 14,733 MVP cases among 1,485,696 individuals from the Million Veteran Program, Finngen, and a recently published GWAS of MVP by Roselli et al. We functionally annotated potential causal variants at MVP loci by evaluating for missense variants and variants with potential regulatory functions in mitral valve tissue (both normal and diseased) or cardiac related tissues (heart and aorta). Results were extended with transcriptome wide association analysis (TWAS) incorporating cardiovascular relevant tissues from the GTEx database.
Results: There were 49 unique genome-wide significant (GWS) genomic regions, of which 34 were novel. Potential causal variants with relevance in mitral valve tissue or heart tissue were identified in 47 out of 49 genomic regions. Of these, 25 loci included either missense variants or variants overlapping a promoter active in valve tissue as suggested by ATAC-seq data. MVP-associated variants overlapping candidate distal cis-regulatory elements active in either mitral valve tissue or heart tissue were identified in the remaining 22 loci. TWAS corroborated gene-expression associations for 24 loci, and further prioritized several sub-GWS loci, including *MFAP2*, which encodes an important extracellular matrix (ECM) protein. Novel genes corresponded to key pathways in TGF-ß signaling (*SMAD3*), ECM remodeling (*TIMP3*, *ADAMTS10*, *PLEC*, *LOXL1*, *SPTBN1*), and inflammation (*PDLIM7*).
Conclusions: We performed the largest multi-ancestry GWAS to-date of MVP, identifying 34 novel genomic regions with key functions in TGF-ß signaling, ECM remodeling, and inflammation.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1318 A new gene expression environmental decomposition method applied for the study of T2D in Mexican Americans

Authors:

M. Almeida, E. G. MANUSOV, V. Diego, X. Mao, S. Laston, A. Leandro, J. Blangero, S. Williams-Blangero; Univ. of Texas Rio Grande Valley, Brownsville, TX

Background: Type 2 diabetes (T2D) is a complex metabolic disease and Mexican Americans are specially affected by this condition. Many studies were proposed for the identification of candidate genes associated with T2D risk, but their combined contribution substantially fail to account for the total T2D's heritability estimate. Gene expression, like any other quantitative phenotype, is the sum of genetic and environmental variances. Gene-by-environment (GxE) interaction analysis may contribute to the identification of additional candidate genes. We propose a new method to estimate the environmental contribution to the expression of candidate genes and the identification of T2D risk genes on a large cohort of Mexican Americans in south Texas.
Methods: A total of 525 Mexican American participants from an extended family study were evaluated and assessed for obesity, diabetes, hypertension, hyperlipidemia, and depression. mRNA sequencing was performed on blood samples collected from participants. For gene expression, we wrote a linear model $\boldsymbol{y=XB + g + e}$ where $\boldsymbol{X;}$ is a matrix of covariates, $\boldsymbol{B}$ is the intercept, $\boldsymbol{g}$ and $\boldsymbol{e;}$ are respectively genetic and environmental effects. The inverse normalized residuals are denoted $\boldsymbol{D= (y - XB)}$**.** The phenotypic covariance matrix $\boldsymbol{\Sigma}$; defined as: $\boldsymbol{\Sigma; = Kh^2 + I(1-h^2)}$, where **K**; and **I**; respectively give genetic relationship and identity matrices, and $\boldsymbol{h^2}$ is the heritability. The random genetic value of individual *I* is defined as $\boldsymbol{gi= h^2 K_i \Sigma;^{-1}_{-i} D_{-i}}$ where $\boldsymbol{k_i}$ and $\boldsymbol{\Sigma;^{-1}_{-i}}$ where terms where individual i was excluded. The environmental effects vector (EEV) of each gene defined as the subtraction of genetic effects term from the residuals vector.**Results:** Significant associations were found between PNMA1 ($1.2*10^{-5}$), TPRX1($7.3*10^{-5}$), GRIK3 ($1.1 * 10^{-4}$) and CTLA4 ($1.7* 10^{-4}$) and T2D status. These findings support the role of genetic factors interacting with the environment and influencing T2D status of Mexican Americans individuals.**Discussion:** CTLA4 gene is a member of the immunoglobulin superfamily and encodes a protein which transmits inhibitory signals to T cells. Mutations in this gene have been associated with insulin-dependent diabetes mellitus. The GxE interactions identified in this study provide insight into the complex interplay between environment (lifestyle and diet) and the expression of target genes. CTLA4 expression may serve as a potential diagnostic marker for T2D in Mexican American population.**Conclusion:** Our study highlights the importance of GxE interactions in T2D among Mexican Americans. The associations between CTLA4 and T2D provide valuable insights into the inflammation pathways to this condition.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1319 A novel non-recurrent CNV deletion involving *TBX4* leaving *TBX2* intact, in a newborn with congenital alveolar dysplasia.

Authors:

J. Karolak[1], K. Bzdęga[1], M. Biela[2], G. Deutsch[3], J. Kitzmiller[4], M. Rydzanicz[5], R. Płoski[5], J. Whitsett[4], R. Śmigiel[2]; [1]Poznan Univ. of Med. Sci., Poznan, Poland, [2]Med. Univ. of Wroclaw, Wroclaw, Poland, [3]Univ. of Washington Sch. of Med., Seattle, WA, [4]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, [5]Med. Univ. of Warsaw, Warsaw, Poland

Congenital alveolar dysplasia (CAD) belongs to rare lethal lung developmental disorders (LLDDs) in neonates that manifest as acute progressive respiratory failure and pulmonary arterial hypertension refractory to treatment. While largely genetically undefined, recently, a number of cases of CAD have been reported to result from abnormalities involving 17q23.1q23.2 or 5p12. Most copy-number variant (CNV) deletions at 17q23.1q23.2 were recurrent and encompassed two closely located genes *TBX4* and *TBX2*. In mice, depletion of *Tbx4* and *Tbx2* were found to lead to hypoplastic lungs. However, one intragenic frameshifting CNV deletion and four single-nucleotide variants (SNVs) involving *TBX4*, but not *TBX2*, have been described in LLDD neonates. Our recent histopathological and transcriptomic analyses of *TBX4*-deficient LLDD lungs have revealed that TBX4 can regulate expression of the lung endothelial *TMEM100* gene that is also involved in lung development. Here, using molecular and histopathological evaluation, we studied a newborn with clinically suspected LLDD. A male proband born from uncomplicated pregnancy in good condition and without any structural malformations, from the first hours of life manifested severe respiratory insufficiency refractory to treatment and he died at 27th day of life. Family trio genome sequencing revealed in the proband a novel de novo ~1.07 Mb heterozygous non-recurrent CNV deletion at 17q23.2 (chr17:61,451,736-62,521,987, hg38), encompassing *TBX4* but leaving *TBX2* intact. Histopathological evaluation demonstrated lobular maldevelopment with lung growth arrest along the spectrum of CAD, pulmonary arterial hypertrophy, and superimposed acute alveolar inflammation. Immunofluorescence confocal microscopy revealed lack of sacculation and atypical lung tubules lined by AT2-like cells staining intensely for SFTPB and ABCA3; PECAM staining demonstrated abnormal pulmonary vessels without close apposition to respiratory epithelial cells. Immunostaining for TMEM100 in capillaries was significantly reduced compared to a control lung. Our results indicate that perturbations of *TBX4*, rather than *TBX2*, can cause severe lung phenotypes in humans and further imply the possible molecular interactions between TBX4 and TMEM100 that, when disrupted, can lead to lung disease.

PB1320 A Pilot project: Examining gender-specific transcriptional alterations in Myalgic Encephalomyelitis/Chronic Fatigue Syndrome patients under stressful conditions.

Authors:

R. Pangeni[1], J. Gamer[1], D. Van Booven[2], O. Zarnowski[1], M. Perez[3], N. Klimas[1], E. Oltra[4], L. Nathanson[1]; [1]Nova Southeastern Univ., Fort Lauderdale, FL, [2]Univ Miami Miller Sch Med, Miami, FL, [3]3321 Coll. Ave.,, Fort Lauderdale, FL, [4]Catholic Univ. of Valencia, Valencia, Spain

Background Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS) is characterized by symptoms such as profound fatigue, cognitive difficulties, muscle and joint pain, gastrointestinal disturbances, neurological impairments, and hormonal irregularities. The precise mechanisms involved in the development and advancement of this disorder are not yet fully understood. **Objectives** This pilot research project aims to assess how sex differences in individuals with ME/CFS impact their response to stress, specifically through an exercise challenge. Additionally, it highlights the importance of considering sex differences in the diagnosis and treatment of ME/CFS. **Methods** We utilized RNA-seq to examine the differential gene expression (DG) in peripheral blood mononuclear cells of 20 female ME/CFS patients, 14 male ME/CFS patients, and 40 healthy controls (HC) who were matched in for sex, age, and BMI. We evaluated the gene expression changes at three time points: T0 (baseline), T1 (at maximal exertion), and T2 (4 hours into recovery after T1). To ensure consistency, we excluded genes located on the sex chromosomes and performed separate analyses for men and women. Our focus was to compare the response to exercise within each group (ME/CFS patients and HC) between different time points. **Results** In the male ME/CFS cohort, pathways associated with immune cell signaling, particularly IL-12, and natural killer cell cytotoxicity were activated during exercise. However, the female ME/CFS patients did not exhibit significant changes in gene expression that met the study's criteria for inclusion. During the recovery period after exercise, male ME/CFS patients demonstrated distinct alterations in the regulation of specific cytokine signals, including IL-1β. On the other hand, female ME/CFS patients displayed significant changes in gene networks related to cell stress, response to herpes viruses, and NF-kβ signaling. These functional pathways and differentially expressed genes identified in this pilot project provide valuable insights into the sex-specific pathophysiology of ME/CFS. **Conclusion** The identification of sex-specific biomarkers and therapeutic targets in ME/CFS holds great potential for understanding the distinct onset and progression of this disease in different sexes.

PB1321 A polygenic risk score explains variation in monogenic autoimmunity presentation.

Authors:

A. Luckett, G. Hawkes, M. Weedon, R. Oram, M. Johnson; Univ. of Exeter, Exeter, United Kingdom

Introduction: Rare mutations in single genes can lead to syndromes of autoimmunity. Individuals with those mutations present with a variety of autoimmune disorders, including early-onset autoimmune diabetes (diagnosis typically <2 years), though not all develop the disease. We aimed to assess whether polygenic risk, which has recently been shown to have a modifying effect in other monogenic disorders, could explain this variable phenotypic presentation.
Method: We calculated a type 1 diabetes genetic risk score (T1D-GRS) in individuals in the Extremely Early-onset Type 1 diabetes (EXE-T1D) cohort with monogenic autoimmune diabetes (n=71, *AIRE* n=3, *FOXP3* n=36, *IL2RA* n=5, *LRBA* n=11, *STAT3* n=7, *TNFAP3* n=1 and Trisomy 21 n=8), monogenic autoimmunity without diabetes (n=56, *AIRE* n= 54, *FOXP3* n= 1, *STAT3* n=1), and non-autoimmune monogenic neonatal diabetes (NDM) (n= 200, *ABCC8* n=22, *EIF2AK3* n= 34, *INS*= 74, *KCNJ11* n=70). The T1D-GRS model included 67 SNPs (35 HLA and 32 non-HLA variants). We investigated the constituent parts of the T1D-GRS model to assess the contribution of HLA and non-HLA common variants to the phenotype of monogenic autoimmune diabetes.
Results: Individuals with monogenic autoimmune diabetes had higher T1D-GRS (mean = 11.6, 95% CI 11.1-12.1) compared to those with monogenic autoimmunity without diabetes (mean=10.8, 95% CI 10.3-11.3, *P*=0.03) and non-autoimmune NDM (mean= 10.0, 95% CI 9.7-10.3, *P*=1.3e-07). Individuals with monogenic autoimmune diabetes had a higher HLA class II genetic risk score compared to those with non-autoimmune NDM (beta = 0.82 SD, 95% CI 0.48-1.16, *P*= 1.9e-06).
Conclusions: A polygenic risk score for type 1 diabetes explains variation in monogenic autoimmunity expressivity, partly through higher HLA class II risk. How the monogenic and polygenic risks interact is an area for future study and may lead to improved understanding of disease aetiology.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1322 A risk locus on chromosome 12 is suggested by genome-wide association study in Puerto Ricans for Alzheimer disease

Pericak-Vance[1,4,6]; [1]John P Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Univ. Central del Caribe, Bayamon, PR, [3]Clinica de la Memoria, San Juan, PR, [4]Dr John T Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [5]Dept. of Anatomy, Physiology, and Genetics, Uniformed Services Univ. of Hlth.Sci., Bethesda, MD, [6]Dept of Neurology Univ. of Miami Miller Sch. of Med., Miami, FL

Background: Increasing ancestral diversity in genetic studies is important to define the genetic background of Alzheimer disease (AD). Hispanic populations are underrepresented in AD genetic studies. The Puerto Rican (PR) population, the second largest Hispanic group in the continental US, provides an opportunity to assess Hispanic risk for AD. In addition, the PR population is admixed, with average ancestry values of 69% European (EU), 17% African (AF), and 14% Native American (AI). We performed a genome-wide association study (GWAS) in the PR population to identify novel AD susceptibility loci and characterize known AD genetic risk loci.
Methods: The PR dataset includes Whole Genome Sequencing (WGS) and phenotype data from 639 individuals (334 cases; 305 cognitively unimpaired (CU)). We employed a generalized linear mixed model for the GWAS analysis using SAIGE software. Two separate models were analyzed; the first model accounted for sex, age, and population substructure, and the second model also included the dosage of *APOEe4*. A genetic relationship matrix was included as a random effect to account for relatedness in both models. We assessed the polygenic risk score (PRS) using the effect sizes from summary statistics from the non-Hispanic White (NHW) study.
Results: Variants at *APOE* locus ($pv=7.2x10^{-8}$; chr19) and 10 additional loci reached suggestive significance ($pv<1x10^{-6}$); however, there was no genome-wide significance ($pv<5x10^{-8}$) region and only 3 loci were significant in both models: *NACC2*, *AKR1C2*, and *SCN8A*. In addition, 13 known AD loci - *ADAM17*, *ANKH*, *RASGEF1C*, *TREM2*, *SEC61G*, *CLU*, *TSPAN14*, *TPCN1*, *FERMT2*, *DOC2A*, *PRDM7*, *SCIMP*, and *WNT3*- showed nominal significance. NHW-derived PRS has a good prediction power (AUC=0.62) in the PR dataset.
Conclusions: PR GWAS identified a promising AD risk locus in *SCN8A*, a gene associated with reduced pathogenesis of AD in previous mouse model studies. Our results further corroborated chr 12 findings from previous linkage studies. In addition, our study replicated 13 known AD loci, and showed good predictive power with NHW-derived PRS, suggesting that may be related to the high EU ancestral background of the PR population. Including genetic studies for underrepresented and ancestral-heterogeneous populations such as the PR, provides an important opportunity to evaluate the role of admixed populations in AD.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1323 A sex-stratified analysis of the genetic architecture of human brain anatomy

Authors:

r. shafee[1], D. Moraczewski[1], S. Liu[2], T. Mallard[3], A. Thomas[1], A. Raznahan[4]; [1]Natl. Inst. for Mental Hlth.(NIMH), Bethesda, MD, [2]Natl. Inst.s of Mental Hlth., Bethesda, MD, [3]Massachusetts Gen. Hosp., Boston, MA, [4]NIMH Intramural Res. Program, NIH, Bethesda, MD

Large open biobanks have dramatically advanced our understanding of genetic influences on human brain anatomy - but much of this work has combined rather than compared males and females. Here, we screen for potential sex-biases in the influence of common genetic variants on brain anatomy.T1-weighted magnetic resonance images in the UK Biobank (14301 males, 16054 females of “white British ancestry”, age = 64.3 +/- 7.5 yrs) were used to obtain (FreeSurfer) gray matter volume (GMV), surface area (SA) and cortical thickness (CT) for 360 cortical regions (HCP atlas, covaried for total GMV, SA and CT respectively). Additionally, 23 subcortical volumes and mean cortical thickness, total surface area and total brain volume were included. Genotypic data consisted of 17 million SNPs after standard quality control. For each phenotype, I) sex-specific relatedness matrices (GRMs) in GCTA were used to calculate SNP-heritability (h^2) for each phenotype in males and females separately; II) GCTA was also used to estimate autosomal genetic correlation (r_g) between the sexes, and III) sex-stratified GWASs were performed in PLINK to estimate SNP-level sex-differences. SNPs with significant sex-differentiated effects were mapped to genes using FUMA which in turn were analyzed for enrichment of GO categories. Two p-values cutoffs were used for significance at this step: 1.4e-10 ("stringent" - corrected genome wide and across phenotypes) and 5e-8 ("relaxed" - genome wide).After correction for multiple comparisons, no individual phenotype showed a statistically significant sex-difference in h^2. However, paired t-tests between the sexes revealed that mean h^2 for regional GMV and SA tended to be higher in females than males (p = 6.5e-10 , p = 4.3e-6 respectively). In GCTA bivariate analyses, 2 phenotypes showed $r_g < 1$ between the sexes surviving correction for multiple comparisons (Posterior Insula (left) r_g = 046 +/- 0.11, Brodmann area 5m r_g = 0.50+/-0.11). Of the two SNPs that showed significant sex-difference in GWAS at the most stringent cut-off, one (chr16:rs113078989; SA of supplementary motor region; male-specific effect) mapped to RBFOX1, a gene linked to multiple neuropsychiatric and neurodevelopmental disorders. Combined enrichment analysis of the genes mapped from SNPs passing the "relaxed" threshold did not show enrichment of any gene ontology category. Notably, sex-biased SNPs were not enriched on the X-chromosome or in sex-steroid related pathways. This work suggests that common variant influences on human brain anatomy are largely convergent between males and females, with a few exceptions that will guide future research as biobanks continue to grow in size.

PB1324 A systematic analysis of the shared and specific genetic signals among 15 autoimmune diseases.

Authors:

X. Dang[1], Y. Wang[2], W. Yang[1]; [1]The Univ. of Hong Kong, Hong Kong, China, [2]The Chinese Univ. of Hong Kong, Shenzhen(CUHK-SZ), China

Genome-wide association studies (GWAS) have discovered thousands of genetic loci associated with various autoimmune diseases, and nearly half of these loci are shared by multiple traits. These shared loci provide insights into the common genetic factors contributing to the development of autoimmune diseases. However, the specific or shared association mechanisms for these diseases require further investigation.

Our study conducted a comprehensive analysis of the association signals for the 15 most common autoimmune diseases using data from the GWAS catalog. In particular, we obtained 4,017 disease-associated variants and defined loci and shared and independent association signals based on linkage disequilibrium(LD). Our analysis identified 353 loci that are associated with at least two autoimmune diseases out of 620 loci for all 15 autoimmune diseases, and then clustered 325 pleiotropy signals and 1,261 disease-specific signals(R2 >= 0.8). Since the majority of variants are located within noncoding regions, it is challenging to identify target genes, cell types, and biological functions. Therefore, we integrated multimodal genomic data and used five evidence-based strategies to identify and prioritize the candidate target genes of these signals. We also applied pathway analysis and gene network construction to analyze these target genes of pleiotropic and disease-specific signals, and compared the difference and similarity of autoimmune diseases.

Through evaluating all signal-target gene pairs, we analyzed the shared and specific genes, pathways, and cell types among these 15 autoimmune diseases. We identified that about 41.2% and 27.4% of the target genes were shared by at least two and three autoimmune diseases, respectively, in which *STAT4, IL12RB2,* and *BACH2* were the most pleiotropic genes shared by at least nine diseases. Analyzing all these signal-linked target genes, we found they were enriched in the T-cell differentiation, immunological disease, and virus infection pathways. Our systematic analysis of association signals from target genes, regulated immune cells, and pathways using multimodal genomic data for 15 autoimmune diseases reveals the similarities and differences among these diseases, and open a window for facilitating further functional characterizations, drug repurposing and discovering novel drug targets.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1325 A trans-ancestry clinical validation of a polygenic score for height in a cohort of 13,194 children

Authors:

J. Shelley[1], M. Shi[2], S. Van Driest[3], J. Simmons[2], J. Mosley[2]; [1]Vanderbilt Univ. Sch. of Med., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]NIH, Bethesda, MD

Background: Short stature in children, defined as a height more than 2 standard deviations below expectations, may be an early manifestation of systemic disease. The first step in the evaluation for short stature is to determine whether the child has familial/genetic short stature, defined by a deviation between the child's measured height and expected height based on the parental heights. Contemporary polygenic scores (PGS) for height capture up to 40% of variance in adult heights. We tested whether a trans-ancestry PGS for height associates with meeting short stature criteria and whether the PGS associates with familial short stature.

Methods: We utilized a published trans-ancestry PGS (967,127 SNPs) from a GWAS of height in 5.4 million adults. We curated a retrospective cohort of 13,194 children (ages 2-19) of diverse ancestries (68.9% European [EUR], 22.8% African [AFR], 5.9% Hispanic [HIS], and 2.4% Asian [AS]) using VUMC's EHR-linked biobank (BioVU). We used linear and logistic regression to test the association between the PGS and (1) measured height and (2) having a height qualifying as short stature, respectively. AUROC analyses were used to test the ability of a PGS to discriminate between children with and without short stature. We then identified 432 children with parental height measurements who met the criteria for short stature. We used logistic regression to test whether the PGS and mid-parental height (MPH) was significantly different between familial and non-familial short stature. Asian ancestry was excluded from this analysis as there were fewer than 10 individuals with parental heights available. All analyses were adjusted for age, sex, and within-ancestry principal components (PCs).

Results: The PGS explained 15.3% (EUR), 6.8% (AFR), 7.5% (HIS), and 3.9% (AS) of the variation in children's heights. The PGS was significantly associated with short stature: EUR (OR per s.d. decrease in PGS=1.74 [95%CI: 1.61-1.89], AUC=0.68), AFR (1.79 [1.37-2.35], AUC=0.64), HIS (2.11 [1.43-3.17], AUC=0.68), and AS (1.93 [1.16-3.22], AUC=0.68). In the cohort with parental height data available, 97 (22.4%) met criteria for familial short stature (FSS). The PGS was not significantly associated with FSS in children of European (OR per s.d. decrease in PGS=1.02 [0.78-1.32], p=0.89), African (2.17 [0.58-1.20], p=0.29) or Hispanic (1.33 [0.20-9.14], p=0.75) ancestries.

Conclusion: While a trans-ancestry PGS associates with short stature and can discriminate between those with and without short stature, it does not associate with familial short stature among a cohort of children with short stature.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1326 A weak effect of *PIEZO1* short tandem repeat deletions on severe malaria susceptibility estimated in 18,000 samples.

Authors:

E. Leffler[1,2,3], G. Band[2,3], A. E. Jeffreys[2], K. Rowlands[2], C. Hubbart[2], K. Bojang[4], D. J. Conway[5], M. Jallow[6], F. Sisay-Joof[4], U. D'Alessandro[4], C. M. Res. Inst. (KEMRI)--Wellcome Trust Res. Programme, Kilifi, Kenya, [8]Nuffield Dept. of Med., Univ. of Oxford, Oxford, United Kingdom, [9]Dept. of Med., Imperial Coll., London, United Kingdom, [10]Malawi-Liverpool--Wellcome Trust Clinical Res. Programme, Queen Elizabeth Central Hosp., Coll. of Med., Blantyre, Malawi, [11]Liverpool Sch. of Tropical Med., Liverpool, United Kingdom, [12]Coll. of Osteopathic Med., Michigan State Univ., East Lansing, MI, [13]Big Data Inst., Univ. of Oxford, Oxford, United Kingdom

PIEZO1 is a mechanosensitive ion channel involved in regulating hydration levels in red blood cells, an important factor in their susceptibility to infection by malaria parasites. E756del, a deletion allele within a short tandem repeat (STR) in *PIEZO1*, is common in many African populations and has been proposed to influence susceptibility to malarial disease, but association evidence has been inconsistent. Here, we use Illumina sequencing of amplicons covering the *PIEZO1* STR to genotype 5,198 severe malaria cases and 8,176 population controls from The Gambia, Kenya, and Malawi. We find no strong evidence for association but estimate the same direction of effect for E756del as two previous studies. A meta-analysis across all three (7,864 cases and 10,105 controls) indicates weak evidence for a protective effect (OR=0.92, P=0.011). This unifies previous reports and supports a much smaller effect than originally suggested. Finally, although E756del is at higher frequency in African populations than other regions including Europe, which could be consistent with a selective effect, we show that this frequency differentiation is not exceptional compared with STR variants genome wide. Ultimately, our study reinforces the importance of large association studies to achieve sufficient power to estimate smaller effects and suggests that many such variants likely remain to be uncovered for malaria susceptibility.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1327 ABO gene, *Faecalicatena lactaris*, and Covid-19 Susceptibility and Clinical Outcomes

Authors:

W. Xian[1], V. Napolioni[2], J. Huang[1,3]; [1]Southern Univ. of Sci. and Technology, Shenzhen, China, [2]Sch. of BioSci.s and Vet. Med., Univ. of Camerino, Camerino, Italy, [3]Inst. for Global Hlth.and Dev., Peking Univ., Beijing, China

Background: The gut microbiota has been reported to be associated with both non-communicable diseases and infectious diseases including Covid-19. Emerging large GWAS on tens of microbiota identified strong host genetics loci including ABO, which has been reported for significant association with Covid-19 susceptibility and clinical outcomes. **Methods**: We conducted two-sample Mendelian randomization (MR) studies using latest genome-wide association study (GWAS) summary statistics. For the exposure, we focused on *Faecalicatena lactaris*, *Bifidobacterium* and *Enterococcus faecalis*, which are strongly influenced by host genetics. For the instrumental variable, we used the lead single nucleotide polymorphism (SNP) that is associated with each of these three bacteria. For Covid-19 outcome, we included GWAS summary statistics of three phenotypes (susceptibility, hospitalization, severity) made publicly available by the Covid-19 host genetics initiative (HGI, release 7), and two Covid-19 GWAS with over 24,000 Covid-19 critical illness cases (non-HGI). TwoSampleMR R package (v0.5.6) was used for the data harmonization, and MR Base (v0.5.0) was used for calculating the point estimate (Wald Ratio) of causation. For sensitivity analyses, we included more instrumental variants by lowering P-value threshold and by applying methods including inverse variance weighted method, maximum likelihood method, weighted median method, and MR-Egger. We further applied colocalization analyses in the ABO locus to establish the causal link down to the expression quantitative trait locus (eQTL) level. **Results**: Among the 15 pairs (3 bacteria x 5 Covid-19 phenotypes) we tested, we found significant causal association between the *Faecalicatena lactaris* and all five Covid-19 phenotypes: HGI susceptibility ($p = 1.48\times10^{-11}$), HGI hospitalization ($p = 3.95\times10^{-23}$), HGI severity ($p = 4.45\times10^{-80}$), non-HGI critical illness ($p = 7.03\times10^{-12}$), non-HGI infection ($p = 4.47\times10^{-19}$). The effect size is all positive, indicating the abundance of *Faecalicatena lactaris* increases the likelihood of Covid-19 susceptibility and clinical outcomes. Sensitivity analyses did not detect any heterogeneity and horizontal pleiotropy. Colocalization analyses showed that the *Faecalicatena lactaris* is mainly regulated by the expression of ABO locus. **Conclusion**: Based on latest GWAS of microbiota and Covid-19, this study points to a plausible mechanism on how*Faecalicatena lactaris* affects directly Covid-19 susceptibility and clinical outcome and also mediates the effect of ABO blood groups.

PB1328 Abstract: Investigating the causal relationship between glycemic trait and cardiac structure/function using Mendelian randomization

Authors:

T. Daria[1,2], H. Alkhairo[1,2], M. G. Levin[3,4], S. M. Damrauer[3,5], P. S. Tsao[6,7], J. R. Priest[7,8], J. P. Pirruccello[9], J. B. Echouffo Tcheugui[10], C. Tcheandjieu[11,12]; [1]Gladstone Inst., San Francisco, CA, [2]Univ. of California San Francisco, San Francisco, CA, [3]Corporal Michael Crescenz VA Med. Ctr., Philadelphia, PA, [4]Div. of Cardiovascular Med., Dept. of Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [5]Dept. of Surgery and Genetics, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [6]VAPAHCS/Stanford Univ., Palo Alto, CA, [7]Dept. of Med., Stanford Univ., Stanford, CA, [8]Tenaya Therapeautics, South San Francisco, CA, [9]Div. of Cardiology, Univ. of California San Francisco, San Francisco, CA, [10]Dept. of Med., John Hopkins Univ. Sch. of Med., Baltimore, MD, [11]Gladstone Inst., San Francisco, CA, [12]Dept. of Epidemiology and Biostatistics, Univ. of California of San Francisco, San Francisco, CA

Impaired glucose regulation is an established risk factor for cardiovascular diseases. However, it remains unclear whether this relationship is causal. Here, we investigated the relationship between glucose exposure and MRI-derived measures of cardiac structure and function using Mendelian randomization (MR).
We used an inverse-variance weighted method to perform a two-sample MR using summary statistics from genome-wide association studies of glycemic traits (fasting insulin FI, fasting glucose FG, glycated hemoglobin HbA1c, 2-hour glucose after oral challenge 2hGlu), type 2 diabetes (t2d) and MRI-derived measures of cardiac structure/function (left ventricular ejection fraction (LVEF), left ventricular end-systolic volume (LVESV), diastolic (LVEDV) or stroke volumes (LVSV) myocardial interstitial fibrosis (MIF)). We used the MR-Egger method for sensitivity analysis and assessed pleiotropy using the MR-PRESSO method.
We found evidence for associations between glycemic traits and cardiac structure/function measures. Genetically predicted increased FG and HbA1c were associated with increased LVEF (beta=0.11, p=0.02, beta=0.15, p=0.03 for FG and HbA1C respectively) and decreased LVESV (beta=-0.11, p=0.01, beta=-0.16, p=0.009 for FG and HbA1C respectively). FI was associated with decreased LVESV (beta=-0.25, p=0.007), LVEDV (beta=-0.21, p=0.05) and MIF (beta=-0.2, p=0.02). Lastly, t2d was associated with a decrease in LVESV (beta=-0.03, p=0.01), LVEDV (beta=-0.03, p=0.004) and LVSV (beta=-0.03, p=0.004).
Genetic evidence supports the effects of glycemic traits on left ventricular structure. These findings provide additional causal evidence to support the epidemiological evidence that high glucose exposure is associated with cardiac dysfunction and the beneficial effects of glucose-lowering medications on cardiac function recently demonstrated in large randomized controlled trials. Further research is needed to better understand the mechanisms behind these relationships.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1329 Accelerating psychiatric genetics research in Latin American populations, Latin American Genomics Consortia efforts and Novel findings

Authors:

J. Montalvo-Ortiz[1], P. Giusti-Rodriguez[2], E. Atkinson[3], Latin American Genomics Consortium; [1]Yale Univ., Orange, CT, [2]Univ. of Florida Coll. of Med., Gainesville, FL, [3]Baylor Coll. of Med., Houston, TX

There is a pressing need to engage traditionally underrepresented research participants and researchers to diversify both genomics studies and the genetics workforce. For this, collaborative and coordinated efforts are crucial. The Latin American Genomics Consortium (LAGC), established in 2019, aims to accelerate psychiatric genetics research and expand the genomics workforce of Latin America. The LAGC currently has over 150 active members, representing 9 different Latin American countries. LAGC has disorder-specific working groups as well as a methods working group focused on the analyzing admixed Latin American populations. Network analysis of our LAGC membership shows a high research productivity, but efforts should be made to integrate researchers from South America in global and equitable collaborations. Ongoing LAGC research efforts include a meta-genome-wide association study of alcohol consumption in 55,518 individuals of Latin American origin from US- and Latin America-based cohorts. We identified 4 independent loci associated with alcohol consumption mapping to the *ADH1B* and *ADH1C* genes. A transcriptome-wide association analysis also identified six significantly associated genes, including well-known associations such as *ADH1B*, *ADH1C*, and *ADH7*, and three potentially novel top hits mapping to *IQCF1*, *VEGFC*, and *FRG2B*. Our findings revealed both well-known and potentially novel genetic associations for alcohol consumption in Latin American populations. Our consortium initiative not only empowers Latin American researchers to conduct genomic analyses, addressing the enormous underrepresentation in the psychiatric genomics workforce but also diversifies GWAS to ensure that the benefits of GWAS findings are shared beyond European populations.

PB1331 † Activating B cells Facilitates the Discovery of Latent Disease-associated Variants

Authors:

D. Murphy, Y. Fu, J. Kelly, R. Pelikan, G. Wiley, P. Gaffney; Oklahoma Med. Res. Fndn., Oklahoma City, OK

Although millions of disease-associated variants have been discovered using GWAS, most of these occur in non-coding regions and their mechanistic link to disease is unclear. Further, separating causal from neutral variants within haplotypes remains challenging. Analyses of expression quantitative trait loci (eQTLs) in healthy tissues only explain some GWAS hits due to the different mechanisms driving variant discovery in these two approaches. Epigenomic phenotypes, like chromatin accessibility, paired with information about long range chromatin contacts encoded in the 3D genome, may reveal regulatory mechanisms not detected by traditional eQTL analysis. Moreover, latent disease-specific mechanisms encoded in the epigenome may be elicited by stimulating healthy tissues. To this end, we gathered expression data using RNA-seq, epigenomic data using ATAC-seq and CUTNRUN (for H3K27-acetylation and CTCF-binding), and 3D-genome contact data using Hi-C, from B cells in 81 genotyped, healthy individuals for both a resting and immune-stimulated condition. We identified strong effects of stimulation across these “omic” layers, including thousands of differentially expressed genes and tens of thousands of differentially activated epigenomic modifications triggered by stimulation. Pairing this omics data with polymorphism data from our sample, we identified over 300,000 candidate QTLs, with over 1/3 of these exclusive to the stimulated state. We used the Activity-By-Contact (ABC) method to connect epigenomic modifications to gene expression via the 3D-genome HiC contact data. Using this approach, we identified tens of thousands of candidate enhancer-gene (E-G) pairs, including nearly 14,000 E-G pairs revealed exclusively in the stimulated state. Taking advantage of variation in our sample, we were able to validate ABC predictions at 654 E-G pairs where levels of enhancer activity (E) and gene expression (G) had a significant correlation. Finally, we examined 2,320 autoimmune-related GWAS variants and found that 84 of these variants co-localized to QTLs, with an additional 561 variants found to lie within candidate enhancer elements identified by ABC (connecting non-coding disease-associated variants to putative effector genes). Collectively, these results demonstrate the utility of a multi-omic, stimulation-augmented approach for annotating non-coding GWAS variants and identifying regulatory epigenomic modifications.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1332 Acute effects of glucocorticoid treatment on gene expression during oral glucose tolerance testglucose tolerance test

Authors:

J. Gamboa, A. Oeser, J. F. Solus, M. Ormseth, Q. Sheng, S-C. Chen, F. Ye, M. Stein, V. Kawai; Vanderbilt Univ. Med. Ctr., Nashville, TN

Background Glucocorticoids (GCs) are potent anti-inflammatory and immunosuppressant drugs commonly prescribed to treat a wide range of illnesses. GCs are associated with multiple metabolic side effects including GC-induced hyperglycemia, which is more evident during non-fasting states. Nevertheless, the underlying mechanisms of this side effect are poorly understood. We hypothesize that acute administration of prednisone affects multiple gene pathways associated with glucose metabolism during an oral glucose tolerance test (OGTT) **Methods**: Eighteen healthy volunteers were enrolled in a clinical study involving two study visits for OGTTs. Participants fasted overnight before each study visit. On the first visit (off-GC), a finger-stick sample was collected at 7:00 am and a standard OGTT was performed at 11:00 am. On the second study visit, a single oral dose of 60 mg prednisone was administered immediately after collecting the finger-stick sample (7:00 am) and the OGTT was performed at 11:00 am. The area under the curve (AUC, median [IQR]) for blood glucose concentrations during the OGTT was calculated. Total RNA was extracted from samples obtained at the beginning (t0) and 120 minutes (t120) after the initiation of the OGTT with (on-GC) and without (off-GC) prednisone treatment. RNA was used to construct libraries for sequencing using Illumina NovaSeq 6000 system. Differentially expressed genes (DEGs) were identified with a false discovery rate (FDR) <0.05 and fold change > 1.5. Gene Set Enrichment Analysis (GSEA) was performed using WebGestaltR v0.4.4 to identify overrepresented pathways. **Results** Acute administration of prednisone increased the AUC for glucose from 13704 [12741, 1500] to 21525 [16983, 23937] mg/dl x min; p<0.001). The median peak glucose was 205 [163, 218] and 131 [109, 140] mg/dl, on-GC and off-GC, respectively. We identified 2889 DEGs at t0 and 2841 DEGs at t120 of the OGTTT between on-GC and off-GC. GSEA showed that the DEGs were enriched for genes involved in **insulin response** [58 DEGs (with enrichment ratio (ER) of 1.7, FDR< $1x10^{-3}$) at t0, and 51 DEGs (ER 1.5, FDR=0.01) at t120]; in **insulin receptor signaling** [32 DEGs (ER 1.8, FDR=0.007) at t0, and 29 DEGs (ER 1.6, FDR=0.03) at t120]; and in **cellular response to insulin stimulus** [44 DEGs (ER 1.6, FDR=0.008) at t0, and 42 DEGs (ER 1.5, FDR=0.02) at t120]. DEGs common to these pathways are *PID1*, *SOCS1*, *ENHO*, and *IRS2*, among others. **Conclusion:** Acute administration of prednisone induced glucose intolerance and changes in the expression of genes involved in insulin and glucose metabolism. This gene signature profile may be useful to understand the underlying mechanisms of GC-induced hyperglycemia.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1333 AD-by-proxy Polygenic Risk Scores: A New Predictor for Alzheimer's Disease and Age of Onset

Authors:

X. Gao[1], M. Chiariglione[1], K. Nuytemans[2], Y-J. Li[3], E. Martin[4]; [1]The Ohio State Univ., Columbus, OH, [2]Univ. of Miami, Miami, FL, [3]Duke Univ., Durham, NC, [4]Univ. of Miami Miller Sch. of Med., Miami, FL

Alzheimer's disease (AD) is the most common late-onset neurodegenerative disease, affecting approximately six million individuals in the United States. Currently, there is no cure for AD, making early detection crucial. Polygenic risk scores (PRSs) have been constructed for AD and the age at onset (AAO) of AD, using genome-wide association study (GWAS) summary statistics derived from clinically diagnosed AD. In this study, we tested whether PRSs constructed using AD-by-proxy, based on parental AD status, are significantly associated with AD and its AAO. Using 368,865 participants of white British ancestry from the UK Biobank dataset and the REGENIE software, we carried out a GWAS of AD-by-proxy (57,976 proxy AD cases and 310,889 non-AD proxy controls). Subsequently, we constructed an AD-by-proxy PRS for the Alzheimer Disease Genetics Consortium (ADGC) participants (9,205 AD cases and 10,334 non-AD controls) and tested their associations with AD and its AAO. To mitigate the known effects of the *APOE* gene, we excluded *APOE* markers (chr19: 45409053 - 45412650) from our PRS calculation. Logistic regression and case-only linear mixed-effects analyses were utilized to examine the associations of PRS with AD and AAO, respectively. The PRS showed a significant association with AD (odds ratio [95% CI] = 1.99 [1.92, 2.06], $P = 6.59 \times 10^{-310}$, after adjusting for age, sex, principal components [PCs] of genetic ancestry) and its AAO (beta [95% CI] = -1.52 [-1.66, -1.38], $P = 6.51 \times 10^{-101}$, after adjusting for sex, PCs, and cohorts), achieving a performance comparable to PRSs constructed using known genetic markers for AD. These associations remained significant for AD ($P = 6.67 \times 10^{-231}$) and its AAO ($P = 7.38 \times 10^{-82}$) after further adjusting for *APOE*-e4 dosage. AD-by-proxy PRSs could potentially be used to aid in predicting AD and its AAO.

Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [5]Dept. of Anatomy, Physiology, and Genetics, Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD, [6]Dept. of Neurology, Univ. of Miami Miller Sch. of Med., Miami, FL

Background: Puerto Ricans (PR), the second largest Hispanic group in the mainland US, are underrepresented in Alzheimer disease (AD) genetic studies. Their admixed genetic ancestry (Southern European [SEu], African [AF], and Amerindian [AI]) provides a unique opportunity to identify ancestry specific genetic factors associated with AD. Admixture mapping (AM) in comparison to SNP-based genome-wide association studies (GWAS), offers a more powerful approach in such admixed populations, partly due to a lower multiple testing burden. In this study, we employed AM to identify genetic loci associated with AD in PR individuals.
Methods: Our study included 639 individuals (334 cases; 305 cognitively unimpaired [CU]) ascertained through the Puerto Rico Alzheimer Disease Initiative (PRADI). We estimated global ancestry (GA) using the EIGENSTRAT software. To infer local ancestry (LA), we merged the target PR dataset with appropriate reference-population samples from HGDP reference panel. LA was estimated using SHAPEIT, followed by RFMix. Subsequently, we conducted univariate AM (SEu, AF, and AI separately) and joint AM [SEu and AF joint] analysis using the GENESIS software. Finally, we followed up the significant regions using Whole Genome Sequencing (WGS) data with a regression model, including genotype as main effects along with GA, sex, and age as covariates.
Results: Univariate AI AM analysis identified two genome-wide significant ($pv<1.2x10^{-4}$, Kizil et al.) ancestral blocks located on chromosomes 1q41 ($pv=4.4x10^{-5}$) and 3p25 ($pv=3.1x10^{-5}$). Joint AM [SEu and AF] analysis replicated genome-wide significant signal on chromosome 3p25.2. We observed a significant increase of AI ancestry relative to expected local-ancestry proportions at the 1q41 locus, while AI ancestry decreased at the 3p25 locus. The follow-up regional SNP-based regression analysis revealed strong associations on chromosome 1q41 (rs4240935; $pv=1.7x10^{-6}$).
Conclusions: In this study, we identified novel significant loci on chromosomes 1q41 and 3p25 associated with AD in PRs. Our follow-up SNP-based regression analysis further corroborated the findings for the 1p41 locus. Results underscore the intriguing contribution of AI ancestry at these identified novel risk loci. These findings emphasize the importance of including diverse genetic backgrounds in AD research and demonstrate the potential of AM in identifying ancestry-specific genetic risk loci.

PB1335 Advancing genomic research in the Korean population through comprehensive genomic scans using the Korea Biobank Array v2.0

Authors:

B-J. Kim, M. Hwang, I. Jeong, K. Yoon, H-Y. Park, Y. Kim; Korea NIH, Cheongju-si, Korea, Republic of

Over the past decade, there has been a rapid accumulation of genetic factors linked to various complex diseases through the analysis of hundreds of thousands of samples. To conduct comprehensive genomic scans on such large sample sizes, single nucleotide polymorphism (SNP) microarray and genotype imputation analysis have become widely utilized. However, the microarray approach often lacks rare functional or clinical variants, which limits precision medicine research that relies on genomic data obtained from microarray analysis. To address this limitation, the National Institute of Health, Republic of Korea, launched the Korea Biobank Array (KBA) project. This project involved genotyping 200K Korean samples using the KBA v1.1 array, which included around 830K variants specifically optimized for Korean genome research. In the subsequent phase of the KBA project, the KBA v2.0 was employed, incorporating 1.68 million markers. This updated version aimed to provide comprehensive Korean genome information, including approximately 132K clinically actionable variants and 489K functional variants extracted from publicly available clinical variant databases and approximately 28,000 whole genome sequences of East Asians and Koreans. During the pilot phase, approximately 10,000 samples underwent genotyping using the KBA v2.0. Following stringent quality control measures, the KBA v2.0 dataset yielded around 1.4 million non-monomorphic variants. Among these variants, about 424K were categorized as functional or clinical variants, including those classified as pathogenic or likely pathogenic variants documented in databases such as ClinVar or LOVD. Among the 143K clinically related variants, 0.5% were found to be common, (MAF >= 1%), while 0.9% were within MAF 0.1-1% and the remaining 98.6% were MAF < 1% in the Korean population. Additionally, the KBA v2.0 provided extensive genomic coverage, with 99% for variants with MAF >= 5%, and 86% for variants with MAF 1-5%. In a comprehensive genome-wide association study focusing on lipid traits, previously known loci were reaffirmed, and additionally, four newly associated rare genetic variants with strong genetic effects specific to East Asians were identified. These new variants were located at the ALOX5, SLFN14, APOB, and CLPN3 regions, providing further insights into the genetic underpinnings of lipid-related traits in this population. In summary, this study underscored the significance of conducting a comprehensive genomic scan using microarray technology, highlighting its early results and its potential as a valuable resource for precision medicine research within the Korean population.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1336 African ancestry individuals with higher educational attainment are resilient to Alzheimer disease pathology specific blood biomarker pTau181.

Authors:

F. Rajabli[1], B. Akgun[1], L. Adams[1], J. Inciute[1], T. D. Starks[2], R. Laux[3], M. Cuccaro[1], J. M. Vance[1], J. L. Haines[3], G. S. Byrd[2], A. Seixas[4], M. Pericak-Vance[1]; [1]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Maya Angelou Ctr. for Hlth.Equity, Wake Forest Univ., Winston-Salem, NC, [3]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [4](2) Dept. of Psychiatry and Behavioral Sci., Univ. of Miami Miller Sch. of Med., Miami, FL

Background Alzheimer disease (AD) risk is influenced by a wide range of factors, including genetic, psychosocial, environmental, and behavioral elements. *APOE ε4* is the strongest genetic risk factor for late-onset AD. Previous studies suggested that individuals with higher levels of education tend to demonstrate better cognitive capabilities compared to those with less education, even when having comparable degrees of advanced AD-related pathology (ADP). However, it is yet to be determined if educational attainment (EA) has a modifiable effect on the functional decline in individuals with the ε4 risk allele and ADP. Blood pTau181 is a biomarker specific to ADP. Using African American (AA) individuals with elevated blood pTau181 levels, we investigated whether EA promotes functional resilience differently between *APOE ε4* allele carriers and non-carriers. **Methods** We studied 410 AAs with known years of completed education, blood pTau181 levels, and *APOE* genotypes. We constructed a composite score, CDR-FUNC, from the four non-memory components of the Clinical Dementia Rating (CDR) to measure functional difficulties, with a score of 0 indicating no impairment and 12 indicating severe impairment. We divided EA into two categories: low (≤ 8 years), and high (>8 years). pTau181 levels were log-transformed, and individuals with advanced ADP-related pTau181 levels were defined as those whose log10(pTau181) level was greater than one standard deviation above the mean. Further, individuals were categorized based on their *APOE* ε4 carrier status. We utilized the non-parametric Mann-Whitney U test to evaluate the association between EA and CDR-FUNC in individuals with advanced ADP-related pTau181 levels and *APOE* e4 allele. **Results** The results showed that EA promotes resilience to functional problems in AA individuals with advanced blood pTau181 levels, such that individuals with high EA are more likely to have better functional ability compared to those with lower EA (p=0.0007). Additionally, we found that the effect of high EA on functional resilience was stronger in ε4 non-carriers compared to ε4 carriers (p=0.022). **Conclusion** This study found that years of education are associated with better functional abilities in individuals exhibiting high levels of ADP-related blood pTau181 biomarkers. This effect was observed in both *APOE* ε4 carriers and non-carriers, but the protective effect of high EA was stronger in non-carriers. It can be inferred that higher education can help individuals maintain their functional abilities even with AD pathology.

PB1337 Age and parasitemia explain most of the variation in host and parasite gene expression among Malian children infected with *P. falciparum*

Authors:

K. Tebben; Univ. of Maryland, Baltimore, Baltimore, MD

Plasmodium falciparum caused over 600,000 deaths in 2021, primarily in young children. In Bandiagara, Mali, children experience 2 malaria episodes per season, on average. However, even in the same transmission area, the parasitemia and number of uncomplicated, symptomatic infections vary widely between children. The host and parasite factors contributing to this variation remain incompletely understood. To begin to understand this variation, we characterized the host and parasite transcriptomes from 136 blood samples from children symptomatic for falciparum malaria, studying the expression of 2,484 *Plasmodium* and 9,205 human genes. We used gene expression deconvolution to estimate the proportion of parasite stages and immune cells in each sample to investigate differences in cell proportions between children and correct our differential gene expression analyses for these differences. Parasitemia and host age explained most of the variation in both host and parasite gene expression, while few genes were associated with the number of symptomatic infections in the study period, complexity of infection or the sex of the child. Gene expression differences associated with parasitemia were driven by differences in cell composition. Higher parasitemia infections had more ring-stage parasites and neutrophils and fewer trophozoites and T-cells, suggesting parasitemia-dependent parasite sequestration or regulation of the *Plasmodium* life cycle and/or parasitemia-dependent T-cell suppression. Similarly, parasite genes associated with the child's age resulted from differences in stage composition, with older children having proportionally more male gametocytes. By contrast, the host gene expression associated with age was not completely explained by differences in immune cell composition. In particular, many genes involved in innate response (TLR and NLR signaling) were more expressed in younger children while genes involved in adaptive immunity (TCR and BCR signaling) were higher in older children, supporting that the immune response to malaria changes over time. These analyses broaden our understanding of the variations in pathogenesis of *P. falciparum* even within similar clinical syndromes and can provide insight for targeted prevention and treatment strategies based on age and/or parasitemia of infected children.

PB1338 Age of asthma onset and risk of cardiovascular disease: A Mendelian randomization study

Authors:

H-Y. Chung, N. Y. Ng, J. Zhao, C. Mak, S. Lee; The Univ. of Hong Kong, Hong Kong, China

Background Asthma is a heterogeneous, non-communicable disease, with clinical presentations varying with age-of-onset. Longitudinal observational studies have shown consistent associations between asthma as a collective disease and cardiovascular diseases (CVDs). However, observational associations of childhood-onset asthma with CVDs are inconsistent, and causality has not been confirmed. We conducted a Mendelian randomization (MR) study to elucidate the different causal impacts of childhood and adulthood-onset asthma on four CVDs (coronary artery disease, heart failure, atrial fibrillation, and stroke). **Methods** Genetic instruments (instrumental variables) were identified from a published genome-wide association study (GWAS) on childhood-onset asthma (cases: 13,962; controls: 300,671) and adulthood-onset asthma (cases: 26,582; controls: 300,671) using a p-value threshold of $P<3x10^{-8}$. MR analyses were conducted using the largest available GWAS obtained from genome-wide association meta-analysis studies or large consortia for each CVD outcome. Odds ratios (ORs) were calculated using the inverse variance weighted method. Sensitivity analyses (MR-Egger, MR-PRESSO and weighted median methods) were conducted to evaluate the effects of horizontal pleiotropy to imply causality. **Findings** Under the weighted median method, we found a 3.3% increased risk of heart failure per log-odds increase in the risk of childhood-onset asthma ($p=0.032$). Under the MR-Egger method, we found a 5.7% increased risk of atrial fibrillation per log-odds increase in the risk of childhood-onset asthma ($p=0.039$). Genetically predicted adulthood-onset asthma was not causal for any CVD outcomes across all analyses. **Conclusions** Our results reveal potentially different causal effects of asthma subtypes on the risk of CVDs. Clinical interventions directly targeting childhood-onset asthma and its downstream effects may prove effective in reducing the risk of heart failure and atrial fibrillation. These findings should be triangulated with clinical evidence to support the distinct management of asthma subtypes in reducing CVD risk.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1339 Alzheimer's disease APOE4 variant associated with metabolites while Alzheimer's disease polygenic risk score lacks association with metabolites.

Authors:

E. Drzymalla[1], L. Raffield[2], C. Avery[1]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]UNC - Chapel Hill, CHAPEL HILL, NC

Mechanisms underlying Alzheimer's disease (AD) are largely unclear, in part reflecting challenges in phenotype classification and biological pathway identification as well as a late disease onset. Multi-omics studies that integrate metabolomics and AD polygenic risk scores (PRS) can help address these challenges by measuring diverse biological mechanisms (via metabolomics) and identifying individuals at elevated AD risk (via AD PRS) decades before disease onset. AD PRS was constructed using external European-derived weights for 83 variants, excluding the *APOE4* locus which would have a disproportionately high weight given its strong known effects on AD risk. This PRS has been validated previously in external cohorts. To validate AD PRS performance (continuous or dichotomized at the 90th %ile) in UK Biobank, we used Cox proportional hazard models with time to AD diagnosis, defined by ICD-10 G30 or F00 or ICD-9 331.0, as the outcome, AD PRS as the exposure, and adjusted for age, sex, education, first ten principal components (PCs) and self-reported ethnicity. To identify mechanisms by which increased AD genetic risk (continuous AD PRS, dichotomized at the 90th %ile AD PRS, or rs429358 *APOE4* AD risk variant alone) may increase AD incidence, we used linear regression and regressed each of 161 metabolites outcomes (measured using the Nightingale Health NMR platform) on the AD PRS exposure, adjusting for age, sex, education, first ten PCs and self-reported ethnicity, and applying a 5% FDR correction. There were 88,412 UK Biobank participants (mean age = 57, 55% female, 671 AD cases) with complete outcome, follow-up time, AD PRS, covariate, and metabolite data. The AD PRS was as expected associated with AD in UK Biobank (continuous PRS: per SD HR = 1.46, 95% CI = 1.36-1.57, p-value = <2x10-16, binary PRS: HR = 2.05, 95% CI = 1.69-2.49, p-value = 3.99x10-13). No metabolites were significant in the continuous or binary PRS model. Sensitivity analysis restricted to European ancestry had consistent results. However, 134 (83%) metabolites such as cholesterol and phospholipids were associated with *APOE4*. *APOE4* is a strong predictor of AD and has been previously associated with lipid metabolites in plasma including phospholipids and cholesterol, which we confirm here. The lack of association between the AD PRS and metabolites suggests the *APOE4* locus is the main driver between AD genetic risk and the metabolome. However, we analyzed a targeted metabolite platform, and the AD PRS explains only a modest portion of AD risk. We plan to expand this analysis to proteins in the UK Biobank as well as broader metabolite panels in other cohort studies.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1340 Alzheimer's disease is associated with reduced survival across generations in *APOE4* carriers and non-carriers.

Authors:

R. Holmes, H. Duan, K. Arbeev, D. Wu, A. Yashin, S. Ukraintseva; Duke Univ., Durham, NC

Introduction: A strong genetic risk factor for Alzheimer's Disease (AD), *APOE4*, has also been associated with reduced longevity. However, trans-generational impact of predisposition to AD on longevity, including in *APOE4* non-carriers, is less explored. We compared lifespans of parents of UK Biobank (UKB) participants with and without AD diagnosis, considering *APOE4* carrier status. **Method:** We estimated differences in frequencies of parental survival to ages 80+ and 90+ for UKB participants with and without AD. To ensure that parental data are not affected by participants' current AD status, all participants who had AD diagnosis upon entering the study were removed from analysis. We used two binary phenotypes of parental survival: 1) survived age 80+ vs. died before 80; and 2) survived age 90+ vs. died between 80 and 90. SAS procedure PROC FREQ was used. Chi-square test was used to compare significance between groups. **Results:** The proportion of parents who survived age 80+ was significantly (FDR<0.05) lower for participants with AD than without AD, in the total sample (mother's survival: p=1.43E-06, AD: 50.85% vs. NoAD: 55.11%; father's survival: p=1.83E-13, AD: 29.47% vs. NoAD: 35.79%). The results were similar for males, females, and Whites, and non-significant for Blacks. The difference in parental survival to age 80+ was similar for *APOE4* carriers and non-carriers with and without AD (*APOE4* carriers: mother's survival: p=0.026, AD: 51.13% vs. NoAD: 54.32%; father's survival: p=2.85E-06, AD: 28.61% vs. NoAD: 35.06%; *APOE4* non-carriers: mother's survival: p=0.004, AD: 51.37% vs. NoAD: 56.07%; father's survival: p=4.67E-05, AD: 30.19% vs. NoAD: 36.62%), though the proportion of parents surviving age 80+ was overall lower in *APOE4* carriers. Mother's survival to age 90+ was significantly (FDR<0.05) associated with AD diagnosis in the total sample (p=4.52E-08, AD: 26.68% vs. NoAD: 33.55%), with similar results for males, females, and Whites. The difference between participants with and without AD in survival of their mothers was larger for survival to age 90+ than to age 80+, especially for *APOE4* carriers (p=1.82E-05, AD: 22.70% vs. NoAD: 31.12%). **Conclusion:** Parents of UKB participants with AD had lower chances to survive ages 80+ and 90+ than parents of participants without AD. This was true for participants who were *APOE4* carriers, as well as non-carriers. Our results suggest that predisposition to AD may negatively affect survival and longevity across generations and that risk factors beyond *APOE4* may play role in this. They also suggest a larger detrimental impact of predisposition to AD on chances of longevity 90+ than on conventional survival (80+).

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1341 Alzheimer's disease genetic risk and Cognitive "SuperAging" in the Midwestern Amish

Authors:

D. Dorfsman[1,2], M. B. Prough[1], L. J. Caywood[1], J. E. Clouse[1], S. D. Herington[1], S. H. Slifer[1], L. D. Adams[1], R. A. Laux[3,4], Y. E. Song[3,4], A. Lynn[3,4], S. L. Fuzzell[3,4], S. D. Hochstetler[3,4], K. Miskimen[3,4], L. R. Main[4,5], P. Wang[3], Y. Liu[4], P. Ogrocki[6], A. J. Lerner[5], J. M. Vance[1,2], M. L. Cuccaro[1,2], J. L. Haines[3,4], M. A. Pericak-Vance[1,2], W. K. Scott[1,2]; [1]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Dr. John T. Macdonald Fndn. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [3]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [4]Cleveland Inst. for Computational Biology, Case Western Reserve Univ., Cleveland, OH, [5]Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [6]Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH

Alzheimer's disease (AD) is a highly heritable neurodegenerative disorder that accounts for 60-80% of all dementia cases. While cognitive performance often declines with increasing age, some individuals appear to resist this trajectory by maintaining youthful brain capacity well into their later years. One such group, described as SuperAgers (SA), are ≥ 80 years old with episodic memory function at or above the level expected for a middle-aged adult. Studies of SA may provide key insights into the heritable factors that predispose to, as well as those that protect against, AD and cognitive impairment (CI). The purpose of this study is to use an Amish-derived sample to compare SA to those who are cognitively unimpaired (CU) aged ≥ 80 but do not meet the criteria for SA, to assess whether differences between these groups are explained by known genetic risk factors for AD. Enrolled subjects (N=428) are adult members of the Midwestern Amish population, an endogamous group with a shared lifestyle. Subjects were evaluated and adjudicated using clinical information that included a comprehensive neuropsychological test battery that measures performance across multiple cognitive domains. Using normative data, subjects aged ≥ 80 with episodic memory (CERAD Word List Recall) at or above the mean for ages 35-44, and non-memory cognitive test performance (Trail Making Test B, Category Fluency, MINT) within one standard deviation or better for the subject's age, were categorized as SA (n=85). Using called whole-genome sequence variants, an AD genetic risk score (GRS) was calculated for each subject by utilizing effect sizes for 83 genome-wide significant AD-associated variants, excluding *APOE*, published in Bellenguez et al. (2022). The effect of known AD genetic risk factors on CI was confirmed through multivariable logistic regression analysis, which included *APOE* E4 allele count ($p<0.001$), GRS ($p<0.001$), age ($p<0.001$), and sex ($p=0.3$) as predictors of disease status (case: AD, control: SA and CU non-SA). The effect of these predictors on SA was then modeled using an updated case status (case: SA, control: CU non-SA aged ≥ 80). In this scenario, *APOE* E4 allele count ($p=0.7$), GRS ($p=0.6$), age ($p=0.09$), and sex ($p=0.2$) did not exhibit significant differences between the two groups. Moreover, *APOE* E2 allele count, a known protective factor against AD, was not significantly different between the two groups ($p=0.6$). These results suggest that differences between SA and unimpaired non-SA individuals are not due to known AD genetic risk factors in the Amish population. Ongoing studies aim to identify genetic factors that promote SA and enhanced cognitive function at older ages.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1343 † An Alzheimer's Disease risk variant in *TTC3* modifies the actin cytoskeleton organization and PI3K-Akt signaling in iPSC-derived forebrain neurons.

Authors:

H. Cukier[1], C. L. Duarte[1], J. Laverde-Paz[1], S. A. Simon[1], D. J. Van Booven[1], A. T. Miyares[1], P. L. Whitehead[1], K. L. Hamilton-Nelson[1], L. D. Adams[1], R. M. Carney[2], M. L. Cuccaro[1], J. M. Vance[1], M. A. Pericak-Vance[1], A. J. Griswold[1], D. M. Dykxhoorn[1]; [1]Univ. of Miami Miller Sch. of Med., Miami, FL, [2]Bruce W. Carter VA Med. Ctr., Miami, FL

We identified a rare, nonsynonymous variant in the *tetratricopeptide repeat domain 3* (*TTC3*) gene that segregated in a multigenerational non-Hispanic white late onset Alzheimer disease (LOAD) family (Kohli, et al, 2016). This missense alteration, rs377155188 (p.S1038C), is predicted to be deleterious and is extremely rare. Studies have reported that cortical *TTC3* expression is reduced in LOAD patients and negatively correlated with AD neuropathology. To understand the mechanism by which the TTC3 p.S1038C may contribute to LOAD risk, CRISPR/Cas9 genome edited induced pluripotent stem cells (iPSCs) were developed that were homozygous for the variant to examine cellular and transcriptional consequences in neuronal cells (Laverde-Paz, et al, 2021). Quantitative PCR and western blot analysis demonstrated that *TTC3* levels were decreased in edited compared to unedited iPSCs, as well as differentiated neurons. Transcriptome analysis of day 70 neurons identified 979 genes that were differentially expressed (FDR<0.05). This included known AD genes (*BACE1*) and genes in AD GWAS loci (*ADAMTS1*, *MAF*, *NCK2*). Furthermore, there was an enrichment for genes involved in axon guidance, regulation of actin cytoskeleton, and GABAergic synapse. In growing neuronal precursor cells (NPCs), cells with the *TTC3* variant recovered more quickly from a scratch wound. Since there is evidence that modulation of *TTC3* affects neurite growth, morphological measures of axon formation were assessed using the Incucyte Zoom. Studies demonstrate an increase in neurite outgrowth, which phenotypically corresponds with previous studies of a decrease in *TTC3* function. This phenotype was tempered by treatment with Cytochalasin D, an inhibitor of actin polymerization. Additionally, TTC3 ubiquitinates phosphorylated AKT and regulates AKT signaling. The edited cells were found to have an increase in phosphorylated AKT (pAKT) relative to total AKT. Combined, these results suggest that the *TTC3* p.S1038C variant causes a loss of function. Utilizing a CRISPR genome edited iPSC carrying a homozygous alteration in *TTC3*, we were able to identify potential mechanisms by which *TTC3* may contribute to LOAD risk.

PB1344 An analytical framework to identify novel disease genes including common and rare variants

Authors:

C. Salvoro[1], Q. Wang[2], S. Das[1], K. Megy[1], M. Fabre[1,3], S. Petrovski[1,4,5], K. Carss[1]; [1]Ctr. for Genomics Res., Discovery Sci., R&D, AstraZeneca, Cambridge, United Kingdom, [2]Ctr. for Genomics Res., Discovery Sci., R&D, AstraZeneca, Gaithersburg, MD, [3]Dept. of Haematology, Cambridge Univ. Hosp. NHS Trust, Cambridge, United Kingdom, [4]Dept. of Med., Univ. of Melbourne, Austin Hlth., Melbourne, Australia, [5]Epilepsy Res. Ctr., Univ. of Melbourne, Austin Hlth., Melbourne, Australia

Complex diseases arise with the contribution of both common and rare inherited genetic variants. Traditionally, these two types of variants have been investigated separately, however, recent studies have demonstrated that their combination and interaction is critical. Polygenic Risk Scores (PRS), which capture the effect of common variants on a particular phenotype, have been shown to modify the penetrance of rare variants, and subjects who deviate from their phenotypic prediction based on common variants are enriched in potentially causal rare alleles. Consistent with this, including PRS in disease regression models improves rare variant identification. Here we hypothesise that incorporating previous knowledge of both common and rare variants in disease models could increase power to reveal novel implicated genes, and improve our understanding of the contribution of these two classes of variant to complex diseases. Using 470,048 exome sequences from UK Biobank (UKB), we built two frameworks, to investigate binary disease outcome and time to disease occurrence, both including a rare-variant-carrier status and a PRS percentile for each subject. As a proof of concept, we considered 28 diseases for which PRS were released by UKB. To determine whether a subject was a rare variant carrier for a given disease, we used pathogenic or likely pathogenic annotations in ClinVar. We modelled binary disease outcome using Firth's logistic regression, and regressing outcome on gene-level qualifying rare variant carrier status. Rare-pathogenic variant-carrier status and PRS percentile were included as covariates, together with sex, age, sex*age, and the first 4 ancestry principal components. Analogously, we modelled time to disease with the same gene-level genotypes and covariates, using Cox's proportional hazards regression with Firth's penalized likelihood. Time to disease was measured in years considering UKB recruitment as baseline. Preliminary findings identified 6 significant associations ($p<1x10^{-8}$), including positive controls such as *CFH* in age-related macular degeneration ($p=4.0x10^{-11}$, OR=2.1) and *BRCA1* in epithelial ovarian cancer ($p=3.2x10^{-14}$, OR=7.2). PRS were consistently associated with disease outcome in all models, while rare-pathogenic variant-carrier status showed variable contributions, indicating still incomplete knowledge for rare variants. We believe this exploratory study could set the basis for a new approach to identify disease genes with high clinical relevance. With the increasing availability of PRS and rare pathogenic variant annotations, our frameworks could be applied to a growing number of different diseases.

PB1345 An EBV-associated atypical B cell signature in clinically isolated syndromeis implicated in progression of multiple sclerosis

Authors:

S. Gregory[1], E. SoRelle[2], H. Ellora[1], J. Vaibhav[1], J. Giarraputo[3], K. Abramson[1], E. Hocke[1], L. Cooney[4], K. Harris[5], S. Zamvil[6], M. Luftig[2]; [1]Duke Molecular Physiology Inst., Durham, NC, [2]Duke Dept. of Molecular Genetics and Microbiol., Durham, NC, [3]Yale Sch. of Med., New Haven, CT, [4]Immune Tolerance Network, Bethesda, MD, [5]Immune Tolerence Network, Bethesda, MD, [6]Dept. of Neurology, San Francisco, CA

Introduction: Expansion and pathogenicity of CD19+/CD20+/CD11c+/T-bet+ atypical B cells (ABCs) are hallmarks of numerous autoimmune disorders and chronic infections. In many such cases Epstein-Barr virus (EBV) is an associated or etiologic factor, though EBV involvement in these diseases remains poorly understood. Notably, expansion of pro-inflammatory ABCs and a putative causal role for EBV each have been identified independently in multiple sclerosis (MS). A common precipitating event in MS onset is Clinically Isolated Syndrome (CIS), a neuroinflammatory demyelinating condition in which 60-80% of cases progress to relapsing-remitting MS (RRMS).
Methods: We used single-cell gene and surface protein expression (scRNA/CITE-seq) in peripheral B cells collected longitudinally from patients with CIS during the Immune Tolerance Network STAyCIS Trial. We focused on the transcriptomic signatures of ABCs from this cohort, publicly available scRNA-seq datasets from five other autoimmune and chronic infectious diseases, healthy donors, and in vitro EBV infection. Ongoing analyses include the incorporation of MS GWAS loci into our differentially expressed scRNA-Seq ABC pathways.
Results: Patients with CIS exhibited significantly higher frequencies of ABCs than healthy adults (5.4% vs 3.0% of peripheral B cells), establishing ABC compartment expansion as a clinical feature. An EBV-associated transcriptome signature in ABCs from CIS, distinct from healthy controls and other disease contexts, was also identified although direct evidence of EBV infection was not obtained. ABCs from patients with CIS exhibited significantly elevated expression of inflammatory cytokines (CXCL8 / IL8, IL18, VEGFA), some of which (IL-8, VEGF) were secreted by B cells upon de novo EBV infection.
Conclusion: Outcome stratification of CIS samples revealed a rare yet distinctive inflammatory ABC subset that was significantly underrepresented in long-term non-progressors (LTNP) versus cases with primary endpoint RRMS activity (~7x difference). Thus, this study provides evidence for ABC dysregulation - possibly arising from responses to EBV infection - preceding MS onset.

PB1346 Analysis of caudate nucleus transcriptome in individuals with schizophrenia identifies new risk genes and implicates pre-synaptic DRD2 autoreceptor dysregulation as a genetic risk factor for schizophrenia

Authors:

A. Paquola[1], K. J. Benjamin[1], Q. Chen[2], A. Jaffe[3], J. Stolz[3], L. Collado-Torres[1], L. Huuki[3], E. Burke[3], R. Arora[3], A. Feltrin[3], A. Barbosa[3], E. Radulescu[3], G. Pergola[3], J. Shin[4], W. Ulrich[3], A. Deep-Soboslay[3], R. Tao[3], BrainSeq Consortium, T. Hyde[3], J. Kleinman[3], J. Erwin[1], D. Weinberger[3]; [1]Lieber Inst. for Brain Dev. / Johns Hopkins Med., Baltimore, MD, [2]LIBD, Baltimore, MD, [3]Lieber Inst. for Brain Dev., Baltimore, MD, [4]Lieber Inst. for Brain Devel, Baltimore, MD

Most studies of gene expression in the brains of individuals with schizophrenia have focused on cortical regions, but subcortical nuclei such as the striatum are prominently implicated in the disease, and current antipsychotic drugs target the striatum's dense dopaminergic innervation. Here, we performed a comprehensive analysis of the genetic and transcriptional landscape of schizophrenia in the postmortem caudate nucleus of the striatum of 443 individuals (245 neurotypical individuals, 154 individuals with schizophrenia and 44 individuals with bipolar disorder), 210 from African and 233 from European ancestries. Integrating expression quantitative trait loci analysis, Mendelian randomization with the latest schizophrenia genome-wide association study, transcriptome-wide association study and differential expression analysis, we identified many genes associated with schizophrenia risk. We found that reduced expression of the pre-synaptic DRD2 autoreceptor is associated with increased genetic risk for schizophrenia. We also found that antipsychotic medication has an extensive influence on caudate gene expression. Using a deep learning approach based on variational autoencoders, we constructed gene expression networks that highlight interactions involving schizophrenia risk. These analyses provide a resource for the study of schizophrenia and insights into risk mechanisms and potential therapeutic targets.

PB1347 † Analysis of de novo variants in trios with orofacial clefts identifies GRHL2 as a novel gene

Authors:

C. Yang[1], S. W. Curtis[1], J. C. Murray[2], C. D. Padilla[3], T. H. Beaty[4], L. M. Moreno[5], S. E. Daack-Hirsch[6], E. Feingold[7], S. M. Weinberg[7], M. L. Marazita[8], M. P. Epstein[9], D. J. Cutler[10], H. Brand[11], E. J. Leslie[1]; [1]Emory Univ., Atlanta, GA, [2]U of Iowa, Iowa City, IA, [3]Univ. of the Philippines Manila, Manila, Philippines, [4]Johns Hopkins Univ, Sch PubHlth, Baltimore, MD, [5]Univ Iowa, Iowa City, IA, [6]Univ Iowa Hosps & Clinics, Iowa City, IA, [7]Univ of Pittsburgh, Pittsburgh, PA, [8]Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, [9]EMORY Univ., Atlanta, GA, [10]Emory Univ. Sch. of Med., Decatur, GA, [11]MGH, Boston, MA

Orofacial clefts (OFCs), including cleft lip and cleft palate, are among the most common birth defects, occurring in approximately 1 in 700 live births worldwide. The prevalence of OFCs varies around the world with many populations at much higher risk than those of European ancestry. However, genetic studies in individuals of non-European ancestry are more limited and require further exploration. OFCs have a strong genetic basis, with genetic variants of all types and frequencies increasing risk for an OFC. Here, we focused our analysis on de novo variants (DNVs) found in whole genome sequence (WGS) data from 419 child-parent trios of Filipino ancestry with OFCs from the Gabriella Miller Kids First (GMKF) Research Program, in order to determine the contributions of coding DNVs to OFC risk. After DNVs were called and rigorously filtered for quality, we identified 438 coding DNVs. There was a significant enrichment of loss-of-function ($p = 0.00708$) and protein-altering DNVs ($p = 0.000143$), with 45 loss-of-function and 313 protein-altering mutations identified. Two loss-of-function DNVs were identified in GRHL2 ($p = 4.74E-06$), a gene intolerant to loss-of-function variants (LOEUF = 0.27, pLI = 1). We then investigated DNVs from three other GMKF cohorts with OFCs of Colombian, Taiwanese, and European ancestries, totaling 1,114 trios. In these samples, we identified a third DNV, a structural variant deleting exons 2-9 of GRHL2. GRHL2 is one of a family of conserved transcription factors important for embryonic development. Mice deficient for Grhl2 or Grhl3 are known to have craniofacial anomalies, including facial and palatal clefts. Although heterozygous GRHL3 variants are known to cause Van der Woude syndrome and isolated cleft palate in humans, GRHL2 was previously only implicated in craniofacial anomalies by virtue of being one of many genes deleted in microdeletions of the 8p22. Truncating GRHL2 mutations are associated with autosomal dominant progressive hearing loss and missense variants are associated with autosomal recessive ectodermal dysplasia. The three loss-of-function DNVs identified here conclusively implicate GRHL2 in orofacial clefting and suggest that these families may also be at risk for developing hearing loss. We also identified a de novo truncating variant in GRHL1 and a de novo missense variant in GRHL3, which suggests that this family of transcription factors is important to craniofacial development in humans. These findings support a need for additional work on the GRHL gene family to determine their association with OFCs and other birth defects, plus their role in comorbidities such as deafness.

PB1348 Analysis of gut microbiome in a low and high endotoxin house dust mite induced airway hyperresponsiveness mouse model

Authors:

K. Mulholland, N. Fuentes, P. Warrener, C. Caceres, B. Mindt, B. Sellman, C. Tkaczyk, V. Gopalakrishnan; Astrazeneca, Gaithersbug, MD

Asthma affects nearly 339 million people worldwide; the gut microbiome has been growing in importance as a key mediator of asthma. Although therapies exist, there is an unmet need for patients with a neutrophilic phenotype. We characterized the impact of endotoxin abundance in house dust-mite (HDM) on gut microbiome dynamics. C57BL/6J male mice were challenged with low (LE-HDM) or high (HE-HDM) endotoxin abundance or PBS over 21 days. The gut microbiome was characterized by 16S rRNA sequencing on fecal samples collected before challenge, on day 14 and day 21. Inflammatory markers in BAL were characterized by flow cytometry. Firmicutes, Bacteroidota and Actinobacteriota were the most prevalent phyla in all groups. Alpha diversity was higher in LE-HDM, but there were no appreciable differences in microbiome composition at any timepoint. Differential abundance comparisons revealed unique microbial signatures with enrichment of Firmicutes and *Intestinimonas* in LE-HDM and Bifidobacteriaceae and *Bifidobacterium* in HE-HDM. Differential taxa between HE-HDM and LE-HDM significantly associated with levels of Th1 and Th17 or Th2 cytokines in BAL at day 21, respectively.
These findings reveal that differences in specific taxa in gut microbiomes are associated with endotoxin abundances in HDM and are also correlated with inflammatory responses in asthma.

Bonn, Bonn, Germany, [2]Univ. of Tuebingen, Tuebingen, Germany, [3]Univ. of Cologne, Cologne, Germany, [4]Univ. of Oxford, Oxford, United Kingdom, [5]McGill Univ., Montreal, QC, Canada, [6]King's Coll. London, London, United Kingdom, [7]5 Prime Sci. Inc, Montreal, QC, Canada, [8]Deutsches Zentrum für Neurodegenerative Erkrankungen (DZNE), eV, Bonn, Germany, [9]Univ. of Bonn, Bonn, Germany, [10]Technical Univ. Munich/Helmholtz Munich, Munich, Germany, [11]Univ. of Munich, Munich, Germany

SARS-CoV-2 infections can result in variable courses of disease, with substantial contribution by the genetic make-up of the host. While large-scale GWAS have identified common variants associated with different SARS-CoV-2-related traits, analyses of extreme phenotypes have identified rare variants causing monogenic predispositions for severe COVID-19, such as *TLR7*-deficiency. Genome sequencing covers both common and rare genetic variation, but so far has rarely been performed in the context of SARS-CoV-2 infections. We here describe the analysis of genome sequencing data of 1,220 individuals with mild, moderate (hospitalization required) and severe (mechanical ventilation required) COVID-19. We did not observe any individual with *TLR7* deficiency, but identified homozygous variants known to be causative of autosomal recessive disease (genes: *BBS1*, *AGXT*, *SERPIN1C*, *AIRE*) in four young men (mean age: 33 years) with moderate (n=2) or severe (n=2) COVID-19. Gene-set based collapsing analyses provided evidence for nominally significant enrichment of rare predicted loss of function and missense variants in genes of the innate immune system, in individuals with severe COVID-19, with a stronger effect in males. Finally, GWAS on the genome sequencing data confirmed the association of common variants at 12 previously associated loci, and polygenic risk scores were highest in young and severely affected individuals. Overall, this analysis comprehensively analyzes COVID-19 host genetics and generates valuable hypotheses that can be tested by future studies.

PB1350 Analysis of variants of uncertain significance in familial dyslipidemia in the Puerto Rican population: Implications for risk stratification and early intervention.

Authors:

F. Benítez Ríos[1], M. Gómez Ocasio[1], A. de Jesús Barbosa[2], S. Flórez Marqués[2], A. Ortega Vega[2], S. Carlo[1], J. García Mateo[1], M. Mangual García[3], A. González Bóssolo[3], E. Albino[4]; [1]Ponce Hlth.Sci. Univ., Ponce, PR, [2]Univ. of Puerto Rico, San Juan, PR, [3]San Juan City Hosp., San Juan, PR, [4]Univ. of Puerto Rico - MSC, San Juan, PR

Introduction: Dyslipidemia, characterized by abnormal lipid levels, is a major risk factor for atherosclerotic cardiovascular disease (ASCVD). Familial dyslipidemias, including familial hypercholesterolemia (FH), familial chylomicronemia syndrome (FCS), and familial dysbetaloproteinemia, often exhibit a high prevalence of variants of uncertain significance (VUS) in genetic tests. This study aims to catalog all genetic variants associated with selected familial dyslipidemias in the Puerto Rican population and establish a phenotype/genotype correlation.
Methods: Demographic and clinical data were retrospectively collected from electronic medical records of Puerto Rican patients with a clinical diagnosis of familial dyslipidemia who underwent genetic testing from February 2023 through June 2023. Vital clinical data, including age, sex, body mass index, lipid tests, VUS results, comorbidities, treatment and familial history, were analyzed. Statistical analysis was performed to determine the diagnostic yield.
Results: Genetic testing reports from 24 Puerto Ricans with suspected familial dyslipidemia were analyzed. Among them, 2 (8.33%) tested positive, 4 (16.67%) had uncertain results, and 18 (75%) tested negative. VUS were meticulously cataloged, providing valuable information for reporting and further investigation.
Conclusion: The diverse genetic makeup of Puerto Rican population necessitates the establishment of comprehensive clinical and genetic profiles of familial dyslipidemia, along with the associated risk of ASCVD. This knowledge is crucial for implementing preventative treatments and conducting cascade screening to identify individuals at increased risk of ASCVD due to familial dyslipidemias. The cataloging of VUS at a larger scale can pave the way for early interventions and improved patient outcomes.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1351 Analyzing large-scale Tourette Syndrome whole-exome sequencing data reveals a significant contribution of de novo mutations.

Authors:

L. Zhan[1], D. Yu[2], L. Domenech-Salgado[3], F. Ivankovic[4], P. Giusti-Rodriguez[5], Tourette Association of America International Consortium for Genetics (TAAICG), M. Niarchou[6], L. K. Davis[7], C. A. Mathews[8], J. M. Scharf[9], R. A. Ophoff[10]; [1]UCLA, Los Angeles, CA, [2]Massachusetts Gen. Hosp., Hopkinton, MA, [3]Massachusetts Gen. Hosp., Boston, MA, [4]Massachusetts Gen. Hosp., Arlington, MA, [5]Univ. of Florida Coll. of Med., Gainesville, FL, [6]Vanderbilt Univ. Med. Ctr., Nashville, TN, [7]Vanderbilt Univ Med Ctr., Nashville, TN, [8]Univ. of Florida, Gainesville, FL, [9]Massachusetts Gen Hosp, Newton Center, MA, [10]Univ California Los Angeles, Los Angeles, CA

Tourette syndrome (TS) is an early-onset neurodevelopmental disorder (NDD) characterized by vocal and motor tics. TS is highly heritable (60-80%) and has a complex genetic architecture with both rare and common variants contributing to the genetic etiology. However, the contribution of *de novo* variants has not been widely studied due to the lack of large-scale high-quality family-structured sequencing datasets and insufficient statistical power. In this study, we generated whole-exome sequencing (WES) data for over 1,300 TS trio families and jointly called the data with a selected subset of over 6,600 families from SSC and SPARK datasets containing at least one Autism Spectrum Disorder (ASD) proband. This produced a high-quality unified dataset with 30,803 individuals and 4,425,974 variants. Our principal component analysis showed a diverse ancestry background with all major population groups present in the ASD cohorts, while only Europeans and Admixture Americans were present in the TS cohort. Analyzing samples from all three cohorts demonstrated a trend of increased burden of *de novo* pathogenic singletons ($FC_{TS/Control}$=1.23; n.s.), defined as protein-truncating variants (PTVs), in TS probands compared to healthy controls, while confirming a significant enrichment of *de novo* mutations in ASD probands compared to healthy controls ($FC_{ASD/Control}$=1.05; $P_{ASD,Control}$=4.70*10^{-2}). Considering the phenotypic heterogeneity previously reported for the SPARK cohort, we further investigated a subset with only TS and SSC cohorts ($N_{Proband+Control}$=3,655) and revealed a significant stepwise enrichment of *de novo* pathogenic variants across healthy controls, TS probands, and ASD probands ($FC_{TS/Control}$=1.04; $P_{Control,TS}$=2.59*10^{-2}; $FC_{ASD/TS}$=1.11; $P_{TS,ASD}$=4.62*10^{-7}), recapitulating the phenotypic spectrum of NDD. In brief, our study includes one of the largest TS-ASD WES family datasets that will facilitate future genetic and clinical studies on TS and comorbidities with improved power. Moreover, our work provides evidence of the contribution of *de novo* mutations to TS etiology, as well as the shared genetic architecture between TS and ASD. Further studies will focus on locating TS-specific and TS-ASD shared risks through gene-specific and gene-set analysis, bridging rare variant effects to polygenic scores to boost modeling accuracy, and dissecting the heterogeneity in the SPARK cohort for improved statistical power.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1352 Analyzing the impact of genetic loci that decouple obesity from abdominal fat distribution through in vitro adipocyte perturbation and differentiation

Authors:

J. Belanich[1,2], M. Urena[1], T. Batista[2], T. Kilpeläinen[1]; [1]Univ. of Copenhagen, Copenhagen, Denmark, [2]Broad Inst., Cambridge, MA

Obesity is often linked to abdominal fat distribution which can negatively influence cardiometabolic health. However, the relationship between overall and abdominal fat can vary greatly among individuals due to genetic differences. The biological mechanisms that regulate this relationship remain incompletely understood. Intriguingly, some genetic loci have been found to show an inverse relationship between higher body mass index (BMI) and abdominal fat distribution, indicated by a higher waist-hip ratio (WHR). We aimed to systematically screen for genetic loci that invert the relationship between higher BMI and WHR and characterize their function in human adipocytes. Leveraging summary results from the largest published GWAS for BMI and WHR, which included ~700,000 participants each, we identified >100 independent loci associated with higher BMI but lower WHR. Several of these loci were also associated with higher insulin sensitivity and a lower risk of type 2 diabetes.To understand the biological mechanisms underlying these findings in adipose tissue, we studied the impact of two selected novel loci, *ADAMTS9* and *EMILIN2*, in mouse and human preadipocytes. In vitro knockdown of these genes using siRNA in mouse and human white preadipocytes led to decreased differentiation and function of the cells, affecting cellular metabolism as well as adipogenic marker genes. Perturbed cells experienced reduction in lipid storage, as well as glucose uptake, without affecting proliferation, or cellular size. We are consequently following up on these two genes through additional CRISPRi perturbation studies and the LipocyteProfiler platform, which utilizes a combination of staining, sequencing, and other cellular profiling methods, to detect distinct phenotypic and cellular signatures. Our studies will provide new insights into how genetic variants may uncouple obesity from abdominal fat distribution and could identify new targets for therapeutics to increase insulin sensitivity and improve cardiometabolic health. Grants from the Novo Nordisk Foundation (NNF18CC0034900, NNF20OC0063707).

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1353 Ancestry Specific Polygenic Risk Score, Dietary Patterns and Cardiovascular Disease

Authors:

D. Hardy[1], J. Garvin[2], T. Mersha[3]; [1]Morehouse Sch. of Med., Atlanta, GA, [2]Walden Univ., Minneapolis, MN, [3]Cincinnati Children S Hosp. Med. Ctr., Cincinnati, OH

Background: Healthy dietary patterns can lower risk for atherosclerotic cardiovascular disease (ASCVD). A gap in knowledge is whether the impact of healthy dietary patterns in different ancestries is polygenic risk score (PRS) dependent. **Objective:** Our main aim was to examine the associations between a risk-raising functional PRS, dietary patterns, and high physical activity with ASCVD in European Americans and African Americans. A secondary aim examined the biological pathways associated with PRS mapped genes and their relationship with dietary intake. **Methods**: Our cross-sectional study utilized de-identified data from 7-National Heart, Lung, and Blood Institute Candidate Gene Association Resource studies obtained from the Database of Genotypes and Phenotypes for European Americans (n=6,575) and African Americans (n=1,606). Data collection years spanned from 1987 to 2010. **Results:** In the highest PRS tertile, ASCVD risk increased by 59% (Risk Ratio=1.59; 95% confidence Interval:1.16-2.17) in African Americans and by 18% (RR=1.18; 1.04-1.35) in European Americans compared to the lowest tertile. The Dietary Approaches to Stop High Blood Pressure (DASH) and Mediterranean healthy dietary patterns lowered ASCVD risks in the highest PRS tertiles by 5% (RR=0.95; 0.91-0.98) to 6% (RR=0.94; 0.91-0.98) in European Americans but did not have a significant effect in African Americans. The harmful Southern diet increased ASCVD risk in African Americans by 11% (RR=1.11; 1.02-1.21) to 12% (RR=1.12; 1.03-1.23). However, within the highest PRS tertiles, high physical activity together with the DASH, or Mediterranean, or Southern diet reduced ASCVD risks by 9% (RR=0.91; 0.85-0.96) to 15% (RR=0.85; 0.80-0.90) in European Americans. Among African Americans, high physical activity with the DASH diet lowered ASCVD risk by 13% (RR=0.87; 0.78-0.97) and the Mediterranean diet by 18% (RR=0.82; 0.72-0.95). Top biological pathways included fructose metabolism and catabolism linked to obesity, insulin resistance, and type 2 diabetes present in both ancestries. Additional pathways present for African Americans were for Vitamin D which is linked to depression; aging acceleration; and death signaling associated with cancer. Conclusions: The effects of healthy dietary patterns and high physical activity can counterbalance the effects of a risk-raising functional PRS. This can give more health benefits especially in African Americans to reverse metabolic responses regardless of a high PRS burden in associated pathways.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1354 Ancestry-informed regression identifies ancestry-specific effects for multiple sclerosis risk in Hispanic / Latino and African American populations.

Authors:

A. Beecham, Alliance for Research in Hispanic MS (ARHMS) Consortium; Univ Miami, Coral Gables, FL

Despite the rising incidence of MS in African Americans and Hispanics, these communities remain underrepresented in genetic research. The genetic admixture and unique linkage disequilibrium (LD) structure inherent to these populations affords the opportunity to identify novel susceptibility variants which may be ancestry-specific. In total, 3131 African Americans (1625 MS cases, 1506 controls) and 4160 Hispanics (2046 MS cases, 2114 controls) ascertained from more than 10 sites across the United States were genotyped on a customized Illumina genome-wide array and imputed with TopMed. Local ancestry was computed with RFMixV2. Genome-wide association was performed using Tractor to obtain ancestry-specific effect size estimates. We used an inverse variance-weighted fixed-effects meta-analysis of summary statistics from the European (EUR), African (AFR), and Native American (NAM) deconvolved tracts to estimate the combined effect. We identified three loci outside of the Major Histocompatibility Complex with genome-wide significance in the meta-analysis; all within 500KB of a previously identified European MS susceptibility variants (*LCK* in 1p35.2, *CD58* in 1p13.1, and *ETV7* in 6p21.31). The most strongly associated variant in the *LCK* gene region (rs145088108, OR = 1.18, P = 1.2E-13) is a missense mutation that is common on the NAM background (MAF= 0.38) but rare otherwise (MAF= 0.00017 and 0.00044 for AFR and EUR, respectively) and represents a novel NAM-specific signal at this locus. Several additional variants within 500KB of the European identified risk variant (rs79979643) for the *LCK* gene region achieved genome-wide significance in the subset of NAM alleles but were not significant for EUR or AFR alleles, including three coding mutations in proximal genes *FAM167B, TMEM39B*, and *IQCC*. The previously identified European risk variant demonstrated association with MS in only EUR alleles (OR = 1.07, p = 3.78E-06) but not in AFR or NAM alleles, and no LD is observed between the previously identified European risk allele and any of the novel NAM alleles (R2 less than 0.2 in all three ancestral populations). In alleles residing on an AFR haplotype, we identified a novel genome-wide significant signal for MS on chromosome 13q14.2; a non-coding transcript variant (rs3803245) with a frequency of 0.09 in AFR alleles but approximately 0 in EUR and NAM alleles. We have demonstrated that novel ancestry-specific risk alleles are present both within known susceptibility loci and in novel loci. These findings highlight the utility of a trans-ethnic approach to variant discovery in a way that will facilitate treatment and prevention in diverse populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1355 Application of scDRS in autism spectrum disorder characterizes cell type and single cell level disease association.

Authors:

X. Li, K. Hou, K. W. Eyring, C. Liu, K. Abuhanna, Y. Zhang, D. H. Geschwind, C. Luo, B. Pasanuic; UCLA, Los Angeles, CA

Identification of cells exhibiting disease related transcriptomic changes in autism spectrum disorder (ASD) remain one of the main hurdles to better understanding ASD disease mechanism. Statistical tools such as scDRS (Zhang et al. 2022 Nature Genetics) that quantifies enrichment in gene expression toward disease associated genes and assign single cell level disease risk scores would allow interrogation of within cell type heterogeneity of disease associated transcriptomic profile.

To identify such patterns, we first searched previously published gene sets that are manually curated such as SFARI gene list (Abrahams et al. 2013 Molecular autism). We retained 931 genes with high confidence (gene score 1, 2) and used number of publications as weight. We also derived 1000 genes computed with MAGMA (de Leeuw et al. 2015 PLoS computational biology) on ASD GWAS (Grove et al. 2019 Nature genetics).

Next, we deployed these disease associated gene sets onto the publicly available transcriptomics atlas (TMS) (The Tabula Muris Consortium 2020 Nature) with scDRS and identified 123 and 56 cells with significant disease risk score (fdr < 0.1) when using SFARI gene set and ASD GWAS gene set respectively. Across cells with significant risk score, the majority of them are neuronal cells at 87.8% and 85.7% respectively when computed using SFARI gene set and ASD GWAS gene set.

To further quantify how the signal could manifest in a case and control setting, we computed scDRS on ASD scRNA dataset with case and control individuals. This approach revealed 13 cells with significant scDRS score (FDR < 0.1) when using SFARI gene set but retained little signal when gene sets computed from ASD GWAS were deployed.

In this study, we report scDRS score for ASD in the TMS atlas using SFARI gene set as well as gene set computed from ASD GWAS using MAGMA. We also followed up by applying scDRS with those two gene sets on scRNA data with case and control. We noticed SFARI gene set provided stronger signal in both settings compared to the gene set derived from ASD GWAS. We attribute this result to the small sample size of ASD GWAS and warrants additional research on including more individuals in ASD GWAS to allow for higher statistical power in detecting disease associated genes and how they manifest in disease.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1356 Arginine, Glycine, and Creatine Supplementation Improves Symptoms in a Female with *SLC6A8* Creatine Transporter Deficiency

Authors:

C. Theile, K. Tauer, J. Owens, K. Cecil, A. Shillington; Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

X-linked Creatine Transporter Deficiency (CTD) is caused by pathogenic variants in *SLC6A8* and is characterized by intellectual disability, behavioral / developmental disorders, and seizures. The *SLC6A8* protein has critical roles in synthesis and distribution of creatine throughout the body. The central nervous system is especially reliant on *SLC6A8* to allow creatine to cross the blood brain barrier. Cerebral creatine deficiency disorders are found in up to 2.6% of males with intellectual disability, but few female cases have been reported. Small cohorts have suggested that supplementation of creatine, arginine, and glycine can stop disease progression in males and improve symptoms in females with CTD, though only four females on this therapy have been reported in the medical literature. We offer a case of a female with a de novo pathogenic *SLC6A8* variant who significantly improved with supplementation.

At time of diagnosis, the reported patient had weight loss, mild intellectual disability, attention deficit hyperactivity disorder, generalized anxiety disorder, and intermittent explosive disorder. Magnetic resonance spectroscopy (MRS) of the brain showed reduced creatine on all acquired spectra. Based on literature review of previously treated female patients, the reported patient was started on creatine-monohydrate at 200 mg/kg/day, L-arginine at 400 mg/kg/day, and L-glycine at 150 mg/kg/day. Within three weeks of starting supplementation, her caregiver reported that she was "doing better in almost every way." She gained 5 kg and symptom improvement was also seen through her mood: she was sleeping through the night, was more alert during the day, and was showing more appropriate behaviors. After 8 months of supplementation, MRS showed improved creatine concentrations with normalizing semi-quantitative ratios with other brain metabolites.

Previous small cohort studies of male patients with *SLC6A8* deficiency demonstrated neither improvement nor decline on treatment. One female supplemented only with creatine showed increased aggression and worsening of self-injurious behaviors. However, two female patients in the literature supplemented with dosages of creatine, arginine, and glycine demonstrated improvement in neuropsychiatric symptoms. The reported patient's experience in conjunction with similar results in the literature, provides evidence to clinicians trialing creatine, arginine, and glycine supplements for female patients with CTD.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1357 Assessment of the Impacts of Blood Collection Tube Types on Blood Acylcarnitine Determinations.

Authors:

D. Shao, L. Zhai, R. Giles, K. Pap, M. Natowicz; The Cleveland Clinic Fndn., Cleveland, OH

Background:
Blood acylcarnitine profile analysis is a powerful tool to diagnose numerous inherited metabolic disorders, including many mitochondrial fatty acid oxidation disorders and organic acidemias. It is used for follow-up testing of screen positive results from newborn screening programs and in the evaluation of children and adults suspected of having a fatty acid or organic acid disorder. Serum or plasma samples, the latter obtained with a variety of anticoagulants, are normally accepted for acylcarnitine profile analysis. In view of the diverse types of blood collection tubes used in acylcarnitine analyses, it is important to evaluate possible matrix effects on the measurement of the many acylcarnitines that are assessed in blood acylcarnitine assays.
Methods:
52 acylcarnitines and related analytes were measured by liquid chromatography-tandem mass spectrometry using plasma obtained from sodium heparin (green top tube), lithium heparin (green top tube), and EDTA (lavender top tube) anticoagulated tubes, as well as serum (red top tube). Samples from each blood tube type were obtained at the same time from three healthy individuals. Each sample is assayed in triplicates.
Results/Conclusions:
At least three of 50+ measured analytes showed significant (>25-30%) matrix effects. Butyrobetaine was ~30-75% higher in heparinized plasma than in serum or EDTA anticoagulated plasma. Decanoylcarnitine (C10) was ~25-30% higher in heparinized plasma or serum compared to EDTA anticoagulated plasma. Propionylcarnitine (C3) was about 25-35% lower when measured in serum than the other tube types. When such differences straddle medical decision cut-offs, diagnostic decisions can be impacted; this may be particularly relevant for mild and late-onset forms of inherited metabolic disorders. These data suggest the utility of using matrix-specific reference intervals for those analytes that differ significantly between tube types.

PB1358 Association between *APOL1* risk variants and progression from infection to sepsis

Authors:

L. Jiang[1], G. Liu[1], A. Oeser[1], A. Ihegword[1], A. Dickson[1], L. Daniel[2,3], A. Hung[1,4], N. Cox[1], C. Chung[2,3], W-Q. Wei[1], M. Stein[1], Q. Feng[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Univ. of Miami, Coral Gables, FL, [3]Miami VA Hosp., Coral Gables, FL, [4]Tennessee Valley Hlth.care System, Nashville, TN

Abstract Importance: Two risk variants in the apolipoprotein L1 gene (*APOL1*) have been associated with increased susceptibility to sepsis in Black patients. However, it remains unclear whether *APOL1* high-risk genotypes are associated with either progression from infection to sepsis or sepsis-related phenotypes, independent of their association with severe renal disease.**Objective:** To examine the association between *APOL1* high-risk genotypes and the risk of progression from infection to sepsis and sepsis-related phenotypes.**Design, setting, and participants:** A retrospective cohort study of 2,242 Black patients hospitalized with an infection.**Exposure:** *APOL1* high-risk genotypes.**Main outcomes and measures:** The primary outcome was sepsis; secondary outcomes were in-hospital death and organ failure related to sepsis.**Results:** Of 2,242 Black patients hospitalized with infections, 565 developed sepsis. Patients with *APOL1* high-risk genotypes had a significantly increased risk of sepsis (odds ratio [OR]=1.29 [95% CI, 1.00-1.67; p=0.047]); however, this association was not significant after adjustment for pre-existing severe renal disease (OR=1.14 [95% CI, 0.88-1.48; p=0.33]), nor after exclusion of those patients with pre-existing severe renal disease (OR=0.99 [95% CI, 0.70-1.39; p=0.95]). *APOL1* high-risk genotypes were significantly associated with the renal dysfunction component of the Sepsis-3 criteria (OR=1.64 [95% CI, 1.21-2.22; p=0.001], but not with other sepsis-related organ dysfunction or death. The association between high-risk *APOL1* genotypes and sepsis-related renal dysfunction was markedly attenuated by adjusting for pre-existing severe renal disease (OR=1.36 [95% CI, 1.00-1.86; p=0.05]) and was no longer significant after exclusion of patients with pre-existing severe renal disease (OR=1.16 [95% CI, 0.74-1.81; p=0.52]). A restricted PheWAS, designed to assess significant outcomes from a previous PheWAS among Million Veteran Program (MVP) patients, yielded similar results; we replicated the association between high-risk *APOL1* genotypes and sepsis-related phenotypes previously reported in MVP, and additionally found that those associations were attenuated or no longer present after accounting for pre-existing renal disease.**Conclusion and relevance:** *APOL1* high-risk genotypes were associated with an increased risk of sepsis; however, this increased risk was attributable predominantly to pre-existing renal disease.

PB1361 Association of OCT-1 gene polymorphism in type II diabetes mellitus patients from North Indian population

Authors:

H. Parveen, S. kumari; King George Med. Univ., Lucknow, Lucknow, India

Background: Diabetes mellitus has become a most important health problem worldwide in recent times. **Aims and objective:** To investigate the possible association of organic cation transporter- 1(OCT1) gene polymorphism (A-G) in type II Diabetes mellitus. **Methodology**: 100 diagnosed T2DM patients were recruited for the study and the genotypes for OCT-1 gene polymorphism using polymerase chain reaction (PCR) followed by restriction fragment length polymorphism (RFLP) were done. **Result:** We did not find any significant association between GG homozygous alleles ($p<0.079$) and AG heterozygous alleles ($p=0.209$) in type 2 diabetes mellitus patients compared to the control. It this case-control study, the frequency of the G allele of OCT-1 was found significant in alcoholic type 2 diabetes mellitus patients ($p=0.026$*). **In conclusion,** OCT-1 gene G allelic polymorphism is associated with type 2 diabetes mellitus patients in the north Indian population.

Inst., Singapore, Singapore

Parkinson's disease is a progressive neurodegenerative disease that adversely affects balance, muscle control and movement. Current understanding of Parkinson's disease pathogenesis mechanisms is poor and can be improved by gleaning mechanistic insights from rare protein-altering genetic variants associated with the disease.
We performed whole-exome sequencing on a total of 9,810 individuals (Discovery cohort: 4,298 Parkinson's disease patients and 5,512 unaffected controls) of East Asian ancestry from Singapore, Malaysia, Hong Kong, South Korea and Taiwan. After conducting stringent filtering for sample quality, variant quality and variant pathogenicity prediction, we tested for gene-based association of rare protein-altering variants with Parkinson's disease status and observed two genes (*GBA1* and *SMPD1*) which surpassed exome-wide significance ($P<2.5\times10^{-6}$). Exome-wide significant association of both *GBA1* and *SMPD1* was replicated in another 11,227 individuals (Replication cohort: 5,585 Parkinson's disease patients and 5,642 unaffected controls) of Asian and European ancestry.
The association of rare protein-altering *GBA1* variants with Parkinson's disease has been well established, while reports of rare protein-altering *SMPD1* association in Parkinson's disease in the literature is inconsistent and implicated *SMPD1* variants of unclear pathogenicity. As *SMPD1* encodes for the enzyme acid sphingomyelinase, we conducted functional assay for enzyme activity level of rare protein-altering *SMPD1* variants observed in the Discovery and Replication samples. We established that rare protein-altering *SMPD1* variants with less than 44% of normal acid sphingomyelinase activity were associated with Parkinson's disease risk in both Discovery (odds ratio (OR) = 2.37, 95% CI = 1.68 - 3.35, $P = 4.35\times10^{-7}$) and Replication cohorts (OR = 2.18, 95% CI = 1.69 - 2.81, $P = 4.80\times10^{-10}$), thus resulting in highly significant association observed when all cohorts were meta-analyzed (OR = 2.24, 95% CI = 1.83 - 2.76, $P = 1.25\times10^{-15}$).
Our findings show that rare functionally deficient *SMPD1* variants are associated with increased risk of Parkinson's disease and emphasize the significance of sphingomyelin metabolism in the pathobiology of Parkinson's disease. Further research is warranted to delve into the precise mechanisms underlying impaired sphingolipid and ceramide metabolism in the development of Parkinson's disease. Our approach also underscored the usefulness of functional assays to delineate pathogenic variants in exome sequencing investigations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1363 Association of angiotensinogen rs699 SNP with pre-eclampsia in Lagos, Nigeria: Case-control study

Authors:

T. Fagbayi[1], A. O. Somade[2], A. K. Adefemi,[3], O. G. Shonde[1]; [1]Univ. of Lagos, AKOKA, YABA,, Nigeria, [2]Univ. of Lagos, Akoka, Nigeria, [3]Lagos State Univ. Teaching Hosp. (LASUTH), Lagos,, Nigeria

Pre-eclampsia is a pregnancy-specific disorder that is influenced by genetics and socio-medical factors. Angiotensinogen rs699 (AGT rs699) polymorphism affects spiral arteries in the uterus and controls blood pressure. This SNP has been associated with pre-eclampsia and there have been conflicting results in certain populations of negative associations. This study aimed to investigate the association of AGT rs699 and ascertain the socio-medical factors with pre-eclampsia in Lagos, Nigeria. Ethical approval and informed consent were obtained from Health Research and Ethical committees. Thirty (30) preeclamptic (P) and 39 normotensive (N) pregnant women from a selected maternity hospital were recruited for this study. Demographic characteristics, medical history, and present medical conditions were assessed using questionnaires. Blood samples were collected and AGT rs699 was genotyped. Descriptive statistics, independent sample t-test, chi-square, and multiple regression analysis were used to analyze the data obtained ($p < 0.05$). The mean age and weight of women with pre-eclampsia were higher in preeclamptic women with no significant difference (P = 32.43 ± 5.76, N = 30.97 ± 4.54, and P =79.04 ± 10.28, N = 76.82 ± 15.35 respectively). Diastolic blood pressure (DBP), Systolic blood pressure (SBP), and Proteinuria were significantly higher in preeclamptic patients. Surprisingly, the incidence of AGT rs699 was significantly higher in normotensive (82%) women than in preeclamptic women (17%) ($X2 = 29.15$, $p=<0.05$). A significant correlation was observed between AGT rs699 and SBP in normotensive patients ($r2 = 0.201$, $p=0.003$) and a negative correlation in preeclamptic patients. In contrast, AGT rs699 was negatively related to DBP with no statistical difference in both the normotensive and preeclamptic groups. In addition, no correlation was observed between AGT rs699 and weight nor was there any significant difference. In conclusion, this study revealed a negative significant association between pre-eclampsia and AGT rs699 among cases and the control population. Invariably, this will serve as baseline information and strengthen population-specific biomarkers for pre-eclampsia.

PB1364 Associations between Microbiome-Associated Variants and Diseases: Insights into the Role of the Gut Microbiome in Deep Vein Thrombosisin diverse populations.

Authors:

T. Cherlin[1], C. Morse[1], S. Bordenstein[2], A. Verma[1], S. Verma[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Penn State Univ., University Park, PA

Recent efforts have been made to understand the role of gut microbiome in disease etiology. Using high throughput sequencing, studies have investigated the microbiome's association with diseases and genetic variants Markowitz et al. discovered 33 significant microbiome-associated variants (MAVs) linked to diseases in a European population, but none identified in African population. We aim to identify MAVs in diverse populations by including more MAVs from various populations and conducting phenome-wide association studies (PheWAS) in large cohorts like the Penn Medicine Biobank (PMBB). We extended the initial 908 MAVs from 11 microbiome GWASs to 1,003 unique MAVs from 13 GWAstudies including the two newer non-European population studies: the Multi-ethnic cohort (MEC) and Helius. We performed PheWASs for these 1,003 variants and 1,227 phenotypes in an African population (n = 10,995) and European populations (n = 28,853) in the PMBB dataset. Subsequently, a meta-analysis was conducted. Notably, one MAV (rs8176645) showed Bonferroni significant association (p-value<$4.06x10^{-08}$[SS1]) with deep vein thrombosis (DVT), venous embolism, replicating the findings of Markowitz et al. Our findings demonstrate significant associations between microbiome-associated variants (MAVs) from microbiome GWASs and diseases in individuals of African populations. Particularly, we identified a MAV (rs8176645) associated with DVT, indicating the potential role of the gut microbiome in DVT development. These results suggest that specific microbiome compositions or MAVs may contribute to the susceptibility or progression of DVT. Understanding the microbiome's involvement in DVT has implications for novel preventive and therapeutic approaches. Further investigation is needed to elucidate the underlying mechanisms of the MAV-DVT association in diverse populations. Future studies can explore the functional implications of these MAVs, examine the interplay between genetic factors and the gut microbiome, and evaluate microbiome-based interventions for DVT management and prevention. In summary, our findings provide valuable insights into the associations between MAVs from microbiome GWASs and diseases, particularly highlighting the potential significance of the gut microbiome in DVT. This research sets the stage for further investigations aiming to uncover the mechanisms and clinical implications of microbiome-DVT associations, potentially advancing personalized medicine and precision therapeutics for DVT patients.

PB1365 Assortative mating and parental genetic similarity drive pathogenicity of variably expressive variants

Authors:

C. Smolen[1], M. Jensen[2], D. Banerjee[3], L. Pizzo[4], 16p12.1 Deletion Consortium, S. Girirajan[5]; [1]Pennsylvania State Univ., State College, PA, [2]Yale Unversity, New Haven, CT, [3]Penn State, State College, PA, [4]Univ. of Utah, Salt Lake City, UT, [5]Pennsylvania State Univ., University Park, PA

Many disease-associated rare variants are variably expressive, conferring a range of neurodevelopmental features at varying levels of penetrance. Understanding the mechanisms underlying this variable expressivity is critical in predicting the phenotypic trajectory of individuals carrying these variants. Given the well-known role of family history in predicting phenotypes in affected individuals, we examined phenotypic and genetic patterns in parents associated with neurodevelopmental disease risk in children by analyzing more than 38,000 spouse pairs form the UK Biobank and parental pairs from four neurodevelopmental disease cohorts. We identified correlations between neurological and psychiatric features in parents and children, including clinical diagnoses, such as obsessive-compulsive disorder ($R=0.31-0.49$, $p<0.001$), and sub-clinical autism features in parents affecting autism severity in children, such as bi-parental mean Social Responsiveness Scale (SRS) scores affecting proband SRS scores (regression coefficient=0.11, $p=0.003$). We also observed patterns of both within-and cross-disorder correlations for seven neurological and psychiatric phenotypes among spouse pairs across cohorts, including a within-disorder correlation for depression ($R=0.25-0.72$, $p<0.001$) and a cross-disorder correlation between schizophrenia and personality disorder ($R=0.20-0.57$, $p<0.001$). Further, these spouses with similar phenotypes were also significantly correlated for rare variant burden ($R=0.07-0.57$, $p<0.0001$). We propose that assortative mating on these neurological and psychiatric features drives the increases in genetic risk over generations and “anticipation” associated with many variably expressive variants. We further identified parental relatedness as a risk factor for neurodevelopmental disorders through its inverse correlations with burden and pathogenicity of rare variants and propose that parental relatedness drives disease risk by increasing genome-wide homozygosity in children ($R=0.09-0.30$, $p<0.001$). Our results highlight the utility of assessing parent phenotypes and genotypes in predicting features in children carrying variably expressive variants and counseling families carrying these variants and provide insights into the phenotypic trajectory of families carrying these variants.

PB1366 Bilateral hearing loss & mild dysmorphism associated to a DSPP gene variant.

Authors:

A. Rodriguez Rivera[1], A. Cornier[2], E. Albino[3], S. Carlo[4]; [1]Univ. of Puerto Rico Bayamon Campus, Bayamon, PR, [2]San Jorge Children s & Women s Hosp., San Juan, PR, [3]Ponce Sch. of Med., Ponce, PR, [4]Ponce Hlth.Sci. Univ., Cabo Rojo, PR

Non-syndromic sensorineural hearing loss can represent a diagnostic challenge from a molecular point of view. We are presenting the case of a 10-year-old boy who was initially referred to Genetics due to bilateral sensorineural hearing loss. A comprehensive hearing loss gene panel demonstrated genetic variants of DSPP and OTOf genes. DSPP c1786_1788del & OTOF c.788C>T were identified. DSSP is associated with autosomal dominant disease and is predicted to result in an in-frame deletion in the DSPP gene. This variant has been associated with a clinical condition in the Human Gene Mutation Database (HGMD). Although the exact function (s) of DSPP-derived proteins are unknown, these appear to be essential for the development and mineralization of the tooth. The DSPP gene is also presently active in the inner ear with an unclear role in the hearing process. Hearing loss was initially documented at age 5 years when language & learning difficulties were identified. Hearing test & ABR studies identified bilateral sensorineural mild to moderate hearing loss at high frequencies of 3 -8K Hz., that has remained stable for the last 5 years. Clinical description of the patient includes synophrys of the eyebrows, epicanthal folds, brad nasal bridge, low set, posteriorly rotated & overfolded ears. Flat philtrum & thin upper lip were also documented upon examination. He presents mild dentinogenesis imperfecta with history of frequent and multiple dental caries. Chromosomal microarray studies were essentially normal: arr[GRch37] 14q21.3q23.1 x2 hmz. Interestingly, the maternal grandfather & a grand uncle & aunt presented moderate hearing loss throughout their lives, but his mother does not, suggesting a reduced penetrance of this genetic variant (gene). As mentioned before the patient also carries a heterozygous genetic change on the OTOF gene predicted to be pathogenic. This gene is associated with autosomal recessive hearing loss. We do not know if this haploinsufficiency has any potential adding effect on this patient hearing loss.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1367 Biological Insight into Alzheimer's Disease Sex Dimorphism Leveraging Predictive Clinical Models, Knowledge Graphs, and Colocalization Analysis

Authors:

A. Tang[1], K. P. Rankin[1], G. Cerono[1], S. Miramontes[1], H. Mills[1], J. Roger[1], B. Zeng[1], C. Nelson[1], K. Soman[1], S. Woldemariam[1], Y. Li[1], A. Lee[1], R. Bove[1], M. Glymour[1], T. Oskotsky[1], Z. Miller[1], I. E. Allen[1], S. J. Sanders[2], S. Baranzini[1], M. Sirota[1]; [1]UCSF, San Francisco, CA, [2]Univ. of Oxford, Oxford, United Kingdom

Predicting Alzheimer's Disease (AD) risk can allow for insights or interventions before irreversible disease progression. Electronic health records (EHRs) are emerging as a rich source of longitudinal data that can in combination with knowledge graph databases like SPOKE (Scalable Precision Medicine Open Knowledge Engine) and genetic colocalization analysis elicit biological meaning from complex constellation of phenotypic data. We trained random forest (RF) models on the UCSF EHR data (conditions, drugs, abnormal measurements) to predict AD onset, with index time as the first dementia diagnosis or drug prescription among the AD cohort and one year before last visit for controls. Models were also trained with sex stratification, and with matching, at various time points before index time, and evaluated with AUROC/AUPRC on 30% held-out sample. Top clinical conditions were mapped to the SPOKE knowledge graph for high order biological insight. Select clinical predictors were validated in an independent EHR across the UC health system with survival analysis, and genetic validation with colocalization analyses and evidence from UK Biobank and Open Targets Genetics. From over 5 million patients in the UCSF EHR, 2,996 AD patients were identified. After quality filtering, 749 AD (468 F, 281 M) and 250,545 controls (139,548 F, 110,829 M) were selected. RF models predict AD onset with mean AUROC/AUPRC of at most .86/.07 (.85/.07 F, .82/.08 M) at -7 years to .89/.18 (.87/.13 F, .85/.16 M) at -1 day. Top features of models trained on matched cohorts identified predictors among all patients (e.g., hyperlipidemia, dizziness), female-enriched (e.g. osteoporosis), or male-enriched (e.g. prostate hyperplasia). Survival analysis of osteoporosis exposure in external EHRs supports a significantly increased risk of AD diagnosis (HR 1.81 (95% CI 1.70-1.92) p<.005). SPOKE network highlight high-order shared genetic relationships between osteoporosis and AD including ALB, IL6, TNF, INS, and HFE. Genetic colocalization of osteoporosis and AD identifies a shared locus near MS4A6A with stronger association in females, which is further supported by MS4A6A eQTL relationship with AD and female heel bone mineral density and literature association between MS4A6A and AD and bone density. This study demonstrates opportunity to integrate molecular and clinical data to derive biological insight, leading to identification of MS4A6A relationship for both osteoporosis predictor and AD with possible sex specificity. Future extensions of this work include AD early identification and personalized insights to inform hypotheses between biology, sex, and AD.

Abdominal aortic aneurysm (AAA) is a dilatation of the body's main artery estimated to affect 0.92% of adults (aged 30-79) worldwide. The risk of rupture increases as an aneurysm grows, which is fatal without surgical intervention. There is no treatment to slow aneurysm growth aside from lifestyle recommendations including smoking cessation. We have previously used Mendelian Randomisation (MR) to identify evidence of a causal link between Metformin, a drug prescribed to treat type 2 diabetes, and a reduction in AAA risk. We now use MR to test for evidence of a causal effect between several Metformin pathways and AAA progression. We conducted two sample MR analyses using previously published genetic instruments for several Metformin drug pathways associated with both gene expression and decreased glycated haemoglobin (HbA1c) levels. Effect sizes were obtained from within UK Biobank for HbA1c, and from the largest existing AAA progression genomic dataset, consisting of 6,760 patients of European ancestry. We found evidence of a causal association of the AMPK Metformin pathway with AAA progression where a reduction in HbA1c is associated with slower AAA progression. We found no evidence of a causal association between a combined multiple pathway Metformin instrument and AAA progression. Clinical trials currently underway will assess the efficacy of Metformin in reducing AAA growth.

PB1369 Candidate and genome wide pathway analyses of healthy aging in 'Super Seniors'

Authors:

R. Hoque[1], A. Brooks-Wilson[2]; [1]BC Cancer Genome Sci. Ctr., Vancouver, BC, Canada, [2]BritishColumbia Cancer Res Ctr, Vancouver, BC, Canada

The Super Seniors Study aims to identify genetic factors that influence healthy aging. 'Super Seniors' are individuals 85 or older who have never been diagnosed with cancer, cardiovascular or major pulmonary disease, diabetes or dementia. We conducted candidate and genome-wide pathway analyses (GWPA) of the Super Seniors' phenotype to identify biological pathways for which genetic variation may contribute to healthy aging. The analysis was performed using 6.6 M imputed variants, in individuals of European ancestry. Cases were 541 Super Seniors; controls were 373 population-based mid-life individuals ascertained without regard to health status. Using MAGMA-1.08b, gene-based association tests were performed, then the outputs of the gene-based association were used to test for pathway-based associations that compare genes in a specific pathway with rest of the genome. The KEGG database was used to define gene sets for pathway analyses. Initially, analysis of 3 candidate pathways identified that one pathway, insulin signaling (P = 0.008) remained significant after Bonferroni correction for 3 tests, whereas two did not: the mammalian (mechanistic) target of rapamycin (mTOR) signaling (P = 0.58), and AMP-activated protein kinase (AMPK) signaling (P = 0.10). For further exploration, GWPA was performed for 186 gene sets representing all KEGG canonical pathways. No pathway remained significant after Bonferroni adjustment for 186 tests. The pathways were ranked based on their P values. Top ranked pathways included several known to be relevant to healthy aging or longevity, including Alzheimer disease (P = 0.003), P53 signaling (P = 0.004), Insulin signaling (P = 0.008), Type 1 diabetes mellitus (P = 0.01), Huntington disease (0.02), Lysosome (P = 0.02), nicotinate and nicotinamide metabolism (P = 0.02), phosphatidylinositol signaling (P = 0.03), glycosaminoglycan degradation (P = 0.03), TGF Beta signaling (P = 0.03), mitogen-activated protein kinase (MAPK) signaling (P = 0.04), adipocytokine signaling (P = 0.04), and apoptosis (P = 0.04). Though the results are not genome wide significant, the results of candidate pathway analyses and the observation of pathways of known relevance among the lowest p-values supports that multiple genetic variants in these pathways may contribute to healthy aging in this unique cohort of Super Seniors.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1370 Candidate genetic modifier of Alagille Syndrome, *THROMBOSPONDIN2*, worsens the liver phenotype in a transgenic Alagille Syndrome zebrafish model

Authors:

E. Keefer-Jacques, N. Valente, G. Matwijec, J. Nassur, B. Wilkins, K. Loomes, N. Spinner, M. Gilbert; The Children's Hosp. of Philadelphia, Philadelphia, PA

Alagille syndrome is a multi-organ, autosomal dominant disease caused by loss-of-function mutations in the Notch signaling genes *Jagged1* (*JAG1*) and *NOTCH2*. Variable expressivity with the associated liver disease is a hallmark feature of Alagille syndrome, however no genotype-phenotype correlation has been established. We previously identified the matricellular protein, Thrombospondin2 *(THBS2*), as a candidate genetic modifier of liver disease severity and showed that it interacts with NOTCH2 and is expressed in the bile ducts. These results indicated that *THBS2* overexpression reduced Notch signaling and could be associated with a worsened liver phenotype. We are now investigating the functional effects of THBS2 overexpression using an Alagille syndrome zebrafish model. We created transgenic fish overexpressing human THBS2 from a liver-specific promoter and crossed this to a second line containing a loss-of-function mutation in the *JAG1* zebrafish homolog, *jag2b*. These loss-of-function/transgenic fish (*jag2b*+/-; *THBS2*+) had lower survival rates than fish without THBS2 overexpression, with some exhibiting signs of heart edema and curved spines. The *jag2b*+/-; *THBS2*+ fish that survived to adulthood were smaller than those without THBS2 overexpression. To measure liver function, we used a fluorescent lipid, BODIPY FL C5, and measured the accumulation of fluorescence in the gallbladder as a readout of bile flow. We found that *jag2b*-/-; *THBS2*+ fish had reduced gallbladder fluorescence than *jag2b*-/-; *THBS2*- fish, indicating a more severe liver defect in fish with more THBS2. Additionally, gallbladders were larger in *jag2b*+/+ and *jag2b*+/- fish than in *jag2b*-/-fish but did not differ in size between *THBS2*- and *THBS2*+ expression. This shows that while *THBS2* influences bile flow, it is not the driver of gallbladder size. Further characterization, such as immunohistochemistry to study liver morphology and gene expression analysis of downstream Notch signaling genes is planned to better elucidate the effect of THBS2 overexpression. We expect that these studies will help to explain the phenotypic variability of Alagille Syndrome and lead to improvements in diagnostics and the ability to better predict disease course.

PB1371 Cannabis and psychosis: Genetic pathway analysis.

Authors:

I. Austin-Zimmerman[1], E. Johnson[2], E. Vassos[1], G. Trotta[1], E. Spinazzola[1], R. Murray[1], M. Di Forti[1]; [1]King's Coll. London, London, United Kingdom, [2]Washington Univ. Sch. of Med., St. Louis, MO

Cannabis use has been associated with an increased risk of psychosis and psychotic like experiences. Previous studies have demonstrated that this is a dose-dependent relationship, where more frequent use or the use of high potency cannabis is associated with increased risk. Both psychosis and cannabis use are complex and heritable traits. Previous GWAS have identified evidence of shared genetic liability for these traits. However, the specific genes and pathway underlying the association have not been extensively studied. We have built on the existing literature by conducting localised genetic correlation and pathway analyses to identify the shared pathways and pleiotropic variants, and to define potential differences in the genetic architecture of psychosis that develops with and without cannabis use.

We have meta-analysed the most recent GWAS of schizophrenia and bipolar disorder from the Psychiatric Genetics Consortium (PGC) to create a broad psychosis phenotype, as well as data from the Genomic Psychiatry Cohort (GPC) to enable cross-population analyses. We use these summary statistics and a recent GWAS of cannabis use disorder to the genome-wide genetic correlation between the traits, within and across ancestry. We conduct localised genetic correlation analysis using SUPERGNOVA to fine map the specific regions that contribute to the overall genetic correlation. We used PASCAL to conduct genetic pathway analysis in psychosis and CUD. A meta-analysis of schizophrenia and bipolar disorder GWAS results identified 413 independent genomic risk loci, and 1,479 mapped genes. The genetic correlation between the primary studies (PGC schizophrenia and PGC bipolar) was r^2=0.7. MAGMA analysis reveals enrichment of gene sets in the brain, including the frontal cortex, basal ganglia, and hippocampus, as well as the pituitary. SNP-based heritability (h^2) for our broad psychosis phenotype is estimated to be 0.14±0.004, p=$6.3x10^{-25}$. SNP-based h^2 = CUD is 0.12±0.01, p=$3.6x10^{-33}$. The global genetic correlation between CUD and the broad psychosis phenotype was 35% (p=$3.2x10^{-30}$). We identified three regions of local genetic correlation, after multiple testing correction, on chromosomes 1, 2, and 11. Many genes within these regions have been previously linked to a range of neuropsychiatric traits and substance use. Genetic pathway analysis identified nine pathways of potential shared importance between the two traits. These pathways played a role in synaptic transmission, neurodevelopment, signal transduction, and metabolism.

PB1372 Capturing Personal Health History and Family Health History in Genomic Risk Assessment Framework

Authors:

J. Cortopassi, J. Cimino, B. Davis, C. Dillon, B. Etheridge, E. Fields, A. Garrett, B. Goff, R. Johnson, B. Korf, J. Lucky, M. Wyatt, N. Limdi; Univ. of Alabama at Birmingham, Birmingham, AL

Genomic risk assessments are increasingly being used to predict risk of common complex diseases. These assessments present monogenic and polygenic risks while considering (or integrating) clinical factors, personal health history (PHHx) and family health history (FHHx).

To enable providers to contextualize the genomic risk(s) for the individual patient, accurate documentation of PHHx and FHHx is essential. However, reliance solely on patient self-report can introduce inaccuracy and/or missingness and may result in inadequate contextualization of genomic risk.

The Electronic Medical Records & Genomics (eMERGE) study aims to integrate genomic, clinical, family history and lifestyle/behavioral data into a genome informed risk assessment for several common chronic conditions. As part of the eMERGE network, the University of Alabama at Birmingham (UAB) has a focus on recruiting underrepresented and medically underserved patients. Here, we share our experience in obtaining PHHx and FHHx and identify discrepancies between actual and perceived risk of disease. We present with a focus on coronary heart disease and breast cancer, as these are conditions that combine genomic, clinical, PHHx, and FHHx data to generate an integrated risk score in the eMERGE study. Methods to minimize inaccuracies in PHHx and FHHx are considered.

Of the 2405 adults enrolled at UAB, as of June 2023, 72% are underrepresented or medically underserved. Of the 268 patients with results, 22.0% were found to be at high polygenic risk for one or more condition, 2.2% had one high monogenic risk, 2.2% had a high integrated risk for breast cancer and 31.7% had a high FHHx for at least one condition. We evaluated self-reported PHHx and FHHx and assessed the influence of missingness of data elements that trigger high risk. Missingness was also assessed by social determinants of health and under-represented status.

As genomic medicine efforts expand to include more under-represented and medically underserved populations, accurate recalling and reporting of FHHx and PHHx is needed to minimize exacerbating disparities for medically underserved groups. This is vital to ensuring that all individuals benefit from medical advances.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1373 Cardiovascular measures from abdominal MRI provide insights into abdominal vessel genetic architecture

Authors:

E. Sorokin[1], N. Basty[2], M. Thanaj[2], B. Whitcher[2], Y. Liu[1], J. Bell[2], E. Thomas[2], M. Cule[1]; [1]Calico Life Sci. LLC, South San Francisco, CA, [2]Univ. of Westminster, Res. Ctr. for Optimal Hlth., London, United Kingdom

Population-scale cardiac imaging studies have yielded many insights into the genetic basis of cardiac structure and function, by applying deep-learning-based segmentation models to tens of thousands of images of genotyped participants. In this study, we extend these principles to abdominal magnetic resonance imaging (MRI) to explore the genetic basis of quantitative traits both within and beyond the thoracic region typically studied with cardiac MRI or ultrasound.

We developed a deep learning model to segment the heart, aorta, and vena cava from abdominal MRI scans of 44,541 UK Biobank participants. From these, we generated six image-derived phenotypes (IDPs): heart volume, and four aortic and one vena cava cross-sectional areas (CSA). We performed genome- and phenome-wide association studies, and constructed a polygenic risk score for each phenotype.

Traits derived from abdominal MRI are highly correlated with previously published traits derived from cardiac MRI. We replicated previous findings related to age-related changes in heart and vessel dimensions. Infrarenal descending aorta CSA was associated with increased risk of abdominal aortic aneurysm, and heart volume was associated with several cardiovascular disorders. We demonstrated substantial genetic correlation with cardiovascular traits including aneurysms, varicose veins, dysrhythmia, and cardiac failure. Heritability enrichment analysis confirmed vascular tissue in the heritability of these traits. Genetic association study revealed 72 associations at 59 independent loci, 15 of which are novel. Colocalization with eQTL data implicated *MRC2*, which plays a major role in collagen degradation, in infrarenal aortic diameter. We derived a polygenic risk score for each trait and demonstrated an association with thoracic aortic aneurysm, pointing to a potential screening method for individuals at elevated risk for this condition.

PB1374 Categorization of Alzheimer's Disease Risk Variants Identifies Tissue Shared and Tissue Specific Genetic Regulatory Effects

Authors:

R. Sale[1], M. Betti[1], G. Kass[1], E. Gamazon[1,2]; [1]Vanderbilt Univ., Nashville, TN, [2]Claire Hall, Cambridge Univ., Cambridge, United Kingdom

Genome Wide Association Studies (GWAS) of Alzheimer’s Disease (AD) have identified over 70 associated loci. Many of these associations lie in intronic and intergenic regions and are assumed to regulate gene transcription. Identifying a causal link between genetic variation and gene expression may identify novel therapeutic targets for AD. Furthermore, AD presentation is heterogeneous and by partitioning AD risk variants into functional and tissue specific categories, one can identify context-specific risk factors for personalized medicine approaches. To understand the tissue and cell type specific genetic regulation of gene expression, we utilized a functional prediction framework developed in the Gamazon lab, CoRE-BED. CoRE-BED leverages cell types and various functional assays from the EpiMap compendium to train a decision tree that categorizes individual variants into cell type specific functional categories, such as promoter or enhancer. These functional annotations are then utilized to estimate cell type contributions to AD heritability and risk by generating partitioned heritability and cell type specific Polygenic Risk Scores (PRS) in each cell type. Finally, to determine causal relationships between cell-type dependent gene expression and AD, we utilized Mendelian Randomization with Joint Tissue Imputation (MR-JTI). MR-JTI leverages instrumental variables (Z) to estimate the causal effect of a gene (G) on the trait (Y). This causal framework will provide mechanistic insights into AD genetic predisposition.

PB1375 Causal association between celiac disease & autism spectrum disorder: A twosample Mendelian randomization approach.

Authors:

A. Fatoba, C. Simpson; Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN

The association of celiac disease (CD) and autism spectrum disorder (ASD) remains inconclusive. Reports from different observational studies have become controversial, necessitating exploring the causal relationship between CD and ASD. This study used two-sample Mendelian randomization analysis to determine the causal link between CD and ASD. Summary-level data from a genome-wide association study (GWAS) of the European population was used to screen instrument variables (IVs) at genome-wide significance ($P < 5 \times 10\text{-}8$). The strength of instrument variables was also evaluated with F-statistics. Inverse variance weighted method (IVW) was the primary MR analysis, followed by sensitivity analyses such as pleiotropy, heterogeneity, and leave-one-out analysis. Our results showed no association between CD and ASD (OR, 0.997; 95% CI, 0.974-1.019; P = 0.770). There was also no evidence of horizontal pleiotropy (MR-Egger intercept = -0.001; P-value = 0.813) and heterogeneity (Q =16.187; P-value= 0.239). These results were also complemented by the leave-one-out analyses and scatterplot, which showed that none of the SNPs influenced the result. In conclusion, our MR study showed no causal relationship between CD and ASD.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1376 Causal effects of the plasma proteome on MRI-quantified liver fat within the UK Biobank.

Authors:

R. Smit[1,2,3], V. Diez-Obrero[1], S. D'Silva[1,4], R. Loos[1,2,3]; [1]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Faculty of Hlth.and Med., Univ. of Copenhagen, Copenhagen, Denmark, [2]Charles Bronfman Inst. for Personalized Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Dept. of Environmental Med. and Publ. Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Ctr. for Cardiovascular Sci., Univ. of Edinburgh, Edinburgh, United Kingdom

Introduction: Excess liver fat is increasingly recognized as a sensitive proxy of cardiometabolic disease. By leveraging results from proteo-genomic studies through Mendelian randomization (MR), we aimed to gain insight into the potential druggability of liver fat. **Methods:** We employed a two-pronged approach for instrumental variable selection. First, we selected independent (LD r2<0.001) cis- and trans-pQTLs for 1,436 OLINK-measured proteins that attained genome-wide significance (p<5x10-8) in the discovery phase pQTL analyses (n=35,571 EUR) of the UK Biobank Pharma Proteomics Project (UKB-PPP). Separately, we restricted analyses to cis-pQTLs for 1,161 proteins with ≥1 primary cis-pQTL at a more stringent, protein-wide, genome-wide significance threshold (p<3.4x10-11) in discovery with nominal significance and directional consistency in replication (n=18,181). SNP-outcome weights were obtained by performing a GWAS on magnetic resonance imaging (MRI)-derived liver fat % in up to 34,308 UKB participants of White-British descent. To exclude confounding by LD, co-localization analyses were undertaken for proteins with cis-pQTL evidence of a causal effect. **Results:** In our cis/trans-pQTL combined analyses, the median per-protein number of independent instruments was 17, whereas only one protein had >1 instrument in our cis-pQTL only approach. Sufficiently strong instruments were available for both approaches (median F-statistic of 47 and 866, respectively). After FDR-correction, our combined cis/trans-pQTL approach identified Calsyntenin-1 (CLSTN1) and Heat Shock Protein beta-6 (HSPB6) as having a potential causal effect on liver fat % (random-effects IVW; CLSTN1: -0.48 (-0.69, -0.27) SD difference in liver fat % per doubling in protein concentration; HSPB6: -0.20 (-0.30, -0.11)). Pleiotropy-robust sensitivity analyses showed consistent results for HSPB6, but were not possible for CLSTN1 due to its small number of instruments (n=2). Separately, the cis-pQTL approach identified Apolipoprotein H (APOH), Neurocan (NCAN), and TNF receptor superfamily member 6B (TNFRSF6B) as having potential causal effects (Wald ratio; APOH: -0.07 (-0.10, -0.04); NCAN: -0.65 (-0.75, -0.56); TNFRSF6B: -0.12 (-0.17, -0.07)). However, co-localization analyses showed strong evidence of confounding by LD for NCAN (posterior probability for distinct causal variants near 1). **Conclusion:** With previous NAFLD-GWAS literature showing evidence for several of the loci underlying the currently identified putatively causal proteins, our results provide proteo-genomic evidence in favor of four potential drug targets aimed at modifying liver fat content.

Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [6]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [7]Dept. of Neurology, Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH, [8]Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Telomere length (TL) is a candidate biomarker for aging and many aging-related diseases. To date, mixed results have been reported regarding the relationship between TL and Alzheimer's Disease (AD). As a result, the precise role of TL in AD remains uncertain. The Midwestern Amish population is a founder population demonstrating less genetic variation compared to the general population. There have been limited efforts devoted into characterizing TL in the Amish, in particular in relationship to age-related disorders such as AD. In this study, we aimed to characterize the TL from whole genome sequencing (WGS) and investigate the association between TL and both aging and cognitive function in the Amish. The study sample comprises 1,055 Amish individuals over age 60 residing in Indiana and Ohio, and their cognitive status was determined based on both adjudication from clinical experts and education-adjusted mini-mental status exam results (3MS) scores at the time of blood draw. Individuals were classified as cognitively unimpaired (CU, N=713) either due to adjudication or had a 3MS score ≥ 87. Individuals were classified as cognitively impaired (CI, N=228) either due to adjudication as mild cognitively impaired (MCI, N=87), AD Dementia (AD, N=102), or cognitively impaired but not AD (CINAD, N=25), or had a 3MS score < 87 (N=14). Blood WGS data was obtained via Illumina NovaSeq 6000 platform. TLs were calculated from WGS using Telseq (Ding et al., 2014). Linear regression models were used to study the effects of age, sex, *ApoE* genotype, smoking history, and medical history on TL. Association between TL and cognitive function was assessed using multivariate linear regression models, adjusting for age only. As expected, age showed a significant impact on TL (β = -0.02, p=4.21x10^{-08}), whereas no statistically significant effects were observed for other factors (sex: p=0.88, *ApoE*ε4: p=0.26, smoking: p=0.70, cancer: p=0.51, AMD: p=0.81, anxiety: p=0.95). Association between TL and education-adjusted 3MS score was not observed both before (β = 0.00, p=0.86) and after adjusting for age (β = -0.02, p=0.16). The distribution of TL between CI and CU groups was not significantly different both before (β = -0.02, p=0.60) and after adjusting for age (β = -0.08, p=0.09). A similar result was also seen between the more restrictive AD and CU comparison (β = -0.01, p=0.89, age-adjusted: β =-0.09, p=0.17). These data confirm the association of shorter TL with increasing age and provide the basis for additional studies of TL with multiple phenotypes in the Amish.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1378 Characterization of the genomic landscape of a rat model of Alcohol Use Disorder: Initial findings

Authors:

J. Calderon[1,2], G. Garrido[1], J. Ugalde[3], V. Jaramillo[1,2], F. Ezquer[1,2], Y. Israel[1,2]; [1]Univ. del Desarrollo, Santiago, Rm, Chile, [2]Res. Ctr. for the Dev. of Novel Therapeutic Alternatives for Alcohol Use Disorders, Santiago, Chile, [3]Univ. Natl. Andrés Bello, Santiago, Rm, Chile

Alcohol Use Disorder (AUD) is one of the most widespread causes of preventable diseases in the world and accounts for 4.2% of all disease burden measured in disability-adjusted life years. AUD has been associated primarily to social determinants but genetic associations to this trait have never been undisputedly identified and described. In an attempt to identify potential genes and variants underlying AUD we performed Whole Genome Sequencing (WGS) to two rat models: a set of low-alcohol drinking Wistar rats (UChA) and a set of high-drinking rats (UChB) that have been selectively bred for over 90 generations via brother-sister mating and subsequent phenotypic selection upon exposure to ethanol.
Genomic DNA (gDNA) from 3 high-drinking animals and 2 low-drinking animals were sequenced at BGI with DNBseq PE150 platform and approximately 38Gb of clean data were obtained per sample. We aligned these data to mRatBN7.2 reference genome and generated variant call files (VCFs) using GATK best practices workflow for variant discovery. The genomic landscape of high- and low-drinking animals has been characterized considering several different approaches. First, we investigated whether there were variants of significant functional impact on a subset of approximately 70 genes that have been previously associated to AUD. Secondly, we decided to inquiry whether there were other genes that carried variants that were not previously associated to AUD. We also performed Gene Ontology (GO) analysis to understand whether these animals had a non-random distribution of genetic variants in regard to any particular cellular process or structure. Our results show that UChA and UChB rats have significant differences in frequency and impact of variants associated with oxidoreductase and aldehyde catabolism activity, implying that an impaired metabolism of alcohol derived products could be product of selection over generations in our model. These results suggest that further characterization of the genomic architecture of our animal model of AUD could shed light on novel variants and/or genomic regions potentially implicated in the onset of this devastating phenotype

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1379 Characterizing BIN1K358R SNP rs138047593 effects in 5xFAD plaque pathology of Alzheimer's disease using snRNA-seq

Authors:

Z. Shi, L. Garcia-Agudo, S. Kawauchi, H. Liang, C. Da Cunha, G. Milinkeviciute, K. Tran, V. Swarup, A. J. Tenner, F. M. LaFerla, A. Mortazavi, G. R. MacGregor, K. Green; Univ. of California Irvine, Irvine, CA

Background: Recent genome-wide association studies (GWAS) in AD have identified more than 70 risk loci, including bridging integrator 1 (BIN1). Previous studies elucidated BIN1's basic role as an important regulator of endocytosis and membrane dynamics. But as an important late-onset Alzheimer's disease genetic risk locus with multiple isoforms expressed in the brain, determining the pivotal role of BIN1 in pathogenesis has been challenging due to conflicting findings and its presence in both neurons and glial cells. The presence of a mutated form (K358R) in BIN1 has been associated with heightened susceptibility to Late-Onset Alzheimer's Disease. Our study introduced this variation into mice to comprehend the effects of BIN1K358R risk variants on brain biology, used snRNA-seq to characterize its status in different celltypes, and assessed any resulting effects on plaque formation or subsequent impairments.
Method: The study involved the breeding of BIN1K358R mice with 5xFAD mice, generating distinct groups, WT, BIN1K358R homozygous, 5xFAD and 5xFAD/BIN1K358R mice. After aging all test subjects to 12 months old, snRNA-seq were performed on the prefrontal cortex to analyze BIN1-related celltype specific changes. We investigated on celltype subpopulation status, and inferred the subpopulation changes through pseudotime trajectory. Differential module eigengene analysis followed by gene ontology analysis was performed across genotypes to understand celltype changes with the presence of BIN1K358R in mice.
Result: Our results in functional enrichment analysis on the differentially expressed genes showed that the 5xFAD/BIN1K358R mice had enriched inflammatory response in microglia and attenuated activity of neurons and synaptic structure in oligodendrocytes at 12 months. Our disease module and network analysis further revealed both 5xFAD and 5xFAD/BIN1K358R mice had induced response of active glial cells but also differential co-expressed module eigengenes.
Conclusion: The presence of LOAD risk variant-carrying mice, coupled with comprehensive phenotyping and transcriptomic information across distinct age groups and pertinent AD pathologies, will significantly augment our knowledge of the fundamental biology of LOAD. This can potentially contribute to the creation of novel therapeutic approaches.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1380 Characterizing pleiotropic effects of schizophrenia and insomnia.

Authors:

M. Ewald[1], W. A. Houssain[1], O. Ponnuru[1], E. Young[1], O. Veatch[2]; [1]Kansas Univ. Med. Ctr., Kansas City, KS, [2]Univ. of Kansas Med. Ctr., Kansas City, KS

Schizophrenia is a complex neurodevelopmental condition defined by positive (e.g., delusions, hallucinations) and negative (e.g., apathy, lethargy) symptoms. Schizophrenia has no cure, requiring lifelong treatment. Many individuals affected by schizophrenia experience co-occurring sleep disturbances, like insomnia. Often, sleep issues precede positive and negative symptoms of schizophrenia. Sleep problems are associated with increased severity of daytime schizophrenia symptoms. It is possible that targeting and treating sleep problems could help reduce severity of other symptoms present in individuals with schizophrenia. Several schizophrenia risk genes overlap with genes implicated in sleep problems, suggesting pleiotropic effects. To search for central driving genes and factors with a role in co-occurring sleep problems in individuals with schizophrenia, more comprehensive investigations using evidence from multiple sources are necessary to elucidate these complex mechanisms, specifically pleiotropic effects. By characterizing these pleiotropic effects, we can develop more targeted treatment options instead of merely managing symptoms. To do this, we developed a bioinformatics pipeline to prioritize high confidence pleiotropic genes more likely to be functionally relevant. Briefly, the GWAS Catalog v1.0 was queried using the application program interface, API, to identify single nucleotide variants (SNVs) associated at a genome-wide significance ($p<5x10-8$) with both schizophrenia and insomnia. This search resulted in 15 SNVs which were then assigned to 12 unique genes based on positional, eQTL and 3D chromatin interaction mapping using FUMA GWAS v1.5.4. We then mapped human genes to mouse orthologs using DIOPT v9.0 and determined whether any potentially pleiotropic genes were associated with schizophrenia-relevant phenotypes, i.e., increased exploration and hyperactivity, in the International Mouse Phenotype Consortium database v1.5.0. There were two protein-coding genes, *Cnksr2* (connector enhancer of kinase suppressor of Ras 2) and *Gtpbp2* (GTP binding protein 2), where single gene knock out mice exhibited a schizophrenia-like phenotype. Both encoded proteins have been implicated in the altered development characteristic of epilepsy and neurodevelopment disorders. Upon querying the Pharos database v3.16.1 both proteins are currently categorized as TBio, meaning these proteins do not have any known drug target properties. Follow-up studies examining how these two genes interact together or independently are warranted.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1381 Characterizing the microbiomes of diseased and adjacent non-diseased ileum of patients with varying Crohn's disease severity.

Authors:

E. Ryu[1], W. Koltun[2], G. Yochum[2], E. Davenport[1]; [1]Pennsylvania State Univ., University Park, PA, [2]Pennsylvania State Coll. of Med., Hershey, PA

Crohn's disease (CD) is a chronic disease of inflammation in the gastrointestinal tract. Characterized by its patchy distribution, CD remains incurable due to limited understanding of its complicated pathogenesis involving both genetic and environmental components. One known contributing factor is the human gut microbiome, which has been demonstrated to play a vital role in CD. Prior research has primarily focused on characterizing the microbial signature of CD by comparing healthy to diseased individuals, identifying key microbial contributors driving the onset of CD, and determining important microbes that discern ulcerative colitis and CD. We still, however, lack a complete understanding of how the gut microbiome varies with severity of CD, and what microbes might contribute to the development of more severe CD. Furthermore, studies have often utilized fecal samples. While convenient, fecal samples represent an amalgamation of the microbes residing in the gut. CD generally manifests as patchy areas of inflammation, so it is even more important to specifically target the microbiome in an inflamed area vs. nearby non-inflamed tissue. To address these gaps, I will investigate the gut microbiomes of patients with either moderate (surgery > 6 years post-diagnosis) or severe (surgery < 6 years post-diagnosis) Crohn's disease. I will specifically be comparing the microbial communities located on inflamed and proximal non-inflamed areas of the mucosal lining of the ileum within each patient (n = 23 * 2 for moderate CD and n = 23 * 2 for severe CD; for a total n = 92). I will extract the microbiome from mucosal scrapings acquired from the Inflammatory Bowel Disease Tissue Biobank at the Penn State Milton S. Hershey Medical Center. This study will be one of the first to investigate the microbiomes of inflamed and proximal non-inflamed ilea as they vary with CD severity. As genetic factors have also been demonstrated to contribute to CD pathogenesis, the results will also allow us to subsequently pair microbiome findings with human gene expression data and better understand how host genes and microbes physiologically interact to influence Crohn's disease pathogenesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1382 Chronic Kidney Disease and Kidney Function Genome-Wide Association Study Reveals Population-Specific Associations.

Authors:

M. D'Antonio[1], W-Y. Park[1], W. Gonzalez Rivera[1], K. Frazer[2], M. Gymrek[3]; [1]Univ. of California, San Diego, La Jolla, CA, [2]UC San Diego, San Diego, CA, [3]Univ California San Diego, La Jolla, CA

The prevalence of chronic kidney disease (CKD) is increasing worldwide due to the rising rates of chronic conditions such as diabetes and hypertension, as well as the aging population. It is estimated that more than 15% of US adults have CKD. Prevalence of CKD is almost twice as high in African Americans (AFR) than individuals of European descent (EUR) that have hypertension as a comorbidity, suggesting the presence of ancestry-specific effects for this disease. Genome-wide association studies (GWAS) have been performed mostly on EUR individuals on CKD and kidney function, measured as estimated glomerular filtration rate (eGFR), and have identified hundreds of genome-wide significant loci. However, differences in the effects of genetic variation between populations on kidney function are currently unknown, rendering polygenic risk scores poorly transferrable across populations.To address this issue, we performed a GWAS on CKD and eGFR on >475,000 UK Biobank (UKBB) individuals divided into four populations: AFR, EUR, East Asians (EAS) and South Asians (SAS). Overall, we identified 417 loci, including 112 (26.9%) novel loci not previously in CKD and eGFR GWAS.We observed 14 loci in non-EUR populations, including 11 unique to non-EUR populations. There are two possible explanations as to why these loci were not found in the EUR population, which accounts for >90% of UKBB individuals: 1) the causal variant is rare in the EUR population; or 2) LD structure in these regions vary between populations, suggesting possible evolutionary differences between populations. Indeed, for three of the 11 signals, the non-EUR causal variant had an allele frequency <1%, and for seven of the remaining eight signals the LD structure was significantly different between populations.The most significant locus, which overlapped GATM, a gene well known to be associated with kidney function and disease, was shared across AFR, EUR and SAS, but each population had a different lead variant, only in moderate LD with each other. Fine mapping using Susie and simulations with haptools showed that, while there exists a certain overlap between the GWAS signals across the three populations, at least partial population-specific GWAS signals occur in the GATM locus.Our study shows the presence of multiple population-specific GWAS loci associated with kidney function, indicating a possible reason for the differences in CKD prevalence between EUR and AFR. Further studies on larger non-EUR populations are needed to improve the statistical power of GWAS and better characterize differences between populations, in order to improve the accuracy of polygenic risk scores in diverse and admixed individuals.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1383 Circulating metabolite levels associated with risks of psychiatric disorders: a Mendelian randomization study for biomarker and drug target identification.

Authors:

T. Lu[1], Y. Chen[2], S. Yoshiji[3], Y. Ilboudo[4], V. Forgetta[5], C. Greenwood[4], S. Zhou[2], B. Richards[3]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]McGill Univ., Montréal, QC, Canada, [3]McGill Univ., Montreal, QC, Canada, [4]Jewish Gen. Hosp., Montreal, QC, Canada, [5]5 Prime Sci., Montreal, QC, Canada

Preventive measures and treatments for psychiatric disorders are limited. Circulating metabolites are potential candidates for biomarker and therapeutic target identification, because they play essential roles in biological processes, and their levels are measurable. Leveraging large-scale genome-wide association studies (GWASs) of psychiatric disorders, we performed Mendelian randomization (MR) analyses to assess the associations between circulating metabolite levels and the risks of bipolar disorder, major depressive disorder, and schizophrenia.
We conducted GWASs for circulating metabolite levels in the Canadian Longitudinal Study of Aging (N = 8,299 European ancestry individuals). To select genetic instruments while reducing the risk of horizontal pleiotropy, we combined gene expression profiles in GTEx and evidence in literature to identify variants which affect metabolite levels by altering expression of genes that are central to the metabolic pathways. MR analyses were performed, followed by multiple sensitivity analyses, colocalization analyses, and replication based on the UK Biobank, INTERVAL, and EPIC-Norfolk studies.
Low-pleiotropy genetic instruments were selected for 94 metabolites. After validating MR assumptions and colocalization evidence, we found that genetically increased circulating levels of n-3 unsaturated fatty acids, such as eicosapentaenoate (EPA) and docosapentaenoate (n-3 DPA), were associated with a decreased risk of bipolar disorder (maximum false discovery rate, FDR = 8.1×10^{-10}). Findings in replication cohorts confirmed the protective effects of increased n-3 unsaturated fatty acids level and n-3-to-total fatty acids ratio, as well as a decreased n-6-to-n-3 ratio. Genetically predicted circulating level of N-alpha-acetylornithine was associated with increased risk of schizophrenia with an odds ratio (OR) of 1.31 (95% CI: 1.18-1.44; FDR = 6.3×10^{-6}) per one standard deviation increase. Furthermore, a one standard deviation increase in genetically predicted circulating level of hypotaurine, a key intermediate in taurine biosynthesis, was associated with an OR of 0.85 (95% CI: 0.78-0.93; FDR = 5.5×10^{-3}) for major depressive disorder.
In conclusion, through a metabologenomics-guided MR, we have validated n-3 unsaturated fatty acids as a protective risk factor against bipolar disorder. We have identified N-alpha-acetylornithine as a candidate biomarker for schizophrenia, and hypotaurine as a candidate biomarker and possible therapeutic target for major depressive disorder. These findings encourage further explorations of these metabolites in the context of psychiatric disorders.

PB1384 Classification of Variants in Systemic Autoinflammatory Diseases using 3D Structures and Protein-protein Interactions

Authors:

A. Bülbül[1], E. Timucin[1], A. C. Timucin[2], **U. Sezerman**[1], E. Tahir Turanli[2]; [1]Acibadem Univ., Graduate Sch. of Hlth.Sci., Dept. of Biostatistics and Bioinformatics, Istanbul, Turkey, [2]Acibadem Univ., Faculty of Engineering and Natural Sci., Dept. of Molecular Biology and Genetics, Istanbul, Turkey

Systemic Autoinflammatory diseases (SAIDs) are a group of diseases, mainly of innate immunity, that have high heterogeneity at both clinical and genetic level. Depending on the inheritance of pattern of the disorder (monogenic or polygenic) approximately 20-50% of the time. Moreover, 420 of identified variants fall into the category of VUS (variants of uncertain significance).The efficacy of in silico variant prediction tools varies depending on the specific type of genetic variation and the functionality of the protein in question. The aim of our study is to utilize protein-protein interactions (PPI), 3D analysis, and to implement machine learning techniques for pathogenicity prediction of variants of SAIDs genes. We analyzed 702 missense variants from 34 genes such as *ADA2*, *IL10*, *IL10RA*, *MEFV*, and *MVK* implicated in SAIDs, as sourced from the Infevers database (Available at: https://infevers.umai-montpellier.fr. Accessed on 20.04.2022). Among these variants, 572 were pathogenic, 130 were benign.We computed ddG values. ZDOCK and SPRINT scores from 3D protein docking and sequence based PPI networks in STRING and IntAct databases. Scores were normalized using HGPEC rank scores. Additional features of PSIC, ASA, BLOSUM62 scores as well as volume and alpha helix propensity changes of variants were also considered. To overcome the sample imbalance issue, we utilized the SMOTE algorithm. For predictive modeling, we employed the Random Forest algorithm, optimized using Grid Search.
According to the model, which is trained on 80% splitted data, results obtained from an average of 20 split cross validations, we achieved a ROC AUC value of 984%, an F1 value of 0.955, precision of 0.968, recall of 0.948, accuracy of 0.956, and balanced accuracy of 0.955.. Our prediction method exhibited superior performance compared to commonly used mutation prediction methods, namely SIFT, PolyPhen, and CADD. Evaluation on a small test set of 59 variants found in the exons 2 and 10 of the *MEFV* gene showed that our model outperformed all of the predictors achieving an accuracy of 0.864 while the performance of the other predictors ranged in between 0.694 to 0.813. The prediction results for an additional set of 420 VUS missense variants is available at https://github.com/(autor)/Variant_Prediction_Tool. The implemented pathogenicity prediction strategy is particularly valuable in monogenic diseases and proves promising for complex diseases when genes are considered according to disease subgroups.

PB1385 Clinical application of polygenic risk scores in obesity

Authors:

N. Vos, J. van Uhm, E. Bulthuis, L. kleinendorst, M. Mannens, P. Jansen, M. van Haelst; Amsterdam UMC, Amsterdam, Netherlands

Introduction: In recent years, significant progress has been made in unravelling both polygenic and monogenic factors in obesity. Developments in polygenic risk score (PRS) analyses have emerged as a promising strategy in predicting obesity risk and understanding the variable penetrance of monogenic mutations. Despite this, translation and implementation of PRS into clinical settings remain limited.
Methods: Our current study aims to evaluate the feasibility, utility and predictive value of PRS in genetic diagnostics in real-world settings of a clinical obesity cohort. We include patients referred to the clinical genetics department (Amsterdam UMC) for suspected genetic obesity (n=83), and those with chromosome 16p11.2 deletions (n=10), of which polygenic susceptibility are compared with the general population (GO-NL cohort, n=498). PRS are extracted from clinical SNP arrays and calculated based on the largest available BMI GWAS (N= 681,275). We tested whether: 1) our clinical cohort differs in polygenic susceptibility for obesity compared to the general population; 2) PRS can aid in identifying patients at the highest risk of carrying a monogenic mutation for obesity.
Results: We show high feasibility to extract PRS from clinical SNP arrays in a high throughput manner. PRS of obesity was significantly higher in the obesity cohort ($P<0.001$), but not 16p11.2 deletion cohort, compared to the general population, suggesting a strong polygenic contribution to clinically referred patients. No such effect was observed for other non-obesity PRS. We found significantly lower PRS in patients with obesity and a mutation in an obesity gene, (suspected) monogenic obesity, compared to those in which no mutation is observed ($P=0.015$-0.049, depending on threshold), with PRS showing an area under the curve (AUC) of 0.73 for predicting mutation status.
Conclusions: We show that PRS explains the obesity phenotype in a considerable fraction of patients suspected of monogenic obesity. Our real-world results show that PRS aids in identifying patients with the highest probability of finding a monogenic form of obesity, which has important implications for the clinical use of PRS in genetic obesity.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1386 Clinical utility of exome sequencing in pediatric patients with extracorporeal membrane oxygenation for refractory lung disease

Authors:

J-H. Wu[1,2], E-T. Wu[1], C-C. Wang[1], F. Lu[1], H-W. Chou[3], C. Yih-Sharng[3], S-C. Huang[3], N-C. Lee[4]; [1]Dept. of Pediatrics, Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [2]Dept. of Med., Natl. Taiwan Univ. Hosp. Jinshan branch, New Taipei City, Taiwan, [3]Dept. of Surgery, Natl. Taiwan Univ. Hosp. and Coll. of Med., Taipei, Taiwan, [4]Dept. of Pediatrics and Med. Genetics, Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Purpose: Pediatric refractory lung disease is rare, has a broad differential diagnosis, and results in high morbidity and mortality even under extracorporeal membrane oxygenation (ECMO) support. The etiologies for these rare pediatric end-stage pulmonary conditions include lethal alveolar capillary dysplasia with misalignment of the pulmonary veins (ACD-MPV) and childhood interstitial lung disease which progress rapidly or chronically and require ECMO for bridge to lung transplants. In contrast to pathological diagnosis by invasive procedure, exome sequencing has reported timely diagnostic yields about 52.5% for pediatric patients in intensive care units. We aimed to characterize the clinical utility of exome sequencing in pediatric patients with extracorporeal membrane oxygenation for refractory lung disease. Methods: Children (age below 18 years) who required ECMO support for refractory lung disease at a tertiary children's hospital were recruited from 2017 to 2022. Prematurity and patients with complex congenital heart diseases were excluded. Demographic and diagnostic information was obtained from medical records. A standard whole-exome sequencing platform with text mining-assisted variant prioritization was applied to selected patients for genetic diagnosis. Results: A total of 30 (19 neonates and 11 children) patients under ECMO for refractory lung disease during 2017 to 2022 were recruited with mortality rate of 27% (8/30) and the diagnoses as follows: ten congenital diaphragmatic hernia, nine persistent pulmonary hypertension (PPHN), six lung infection, three pulmonary fibrosis, one asthma, and one trauma. Three children with pulmonary fibrosis and one neonate with refractory PPHN received exome sequencing and a molecular diagnosis was identified in 3 patients (67%) including a de novo heterozygous mutation in *FOXF1*, a hemizygous mutation in *DKC1* and a homozygous mutation in *SFTPC.* After diagnosis, all three patients were prepared for lung transplant but died in the prolonged waiting time due to limited organ donation for these young children. On the other hand, the remaining young teenager without genetic diagnosis received living-donor lung transplantation and recovered smoothly. Conclusions: Given the broad differential diagnosis and critical status of pediatric patients with ECMO for refractory lung disease, exome sequencing provides timely diagnoses which helps clinicians in shared decision-making with parents. However, hospice care for patients with lethal genetic disease, especially young children with limited organ donation, is an another choice.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1387 Clustered Mendelian randomization analyses identify distinct biological mechanisms that link adiposity to type 2 diabetes: towards precision medicine.

Authors:

H. Yaghootkar[1], M. Cule[2], M. Thanaj[3], N. Basty[3], A. Hashemloo[4], E. Sorokin[5], B. Whitcher[3], S. Burgess[6], J. Bell[3], N. Sattar[7], E. Thomas[1], A. Abraham[1]; [1]Univ. of Lincoln, Lincoln, United Kingdom, [2]Calico Life Sci., San Francisco, CA, [3]Univ. of Westminster, London, United Kingdom, [4]Brunel Univ., London, United Kingdom, [5]Calico Life Sci. LLC, South San Francisco, CA, [6]Univ. of Cambridge, Cambridge, United Kingdom, [7]Univ. of Glasgow, Glasgow, United Kingdom

Understanding the mechanisms that link adiposity to type 2 diabetes is challenging due to their complex nature and the heterogeneity of the conditions and individuals affected by them. Individuals with similar adiposity levels can exhibit different risks for cardiometabolic diseases. This study aims to identify genetic subtypes of adiposity and characterize their metabolic signature, specifically focusing on their impact on type 2 diabetes and its complications. We utilized 388 genetic variants associated with body fat percentage ($p<5E-8$) and assessed their effect on type 2 diabetes to identify distinct clusters representing different causal pathways using MR-clust, a statistical method for clustering variants based on their associations with an outcome trait. We then characterized the metabolic signature of each cluster based on various markers using published genome-wide association studies. We further analyzed MRI scans from the UK Biobank (in 40,000 individuals) to compare the impact of these clusters on measures of fat distribution and muscle quality. Finally, using FinnGen, we estimated the causal effect of each cluster on type 2 diabetes and its complications. Our findings revealed the identification of three clusters of alleles associated with both higher adiposity and higher type 2 diabetes risk (odds ratio [95% confidence intervals] per 1-standard deviation higher body fat percentage 11.20 [6.90,18.21]; 4.42 [3.72,5.25]; 1.41 [1.07,1.86]). Additionally, two clusters were associated with higher adiposity but lower type 2 diabetes risk (0.29 [0.18,0.48]; 0.05 [0.03,0.08]). All clusters exhibited associations with higher childhood obesity, body mass index, leptin, C-reactive protein, subcutaneous fat (abdominal and thigh), pancreas fat, and muscle fat. However, the associations with liver fat, lipids, insulin resistance, liver enzymes, adiponectin, and pro- and anti-inflammatory cytokines demonstrated opposing directions, with type 2 diabetes-decreasing clusters showing a favorable effect. Higher adiposity through type 2 diabetes-increasing clusters was causally associated with higher risk of all complications, while higher adiposity through type 2 diabetes-decreasing clusters was causally associated with lower risk of cardiometabolic complications but still higher risk of thrombotic events and osteoarthritis. These findings provide further support for adiposity-increasing mechanisms that may serve as protection against type 2 diabetes and its complications, particularly when accompanied by decreased ectopic liver fat. This may aid future optimisation of prediction, prevention, and treatment of type 2 diabetes.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1388 Coding and non-coding sequence variation across keratoconic cone surface

Authors:

M. Gajecka[1,2], M. Maleszka-Kurpiel[3,4], M. Kabza[1], J. Karolak[1], K. Jaskiewicz[2]; [1]Chair and Dept. of Genetics and Pharmaceutical Microbiol., Poznan Univ. of Med. Sci., Poznan, Poland, [2]Inst. of Human Genetics, Polish Academy of Sci., Poznan, Poland, [3]Chair of Ophthalmology and Optometry, Poznan Univ. of Med. Sci., Poznan, Poland, [4]Optegra Eye Hlth.Care Clinic, Poznan, Poland

Background: Keratoconus (KTCN) has been originally described by ophthalmologists as a non-inflammatory eye disease with multifaceted etiology. Although reported transcriptomic and proteomic findings suggested inflammatory aspects in KTCN, genetic features relating to immune system function in KTCN have not yet been demonstrated. Here, coding and non-coding sequence variation in the corneal epithelium (CE) across the keratoconic cone surface in patients with KTCN and its relevance in the functioning of the immune system were assessed.

Materials and methods: We performed WGS in an experimental model consisting of three CE topographic regions (TRs), *central*, *middle*, and *peripheral*, derived from four unrelated adolescent patients with KTCN and two adequate controls (Σ=18 experimental samples). The RNA/DNA/protein samples were extracted simultaneously (RNA/DNA/Protein Purification Plus MicroKit, Norgen Biotek), and after library preparation (TruSeq Nano DNA HT LibraryPrep Kit, Illumina), were sequenced with 30X coverage. SNP and indel calling was performed using Platypus, and detected variants were annotated with Ensembl Variant Effect Predictor software. Next, the recognized variants were evaluated together with the previously reported transcriptomic outcomes for the same CE samples, and the full-thickness corneas.

Results: Pathway enrichment analysis of genes with identified coding variants pointed to 'Antigen presentation' and 'Interferon alpha/beta signaling'. Both coding and non-coding sequence variants were found in genes (or in their close proximity) linked to the previously revealed KTCN-specific cellular components as 'Actin cytoskeleton', Extracellular matrix', and 'Collagen-containing extracellular matrix', and pathways as 'Focal adhesion', 'Hippo signaling pathway', and 'Wnt singling'. No genomic heterogeneity across the corneal surface was found comparing the assessed TRs. 35 chromosomal regions enriched in KTCN-specific sequence variants were revealed, with a most representative 5q locus, previously recognized as involved in KTCN.

Conclusions: Identified variants in non-coding regions of the genome further emphasized the genetic heterogeneity in KTCN and complemented the KTCN-specific sequence variation previously identified in ES. Moreover, the identified genomic features pointed to the involvement of innate and adaptive immune system responses in KTCN pathogenesis.

Support: The National Science Centre grant no. 2018/31/B/NZ5/03280.

PB1389 Co-expression of subgenual anterior cingulate cortex transcriptomehighlights translational modifications of synaptic signaling during early development in Schizophrenia.

Authors:

R. Smith[1,2], A. Mihalik[2], N. Akula[1], A. Schulmann[1], S. Marenco[3], P. K. Auluck[3], E. Bullmore[2], A. Raznahan[1], P. Vertes[2], F. J. McMahon[1]; [1]Human Genetics Branch, Natl. Inst. of Mental Hlth., NIH, Bethesda, MD, [2]Brain Mapping Unit, Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom, [3]Clinical Brain Disorders Branch, Intramural Res. Program, Natl. Inst. of Mental Hlth., Bethesda, MD

Weighted gene co-expression network analysis (WCGNA) applied to postmortem brain tissue is useful in identifying functional gene modules that are differentially regulated in neuropsychiatric disorders. However, current analysis techniques linking modules to diagnosis are limited by inability to 1) account for full variation in gene expression data and 2) quantify the influence of individual features and covariates. To address these issues, we performed gene co-expression followed by multivariate canonical correlation analysis. Total RNA was extracted from the sgACC of 185 human postmortem brain samples (55 controls, 44 schizophrenia (SCZ), 35 bipolar disorder (BD), and 51 major depressive disorder (MDD)) and sequenced. Gene co-expresssion was perfomed using WGCNA, and each module was functionally annotated. To establish relationships between modules and diagnostic groups at the univariate level, linear regression was run on each module, with the outcome variable as the first principal component (module eigengene) and the dependent variable as diagnostic group with and without drug covariates. To quantify the module-diagnosis-drug relationships and the importance of specific genes, Group Regularized Canonical Correlation Analysis (GRCCA) was run on the full expression dataset. At the gene level, 23 functionally significant co-expression modules were identified. Topic modeling of these modules highlights synaptic signaling, immune process, cellular organization and transport among others. Linear regression (without covariates) identified a link between SCZ and modules related to immune and inflammatory processes. However, post-hoc analyses with the inclusion of drug covariates suggested a strong influence of drug use. GRCCA run with drug covariates in the model matrix identified genes in modules related to translation, synaptic signaling, inflammatory response, and mitochondrial activity as robust drivers of a relationship with SCZ. No robust link was identified between BD and MDD and gene expression. The functional annotation of co-expression modules followed by GRCCA suggests a strong role of transcription and translation processes related to synaptic signaling in early development of SCZ. This key result corroborates what has been reported in the literature but provides an additional dimension by ensuring the effect is due to SCZ and not drug use. In conclusion, multivariate results are more specific than results obtained using traditional univariate methods applied to WGCNA, suggesting that the multivariate GRCCA is the key in identifying functional links between psychiatric disorders and gene co-expression networks.

PB1390 Colocalization and Mendelian randomization unveil interactions between eGFR, lifestyle, molecular pathways, and diseases for improved CKD management

Authors:

M. Masala, M. Pala; Consiglio Nazionale delle Ricerche, Monserrato, Italy

Chronic Kidney Disease (CKD) impacts more than 10% of adults in developed countries, constituting a substantial global health concern. CKD is linked to various health issues such as hypertension, diabetes, cardiovascular disease, and bone disorders. However, the molecular causes of CKD, as well as whether CKD is an effect or a cause of these related health conditions, remain unclear. A key indicator of CKD is a reduction in the glomerular filtration rate (GFR), estimable via serum creatinine or cystatin levels, which serve as widely accepted markers of kidney function.Recent genome-wide association studies (GWAS) on eGFR have encompassed over a million individuals, revealing over 400 associated loci. However, comprehensive characterization of these loci necessitates post-GWAS analyses, such as colocalization and Mendelian Randomization, which have thus far been limited to a restricted number of traits and diseases.To gain a deeper understanding of the complex interplay between eGFR, lifestyle factors, molecular pathways, and disease susceptibilities, we propose creating a platform that includes standardized GWAS and QTLs summary statistics for over 40,000 diseases and traits. This platform would enable the rapid evaluation of millions of GWAS combinations for standard post-GWAS analysis. The summary statistics include molecular traits (such as RNA, plasma proteins, and surface receptor proteins), biochemical measurements, immunophenotypes, lifestyle information, and diseases.Our initial findings have identified colocalization of eGFR (with a posterior probability H4 > 0.8) at 192 loci with 158 diverse quantitative traits or diseases. These include anthropometric measurements, physiological markers, lifestyle factors, immunophenotypes, and various diseases, such as Alzheimer's, type 2 diabetes, diverse cancers, cardiovascular diseases, and autoimmune conditions.Our systematic post-GWAS analysis will provide a comprehensive catalog of traits and diseases that have a genetic correlation with eGFR. It will offer scores for causal inference and could be used to suggest potential therapeutic targets, inform therapeutic strategies (for example, which pathways should be inhibited), and identify potential side effects of therapeutic intervention.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1391 Combined effects of genetics and oral contraceptive use on the risk of venous thromboembolism.

Authors:

V. Lo Faro[1], T. Johansson[2], Å. Johansson[1]; [1]Uppsala Univ., Uppsala, Sweden, [2]Immunology, genetics and pathology, Uppsala, Sweden

Background. Over 150 million women worldwide use oral contraceptives, and the risk of venous thromboembolism (VTE) is increased in oral contraceptive users. Women with inherited thrombophilia and carriers of certain thrombophilia gene mutations, such as factor V Leiden (FVL) and prothrombin mutation (PTM), are at increased risk of VTE, especially in combination with oral contraceptive use. VTE is a complex disorder involving many genetic risk factors and recently polygenic risk scores (PRS) have been proposed to capture a significant proportion of the genetic risk of VTE. The aim of this study is to estimate the risk of VTE at initiation and during continued use of oral contraceptives in women with a high genetic liability.

Methods. We used a prospective study design in which 244,420 participants from the UK Biobank were followed from birth. The effect of oral contraceptive use initiation and continuation on VTE risk was estimated using Cox regression with a time-dependent exposure variable. Women were stratified according to their PRS and whether they were carriers of FVL and/or PTM.

Results. When genetic risk was not considered, an increased risk of VTE was observed during the first two years of oral contraceptive use (HR=3.09; 95% CI = 3.00 - 3.20), but not during continued use (HR=0.92;95% CI, 0.80 - 1.05). However, when genetic risk was considered, women with the highest PRS risk category had a more pronounced increased risk of VTE associated with initiation of oral contraceptive use (HR=7.27; 95% CI, 6.61 - 7.99), and a similar risk was also seen in FVL (HR, 8.29 [95% CI, 7.40 - 9.28]) and PTM carriers (HR, 11.61 [95% CI, 9.76 - 13.81]). A high PRS in combination with FVL and PTM carriers resulted in the highest risk of VTE at the initiation of oral contraceptive use (HR, 38.14 [95% CI, 22.7333 - 64.01]). Women with a high genetic liability also had an increased risk during continued use, with the highest risk in women with a high PRS in combination with carriers of both FVL and PTM (HR, 7.14 [95% CI, 4.33 - 11.76]).

Conclusions. Polygenic risk can capture additional VTE risk that is not included in the commonly investigated genes for inherited thrombophilia. Our results indicate that oral contraceptive use is associated with an increased risk of VTE, particularly in women with a high genetic predisposition. Finally, our results also show that oral contraceptive use dramatically increases the risk of VTE just before starting use, but that this risk gradually decreases with continued use.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1392 † Combining GWAS and tissue-specific multiomic data to identify candidate human height genes.

Sch., Boston, MA, [10]Inst. for Molecular BioSci., The Univ. of Queensland, Brisbane, Australia, [11]William Harvey Res. Inst., Barts and the London Sch. of Med. and Dentistry, Queen Mary Univ. of London, London, United Kingdom, [12]Dept. of Orthopedic Res., Boston Children's Hosp., Boston, MA, [13]Dept. of Orthopedic Surgery, Harvard Med. Sch., Boston, MA, [14]Harvard Stem Cell Inst., Cambridge, MA, [15]Dept. of Human Evolutionary Biology, Harvard Univ., Cambridge, MA, [16]Broad Inst. of MIT and Harvard, Cambridge, MA, [17]Dept. of Statistical Genetics, Osaka Univ. Graduate Sch. of Med., Osaka, Japan, [18]Genetics of Complex Traits, Coll. of Med. and Hlth., Univ. of Exeter, Exeter, United Kingdom

The largest genome-wide association study (GWAS) on adult height conducted by the GIANT consortium in 5.4 million individuals of diverse ancestries identified 12,111 independent genetic variants associated with height (Yengo et al., 2022). These span 21% of the human genome and together explain over 90% of SNP-based heritability. Despite this significant coverage, the specific mechanisms through which these regions affect human height remain largely unknown. The aim of this study is to gain deeper insights into the role of these genetic variants in the biology of skeletal growth by leveraging multiple independent lines of genetic and genomic evidence.
We applied the newly-developed method SCENT (Single-Cell ENhancer Target gene mapping) to predict enhancer-gene pairs from multimodal single-cell data of 8 cell types (Sakaue et al., 2022). Of the 12,111 lead COJO variants reported by the GIANT study, 181 SNPs mapped to the regulatory regions of 267 genes.
We performed fine-mapping with SuSIE to identify putative causal variants associated with height in UK Biobank individuals of White British ancestry. Among the 2881 finemapped credible sets, 302 overlapped with predicted gene regulatory regions, implicating a total of 518 genes. Of these, 31 genes were implicated by credible sets containing only one SNP. Only 24 of the 518 genes were previously known to be functionally implicated in height (as part of the OMIM gene set, Yengo et al. 2022). As a complementary line of evidence, we used a combination of gene prioritization methods (PoPS, MAGMA, and DEPICT) to generate a shortlist of high-confidence height genes. Collectively, we identified 11 genes that were implicated by both enhancer-gene mapping and at least one gene prioritization method. Notably, 3 genes (STAT6, CTDSP2 and ARID3A) were implicated by all methods. We are extending this pipeline to human fetal distal femur tissues, in order to infer enhancer-gene pairs implicated in human skeletal development. Preliminary analysis of single-cell ATAC-seq data across 9 cell types shows significant enrichment of accessible chromatin regions for height heritability compared to other traits.
Using a combination of computational approaches combined with tissue-specific multiomic data we were able to implicate through converging lines of evidence a set of high-confidence height genes for further functional follow-up.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1393 Combining proteomics and metabolomics to identify signatures protective of neurological consequences of post-acute SARS-CoV-2 infection.

Authors:

C-Y. Su, S. Zhou; McGill Univ., Montréal, QC, Canada

Introduction: Post-acute sequelae SARS-CoV-2 (PASC) is an emerging public health concern with heterogeneous manifestations. Among PASC symptoms, long-term neurological manifestations are particularly debilitating. Their molecular underpinning remains poorly understood. Here, we combined proteomics and metabolomics to address this issue. **Methods:** Proteomic and metabolomic data were generated for 1,234 individuals from the Biobanque Québécoise de la COVID-19 (BQC19), which followed COVID-19 patients over two years. After quality control, 4,984 proteins and 943 metabolites were retained for analysis. Using 689 clinical entries from the BQC19, we defined broad neurological PASC (BNP) as any neurological manifestations, whereas refined neurological PASC (RNP) was defined as neurological complications that either recently appeared or deteriorated due to COVID-19. We then fitted single biomarker logistic regression models while adjusting for age at diagnosis and sex to determine the association of each protein or metabolite with BNP or RNP. **Results:** A total of 381 and 65 cases with both proteomics and metabolomics data met our definition of BNP and RNP and were compared with 535 and 713 controls, respectively. A total of 1,416 and 734 proteins were found significantly associated with BNP and RNP, respectively, with 544 overlapping proteins. In addition, 158 and 130 metabolites were found significantly associated with BNP and RNP, respectively, with 53 overlapping metabolites. In particular, we identified phosphatidylethanolamine-binding protein 1 (PEBP1) as being protective against BNP (OR (95% CI) = 0.76 (0.66-0.87), FDR p = 0.002) and RNP (OR (95% CI) = 0.61 (0.46-0.81), FDR p = 0.014). Interestingly enough, previous studies suggested downregulation of PEBP1 may lead to Alzheimer's disease. Moreover, PEBP1 functions as an enzyme for 1-palmitoyl-2-docosahexaenoyl-GPE, a phosphatidylethanolamine (PE) whose impairment may lead to neurodegenerative disorders, which is concordant with our finding that increased circulating PE is associated with decreased neurological PASC risk (BNP: OR (95% CI) = 0.78 (0.68-0.90), FDR p = 0.01; RNP: OR (95% CI) = 0.56 (0.41-0.75), FDR p = 0.006). **Conclusion:** Here, we used an integrative bi-omics approach combining proteomics and metabolomics to provide new insight into the pathophysiological mechanisms underlying neurological PASC risk which, possibly, could point to new ways to treat this condition.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1394 Combining research in humans and flies to uncover the genetic basis of ageing: A Transcriptome-wide Association Study identifies putative ageing genes in humans with experimental validation in flies.

Authors:

G. Navoly[1], A. Alizan[2], L. Partridge[2], N. Alic[2], K. Kuchenbaecker[1,3]; [1]UCL, Genetics Inst., London, United Kingdom, [2]Inst. of Hlth.y Ageing, UCL, London, United Kingdom, [3]Div. of Psychiatry, UCL, London, United Kingdom

Ageing and age-related diseases represent a major challenge for public health systems worldwide. While we have a solid grasp of the genetic architecture of ageing in model organisms, our understanding of human ageing is limited to a few candidate genes. To better connect research in model organisms and humans, we first performed a multi-tissue Transcriptome-wide association study (TWAS) on human lifespan, using >1 million parental lifespans from the UK Biobank and the LifeGen Consortium; followed by validation TWAS on two different ageing outcomes: Longevity and Healthspan. We also performed TWAS fine-mapping, to identify putative causal genes. We tested the role in ageing of the fly orthologues of four of the candidate genes: *COASY, MAD2L, SH3PXD2A* and *TOMM40*, by modulating their expression in specific tissues via RNA interference or over-expression. Lifespan assays were then carried out to assess the effects the genes have on *Drosophila l*ongevity. TWAS uncovered 563 significant gene associations, of which 139 genes were replicating in Longevity or Healthspan outcomes (replication threshold p<0.05). *TOMM40*, a gene that has an important role in maintaining mitochondrial function, had the strongest association with Parental lifespan (p=2.79E-66) and Longevity (p=1.30E-45) at the *APOE-TOMM40* region. *TOMM40* was successfully fine-mapped as the putatively causal lifespan gene, yielding a higher posterior inclusion probability (PIP) than *APOE* ($TOMM40^{PIP}$=0.99 vs. $APOE^{PIP}$=0.2). Using TWAS, we identified 9 novel genes associated with all the three ageing outcomes tested, including *TOMM40, HTR3B* and *COASY*. *COASY* plays an important role in synthetic and degradative metabolic pathways. Mutations in this gene have been associated with cognitive decline and neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease, which are strongly associated with ageing. Knocking down the fly orthologue of *COASY, Ppat-dpck*, and *SH3PXD2A, Cindr*, resulted in significant lifespan extension in flies, validating their role in ageing across organisms. In conclusion, TWAS uncovered significantly more associations with Parental lifespan than the GWAS. Using multiple ageing outcomes may yield more robust results and highlight genes involved in fundamental ageing processes that are conserved across species. Our results, highlighting the role of fly orthologue of *COASY, Ppat-dpck*, and of *SH3PXD2A, Cindr* in ageing in humans and flies show that TWAS can be an important tool in investigating the transferability of findings from model organisms to humans, as it identifies putative genes that can be validated experimentally.

Univ. of Hlth.and Welfare, Tokyo, Japan

Genome-wide association studies (GWAS) have successfully identified common-variant associations with atrial fibrillation (AF), while the proportion of phenotypic variation captured by common variants is substantially less than the estimates from pedigree-based analyses. To address this remaining heritability, whole-exome and whole-genome sequencing studies have examined rare-variant associations, but the contribution of rare genetic variation to AF risk is not well characterized. Furthermore, the relationship in genomic architecture of common and rare variants remains unexplored. Here, we performed GWAS using imputed array-based genotype data and whole-genome sequence data, respectively, and assessed the contributions of common variants and rare variants to AF genetics. First, a cross-ancestry meta-analysis of large-scale AF-GWAS comprising 116,532 AF cases and 1,338,446 controls identified 76 novel genetic loci among 223 genome-wide significant associated loci. We then conducted transcriptome-wide and proteome-wide association studies leveraging the models of expression and protein quantitative trait loci, respectively. These studies implicated 172 genes and 10 proteins associated with AF, and in particular we found that IL6R revealed a significant association in both studies. Next, we analyzed the whole-genome sequence data of two datasets from 547 patients with early-onset AF (less than 46 years of age) extracted from BioBank Japan and 315 patients who underwent catheter ablation for AF, and explored the consequences of rare variants using the LOFTEE plug-in implemented in the Variant Effect Predictor. Some genes with rare loss-of-function (LOF) variants were identified in both datasets including *TTN*, whereas other genes with rare LOF variants were detected only in individual dataset. Then, we performed enrichment analysis of LOF variants to identify genes associated with early-onset AF. Moreover, we conducted a gene-based burden analysis using rare LOF variants in a case-control study including control samples extracted from whole-genome sequencing data of 7,825 samples. Finally, we applied a polygenic risk score derived from a previous cross-ancestry meta-analysis of AF-GWAS to individuals who had whole-genome sequencing data available, and assessed the distribution of the polygenic risk score from common-variant associations in rare LOF variant carriers and non-carriers. Our results provide the contribution of common-variant and rare-variant associations to AF pathophysiology and revealed the relationship between these associations in genomic architecture of AF.

PB1396 Common and unique genetic effects contribute to development of alcohol related liver disease.

Authors:

A. Oliveri, K. C. Cushing, E. Speliotes; Univ. of Michigan, Ann Arbor, MI

Background: Alcoholic-related liver diseases (ALD) affects about 5% of individuals worldwide. Alcoholic liver diseases are heritable or genetically influenced. Identifying genetic predictors of disease can help us identify causal factors to inform risk stratification efforts and development of novel therapeutics. Here we carried out analyses to identify which alcohol consumption risk loci had effects on ALD and determine their effects on alcoholic hepatitis (AH) and alcoholic cirrhosis (AC).
Methods: We carried out a genome wide association study of alcohol consumption in the UK Biobank cohort. Genome-wide significant variants were then tested for association with ALD, AH, and AC in the UK Biobank using established ICD-10 codes (ALD: K70.1 and/or K70.3, AH: K70.1, AC: K70.3). Significantly ($p < 0.05$) associated variants and implicated genes were then evaluated for having expression QTL (eQTL) and gene expression effects in liver in the GTEx Portal.
Results: A total of 23 variants significantly associated with alcohol consumption. This included rs1229984-C (*ADH1B*, p= 3.7e-154), rs28712821-A (*KLB*, p= 2.4E-34), and rs1260326-C (*GCKR*, p= 6.5E-30). Of the 23 alcohol intake associated variants, 2 associated with ALD (*ADH1B*-rs1229984-C [p=0.000419], *MLXIPL*-rs7805504-C [p=0.0453]), 4 associated with AH (*MLXIPL*-rs7805504-C [p=0.0104]; *ADH1B*-rs1229984-C [p= 0.017]; *BRD3OS*-rs109536-C [p=0.0223]; *CYP1A1*-rs2470893-T [p=0.0255]), and 1 associated with AC (*ADH1B*-rs1229984-C [p=0.00208]). Several implicated genes were found to be expressed in the liver (*ADH1B*, *MLXIPL*, *CYP1A1*) and several genes were found to serve as variant-specific eQTLs in the liver (*LINC00094*, *ULK3*, *MPI*).
Discussion: These results show overlapping (*ADH1B*) and unique risk (*MLXIPL*, *BRD3OS*, and *CYP1A1*) of developing ALD, AH, and AC. These results suggest there are multiple ways to curb development of alcoholic liver disease. Further studies will help us to understand the functional effects of these genes on the risk of AH.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1397 Common genetic risk factors for scleroderma renal crisis in African Americans

Authors:

E. Roberson[1], G. Pravitt[2], J. Atkinson[1], J. Varga[3]; [1]Washington Univ., Saint Louis, MO, [2]NIH, Bethesda, MD, [3]Univ. of Michigan, Ann Arbor, MI

Systemic sclerosis (**SSc**) is a systemic disease with autoantibodies, increased connective tissue deposition, immune dysregulation, and vasculopathy. Some people with SSc develop scleroderma renal crisis (**SRC**), which has sudden onset hypertension, rapid renal failure, thrombocytopenia, and microangiopathic hemolysis. Pathologically, the kidney and endothelial damage in SRC is similar to that in thrombotic microangiopathies, some of which are caused by loss-of-function in inhibitors complement activation. *These pathological similarities made us question whether SRC risk was at least partially driven by common variants in complement regulators leading to an increased likelihood of complement activation leading to endothelial damage.*

Testing for common variant modifiers a sub-phenotype of an orphan disease is a challenge. We collaborated with the Genome Research in African Scleroderma Patients (**GRASP**) project to obtain genome-wide SNP data from African American disease controls with SSc only (44) and disease cases with SSc and SRC (50). The samples were typed on the Illumina Multiethic Global Array and were imputed using the 1000G phase 3 v5 reference after QC. We tested each SNP for SRC risk as an additive, dominant, or recessive trait using logistic regression, taking the first 5 principal components into account.

No variant passed a genome-wide significance threshold ($5x10^{-8}$). Despite the small sample size available, 91 variants passed a suggestive threshold ($1x10^{-5}$) under at least one model. One of these suggestive SNP regions was within 200kb of *C8A* and *C8B*, genes that are terminal complement effectors. MAGMA analysis similarly didn't have Bonferroni correction significant hits, but nominally significant hits in alpha/beta T cell activation and the activation/regulation of Th17 responses. It is striking that even using this small sample size that identified SNPs near complement effector genes. Further work is required to determine if these common variants are true risk factors for SRC and to decipher their molecular mechanism.

Given that we have a rare phenotype, it may be more fruitful to look for rare variant enrichment of target complement genes in people with SRC versus the expected population distribution. To this end, we have an ongoing orthogonal project with 300 SRC exomes to generate additional biological insights.

Hosp., Boston, MA, [21]Dept. of Pediatrics, Univ. of California, San Diego Med. Sch., San Diego, CA, [22]Pediatric Surgical Res. Lab., Massachusetts Gen. Hosp., Boston, MA, [23]Unit of Pediatric Surgery, Dept. of Gen., Visceral, Vascular and Thoracic Surgery, Univ. Hosp. Bonn, Bonn, Germany, [24]ErasmusMC, Breda, Netherlands, [25]Columbia Univ., New York, NY

Background - Congenital diaphragmatic hernia (CDH) is a severe congenital anomaly that is often accompanied by other anomalies and/or neurodevelopmental manifestations. Previous studies showed that rare *de novo* protein-coding variants and copy number variations contribute to CDH. However, the majority of CDH cases cannot be explained by rare *de novo* changes.**Methods** - To investigate the role of common variants in CDH risk, we utilized a cohort of 1,439 cases from the multicenter Diaphragmatic Hernia Research & Exploration; Advancing Molecular Science (DHREAMS) study and Boston cohorts. The cases were comprised of approximately 66% isolated and 34% complex cases, with complex including 52% cardiac defects, 19.5% neurodevelopmental manifestations, and 6.5% pulmonary defects (excluding pulmonary hypoplasia and hypertension). We performed a genome-wide association study (GWAS) using 1,005 unrelated European cases and 4,565 ancestry-matched, unaffected parents from the Simons Powering Autism Research for Knowledge (SPARK) study as controls. For replication, we used an independent cohort of 389 unrelated Dutch/German CDH cases (82% isolated, 18% complex) and 4,815 ancestry-matched controls, and then performed a meta-analysis.**Results** - We identified two loci with genome-wide significance in the discovery cohort - chromosome 3p14.3/lead SNP rs55705711 and chromosome 7q36.3/lead SNP rs7777647 - with replication in the Dutch/German cohort. Meta-analysis confirmed the associations and directionalities: rs55705711 ($p=1.410^{-16}$, OR=1.54) and rs7777647 ($p=3.410^{-11}$, OR=1.26). Allele frequencies of top SNPs at both loci were similar in isolated and complex CDH cases and between cases with and without likely pathogenic *de novo* variants. The lead SNPs explained 1.31% (rs55705711) and 0.7% (rs7777647) of the variance in susceptibility to CDH. The chromosome 3p14.3 locus resides in an intron of *ERC2* (ELK2/RAB6-interacting/CAST family member 2) and adjacent to *WNT5A* (Wnt family member 5A), a developmental patterning gene. Epigenomic data (ATAC-seq, Hi-C, and capture Hi-C) suggest the causal variant is likely in an enhancer region regulating *WNT5A* expression. The 7q36.3 locus resides in a topologically associated domain containing five protein coding genes and a long-range *cis*-acting regulatory domain upstream of sonic hedgehog (*SHH*).**Conclusions** - This first genome-wide association study of CDH identifies new CDH risk loci with potential enhancer functions for known developmental genes and supports a polygenic model as part of the CDH genomic architecture.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1399 Comparing the effect profile of CETP in individuals of East Asian and European ancestries

Authors:

D. Dunca[1], S. Chopade[1], M. Gordillo-Maranon[2], A. Hingorani[2], K. Kuchenbaecker[3], C. Finan[2], A. Schmidt[4]; [1]UCL, London, United Kingdom, [2]Univ. Coll. London, London, United Kingdom, [3]Univ Coll. London, London, United Kingdom, [4]Amsterdam UMC Heart Ctr., Amsterdam, Netherlands

Cholesteryl ester transfer protein (CETP) is a lipid drug target under development for coronary heart disease (CHD) in both European and East Asian populations. Previous drug target Mendelian randomization (MR) studies conducted in East Asians failed to show a CHD effect, which has been interpreted as lack of effectiveness of CETP inhibition for CHD prevention in this population. In this study, we inferred the effect of CETP inhibition in individuals of European and East Asian ancestries using drug target Mendelian randomization.

We leveraged genetic associations of *CETP* variants with major blood lipid fractions for individuals of European (n=1,320,016) and East Asian (n=146,492) ancestries. Colocalization was employed to identify potential cross-ancestry signals of CETP variants for plasma concentrations of LDL-C or HDL-C. Drug target MR was used to estimate ancestry-specific effects of on-target CETP inhibition on cardiometabolic biomarkers, cardiovascular disease endpoints, and potential safety outcomes. Differences between ancestries were evaluated using interaction tests, applying a multiplicity corrected alpha of 1.9×10^{-3} based on the 26 considered traits.

There was strong support (posterior probability=1.00) of a shared causal *CETP* variant affecting HDL-C in both populations, which was not observed for LDL-C. Employing drug target MR scaled to a standard deviation increase in HDL-C, we found that lower CETP was associated with lower LDL-C, Lp[a], systolic blood pressure and pulse pressure in both groups, but the effects were more pronounced in European individuals (interaction p-values < 1.9×10^{-3}). Lower CETP was protective against CHD, angina, intracerebral haemorrhage and heart failure in both ancestries, for example for CHD in East Asians (OR 0.89, 95%CI 0.84;0.94) compared to Europeans (OR 0.95, 95%CI 0.92;0.99, interaction p-value=0.05).

In conclusion, on-target inhibition of CETP is anticipated to decrease cardiovascular disease in individuals of both European and East Asian ancestries.

PB1400 Comprehensive analysis of genetic factors and subjective response to alcohol in Japanese youths.

Authors:

K. Hikino[1], I. Otsuka[2], A. Hishimoto[2,3], K. Ozaki[4], X. Liu[1], Y. Ishikawa[5], T. Mushiroda[1], S. Matsushita[6], C. Terao[1,7,8]; [1]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [2]Kobe Univ. Graduate Sch. of Med., Kobe, Japan, [3]Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan, [4]Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [5]Riken, Ctr. for Integrative Med. Sci., Yokohama, Japan, [6]Natl. Hosp. Organization Kurihama Med. and Addiction Ctr., Kanagawa, Japan, [7]Shizuoka Gen. Hosp., Shizuoka, Japan, [8]Univ. of Shizuoka, Shizuoka, Japan

Background: Alcohol metabolism is known to be influenced by both environmental and genetic factors. Numerous studies have utilized the subjective response to alcohol (SR) as an intermediate phenotype to examine its significant variability, heritability, and predictive potential for alcohol-related disorders. However, comprehensive analyses linking alcohol reactivity indicators to genetic factors using a substantial number of study participants are still lacking. Methods: We conducted the first comprehensive study to assess the relationship between pharmacodynamics (subjective response to alcohol, SR) using various scales, including the Bodily Sensation Scale (BSS), the Biphasic Alcohol Effects Scale (BAES), and the Subjective High Assessment Scale (SHAS), with a sample of 429 healthy Japanese youths. This study used the intravenous clamp technique and analyzed key genes related to alcohol metabolism, namely rs671 in *ALDH2* and rs1229984 in *ADH1B*. We also examined three loci associated with alcohol behaviors (rs1260326 in *GCKR*, rs3043 in *ALDH1B1*, and rs8187929 in *ALDH1A1*), in conjunction with whole-genome genotyping and imputed data. Results: Our findings showed that (1) SR, as measured by BSS, BAES, and SHAS, were divided into three categories by clustering and principal component analysis. (2) SR may be more significantly influenced by five alcohol-related loci—*ALDH2*, *ADH1B*, *ALDH1B1*, *ALDH1A1*, and *GCKR*—in that specific order. It appears that higher acetaldehyde concentrations have a more profound impact on SR scores. Importantly, these genetic influences also tend to segregate into three distinct clusters. (3) All five loci contributed to the SR at different proportions and stages of alcohol metabolism, the most significant being rs671 in *ALDH2* with 30% of variance explained. The subscales within cluster 1 exhibited a larger explained variance compared to clusters 2 and 3. (4) ADH1B functioned at later stages when ALDH2 function decreased. (5) *ALDH2* and *ADH1B* affected the SR independently. (6) None of the genes significantly contributed to any time points on the BAES (stimulant) scale. (7) Regions unrelated to the five loci were correlated with SR at the polygenic level. Conclusions: This study reveals a more detailed understanding of the involvement of alcohol and related genes, suggesting a risk for alcohol-related diseases based on specific types of sensation. These findings could lead to better preventive measures through preemptive genetic testing against health hazards.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1401 Comprehensive serological profiling in juvenile idiopathic arthritis identifies novel viral and gene-viral interactions.

Authors:

O. Arege[1], M. Sudman[2], M. C. Marion[1], T. D. Howard[3], D. A. Ornelles[1], P. A. Nigrovic[4], S. D. Thompson[5], C. D. Langefeld[6]; [1]Wake Forest Univ., Winston-salem, NC, [2]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, [3]Wake Forest Sch. of Med., Winston-salem, NC, [4]Havard Med. Sch., Boston, MA, [5]Cincinnati Children's Hosp., Cincinnati, OH, [6]Wake Forest Univ. Sch. of Med., Winston-salem, NC

Juvenile idiopathic arthritis (JIA) is the most common childhood chronic rheumatic disease. Patients with JIA tend to have stiffness, swelling, and pain in the joints that can lead to long-term complications (joint and bone damage). JIA disproportionately affects girls, particularly at earlier ages, and has a strong genetic contribution to risk from both HLA and non-HLA genes. Since non-genetic factors explain a majority of the risk of JIA, we hypothesize that viral infection history, in combination with specific HLA alleles, may contribute to the risk for JIA. To test this hypothesis, we performed serological comparison of the viral infection history of 83 children with predominately oligoarticular or polyarticular JIA to 83 healthy age-, sex-, and geographic region-matched controls (37 pairs from Boston Children's Hospital; 46 pairs from Cincinnati Children's Hospital) using high-throughput phage immunoprecipitation sequencing assay (PhIP-Seq, VirScan) covering the complete reference protein sequences of the human virome. We tested seropositivity and antiviral antibody breadth (number of antigens) for each virus using McNemar's test, Wilcoxon signed-rank test, and a paired t-test. We jointly tested antiviral antibody breadth in taxonomic groups of viruses (Baltimore classification) using a permutation-based MANOVA. Finally, we tested five established HLA-*DRB1* four-digit JIA risk alleles in 23 pairs of subjects to determine if a virus-JIA association was modified by the presence of an HLA risk allele. **Results**: JIA patients (76% female, mean ± SD 7.07 ± 2.83 years) and matched healthy controls (77% female; 5.77 ± 2.95 years) exhibited differences ($p<0.05$) in antiviral antibody profiles for seropositivity (HPV-10: OR=5.06; Norwalk virus: OR=0.44) and antibody breadth (HPV-10: JIA 1.94 ± 3.77 vs control 0.74 ± 1.71; BKV: JIA 1.79 ± 2.59 vs control 1.07 ± 1.66; Human parechovirus: JIA 0.91 ± 1.55 vs control 0.50 ± 1.31). Importantly, *DRB1*08*01* modified the viral breadth association with JIA for Adenovirus ($p=0.0476$) and Human papillomavirus ($p=0.057$). **Conclusion:** We tested the paradigm that in JIA, an important childhood autoimmune disease, viral exposures may contribute to risk for JIA and that exposure-induced risk is modified by genetic background. We observed serological differences in viral exposures and antiviral antibody breadth between JIA patients compared to healthy controls, and for some viruses, that relationship was modified by a known JIA-risk HLA allele. This pilot study is limited by the modest sample size and requires replication but puts forth an important gene-environment paradigm in autoimmune disease.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1402 Constructing and Evaluating Sex-Specific Obesity Predictive Genetic Risk Scores Using Taiwan Biobank Data.

Authors:

K-M. Chiang, W-H. Pan; Academia Sinica, Taipei, Taiwan

Background: Obesity has emerged as a significant global public health issue. Over the past three decades, there has been a noticeable increase in the prevalence of obesity and morbid obesity in Taiwan. Previous research has highlighted the important role of genetic factors in the development of obesity. Predicting individualized genetic risk for obesity can enable early interventions to prevent obesity and reduce the risk of related diseases and associated medical costs. Polygenic risk scores (PRS) have emerged as a promising tool for predicting individual clinical phenotypes. However, most studies investigating obesity-related single nucleotide polymorphisms (SNPs) have focused on European and American populations, limiting their applicability in predicting obesity risk in Asian and Chinese populations. Additionally, the influence of gender-specific obesity-related SNPs needs to be considered. **Methods:** In this study, we collected 6,056 obesity-related SNPs from 284 relevant publications. Using biological data from 68,960 Chinese individuals (20,693 males and 46,158 females) from the Taiwan Biobank, we selected 191 SNPs for males and 378 SNPs for females after removing SNPs with high linkage disequilibrium (R^2 > 0.8) and those lacking statistical significance (p-value >0.01) in the Chinese population. These SNPs were utilized in the calculation of gender-specific PRS. The PRS were further divided into deciles to analyze their associations with obesity. Additionally, we further validated the efficacy of these PRS using an independent sample set comprising 27,701 participants (13,806 males and 13,895 females). **Results:** The highest PRS group showed a significant association with obesity (BMI ≥ 24) in both males (OR = 4.35, p-value <0.0001) and females (OR = 5.22, p-value <0.0001). For severe obesity (BMI ≥ 35), the OR was even higher, reaching 14.69 (p-value <0.0001) in males and 26.04 (p-value <0.0001) in females. In the independent sample, we successfully validated the association between PRS and obesity, with an OR of 2.26 (p-value <0.0001) in males and 2.5 (p-value <0.0001) in females for obesity and 2.86 (p-value=0.0048) in males and 5.29 (p-value=0.0007) in females for severe obesity. **Conclusion:** In this study, we have developed and validated gender-specific obesity predictive PRS specifically for Chinese males and females. These risk scores can facilitate early intervention strategies targeting high-risk individuals, thereby mitigating the occurrence of obesity and reducing the socioeconomic burden.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1403 † Contribution of common and rare variants to schizophrenia risk in East and South Asian ancestries.

Authors:

S. Kim[1,2], A. Hassan[3], C. Huai[4], Z. Guo[1,2], J. Vincent[5], M. Mattheisen[6], B. Neale[1,2], M. Ayub[7], S. Qin[4], J. Knowles[8], H. Huang[1,2]; [1]Broad Inst. of MIT and Harvard, Boston, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Univ. of Peshawar, Peshawar, Pakistan, [4]Bio-X Inst.s, Shanghai Jiaotong Univ., Shanghai, China, [5]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, [6]Dept. of Community Hlth.and Epidemiology, Dalhousie Univ., Halifax, NS, Canada, [7]Dept. of Psychiatry, Univ. Coll. London, London, United Kingdom, [8]Human Genetics Inst. of New Jersey (HGINJ), Rutgers Univ., Piscataway, NJ

Schizophrenia genetic studies have largely focused on European ancestries, leaving genetic variants in other populations underexplored and potentially increasing health disparities. Recent studies have somewhat rectified this for common variants in East Asian ancestries, but rare variants remain largely uncharacterized in non-European populations. We present the first large-scale schizophrenia sequencing study that examines both common and rare variants in East and South Asian populations, using an innovative, cost-effective sequencing technology.
We developed Blended Genome Exome (BGE), a novel sequencing method merging low-pass whole genome and deep whole exome sequencing. Using the PCR-free library spiked into TWIST exome capture, BGE sequences the exome content at a deep depth (~40x) and the genome content at a low depth (2-4x). This cost-effective technology accomplishes both sequencing tasks in a single experiment, outperforming arrays in non-European ancestries by removing the need to pre-select ancestry-biased variants of interest.
We performed BGE sequencing on large samples of both Chinese (n=17,392) and Pakistan (n=5,181) ancestry, equally split between cases and controls. We performed rigorous processing and quality control followed by association analyses to find schizophrenia-associated genetic variants. We analyzed the exome regions (WES) following the strategy described in the Schizophrenia Exome Sequencing Meta-analysis (SCHEMA) study. Due to its high missing rate, low-pass whole-genome sequencing (WGS) requires special considerations. We used GLIMPSE, a newly developed tool to refine and impute genotype likelihoods for low-pass WGS efficiently. We found BGE outperformed all genotyping arrays for common variants, even dense ones such as the Omni2.5, and has sufficient sensitivity to capture ultra-rare coding variants that were shown to play a key role in schizophrenia. Combining with existing schizophrenia common and rare variant resources, we expect to identify novel genetic loci associated with schizophrenia in East and South Asian ancestries.
This study provides insight into the contribution of common and rare variants to schizophrenia risk in East and South Asia ancestries through a new sequencing technology and a large-scale sample.

In humans, random X chromosome inactivation (XCI) in females ensures one active chrX per female and male cell. However, gene expression studies showed ~25% of genes escape XCI, expressing at a reduced level from the inactivated X. These phenomena complicate the analysis and interpretation of genetic data on chrX, leading to a lack of consensus on the impact of chrX on complex traits and sex differences. Here, by leveraging the UK Biobank data of 184,583 females and 159,112 males across 48 quantitative traits, we show that 1) in population chrX contributes to complex trait heritability comparably to any autosome, yet with clear sex difference introduced by the difference in chrX copies; 2) escape from XCI can be reflected in the genetic architecture of a trait with subtle impacts on allelic effects and heritability.The hemizygosity of chrX in males could potentially lead to sex difference in chrX contribution (XC) to genetics. By quantifying XC as the ratio of chrX to autosomal heritabilities, we indeed found that XCs in males (median 4.4%) exceeded the expected proportion based on the number of independent chrX SNPs (3.5%). In females, XCs (median 1.7%) were much lower than the expectation, with 67% of the traits significantly depleted of XCs. In the overall population, these sex differences were, however, balanced out, averaging closely to the expectation (median 3.0% vs 3.5%), with height exceptionally enriched with XCs in both sexes (female 3.8%, male 5.9%). While random XCI equalizes chrX dosage between sexes, local escape from XCI potentially introduces a subtle increase in female allelic effects, thus, in theory, further balancing out the sex differences in XCs. To examine if escape is seen on the chromosome-wide level, we compared XCs between sexes per trait. For most traits, we lacked statistical power to distinguish if the observed sex differences in XCs are in line with full XCI or partial escape from XCI as only 1.1-fold difference is expected between the two scenarios. For height, a trait highly heritable on chrX, we observed an increase in female XC consistent with a partial escape from XCI. To assess escape at a finer scale, we quantified the proportion of SNPs with larger effect sizes in females. We observed an excess of female bias in chrX compared to autosomes (75% vs 28%) in height and further pinpointed regions that potentially escape XCI.In conclusion, our study shows chrX as an important source of missing heritability and sex differences of complex trait genetics. We demonstrate that the effect of escape from XCI is reflected in genetic associations, although this effect seems small enough that considerably larger sample sizes are required for traits other than height.

PB1405 Convergent evidence from common and rare variant analyses implicating the immune system and late infancy cerebellar development in ADHD using a Hong Kong sample

Authors:

Y. Zhong[1], B. Larry[1], T. Justin[1], Y. Rui[1], H. Se-Fong[2], T. Chun-Pan[3], H. Ting-Pong[2], L. Chi-Chiu[3], S. Pak C[1], L. Patrick W. L.[2]; [1]The Univ. of Hong Kong, Hong Kong, Hong Kong, [2]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong, [3]Kwai Chung Hosp., Hong Kong, Hong Kong

Attention-deficit hyperactivity disorder (ADHD) is a common neuropsychiatric disorder with a significant genetic component, characterized by persistent symptoms of inattention, hyperactivity and/or impulsivity. The latest genome-wide association study (GWAS) meta-analysis of ADHD identified 27 whole-genome significant risk loci in the European population. However, genetic risk factors for ADHD are less well-characterized in the Asian population, especially for rare variants. Here, we present an analysis of common and rare variant contributions to ADHD in a Hong Kong sample comprising 279 cases and 432 controls, who were genotyped using the Illumina Infinium Global Screening Array. We identified 41 potential genomic risk loci with a suggestive association ($p < 1e-4$), pointing to 111 candidate risk genes, which were enriched for genes differentially expressed in the cerebellum. Furthermore, brain developmental stage enrichment analysis indicated the late infancy stage, a landmark for human nervous system development especially the cerebellum, to be a critical window for ADHD vulnerability. At the polygenic level, we also discovered a strong genetic correlation with resting-state functional MRI connectivity of the cerebellum involved in the attention/central executive and subcortical-cerebellum networks, which is consistent with the neural pathophysiology for ADHD. In rare variant analyses, we discovered that ADHD cases carried an elevated load of rare damaging variants in *TEP1*, *MTMR10*, *DBH*, *TBCC* and *ANO1*. These genes are annotated to be part of functional clusters relevant to the nervous system and immune response. ADHD genetic risk was associated with immune response/signalling, demonstrated in both common (pathway enrichment analysis) and rare (the gene-set-based burden test) variant analyses as well. *POC1B*, a gene previously found in a genome-wide significant locus of ADHD in the European population, was replicated in the current study. In addition, an accumulation of ADHD common-variant risks found in European Ancestry samples was found to be significantly associated with ADHD in the current study, potentially implicating genetic factors with a trans-ancestral effect in ADHD. These findings re-validate the abnormal development of the neural system, especially the cerebellum, in ADHD and extend the existing neuro-dysfunction hypothesis to a multi-system perspective.

PB1406 Coronary heart disease and type 2 diabetes metabolomic signatures in a middle eastern cohort.

Authors:

M. Elshrif[1], K. Isufaj[1], A. El-Menyar[2,3], K. Kunji[1], E. Ullah[4], R. Elsousy[5], H. R. Mokhtar[6], E. Ahmad[6], M. Al-Nesf[7], A. Beotra[6], M. Al-Maadheed[6], V. Mohamed-Ali[6], M. Saad[1], J. Al Suwaidi[5]; [1]Qatar Computing Res. Inst. (QCRI) - HBKU, Doha, Qatar, [2]Clinical Res., Trauma & Vascular Surgery, Hamad Med. Corp., Doha, Qatar, [3]Dept. of Clinical Med., Weill Cornell Med. Coll., Doha, Qatar, [4]Qatar Computing Res. Inst. (QCRI), HBKU, Doha, Qatar, [5]Dept. of Cardiology, Heart Hosp., Hamad Med. Corp., Doha, Qatar, [6]Anti-doping Lab Qatar, Doha, Qatar, [7]Dept. of Internal Med., Allergy and Immunology, Hamad Gen. Hosp., Hamad Med. Corp., Doha, Qatar

Background: The growing field of metabolomics has opened new venues for identifying biomarkers of type 2 diabetes (T2D) and predicting its consequences such as coronary heart disease (CHD). Middle Eastern populations, despite their large size, are underrepresented in omics research.**Methods:** In this study, we used a total of 641 metabolites from a large cohort of 3,679 Qatari adults from the Qatar Biobank (QBB; 272 T2D and 2438 non-T2D individuals) and Qatar Cardiovascular Biorepository (QCBio; all CHD patients; 488 T2D and 481 non-T2D individuals). Univariate analysis was performed to identify metabolites associated with T2D, in the absence or presence of CHD. Multivariate analysis, machine learning (ML) models, and metabolite risk scores were developed to assess the predictive power of the different combination of T2D and CHD.**Results:** Many metabolites were significantly associated with T2D in both QBB and QCBio cohorts. Among these, we observed 1,5-anhydroglucitol (1,5-AG) ($P = 1.33 \times 10^{-68}$ in QBB vs 9.82×10^{-33} in QCBio), glucose ($P = 7.14 \times 10^{-57}$ in QBB vs. 3.26×10^{-29} in QCBio), and mannose ($P = 2.61 \times 10^{-54}$ in QBB vs. 1.01×10^{-27} in QCBio). Other metabolites were significantly associated with T2D only in one cohort, e.g., glutamine ($P = 7.14 \times 10^{-57}$ and β = -4.87 in QBB vs. P= 0.26 and β = 0.3 in QCBio) and N6-carboxymethyllysine (P = 0.38 and β = 0.1 in QBB vs. P= 2.24×10^{-8} and β = 0.37 in QCBio). ML models performed well to predict all T2D and CHD combinations with accuracy reaching 80% for some groups. T2D was predicted with higher accuracy (>80% in both QBB and QCBio). The MRS developed in QCBio and tested in QBB while adjusting for HbA1C yielded an Odds Ratio of 21.18 for the top quintile vs. the remaining quintiles.**Conclusions:** Metabolomics profiling has the potential for early detection of metabolic alterations that precede clinical symptoms of T2D and CHD in the presence of T2D. This early detection potential allows for timely interventions and improved management strategies for both T2D and CHD.

PB1407 Correlation of Interleukin-6 gene (-174G/C) promoter polymorphism &It Human leukocyte antigen DQ genotypes with genetic susceptibility of Type 1 Diabetes Mellitus in Kuwaiti children

Authors:

M. Haider[1], M. Al-Rushood[2,3], H. Alsharhan[4,5], M. A. Rasoul[1], M. Al-Mahdi[6], H. Al-Kandari[7,5]; [1]Kuwait Univ., Coll. of Med., Pediatrics Dept., Safat, Kuwait, [2]Kuwait Univ. Coll. of Med., Pediatrics Dept., Safat, Kuwait, [3]Mubarak Al-Kabeer Hosp., Pediatrics Dept., Jabriya, Kuwait, [4]Kuwait Univ., Coll. of Med., Pediatrics Dept., Kuwait, Kuwait, [5]Farwania Hosp., Pediatrics Dept., Farwania, Kuwait, [6]Al-Adan Hosp., Pediatrics Dept., Al-Adan, Kuwait, [7]Dasman Diabetes Inst., Dept. of Population Hlth., Dasman, Kuwait

Type-1 diabetes mellitus (T1DM) is characterized by autoimmune destruction of the insulin-secreting beta cells by the lymphocytes and inflammatory cytokines. Cytokines play a crucial role in pathogenesis of autoimmune diseases possibly due to their effector and regulatory functions in immune and inflammatory responses. The interleukin-6 (*IL-6)* gene is located on chromosome 17 and carries a single nucleotide polymorphism (SNP, -174G/C, rs1800795) in its promoter region, which has been associated with transcription rates of IL-6 cytokine. We have determined the genotype frequency of *IL-6* gene (-174G/C) promoter polymorphism and human leukocyte antigen (HLA) DQ genotypes in Kuwaiti children with T1DM to investigate their role in genetic susceptibility. This study included 232 Kuwaiti children with T1DM and 200 controls. The criteria by International Society for Pediatric and Adolescent Diabetes (ISPAD) was used for diagnosis of T1DM. The control subjects were healthy Kuwaitis; none had close relative with T1DM and were evaluated by a specialist. The genotypes of *IL-6* (-174G/C) gene polymorphism, were identified by PCR-RFLP method. HLA-DQ alleles were determined by sequence-specific PCR method. The frequency of *IL-6* (-174G/C) gene polymorphism showed a positive correlation with T1DM in Kuwaiti patients in both the co-dominant and dominant models of genetic analysis (OR, 1.10 and 1.02 respectively). We have identified HLA DQ2/2, DQ2/8 and DQ8/8 as the high-risk genotypes for T1DM amongst Kuwaiti children. In this study, we also determined the co-inheritance of *IL-6* gene polymorphism in Kuwaiti T1DM children with different HLA-DQ genotypes. The proportion of Kuwaiti T1DM who carried at least one C-allele of the *IL-6* gene polymorphism was 92% in patients with HLA-DQ2/DQ2 genotype, 96% in those who had DQ2/8 genotype and 96% in patients with HLA-DQ8/DQ8 genotype. Our data highlights the role of C-allele of *IL-6* (-174G/C) gene polymorphism along with HLA-DQ2/2, DQ2/8 and HLA-DQ8/8 genotypes in determining the genetic susceptibility of T1DM in Kuwaiti children.

PB1408 Critical role of GABAergic neurons in driving CGG repeat toxicity associated with Fragile X premutation

Authors:

Y. Jin, Y. Cao, N. Rivera, W. Ma, J. Huang, Y. Li, Y. Kang, S. Yu, R. Li, R. Li, E. Allen, S. Qin, M. Epstein, P. Jin; Emory Univ., Atlanta, GA

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a neurodegenerative disorder characterized by age-dependent symptoms. It is caused by a CGG repeat expansion (55-200) in the 5′ UTR of the fragile X messenger ribonucleoprotein 1 (FMR1) gene, associated with fragile X premutation carrier. The molecular mechanisms underlying FXTAS involve both CGG repeat RNA and a repeat-associated non-AUG (RAN) translation product called FMRpolyG peptide. To further understand the molecular pathogenesis of FXTAS, we performed a transcriptome-wide association study (TWAS) analysis using prediction models of the cortex and cerebellum. Through this analysis, we identified 45 genes significantly associated with the onset of FXTAS, which we further validated using a *Drosophila* model of FXTAS. Among these genes, ten were found to modulate the toxicity associated with expanded CGG repeats. Additionally, we performed single nucleus RNA-Seq on the prefrontal cortex of FXTAS and control mice, revealing cell type-specific gene expression signatures induced by CGG repeat expression. Notably, we observed pronounced gene expression changes in inhibitory neurons, suggesting their strong involvement in the overall transcriptional response. To determine the specific contributions of distinct neuronal cell types to FXTAS pathogenesis, we utilized conditional FXTAS mouse models and various Cre driver lines. Our findings indicated that the expression of CGG repeats in GABAergic neurons alone was sufficient to induce neuronal toxicity, whereas the expression in glutamatergic neurons had minimal impact. Furthermore, employing TRAP-seq, we identified several gene expression alterations specific to GABAergic neurons, some of which were found to be bound by hnRNPA2B1, an RNA-binding protein sequestered by CGG repeat RNA. Notably, PRKCG, a risk gene for SCA14, was among the identified genes and showed potential in modulating CGG repeat-associated toxicity. This suggests that hnRNP A2/B1-mediated regulation of PRKCG plays a significant role in FXTAS pathogenesis. Collectively, our integrated analyses highlight the critical role of GABAergic neurons in driving FXTAS pathogenesis and identify a potential therapeutic target for FXTAS.

PB1409 Cross-ancestry analyses identify new genetic loci associated with 25-hydroxyvitamin D.

Authors:

J. Revez[1], X. Wang[1], V. Hivert[1], S. Groot[1], Y. Wang[2], L. Yengo[1], J. J. McGrath[1], K. E. Kemper[1], P. M. Visscher[1], N. R. Wray[1]; [1]The Univ. of Queensland, Brisbane, Australia, [2]Massachusetts Gen. Hosp., Boston, MA

BACKGROUND: Vitamin D status - a complex trait influenced by environmental and genetic factors - is tightly associated with skin colour and/or genetic background. Yet very few studies have investigated the genetic underpinnings of vitamin D in non-European ancestry groups, and the ones that have, relied on small sample sizes, resulting in inconclusive results.
METHODS: We conduct genome-wide association analyses of 25 hydroxyvitamin D (25OHD) - the main circulating form of vitamin D - in 442,435 individuals from four genetically-inferred broad ancestry groups represented in the UK Biobank: European (N=421,867), South Asian (N=9,983), African (N=8,306) and East Asian (N=2,279). We test additive and dominance effects. Given that vitamin D metabolism occurs in the skin, we conduct GWAS of 25OHD stratified by skin colour. Lastly, we test the interaction between 25OHD-associated variants and skin colour.
RESULTS: We identify a new genetic determinant of 25OHD (rs146759773) in individuals of African ancestry, which was not detected in previous analysis of much larger European cohorts due to low minor allele frequency. We show genome-wide significant evidence of dominance effects in 25OHD that protect against vitamin D deficiency. In skin-colour-stratified analyses, we identify new genome-wide significant associations with 25OHD. Lastly, we identify two loci (rs10832254 and rs1352846) whose association with 25OHD differs in individuals of distinct complexions.
CONCLUSIONS: Collectively, our results provide new insights into the complex relationship between 25OHD and skin colour and highlight the importance of diversity in genomic studies. Despite the much larger rates of vitamin D deficiency that we and others report for ancestry groups with dark skin (e.g., South Asian), our study highlights the importance of considering ancestral background and/or skin colour when assessing the implications of low vitamin D.

PB1410 Cross-ancestry GWAS meta-analysis of keloids discovers novel susceptibility loci in diverse populations.

Authors:

C. Greene[1], G. Hampton[1], H. Seagle[1], Y. Luo[2], G. Jarvik[3], B. Namjou-Khales[4], A. Khan[5], T. Edwards[6], D. Velez Edwards[6], J. Hellwege[6,7]; [1]Vanderbilt Univ., Nashville, TN, [2]Northwestern Univ., Evanston, IL, [3]Univ. of Washington Med. Ctr., Seattle, WA, [4]Children's Hosp. Med. Ctr., Cincinnati, OH, [5]Columbia Univ., New York City, NY, [6]Vanderbilt Univ. Med. Ctr., Nashville, TN, [7]VA Tennessee Valley Hlth.care System, Nashville, TN

Keloids are benign fibroproliferative growths that form after injury to the skin and grow beyond the original wound boundaries. They can result in pain and disfigurement. Darker-skinned individuals are much more likely to develop keloids, particularly those of African and Asian descent. Prevalence estimates vary from less than 0.1% in European-ancestry populations to 16% in some African-ancestry populations. However, most genetic research has been limited to European and East Asian populations despite African-ancestry populations having a 20-fold increased risk for keloids. We have performed a large cross-ancestry genome-wide association study (GWAS) meta-analysis of keloids, incorporating data from 1,600,846 individuals (7,837 cases and 1,593,009 controls). These include 139,538 African-ancestry individuals (2,696 cases and 136,842 controls). We detected 142 novel loci in the cross-ancestry meta-analysis, which included seven replicated variants and 1,233 novel variants. The most significant result (P = 1.65 x 10-79) was at a variant (rs10863683) located downstream of LINC01705. LINC01705 was previously associated with keloids and implicated as a regulatory factor underlying tumorigenesis. Additionally, analysis of genetically-predicted gene expression with S-PrediXcan identified a significant association between decreased risk of keloids and increased expression of LINC01705 in fibroblasts (P = 7.62 x 10-21), which play an important role in wound healing. Other results include associations with NEDD4 and LSP1 in fibroblasts, as well as PHLDA3 in sun-exposed skin (P = 7.94 x 10-11, 5.96 x 10-08, and 3.81 x 10-14, respectively). The most significant result in the African-ancestry meta-analysis (P = 1.95 x 10-32) was an intergenic variant (rs34647667) in a conserved region downstream of ITGA11, though NEDD4 was the only gene in this region of chr15 to reach significance (P < 2.6 x 10-6) in the gene-based test. Previous research in our group identified an African ancestry-specific susceptibility locus at chr15q21-22, and our results support these prior findings. Keloid SNP-based heritability estimates using Linkage Disequilibrium Score Regression (LDSC) are 6%, 21%, and 34% for European, East Asian, and African ancestry, respectively. These results support a potential adaptive origin for keloid disparities in African-ancestry populations and significantly increase the yield of discoveries from keloid genetic association studies.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1411 Cross-trait genetic analysis highlights causal effects of chronic pain on older-adult-onset asthma with evidence for mediation by neuroimmune crosstalk in the airways.

Authors:

G. Koli Farhood, C. Chen, Y. Chen, N. Dimitrov, M. Parisien, L. Diatchenko, A. Grant; McGill Univ., Montreal, QC, Canada

Background: Chronic pain (persistence of pain experience $\geq$ 3 months) and asthma are heritable, with similar prevalence of approximately 10% worldwide. People with chronic pain usually suffer from other chronic comorbidities including autoimmune disorders and chronic pulmonary diseases, and recent genetic studies identified asthma as displaying the highest correlation with chronic pain among autoimmune disorders. While reciprocal interactions between the nervous and immune systems are considered to underlie the pathogenesis of both chronic pain and asthma, specific biological pathways have not been identified. We explored the extent to which shared genetics underlying chronic pain and asthma considering age-of-onset (AO) may lead to identification of common biological functions at separate life span stages. **Methods:** Genome-wide association (GWA) scans on chronic pain and AO-stratified asthma phenotypes (< 18 years (childhood), 18-40 years (younger-adult), and > 40 years (older-adult)) were conducted across 9.2 million variants on 457,461 European-descent subjects at baseline visit from the UK Biobank (UKB). We performed bidirectional Mendelian Randomization (MR) to assess whether effects of significant genetic variants in either chronic pain or AO-stratified asthma traits were mediated by a trait from the other set. We assessed the temporal order of cause-and-effect relationships between the two traits sets from baseline to subsequent visits of the UKB and the Canadian Longitudinal study of Aging (CLSA). We also constructed polygenic scores (PGS) in the UKB to predict risk in the CLSA across trait sets. We then implemented gene-based analysis on cross-trait GWA meta-analysis in conjunction with Gene Ontology, GTEx, and Gene Enrichment Profiler datasets. **Results:** We identified 1,416 causal variants with significant effects on older-adult asthma, which were mediated by chronic pain in MR analysis. Chronic pain to older-adult asthma causal directionality was further supported by the observation of increased risk of older-adult asthma at subsequent visits in both the UKB and the CLSA. The UKB PGS for chronic pain predicted increased risk for older-adult asthma in the CLSA. Gene-based analysis on the chronic pain and older-adult asthma meta-analysis highlighted differential nervous system expression, particularly in the cerebellum. Furthermore, we identified strong cell-specific heritability enrichment localizing to the central nervous system, lung, and immune system cells including B and T cells. **Conclusion:** Older adult-onset asthma is activated by long lasting neuroimmune cells communication in the airway, initiated by chronic pain.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1412 Cystic fibrosis risk variants confer a protective effect against inflammatory bowel disease in large-scale exome sequencing analysis

Authors:

M. Yu[1,2]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA

Genetic mutations that lead to the production of defective Cystic fibrosis transmembrane regulator (CFTR) protein are known to cause cystic fibrosis (CF), a lethal autosomal recessive Mendelian disorder. Existing studies have debated the roles of CFTR mutations in Inflammatory Bowel Disease (IBD), with inconclusive evidence supporting both risk and protective effects. Here, leveraging the largest IBD exome sequencing callset with 38744 cases and 69570 controls of European ancestries from the International Inflammatory Bowel Disease Genetics Consortium, we report the first compelling evidence establishing a protective role of CF-causing variants against IBD.

In our association analysis, we found delF508, a known CF-causing variant that accounts for 70% of all CFTR mutations observed in CF patients, protects against IBD with an effect size of -0.30 (SE=0.048, P=1.7E-10). Moreover, we observed a number of rare CF-causing variants in the CFTR2 database, e.g., G542X, G551D, and N1303K, which also conferred protective effects against IBD. To follow up on these observations, we conducted an unweighted gene burden test of CFTR restricted to all variants annotated as CF-causing in the CFTR2 database (excluding delF508). This variant set yields a composite allele frequency (CAF) of 1.2% and a notable protective effect of -0.23 (SE=0.047, P=1.1E-6). As a negative control, another burden test was performed on CFTR using all rare (MAF<0.001) nonsynonymous non-CF-causing variants (CAF=1.7%). This test showed no significant association between CFTR and IBD (P=0.42), demonstrating the importance of selecting relevant variants in burden tests. To evaluate variant selection using in silico evidence, we also performed burden tests using variants with high pathogenicity scores from CADD and REVEL, neither of which yielded comparable significance (P=3.7E-3 and 1.4E-3, respectively).

In this study, we established a protective role for CF-causing variants against IBD through large-scale exome sequencing analysis. We also demonstrated that existing in silico variant classifiers are ineffective at separating pathogenic and neutral variants in the case of CFTR, motivating the need for systemic functional studies to investigate the causal mechanisms for this association.

PB1413 Cytosine-to-Uracil RNA editing is upregulated by inflammatory stimulation of monocytes

Authors:

H. Seo[1,2,3,4,5], W. Cuddleston[1,2,3,4,5], M. Parks[1,2,3,4,5], E. Navarro[1,2,3,4,5], T. Raj[1,2,3,4,5], J. Humphrey[1,2,3,4,5]; [1]Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Nash Family Dept. of NeuroSci. & Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Ronald M. Loeb Ctr. for Alzheimer's Disease, Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Icahn Inst. for Data Sci. and Genomic Technology, Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Estelle and Daniel Maggin Dept. of Neurology, Icahn Sch. of Med. at Mount Sinai, New York, NY

Genome-wide association studies of the neurodegenerative diseases Alzheimer's and Parkinson's have highlighted genes specific to myeloid cells as enriched in disease heritability. Myeloid cells are the innate immune system lineage, including monocytes and macrophages in the periphery and microglia in the central nervous system. By studying transcriptional regulation of myeloid cells we can uncover new insights into their role in neurodegeneration.

RNA editing is a post-transcriptional modification whereby specific enzymes alter the RNA base sequence. This can lead to various downstream consequences, including re-coding of the amino acid sequence or changes in RNA stability. The most well-known form of RNA editing in the brain is Adenosine to Inosine (A-I), facilitated by the ADAR enzyme family. In contrast, the conversion of Cytosine to Uracil (C-U) by the APOBEC enzyme family is largely understudied. C-U editing components are highly upregulated in microglia compared to the rest of the brain, suggesting a key role in myeloid cell function. Previous work has found that C-U editing sites are enriched in exonic re-coding events, and editing is a dynamically regulated process in response to inflammatory stimulation. However, the full extent of C-U editing sites throughout the myeloid transcriptome and the consequences for gene regulation are unknown.

As a proxy for microglia, we sorted monocytes from peripheral blood (n=52) and stimulated them with lipopolysaccharide (LPS), interferon beta (IFNb), or PBS (control) for 24 hours before performing RNA sequencing. We constructed a computational pipeline to measure A-I and C-U RNA editing and perform extensive quality control to remove false positive sites. We also estimated gene expression and isoform usage. We identified 6,278 editing sites in our monocyte samples, of which 1,077 sites were differentially edited in response to LPS and 3,795 in IFNb. Strikingly, 1,223 of the IFNb sites were C-U, which were enriched for re-coding and protein-truncating events within exons. By combining gene expression and splicing of differentially edited genes, we observed complex relationships between the three modalities and the two stimulation types, which also suggest potential regulatory relationships between RNA editing and gene expression levels of several APOBEC enzymes. Finally, we observed stimulation-specific editing of the Alzheimer's disease risk genes PILRA and PLCG2.

This work is the first step towards characterizing the C-U editing landscape in myeloid cells. We next plan to integrate common genetic variants into RNA editing analysis to interpret causality and genetic links to neurodegenerative disease.

PB1414 De novo mutations in bipolar disorder implicate genes involved in neurodevelopment and immunity.

Authors:

T. Shimada[1,2,3], S. Rachel[4,3], H. Sung[3], E. Besancon[3], F. Lopez[3], L. Kassem[3], N. Akula[3], F. J. McMahon[3]; [1]Dept. of Psychiatry and Behavioral Sci., Juntendo Univ. Graduate Sch. of Med., Tokyo, Japan, [2]Dept. of Psychiatry, Juntendo Univ. Urayasu Hosp., Chiba, Japan, [3]Section on the Genetic Basis of Mood and Anxiety Disorders Section, Human Genetics Branch, Natl. Inst. of Mental Hlth., NIH, Bethesda, MD, [4]Brain Mapping Unit, Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Background: Bipolar disorder (BD) is a debilitating disorder affecting ~2% of the world's population. Genome wide association studies have identified over 100 common risk loci, a few copy number variants, and one gene with increased burden of loss of function (lof) mutations, but there have been few studies of de novo variation in BD and no genes can yet be considered genome-wide significant de novo hits. For the first time, this study explores the contribution of de novo mutations (DNMs) to BD and related conditions in multiplex families ascertained from genetically isolated populations. **Methods:** Exomes of 199 complete trios ascertained as part of the Amish Mennonite Bipolar Genetics (AMBiGen) study were sequenced at Regeneron, quality controlled and analyzed using GATK. DNMs were called using HAIL, followed by stringent sample and variant filters and Sanger sequencing of selected putative DNMs. Genes with DNMs in cases were combined with genes hit by DNMs among 354 previously published BD trios for functional enrichment analysis using hypergeometric tests, topic modeling, and tests of cell-type enrichment. **Results:** A total of 42 lof or damaging missense DNMs in 42 genes, including *NRXN1*, *SHANK3*, and *SPECC1*, were detected among individuals with BD and related disorders. Three genes, *SUGP2*, *DICER1*, and *PLEC*, have been reported in previous studies. When combined with previously-published genes, the full set of 275 genes was significantly enriched for functions related to learning, post-synaptic organization, nervous system development, and calcium ion transport. These genes also significantly overlapped with brain co-expression modules associated with neurogenesis and immunity. These modules were significantly enriched in genes expressed in excitatory neurons, endothelial cells, and microglia. **Conclusion:** Although no single gene had a significant excess of DNMs, these findings suggest that DNMs in gene sets involved in neurodevelopment and immunity may contribute to BD. Future studies should focus on replicating these findings in additional samples. Genes with significant burdens of DNMs will be good candidates for functional genomic studies.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1415 Decoding disease and HLA-specific regulation of T cell receptor repertoire in Parkinson's disease

Authors:

T. Naito[1,2,3,4,5], R. Vialle[6], K. Ishigaki[7], Y. Okada[8,9,10], D. A. Knowles[5,11,12], T. Despite the accumulating evidence supporting the involvement of adaptive immune systems in the pathogenesis of Parkinson's disease (PD), the T cell receptor (TCR) repertoire associated with PD has not been well characterized. This is primarily due to the high diversity of the TCR repertoire resulting from human leukocyte antigen (HLA) types and the lack of sufficient resources informative about the TCR repertoire in PD patients that would allow us to characterize the feature stratified by HLA types. To address these issues, we investigated the TCR repertoire features associated with HLA types in PD by utilizing genomic and transcriptomic data from the Accelerating Medicines Partnership Parkinson's disease (AMP-PD) cohort. We targeted 1,127 PD cases and 700 controls from the AMP-PD dataset. We performed TCR repertoire reconstruction from whole blood RNA-seq and HLA imputation from genotype data. Through a comprehensive interaction analysis between HLA alleles of all classical HLA genes and TCR genes, we evaluated how specific HLA features influence the TCR repertoire specifically in PD cases. The strongest interaction was identified at HLA-DRB1*04 and TRAV13-2*01 among TRA genes ($P = 6.42 \times 10^{-7}$) and TRBV14*01 among TRBV genes ($P = 4.30 \times 10^{-6}$). HLA-DRB1*04 was previously shown to be the most risk-associated HLA allele with PD (Naito et al. 2021 and Yu et al. 2021). Notably, HLA-DRB1*04 exhibited the highest enrichment in interaction with various TCR genes compared to other HLA alleles. Furthermore, we conducted longitudinal TCR repertoire analysis and detected TCR features that significantly changed especially in PD cases. We are currently investigating longitudinal TCR regulation depending on specific HLA types. These findings present the evidence supporting the role of PD risk-associated HLA alleles in shaping TCR repertoire in a disease-specific manner. Additionally, specific TCR genes might serve as potential markers for the duration and progression of PD. We will validate our findings using curated samples of TCR sequencing and single-cell RNA-seq. Overall, these findings enhance our understanding of immune dysregulation in PD and may pave the way for future therapeutic interventions targeting the adaptive immune systems.

PB1416 † Decoding Genetic Modifiers of Disease Variants in Large-Scale Biobanks

Authors:

Z. Yu[1], A. Jowell[2], S. Koyama[1], M. Trinder[3], W. Hornsby[4], K. Cho[5], J. Gaziano[5], P. Wilson[6], Y. Sun[7], A. Bick[8], P. Natarajan[4]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Harvard Med. Sch., Boston, MA, [3]Univ. of British Columbia, Vancouver, BC, Canada, [4]Massachusetts Gen. Hosp., Boston, MA, [5]VA Boston Hlth.care System, Boston, MA, [6]Atlanta VA Med. Ctr., Decatur, GA, [7]Emory Univ., Johns Creek, GA, [8]Vanderbilt, Nashville, TN

Phenotypic expressions of DNA sequence variants are influenced by genetic, environmental, and stochastic factors. Unveiling these modifying factors can illuminate disease pathways and refine genetic counseling. However, the discovery of genetic modifiers in humans is limited. Here, we used large-scale genotyping and comprehensive phenotyping for a genome-wide modifier scan in the UK Biobank (UKB), with validation in the US VA Million Veteran Program (MVP). We selected disease mutations that are common, located in coding regions, and categorized as pathogenic, risk factors, or indicative of susceptibility to diseases in ClinVar. We then conducted phenome-wide association tests on these mutations across 1,601 PheCode disease phenotypes in UKB. We selected the five strongest associated disease outcomes for each mutation and conducted modifier scans for disease mutation-phenotype pairs whose disease phenotypes were prevalent and the associations were strong. Modifier searches included an interaction term between the disease mutation and potential modifier mutations in regression models. We modeled each disease mutation in two forms: as an individual SNP and as a binary variable of collapsed rare variants on the corresponding gene. From the analysis of 378,184 UKB EA participants, we pinpointed 16 disease mutations in 12 genes associated with 57 disease outcomes. Notably, we discovered 17,578 significant interactions (959 after pruning). We focused on interactions replicated in MVP EA (N~450K), particularly those where modifiers were coding variants, disease and modifier mutations were located in the cis-region, or disease mutation and its respective rare variant variable were both modified by the same modifier SNP. For instance, *ABCG8 p.Asp19His* allele carriers had a 1.9-fold increase in cholelithiasis risk. This risk was modified by rs6729865, an eQTL for *ABCG8* in liver tissue located in the close *ABCG5* and *ABCG8* 3' UTR ($P_{interaction}=4.5 \times 10^{-8}$ in UKB and 0.001 in MVP), which elevated the risk to 3.5 or 5.8-fold in participants carrying 1 or 2 A alleles at rs6729865, respectively. Also, we observed a significant modification of rs35445101 on the association between *LTA p.Thr60Asn* and celiac disease risk ($P_{interaction}=1.4 \times 10^{-14}$ in UKB and 1.1×10^{-31} in MVP). This missense mutation, located 100Kbp away on the *HLA* gene, posed a 1.5-fold or 2.4-fold higher risk for celiac disease, depending on whether the individual carried the G allele for rs35445101. Our findings underscore the potential of large-scale biobanks in identifying genetic modifiers, contributing to clinical diagnosis and prognosis, and paving the way for novel therapeutic interventions.

PB1417 Decoding pharmacogenomics of second-generation antipsychotic-Induced metabolic syndrome via biobanks and electronic health records.

Authors:

N. El Rouby[1], A. Owusu-obeng[2], M. Preuss[3], R. Nadukuru[4], S. Lee[2], S. L. Van driest[5], W-W. Hsu[1], G. Zhang[6], J. D. Mosley[5], M. DelBello[1]; [1]Univ. of Cincinnati, Cincinnati, OH, [2]Icahn Sch. of Med. at Mt Sinai, New York, NY, [3]Mount Sinai Sch. of Med., New York, NY, [4]Icahn Sch. Of Med. At Mount Sinai, New York, NY, [5]Vanderbilt Univ. Med. Ctr., Nashville, TN, [6]Cincinnati Children's Hosp., Cincinnati, OH

Second Generation Antipsychotics (SGA) are the mainstay treatment of bipolar and psychotic disorders; however, they are associated with metabolic adverse effects. We investigated the genetic determinants of SGA-induced metabolic syndrome (Mets) through a genome wide association study (GWAS) in the UK Biobank with validation in BioMe, Mt Sinai's electronic health record (EHR)-linked biobank data. We created an adult dataset (N=668 controls, 650 cases) for SGA-induced Mets using patient-reported medication use, lab values and ICD codes among European ancestry participants in the UK Biobank data. A case was a patient taking a prescription for an SGA and who met three out of five of the National Cholesterol Education Program (NCEP) criteria: 1) blood pressure ≥ 30/85 mmHg, antihypertensive use or hypertension diagnosis; 2) fasting serum glucose ≥100 mg/dL, antidiabetic medication use or type 2 diabetes diagnosis; 3) serum triglycerides ≥150 mg/dL; 4) HDL-cholesterol < 40 mg/dL in men, and < 50 mg/dL in women or antihyperlipidemic medication use; and 5) body mass index (BMI) ≥ 30 kg/m2. A control was an SGA user who met two or fewer criteria. We conducted a GWAS analysis of imputed genotypes using Scalable and Accurate Implementation of Generalized mixed model (SAIGE), and adjusting for age, sex, BMI, diabetes, and ten principal components of ancestry. We validated the top genomic locus using a meta-analyzed data of White, African American and Hispanic patients in BioMe (N=638 controls, 1825 cases). We identified an association at the *CHD2-RGMA* locus on chromosome 15 that met a suggestive level of significance ($p < 10^{-5}$). The lead SNP was rs12914956 (15:93504501G>A) with the A allele being associated with increased risk for SGA-Mets ($\beta=0.5$, $p= 3.6x10^{-7}$), with a frequency of 39%. According to GTEx, the rs12914956 SNP is an eQTL for *CHD2* in cultured fibroblasts. A different SNP (rs137889996) in the *CHD2-RGMA* region was nominally associated with SGA-induced at $p=6x10^{-5}$ in BioMe. The rs137889996 SNP is in low Linkage Disequilibrium with rs12914956 (R2= 0.0011; D'= 0.57) and was more common in African American with a frequency of 1%. The *CHD2-RGMA* locus has been associated with appendicular lean mass, BMI, insulin levels and high-density lipoprotein levels. In summary, we identified a novel association in *CHD2-RGMA* locus for SGA-induced Mets in the UK Biobank, with nominal association in BioMe. This region has documented association with multiple metabolic phenotypes. Replication and meta-analysis are underway in a third EHR-linked Biobank (BioVU).

PB1418 † Decoding the genetic complexity of immunoglobulin heavy chain locus: Unveiling novel variants and structural complexity with implications for human health

Authors:

O. Rodriguez, K. Shields, C. Silver, S. Schultze, M. Smith, C. Watson; Univ. of Louisville Sch. of Med., Louisville, KY

Genetic variants within the immunoglobulin loci (IG) have been implicated in numerous human diseases and have a significant impact on the efficacy of broadly neutralizing antibodies. Our recent study demonstrated a direct influence of these genetic variants within the IG heavy chain locus (IGH) on the composition of the antibody repertoire. However, the repetitive nature of the IG loci, characterized by segmental duplications, simple repeats, and retrotransposon elements, has posed challenges in the sequencing and assembly of these loci across diverse populations in large cohorts. To address this complexity, we employed a combination of targeted long-read sequencing and a bioinformatics tool called IGenotyper, enabling us to comprehensively characterize single-nucleotide variants (SNVs), insertions and deletions (indels), and structural variants (SVs) in a haplotype-specific manner. In this study, we leveraged our approach to analyze a cohort of 860 healthy individuals representing 24 distinct populations. Through our analysis, we discovered several previously unknown large SVs that have a significant impact on the number of genes within the IGH locus. For example, we identified a 284 Kb deletion deleting 16 out of 49 (33%) IGH variable genes. Additionally, leveraging haplotype-resolved assemblies, we identified a substantial number of novel SNVs within segmental duplications and accurately determined the allele frequency of known SNVs with missing or skewed allele frequencies. These findings contribute to a deeper understanding of the genetic architecture of the IGH locus and provide insights into the potential implications for human health and disease. Our results underscore the importance of considering the genome complexity of the IG loci when investigating their association with diseases and antibody mediated phenotypes. The combination of long-read sequencing and IGenotyper provides a powerful toolset for dissecting the intricate variations within this region, thereby enabling more precise genotype-phenotype understanding and offering insights into disease susceptibility and therapeutic interventions. In conclusion, our study presents a comprehensive characterization of genetic variants within the IGH locus. We anticipate that these findings will enhance our understanding of the IG loci's role in human diseases and antibody function, ultimately contributing to personalized medicine approaches.

PB1419 Deconvoluting immunological, genetic, and clinical heterogeneity across autoimmune rheumatic diseases by cohort-wide immuno-phenotyping

Authors:

Y. Okada[1], H. Tanaka[2], S. Nakayamada[2], Y. Miyazaki[2], K. Sonehara[3], S. Namba[4], S. Honda[5], Y. Shirai[4], K. Yamamoto[4], K. Ikari[5], M. Harigai[5], K. Sonomoto[2], Y. Tanaka[2]; [1]The Univ. Tokyo / Osaka Univ. / RIKEN, Tokyo, Japan, [2]Univ. of Occupational and Environmental Hlth., Kitakyushu, Japan, [3]the Univ. of Tokyo, Tokyo, Japan, [4]Osaka Univ. Graduate Sch. of Med., Osaka, Japan, [5]Tokyo Women's Med. Univ., Tokyo, Japan

Deconvolution of immunological and clinical heterogeneity across autoimmune rheumatic diseases (AIRDs) is essential towards personalized medicine. Here, we conducted large-scale and cohort-wide immuno-phenotyping of 46 peripheral immune cells using the Human Immunology Protocol of comprehensive 8-color flow cytometric analysis. The dataset consisted of >1,000 Japanese patients of 11 AIRDs with deep clinical information registered at the FLOW study, including rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), systemic sclerosis (SSc), ANCA related vasculitis (AAV), idiopathic inflammatory myopathy (IIM), psoriasis, IgG4 related disease (IgG4RD), mixed connective tissue disease (MCTD), ankylosing spondylitis (AS), Sjogren's syndrome (SjS), and giant cell aortitis (GCA). Multimodal clustering of immuno-phenotypes deciphered underlying disease-cell type network, providing novel immune cell type specificity shared or distinct across AIRDs (e.g., close immunological network between MCTD and SLE. Individual patient-level clustering deconvoluted the AIRD patients into several clusters with different immunological features. Of these, RA- or SLE-like clusters were exclusively dominant, showing immunological polarization between RA and SLE across AIRDs. By adopting RA as a flagship disease, in depth clinical analysis revealed that such patient clusters differentially defined clinical heterogeneity in disease activity and treatment responses, such as decreased regulatory T cells and treatment resistance in the RA patients with SLE-like immuno-phenotypes. Inborn human genetics represented by polygenic risk score (PRS) showed associations with dynamics in clinical manifestations and immuno-phenotypes. The PRS estimated based on the RA case-control genome-wide association study (GWAS) and within-case stratified GWAS were associated with patient characteristics, disease activity, and immune-phenotypes such as dendritic cells for RA-interstitial lung disease. Our study demonstrated a value of cohort-wide and cross-disease immuno-phenotyping to elucidate clinically heterogenous patient subtypes existing within the single disease in an immune cell type-specific manner.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1420 *Decrypting the Colon*: Using single colon crypts to study regional somatic mosaicism

Authors:

L. Hiatt, J. Kunisaki, S. Lulla, M. E. Goldberg, A. Hoffman, A. Uchida, X. Nie, Y. Guo, K. Aston, J. Hotaling, A. Quinlan; Univ. of Utah, Salt Lake City, UT

Somatic mosaicism arises from mutations accumulated in cells over an organism's lifespan and can play a pivotal role in disease pathogenesis, from developmental syndromes to cancer. Somatic mosaicism influences fitness and disease predisposition in healthy tissue, and recent experimental advances enable the exploration of mosaicism in healthy organs and throughout disease progression.

Given its uniquely monoclonal epithelial structure, the colon is an exemplary organ for studying somatic mosaicism. Somatic mutations are known to drive colorectal cancer and are hypothesized to contribute to or correlate with inflammatory bowel disease. These diseases impose significant morbidity and mortality, with colorectal cancer ranking as the second leading cause of cancer-related deaths in the United States and inflammatory bowel disease affecting one in 200 individuals of European ancestry.

Interestingly, distinct regional pathologies exist along the colon's length, such as "right" and "left" colorectal cancer and unique subtypes of inflammatory bowel disease. Yet, the genetic origins of these region-specific pathologies remain elusive due to previous experimental limitations. Assessing somatic mosaicism throughout the colon is essential to explore whether local mutagenic events, such as developmental processes or microbiome exposures, drive regional pathogenesis. A preliminary study by Lee-Six et al. reported variation in mutational signature proportions across three colon regions, as determined by biopsy metadata. However, low sequencing coverage (~15x), a lack of germline filtering, and the examination of a small number of non-standardized colonic subregions in a small cohort limited this analysis.

To systematically investigate the mutational landscape of distinct colorectal regions, we are studying cadaveric tissue and colonoscopy samples from the University of Utah Gastrointestinal Biobank taken from ten standardized regions along the colon. Utilizing laser capture microdissection, we isolate single colon crypts, which are monoclonal structures whose ~2000 cells originate from a common ancestral stem cell. By detecting mutations in different crypts with whole-genome sequencing, we can test the hypothesis that distinct mutagenic processes influence regional pathogenesis.

We will present our ongoing efforts to characterize regional somatic mosaicism in the colon, as this knowledge holds promise for innovative strategies in predicting disease risk, optimizing disease management, and advancing personalized therapeutic approaches.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1421 Deep learning based semantic segmentation of adipose tissue histology samples.

Authors:

E. Joersboe[1], J. Honecker[2], P. kubitz[3], M. Claussnitzer[4], H. Hauner[5], M. Blüher[6], P. D. Charles[1], C. Lindgren[7], C. Nellaker[8]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Technical Univ. of Munich, Munich, Germany, [3]Technical Univ. of Munich, Freising, Germany, [4]Massachusetts Inst Technology, Cambridge, MA, [5]Technical Univ. of Munich, Freising-Weihenstephan, Germany, [6]Univ. of Leipzig Med. Ctr., Leipzig, Germany, [7]Big Data Inst., Oxford Univ., Oxford, United Kingdom, [8]Univ Oxford, Oxford, United Kingdom

Fat distribution and macro structure of adipose tissue are important factors in predicting obesity-associated diseases. To investigate the relationship between mean adipocyte area and obesity-related traits, and identify genetic factors associated with adipocyte cell size, we performed the largest study of automatic adipocyte phenotyping using both histological and genetic data. Utilising visual deep learning based tools for doing semantic segmentation of subcutaneous and visceral adipose tissue histology samples (N=2,667) in 5 independent cohorts. We developed a pipeline using U-net for segmentation of adipocytes, and filtered on size (> 200 µm2) and roundness, using the Polsby-Popper test, of the segmented adipocyte. The pipeline was able to do rapid inference across 9,000 whole slide images, and segment over 27 million adipocytes. Mean adipocyte area in both depots is positively correlated with body mass index (BMI) (PSubcutaneous = 4.56·10-54, βSubcutaneous = 0.0020, R2Subcutaneous = 0.55, PVisceral = 5.90·10-31, βVisceral = 0.0019, R2Visceral = 0.47) using a linear model, adjusting for cohort. Additionally, the mean adipocyte area in subcutaneous depots is larger than their visceral counterparts using a simple linear model (P = 4.79·10-132 , β = 0.46, R2 = 0.27). Estimates of mean size of adipocytes were validated against Glastonbury et al. 2020 showing a high level of concordance (R2Visceral = 0.95 , R2Subcutaneous = 0.87). As expected from our novel phenotyping approach, where we segment all adipocytes in the whole slide image, and our new filtering approach for segmented adipocytes, we find a larger estimated mean size of adipocytes in the current study than Glastonbury et al. 2020 (βVisceral = 0.60, βSubcutaneous = 0.56). We performed the largest GWAS (NSubcutaneous = 2066, NVisceral = 1878) and subsequent meta-analysis of mean adipocyte area, however no genome-wide significant (P < 5·10-8) associations were found with mean subcutaneous or visceral adipocyte area, using imputed genetic data (almost 9 million markers with R2/imputation info > 0.3).

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1422 Defining cognitive phenotypes in Peurto Rican individuals for genetic studies using culturally sensitive norms

Authors:

A. Zaman[1], K. McInerney[1], P. Mena[1], S. Tejada[1], K. Celis[1], L. Adams[1], K. Hamilton-Nelson[1], C. Silva[1], V. Glenies[1], J. Sanchez[1], J. Vance[1], B. Feliciano-Astacio[2], M. Pericak-Vance[1], M. Cuccaro[1]; [1]Univ. of Miami, Miami, FL, [2]Univ. Celtral del Caribe, Bayamon, PR

Background: Cognitive testing is used to define phenotypes in genetic studies of Alzheimer's disease (AD). To evaluate cognitive test performance, normative (norm) data are used to adjust for demographics. For example, the National Alzheimer's Coordinating Center Uniform Data Set (NACC) is a nationally representative US dataset (83% White, 14% African American, 3% Other) with norms used to adjust and standardize scores. While these adjustments increase the sensitivity to detect cognitive impairment, they need to be adapted for diverse populations. This pilot study examines norm differences between individuals from the Puerto Rico Alzheimer Disease Initiative (PRADI) and NACC.
Methods: We restricted our PRADI dataset (N=1280) to 141 adults (11%) who were cognitively normal (CN), had a global CDR score = 0, and had no medical conditions of concern (76% Female, 13.6 +3.6 years of education, 70.5 + 10.0 years old). The NACC sample is mostly White and of European ancestry; the PRADI sample is admixed with European (71%), African (18%), and Amerindian (11%) contributions. For all cognitive tests, norms were estimated (population mean, sex, age, and years of education). We then compared the PRADI norms with NACC norms.
Results: The population mean adjustments (PMA) were higher in NACC compared to PRADI, reflecting lower test scores in the PRADI sample. The difference in PMA was large for the Craft Story Immediate (10.2) and Delayed (10.9) tasks and small for Category Fluency [Animal Naming (AN) 0.3; Vegetable Naming (VN) 2.8]. Age adjustment differences were small (<0.1) on all tests. Education adjustments were notably larger in the NACC than PRADI for AN (0.57 vs 0.34) and VN (0.31 vs 0.12) indicating that each educational year was associated with a higher predicted score in the NACC vs. PRADI. Notable sex adjustments were found for AN and VN, where adjustment for AN was large in PRADI where females scored lower than males (-1.3), while the adjustment was smaller and in the opposite direction in NACC (0.3). The sex adjustments on VN were smaller in PRADI where females scored slightly higher than males (0.3), while NACC females had much higher scores than males (2.5).
Discussion: PMAs were greater in the NACC compared to PRADI, and the overall result of using NACC norm adjustments in the PRADI sample could result in presumptively CN individuals showing more impairments on multiple cognitive tests. This suggests that the local PRADI norms may more accurately estimate cognitive performance than the NACC norms in the PRADI group. Culturally sensitive norms should be developed for cognitive tests to measure and define cognitive phenotypes for genetic studies of AD in diverse populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1423 Delineation of functionally important protein domains of CHD8 for assessment of variants identified in individuals with autism spectrum disorders

Authors:

E. Larsen[1], S. Spring-Pearson[1], C. Printzis[2], P. Gerges[1], S. Basu[1]; [1]MindSpec, Inc., McLean, VA, [2]Northwestern Univ., Niles, IL

CHD8, a member of the chromodomain-helicase-DNA binding protein family, is considered a high confidence gene for autism spectrum disorder (ASD) based on the identification de novo damaging variants in individuals with a primary diagnosis of ASD across studies and cohorts. This gene has also been shown to contribute to a neurodevelopmental disorder (NDD) presenting with intellectual disability, overgrowth, sleep disturbances, gastrointestinal problems, and dysmorphic features with or without ASD. However, it remains unclear if any correlation exists between the type and location of CHD8 variants and any specific pattern of phenotypes arising from these mutations. In order to delineate functionally-relevant protein domains, we assessed the genetic landscape of CHD8-associated syndrome using the richly annotated data curated in AutDB, our online genetic database for ASD (http://autism.mindspec.org/autdb/Welcome.do). Rare genetic variations in CHD8 identified in individuals diagnosed with ASD or NDD were extracted from 45 peer-reviewed scientific articles and annotated with multiple attributes for ongoing curation in AutDB. We assembled the largest CHD8 dataset to date comprising a total of 204 individuals carrying rare variants in CHD8, including 144 of whom were reported to have a diagnosis of ASD. Randomization across protein domains was performed on the standardized CHD8 rare variant dataset, as well as on a control dataset of CHD8 variants from gnomAD, to identify protein domains statistically enriched for variations linked to ASD and/or NDD. While disease-associated variants were distributed across the entire length of the CHD8 protein, randomization analysis demonstrated that three identified protein domains (the helicase ATP-binding, the helicase C-terminal, and the chromodomain 2 domains) showed statistically significant enrichment for ASD-associated variants. While no significant findings were observed for NDD-associated CHD8 variants in any identified protein domain, we observed that both the helicase ATP-binding and helicase C-terminal domains had significantly fewer than expected variants in the control cohort. Moreover, CHD8 missense variants in both the ASD and NDD cohorts displayed significantly higher CADD scores than missense variants from the control cohort. Our approach of protein domain-based enrichment of variants improves the understanding of functional consequences of CHD8 variations associated with ASD. Importantly, protein-domain mapping of variants will likely facilitate the interpretation of new CHD8 variants reported in large-scale genetic studies for diagnostic purposes.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1424 Determinants of clonal hematopoiesis expansion rate in *UK Biobank* and*All of Us* Cohorts

Authors:

T. Mack[1], C. Vlasschaert[2], B. Sharber[1], A. Bick[1]; [1]Vanderbilt Univ., Nashville, TN, [2]Queens Univ., Kingston, ON, Canada

Clonal Hematopoiesis of Indeterminate Potential (CHIP) is characterized by the acquisition of a somatic mutation in a hematopoietic stem cell that leads to the formation of a sub-clonal blood cell population. CHIP increases risk of blood cancer, cardiovascular disease, and overall mortality. Larger CHIP clones are associated with worse outcomes. However, CHIP clonal expansion rate is not well characterized because few cohorts have multi-timepoint DNA samples. To date, the largest of such analyses include a few hundred participants. To overcome this limitation, we recently developed a method to quantify clonal expansion rate from a single timepoint whole genome sequenced blood sample termed Passenger-Approximated Clonal Expansion Rate (PACER; Weinstock, Nature 2023). Here we identified 10,727 individuals with CHIP in 298,477 individuals with available whole genome sequence data in All of Us (CHIP N=4,446) and UK Biobank (CHIP N=6,281). We applied PACER to these two datasets to estimate the clonal expansion rate of each CHIP clone. We first identified the contribution of somatic driver mutation to clonal expansion. Consistent with prior observation from smaller multi-timepoint datasets, CHIP mutations in *JAK2* and splicing factors (*U2AF1, SRSF2, & SF3B1*) showed the fastest rates of clonal expansion. *DNMT3A* CHIP mutations were amongst the slowest expansion rates. Next, we identified the contribution of germline genetic variation to clonal expansion. We performed a single variant genome-wide association study (GWAS) of PACER in individuals with CHIP clonal expansion rate in each cohort and performed a fixed effect meta-analysis of the results. Covariates included age, sex, and the first ten genetic ancestry principal components. We identified 9 genome-wide significant loci. We robustly replicated TCL1A (rs2887399, $p= 3.5 \times 10^{-9}$), the only variant previously identified in our NHLBI TOPMed cohort PACER GWAS. Notable novel variants associated with PACER at genome-wide significance include intronic variants in CEP135, a centrosomal scaffold protein (rs73155551, $p=5.3 \times 10^{-9}$); MAU2(rs117352725, $p=3.5 \times 10^{-8}$) involved in cohesin loading and maintenance of mitotic sister chromatids; and DLEU7 (Deleted in Lymphocytic Leukemia 7, rs752066930, $p=1.2 \times 10^{-8}$). In summary, here we perform the largest analysis of CHIP clonal expansion to date, twice the size of our prior effort in TOPMed and >100 times larger than any analysis of multi-timepoint samples. Our findings highlight the power of PACER to estimate CHIP clonal expansion rate from a single timepoint sample and identify a previously unknown link between cell cycle progression and clonal expansion.

Inst., Bethesda, MD, [14]NIH, Bethesda, MD, [15]Northwestern Univ., Chicago, IL, [16]Northwestern Univ, Chicago, IL, [17]Tulane Univ. Sch. of Med., Seattle, LA, [18]Univ. of Alabama at Birmingham, Birmingham, AL, [19]Univ Washington Med Ctr., Seattle, WA

Screening populations for genetic risks includes obtaining family health history (FHH) and testing for monogenic and polygenic diseases. As genomic screening becomes more routine, clinicians will need guidance on how these risks interact, and how to integrate them with clinical risk factors to establish risk-appropriate preventive care practices. The eMERGE network is enrolling a diverse 25,000-person cohort, ascertaining FHH, clinical sequencing for a limited number of monogenic risks (adults only), and genotyping for polygenic risk scores (PRS). We developed a REDCap based platform (R4: Recruitment, Retention, and Risk Reduction) to collect clinical-grade data from multiple sources, apply logical rules to trigger ‘high risk’ status, and generate a comprehensive risk report for clinicians, the electronic health record (EHR), and individuals. These data were obtained directly from individuals (survey), EHRs, clinical laboratories conducting genotyping and sequencing, and a family history data collection tool, MeTree. For each condition, a specific set of rules was developed based on clinical guidelines or expert opinion to trigger ‘high risk’ status. Three conditions (atrial fibrillation, coronary heart disease, prostate cancer) use PRS, limited monogenic, and FHH risk to independently trigger high risk status; chronic kidney disease uses PRS and FHH; hypercholesterolemia uses monogenic and PRS; and four conditions (asthma, obesity, type 1 diabetes, and type 2 diabetes) rely on the PRS score alone. Breast cancer uses a published integrated risk score, BOADICEA, which calculates lifetime risk based on FHH, clinical, and genomic data; high risk status is defined as ≥ 25% lifetime risk. Of the 11,897 individuals enrolled as of June 1st, 2023, 1009 risk reports have been generated, with 285 individuals classified as ‘high risk’; 193 with PRS above the study threshold, 18 with monogenic risk, and 139 with high risk FHH. Eleven individuals were assigned high breast cancer risk using BOADICEA. Individuals may have multiple risk categories and conditions. During R4 report generation testing, challenges were encountered specifically around missingness in survey and FHH data. Protocols to review, update, and regenerate reports and associated recommendations were developed. As the field of population genomic screening evolves, it will be critical to establish reliable and validated methods for capturing, processing, and returning genetic risks that are integrated and delivered in the context of an individual’s health while resilient to incomplete data about individuals’ personal and family history.

PB1426 Differential gene expression analysis reveals genes underlying the transition to T2D in Hispanic/Latino individuals.

Authors:

E. Frankel[1], W. Zhu[1], H-H. Chen[2], P. Sharma[3], L. E. Petty[1], R. Roshani[1], H. Highland[4], E. Gamazon[5], J. McCormick[6], S. Fisher-Hoch[7], K. North[8], J. Below[9]; [1]Vanderbilt Univ., Nashville, TN, [2]Academia Sinica, Taipei, Taiwan, [3]Univ. of North Carolina, Chapel Hill, NC, [4]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [5]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN, [6]UTH SPH Brownsville, Brownsville, TX, [7]Univ. of Texas Sch. of Publ. Hlth., Brownsville, TX, [8]Univ North Carolina, Wake Forest, NC, [9]Vanderbilt Univ Med Ctr., Nashville, TN

Background: Type 2 diabetes (T2D) is a multifactorial metabolic disorder that results from the interactions between genetic, environmental, and multiomic factors. Hispanic/Latino populations are often underrepresented in research studies despite having an increased prevalence of T2D compared to non-Hispanic whites. In this study, we sought to understand the changes in gene expression that occur during the transition to T2D and in quantitative measures such as longitudinal fasting blood glucose (FBG) and glycated hemoglobin (HbA1c) levels. **Methods:** We utilized 1150 longitudinal whole blood specimens from 575 participants (142 incident cases) in the Cameron County Hispanic Cohort. RNA-sequencing data from two time points per individual were used to profile the transition to incident T2D. Incident T2D was characterized using the ADA 2010 criteria, and we excluded individuals taking diabetes medication at either timepoint. We utilized joint mixed-effect regression models of longitudinal measures, accounting for sex, age, smoking status, body mass index (BMI), and probabilistic estimation of expression residual factors to compare changes in gene expression between individuals with incident T2D and controls, as well as in the quantitative traits FBG and HbA1c. We performed an additional analysis removing BMI as a covariate for incident T2D to capture genes highly associated with BMI that may contribute to the development of T2D. **Results:** Our preliminary analysis of incident T2D from a subset of samples revealed three genes independent of BMI that had a significant change in expression across T2D onset after false discovery rate (FDR) correction: *KLF10*, *BPI*, *OR2T2*. Excluding BMI as a covariate revealed six additional significant genes: *TP53INP2*, *PRICKLE2*, *CAMKK2*, *HP*, *MMP8*, and *CEACAM8*. Furthermore, preliminary analyses of longitudinal FBG and HbA1c levels identified 50 and 398 significant genes, respectively, after FDR correction. We further explored our significant genes in proteomic data from 259 CCHC individuals and found MMP8 protein levels are also associated with incident T2D (P=0.0018). **Conclusion:** Our analyses characterized transcriptomic changes related to incident T2D and longitudinal FBG and HbA1c levels in an understudied population with a high disease burden. Numerous genes discovered in these analyses have previously been identified in genome-wide association studies of T2D and other metabolic health and dysfunction measures. Our results provide functional evidence from a key timepoint in disease development that implicates a functional gene at these loci and a mechanism of effect.

PB1427 Differential gene expression analysis using RNA-Seq sheds light on the molecular etiology of chikungunya's chronic manifestations

Authors:

J. Noirel[1], R. Medina-Santos[1], S. Le Clerc[1], T. Labib[1], M. Rahmouni[1], M. J. Mathew[2], H. Hocini[3], L. Bruneau[4], L. Bruneau[4], A. Maillot[4], C. Fontaine[4], C. Fontaine[4], N. Ah-You[4], M. Marimoutou[4], P. Gérardin[4], J-F. Zagury[1]; [1]CNAM, Paris, France, [2]EFREI, Paris, France, [3]Hôpital Henri Mondor, INSERM, Créteil, France, [4]CHU Réunion, Saint-Pierre, France

Background: Chikungunya virus is responsible for a complex disease including fully asymptomatic, acute/post-acute self-limiting, and chronic incapacitating presentations. In the long run arthralgia/arthritis, musculoskeletal pain, fatigue and mental illness are observed in up to 52 % of the infected patients. In 2005-2006, a huge chikungunya outbreak hit La Reunion Island, which left 300,000 people infected and countless with chronic discomfort.
Methods: In the aim to better understand the molecular pathogenesis of the disease and the genetic and immunologic drivers of its chronicity, we conducted a genome-wide scan of a well-phenotyped cohort of 609 individuals from La Reunion Island, within which 244 adult patients were primarily classified as “asymptomatic” (none of the abovementioned manifestations), “nonchronic” (symptoms ≤ 3 months), or “chronic” (symptoms more than 3 months), and sampled for peripheral blood mononuclear cells (PMBCs) transcriptome analysis. We next identified differentially expressed genes (DEGs) and interactions associated with symptomatic status and with chronic symptoms through pathway and gene ontology (GO) analyses in comparing phenotypes (chronic vs nonchronic, asymptomatic vs nonchronic).
Results: In total, patients with chronic symptoms represented 55% of the subsample (136/244). Women were over-represented in this group (109 for 27 men), and to a lesser extent among patients with nonchronic symptoms (58 for 30 men) and asymptomatic individuals (17 for 3 men). DEGs included TMTC1, GSTM1, FRG1CP, CXCL16, RPL10P9, RPL10P6, MEGF6, IRGM and NBPF26, some of these being involved in viral infection susceptibility and/or severity, immune response and muscular diseases. The top gene pathways enriched according to GO deciphered mainly immune system processes, such as “complement activation, classical pathway” and “protein activation cascade”, while the KEGG pathways identified “Extracellular-Matrix receptor interaction” and “bone remodeling” as prominent mechanisms, which was consistent with shorter term RNA-Seq analyses of chikungunya virus infection.
Conclusion: This first RNA-Seq study of post-chikungunya chronic manifestations, performed on a large sample size, provides valuable insights into the molecular mechanisms underlying the complex chronic manifestations of chikungunya.

PB1428 Discovering genes associated with Alzheimer's Disease via multi-tissue and cell type Transcriptome-Wide Association Study.

Authors:

C. Liu[1,2], H. Sun[3], The FunGen-xQTL Consortium, G. Wang[3], F. Morgante[1,4]; [1]Ctr. for Human Genetics, Clemson Univ., Greenwood, SC, [2]Sch. of Computing, Clemson Univ., Clemson, SC, [3]Dept. of Neurology, Columbia Univ., New York, NY, [4]Dept. of Genetics and Biochemistry, Clemson Univ., Clemson, SC

Late-onset Alzheimer’s disease (AD) is a complex neurodegenerative disorder with a substantial genetic component unveiled through Genome-Wide Association Study (GWAS). Identifying genetic risk factors and understanding the mechanisms of their role in complex diseases remains challenging, particularly for non-coding variants which, on average, consist of >90% GWAS signals. Transcriptome-Wide Association Study (TWAS) has been developed to leverage expression Quantitative Trait Loci (eQTL) for gene mapping in GWAS, by imputing gene expression in GWAS samples using pre-trained models from eQTL studies and testing for their disease associations. Such imputed expression data aggregates functional evidence of non-coding variants, thus improving both the statistical power and biological interpretability of GWAS.

Here, we develop a new TWAS resource by training tissue and cell-specific models from multi-brain region RNAseq harmonized across several AD cohorts by the FunGen-xQTL Consortium. We apply a new Bayesian method, mr.mash, to exploit shared genetic effects across multiple tissues and cell types. Using a data-adaptive approach, mr.mash can improve the accuracy of expression imputation in conditions with inadequate power for TWAS --- such as rare cell types identified through single-nuclei RNAseq or brain regions with small sample sizes --- for genes with shared effects across multiple conditions. It will, nonetheless, retain tissue and cell-specific effects for genes uniquely regulated under specific conditions.

We apply this new TWAS resource to a recently published AD GWAS meta-analysis. To avoid false positives due to horizontal pleiotropy, we adopted the causal TWAS (cTWAS) framework to simultaneously identify putative causal genes and variants. Through cohort-specific analyses and cross-cohort meta-analysis, we report a list of genes with strong TWAS signals, including established AD genes such as APOE and PICALM, as well as novel genes that either exhibit consistent effect across conditions, or are associated with AD only in tissue and cell-specific fashion. Our results provide a powerful TWAS analysis framework and pre-trained models in human brains that can be applied to any other relevant complex traits of interest to improve our understanding of complex trait genetics.

PB1429 Discovery of microglia specific molecular drivers and targeted therapeutics for Alzheimer's disease using network-based deep learning integration of human brain single-cell RNA seq data and real-world patient data validation

Authors:

J. Xu[1], M. Danziger[2], Z. Xu[3,4], C. Zang[3,4], Y. Zhou[1], Y. Hou[1], E. Karavani[2], Y. Shimoni[2], F. Wang[3,4], M. Rosen-Zvi[2], F. Cheng[1,5,6]; [1]Cleveland Clinic, Lerner Res. Inst., Cleveland, OH, [2]AI for Hlth.care, IBM Res., Haifa, Israel, [3]Dept. of Population Hlth.Sci., Weill Cornell Med., New York, NY, [4]Inst. of Artificial Intelligence for Digital Hlth., Weill Cornell Med., New York, NY, [5]Dept. of Molecular Med., Cleveland Clinic Lerner Coll. of Med., Cleveland, OH, [6]Case Comprehensive Cancer Ctr., Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Background: Microglia have been implicated in Alzheimer's disease (AD) for over 100 years. However, high microglial heterogeneities, including disease-associated microglia (DAM), tau microglia, and inflammatory microglia (neuro-toxic), largely limit the development of microglia-targeted treatment for AD and other neurodegenerative diseases.**Methods:** In this study, we conducted integrative analyses of ~0.7 million single-cell/nuclei RNA-seq transcriptomes derived from AD patient frozen brain samples across different brain regions at The Alzheimer's Cell Atlas (https://taca.lerner.ccf.org) using a variational autoencoder-based approach scVI. We used the trajectory analysis to identify microglial subtypes across AD progression, including DAM, tau and inflammatory microglia. We conducted the transition network analysis to identify potential molecular drivers of different microglial subtypes across varying degrees of AD and disease progression under the human protein-protein interactome network. We prioritized candidate drugs by specifically targeting molecular derivers using drug-gene signature enrichment analysis from the Connectivity Map (CMap) database and population-based drug-disease outcome analysis using with two independent real-word patient data (MarketScan insurance claims [172 million insured individuals] and INSIGHT Clinical Research Network (15 million patients).**Results:** We identified that tau microglia were significantly associated with synaptic processes. Compared to DAM, upregulated genes of inflammatory microglia were more significantly enriched with key immune pathways (e.g., toll-like receptor and th17 cell differentiation). We found that transition gene networks of inflammatory microglia and DAM contain potential AD pathobiology regulators (e.g., *SYK*, *CTSB*, and *PRKCA*) and genetic risk genes (including *INPP5D*, *BLNK*, and *ADAM10*). We further conducted network-based drug repurposing prediction by specifically targeting inflammatory microglial subpopulations. Consistent within real-world patient data observation in two independent clinical databases (i.e., MarketScan and INSIGHT CRN), we identified that usage of ketorolac could potentially reduce the risk of AD incidence in both MarketScan (hazard ratio [HR] = 0.81, 95% confidence interval [CI]: 0.69-0.91 after adjusting > 400 covariates); and INSIGHT (HR = 0.52, 95% CI 0.28-0.95, p-value = 0.03, after adjusting 267 covariates) databases. **Conclusion:** This study identifies potential underlying mechanisms of microglial subtypes involved in human AD brains and identified ketorolac as a potential microglia-targeted medicine for AD.

PB1430 Discovery of structural variants in the CARTaGENE cohort using whole-genome DNA sequencing

Authors:

R. Laflamme[1,2], M. Sayahian Dehkordi[3], D. Taliun[3], K. Lo[1], S. Gravel[3], S. Gagliano Taliun[1,2], G. Lettre[1,2]; [1]Montreal Heart Inst., Montreal, QC, Canada, [2]Université de Montréal, Montreal, QC, Canada, [3]McGill Univ., Montreal, QC, Canada

Structural variants (SVs), such as large deletions and duplications, are genetic variants that encompass 50 DNA base pairs or more. Although they are considered the largest source of genetic diversity, SVs have been less studied compared to smaller variants owing to the difficulty to discover and genotype them. As a result, whereas small SNVs and indels have been associated with a large number of human traits and diseases, associations between SVs and human phenotypes are rare. Our aim is to build the first catalog of SVs in the Quebec population and characterize their role in chronic diseases.The CARTaGENE cohort presents a unique opportunity to assess associations between SVs and human phenotypes. CARTaGENE is a population-based cohort of 43,000 individuals recruited from different metropolitan regions of Quebec (Canada) and aged between 40 and 69 years at recruitment. The aims of our project are to generate a map of SVs from high-coverage short-read whole-genome sequence (WGS) data of 2,173 participants of the CARTaGENE cohort, and to test their associations with clinically-relevant phenotypes implicated in chronic diseases. For this experiment, we sequenced the genome of 1,756, 131 and 163 individuals of French Canadian, Moroccan and Haitian ancestry, respectively. We used existing bioinformatics tools and built a pipeline for calling and genotyping SVs from WGS data. SVs were called in each participant with two algorithms (Manta and DELLY), and the intersection between the two callers were kept. Called SVs from all participants were then merged and genotyped using muCNV, a multi-sample SVs genotyper. Genotyped SVs were then used for association testing on 57 quantitative phenotypes with PLINK.We genotyped 25,835 SVs, including 24,034 deletions and 1,801 duplications. 74% of these SVs were present in the gnomAD-SV database, and their frequencies were concordant (Pearson's r=0.81 and r=0.58 for deletions and duplications, respectively). We identified rare SVs associated with known pathologies, including six carriers of the 15+kb deletion encompassing the promoter and first exon of the *LDLR* gene, which causes familial hypercholesterolemia.Finally, we are developing a haplotype reference panel to empower the imputation of these SVs in CARTaGENE and other cohorts to enable more powerful genetic association studies.

Sch. of Med., Baltimore, MD, [6]Biochemistry, Cellular and Molecular Biology (BCMB) Graduate Program, Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [7]South Australian Hlth.and Med. Res. Inst., Adelaide, Australia, [8]Dept. of Neurology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, United States, Boston, MA, [9]Dept. of Molecular Biology and Genetics, Johns Hopkins Univ., Baltimore, MD, [10]Dept. of BioMed. Engineering, Johns Hopkins Univ., Baltimore, MD, [11]Dept. of NeuroSci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

X-linked Dystonia-Parkinsonism (XDP) is an adult-onset fatal neurodegenerative disorder of the caudate nucleus predominantly affecting male descendants from the Panay Islands in the Philippines. It is characterized by progressive degeneration of the adult neostriatum. At molecular level, a disease-specific, hexamer-containing SINE-VNTR-Alu (SVA) retrotransposon insertion occurs within intron 32 of *TAF1* on the X chromosome, which alters splicing and decreases *TAF1* expression. The length of hexamer repeats is inversely correlated with age of onset, as XDP is also a repeat expansion disorder. Efforts have focused on rescuing altered *TAF1* splicing, however, modeling this hexamer expansion to better study the mechanism by which the SVA contributes to XDP pathogenesis remains unexplored.

Here, to understand the mechanism of degeneration driven by SVA insertion, we differentiated induced pluripotent stem cells (iPSCs) from male control and XDP individuals, and isogenic SVA-deleted lines from the same XDP individuals into ventral forebrain organoids. We cryosectioned and immunostained organoids for striatal markers to ensure our model recapitulated human striatal development. We also monitored electrophysiological activity from day 90 to day 180 on multi-electrode arrays. We found that striatal organoids from individuals with XDP displayed increased somatic instability of the hexamer DNA repeat throughout organoid maturation. The XDP organoids showed decreased electrical activity from day 120 to day 180 and increased apoptosis and DNA damage at day 120 compared to SVA-deleted organoids. We recapitulated neurodegeneration in our organoid model and uncovered potential molecular mechanisms by which the SVA contributes to XDP pathogenesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1432 Disentangling the effects of fat mass and fat-free mass on cardiometabolic risk by a genetic approach.

Authors:

X. Jiang[1], M. Christiansen[1], T. Kilpeläinen[2]; [1]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Univ. of Copenhagen, Copenhagen, Denmark, [2]Univ. of Copenhagen, Copenhagen, Denmark

Background: The amounts of fat mass (FM) and fat-free mass (FFM) are linked to the risk of cardiometabolic diseases. However, disentangling the independent effects of FM and FFM on cardiometabolic risk is challenging because of the strong correlation between the traits (r=0.6-0.8) and shared heritability. We aimed to disentangle the effects of FM and FFM on cardiometabolic risk by identifying genetic variants specific to FM and FFM and studying their associations with cardiometabolic disease risk. **Method:** We constructed specific polygenic risk scores (PRS) for FM and FFM from variants that were associated with one trait (P<5E-08) but not the other (P>0.05 and P>0.01, respectively). The associations between the PRS and outcomes were estimated in up to 414,377UK Biobank participants whose body composition was measured by bioimpedance. The specificity of the PRS for FM and FFM were independently validated in 35,010 additional UK Biobank participants whose body composition was measured by dual-energy X-ray absorptiometry. We tested associations between the PRS and cardiometabolic traits and diseases in up to 414,377 UK Biobank participants, as well as by using summary statics from published GWAS for coronary heart disease (CHD), type 2 diabetes (T2D), blood glucose, glycated hemoglobin (HbA1c), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), triglycerides, and systolic and diastolic blood pressure (SBP and DBP). **Results:** We identified 109 specific SNPs for FM and 73 for FFM and constructed the respective PRS. The FM-PRS was strongly associated with FM (?:7.16, P<0.001) and FFM-PRS with FFM (?:-4.84, P<0.001) without showing association with the counterpart (P=0.08, P=0.38). One Kg higher FM was associated with OR 1.25-fold (95%CI 1.10-1.42) higher risk of T2D. Higher FM was also associated with higher HbA1c (P<0.001), SBP (P=0.002), DBP (P<0.001), and lower HDL-C (P<0.001). One Kg lower FFM was not associated with the risk of CHD or T2D (P>0.05). Lower FFM was associated with higher blood glucose (P<0.001), LDL-C (P<0.001), triglycerides (P<0.001), and SBP (P<0.001). **Conclusion:** Through a novel genetic approach to assess the independent effects of FM and FFM on cardiometabolic risk, we find evidence that higher FM increases HbA1C, SBP, DBP and the risk of T2D, and lowers HDL-C, while lower FFM increases blood glucose, LDL-C, triglycerides, and SBP. [2,300 characters, excluding spaces, for the body of the abstract.]

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1433 † Disentangling the link between maternal influences on birth weight and disease risk in 36,211 genotyped mother-child pairs

Authors:

J. Leinonen[1], M. Pirinen[2], FinnGen, T. Tukiainen[3]; [1]FIMM, Univ. of Helsinki, Helsinki, Finland, [2]Univ Helsinki, Helsinki, Finland, [3]Inst. for Molecular Med. Finland (FIMM), Helsinki, Finland

Epidemiological studies have robustly linked lower birth weight to later-life disease risks, including cardiovascular diseases and type 2 diabetes. These observations have been hypothesized to reflect the adverse impact of intrauterine growth restriction on a child's health. However, causal evidence from human data supporting such a mechanism is largely lacking. We assessed the relationship between intrauterine growth restriction and five disease outcomes using 36,211 genotyped mother-child pairs (child mean age = 45.0 years) from the FinnGen study. Using a Mendelian Randomization (MR) framework, we tested how maternal genetic scores for child's birth weight, proxying intrauterine growth restriction, associate with disease in the children, accounting for the direct transmission of alleles between the mother and child. Despite the robust epidemiological associations, we find no significant association between the maternal birth weight genetic scores and offspring disease after adjustment for child's own genetic score of the same SNPs. Rather, in particular for coronary heart disease (CHD) and hypertension, the child's own genetic score associated with disease risk independently of the maternal genetic score (logOdds -0.135, SE 0.039, p = 0.000470 for CHD, and -0.042, SE 0.020, p= 0.0322 for hypertension). These results generally agree with and extend the previous suggestions that genetic pleiotropy in the child's genome may largely account for the known epidemiological associations between birth weight and disease risk in adulthood. In summary, our work provides further support for the concept that modest intrauterine growth restriction is likely not a major risk factor for later-life disease. Based on a large sample of genotyped parent-child pairs identified from a population-based biobank, our study illustrates the opportunities that such data provides for addressing causal questions related to maternal influences.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1434 Dissecting Genetic Associations of Hypercholesterolemia in the Personalized Environmental Genes Study

Authors:

J. House, E. Brown, A. Burkholder, Z. Xu, D. Lloyd, F. S. Akhtari, C. S. Schmitt, D. C. Fargo, J. E. Hall, A. A. Motsinger-Reif; Natl. Inst. of Environmental Hlth.Sci., RTP, NC

Hypercholesterolemia (HC) results from a combination of genetic and lifestyle factors. HC is a prevalent comorbidity for multiple medical conditions including cardiovascular disease, diabetes, hypertension, non-alcoholic fatty liver disease, and metabolic syndrome, although causality is unclear.
The North Carolina-based Personalized Environment and Genes Study (PEGS) cohort consists of more than 9,000 individuals with diverse race, education, and socioeconomic status characteristics for which extensive health and exposure data have been collected, with whole genome sequencing (WGS) data on ~4,700 participants. Individuals who answered yes to, “Have you ever been diagnosed with high cholesterol?” were defined as a case (n = 1,616) and controls numbered 3,084. We conducted a Genome Wide Association Study (GWAS) on common variants (MAF > 1%) using logistic regression adjusting for age, age-squared, sex, and the first 10 principal components. We conducted a structural variation analysis using the same covariates. Lastly, we conducted rare variant analysis (RVA) on variants with MAF < 0.01 using kernal-set based approaches (SKAT).
In GWA analysis, we found variants in *APOE* associated with HC status (lead variant *hg38_19:44909976_TGGT*, OR (95%CI) = 0.51(0.43-0.62), p = 1.07e-12, CAF = 0.09). Genetic variation in other previously identified genes with HC were suggestive genome wide significant (*PCSK9* : p=6.41e-8, *LDLR* : p=2.80e-6). Genome-wide RVA revealed rare variants in and near the coding region of *DBX2* associated with HC (SKAT.p = 1.07e-6). In addition, a targeted RVA in the lead GWAS finding (*APOE*) revealed associations with HC (p=0.004). In an analysis of structural variation, we found a deletion in *DNAH6* (*hg38_2:84691636-84991687*, CAF= 0.08, p = 3.4e-7) significantly associated with HC.
APOE has previously been associated with multiple lipid traits and rare variants in *APOE* have been associated with biomarkers of Alzheimer’s Disease. *DNAH6*, a microtubule-associated motor protein, has been implicated in cognitive traits, as well as late-onset Alzheimer’s disease. Additional work is ongoing to leverage the extensive exposure data on these individuals to identify gene-by-environment interactions that contribute to understanding of HC.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1435 Distilling causality between physical (in)activity and obesity

Authors:

Z. Wang[1], G. D. Smith[2,3], R. Loos[1,4], M. den Hoed[5]; [1]The Charles Bronfman Inst. for Personalized Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]MRC Integrative Epidemiology Unit, Univ. of Bristol and NIHR Bristol BioMed. Res. Ctr., Bristol, United Kingdom, [3]Population Hlth.Sci., Bristol Med. Sch., Univ. of Bristol and NIHR Bristol BioMed. Res. Ctr., Bristol, United Kingdom, [4]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Faculty of Hlth.and Med. Sci., Univ. of Copenhagen, Copenhagen, Denmark, [5]The Beijer Lab. and Dept. of Immunology, Genetics and Pathology, Uppsala Univ. and SciLifeLab, Uppsala, Sweden

Many studies have suggested that lower physical activity and more sedentary time are associated with higher odds of obesity, while obesity itself may contribute to more sedentary behavior and less physical activity. However, observational studies can suffer from confounding and reverse causation. Better instrumental variables and a more thorough consideration of potential confounding variables that may influence the causal inference between physical activity and obesity are needed.Leveraging results from our recent genome-wide association study that identified 11 loci for leisure time moderate-to-vigorous intensity (MV) physical activity and 88 loci for leisure screen time, we now have stronger instruments for causal inference. Given the strong genetic correlations of education with physical activity and obesity, we aim to examine the causal effects between physical (in)activity traits, education (defined by years of schooling), and body mass index (BMI). We applied various advanced univariable Mendelian Randomization (MR) methods - including the Causal Analysis Using Summary Effect estimates and Latent Heritable Confounder MR - as well as multivariable MR methods to disentangle these causal relationships. Univariable MR analyses suggest bidirectional causal effects between years of schooling and physical (in)activity traits. However, multivariable MR analyses show that the estimated causal effects of physical (in)activity traits on years of schooling are abolished when BMI is considered, such that more years of schooling is causally related to more MV physical activity and less screen time, but not vice versa (e.g., screen time on schooling: $\beta_{total} = -0.49$, $P = 7.8\times10^{-24}$; $\beta_{direct} = -0.04$, $P = 0.28$; schooling on screen time: $\beta_{total} = -0.33$, $P = 8.5\times10^{-76}$; $\beta_{direct} = -0.40$, $P = 8.8\times10^{-55}$). In addition, we find that years of schooling has a causal effect on BMI, but BMI does not affect years of schooling. With that, years of schooling may confound the causal relationship between physical (in)activity traits and BMI. Indeed, while univariable MR analyses suggest bidirectional causal effects, multivariable MR analyses that take years of schooling into account reveal that more MV physical activity is causally associated with a lower BMI **(**$\beta_{total} = -0.25$, $P = 2.0\times10^{-3}$; $\beta_{direct} = -0.20$, $P = 1.8\times10^{-6}$**)**, and a higher BMI with more screen time **(**$\beta_{total} = 0.16$, $P = 1.4\times10^{-74}$; $\beta_{direct} = 0.16$, $P = 1.0\times10^{-34}$), but not vice versa. In conclusion, our results highlight the beneficial effect of education on improved health and suggest that a more physically active lifestyle leads to lower BMI, whereas sedentary behavior is a consequence of higher BMI.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1436 Do iron homeostasis biomarkers mediate the associations of liability to type 2 diabetes and glycemic traits in non-alcoholic fatty liver diseases: A two-step Mendelian Randomization study

Authors:

Y. Liang[1], Y. Zhou[2], X. Bai[3], S. Au Yeung[1]; [1]The Univ. of Hong Kong, Hong Kong, China, [2]Natl. Clinical Res. Ctr. for Dermatologic and Immunologic Diseases (NCRC-DID), Beijing, China, [3]Peking Union Med. Coll. and Chinese Academy of Med. Sci., Beijing, China

Background. Previous Mendelian randomization (MR) studies showed liability to type 2 diabetes (T2D) and glycemic traits likely impacted iron homeostasis biomarkers, as well as increased risk of nonalcoholic fatty liver (NAFL) disease. Whether iron homeostasis markers mediate these associations have not been explored using MR design.

Methods. Using a two-step MR design, we assessed the mediating role of iron homeostasis biomarkers in the associations of liability to T2D, glycemic traits in liver diseases using summary statistics of genome-wide association studies (GWAS) of T2D (DIAMANTE n=933,970), glycemic traits (n≤209,605), iron homeostasis biomarkers(n≤246,139), and liver diseases (NAFL and liver cirrhosis (n≤972,707)) and its biomarkers (alanine aminotransferase (ALT) and Magnetic Resonance Imaging (MRI)-derived proton density fat fraction (PDFF) (n≤344,136)) with exclusion of potential pleiotropic genetic variants in *ABO* and *HFE* (rs1800562 and rs1799945). Inverse-variance weighted (IVW) was the main analysis, followed by sensitivity analyses (e.g., MR-Egger, weighted median, Robust Adjusted Profile Score, and MR-PRESSO) and mediation analysis using product of coefficients methods.

Results. In the main analysis, liability to T2D and fasting insulin (FI) increased NAFL ($OR_{\text{liability to T2D}}$ 1.20 per log odds, 95%CI 1.13 to 1.27; OR_{FI} 3.45 per log pmol/l, 95%CI 1.95 to 6.08), as well as ALT and PDFF. Liability to T2D also increased liver cirrhosis (OR 1.11, 95% CI 1.05 to 1.18). Amongst all iron homeostasis biomarkers considered, higher ferritin and serum iron were associated with increased risk of NAFL and liver cirrhosis respectively. In the mediation analyses, we only found ferritin partially mediated the associations of FI in NAFL (mediation effect: 7%, 95%CI 2% to 13%).

Conclusion. Ferritin likely mediated the associations of FI in NAFL. Targeting ferritin may reduce risk of NAFL in people with elevated insulin.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1437 Drastic weight loss alters expression of genes in immune pathways and induces changes in adipose cell-type composition dependent on sex and type 2 diabetes status

Authors:

X. Guo[1], S. Lee[1], D. Kaminska[2,3], V. Männistö[4], U. Arasu[5], T. ÖRd[5], M. Kaikkonen[5], J. Pihlajamäki[2,6], P. Pajukanta[1,7]; [1]Dept. of Human Genetics, David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [2]Inst. of Publ. Hlth.and Clinical Nutrition, Univ. of Eastern Finland, Kuopio, Finland, [3]Dept. of Med., Div. of Cardiology, UCLA, Los Angeles, CA, [4]Inst. of Clinical Med., Univ. of Eastern Finland and Kuopio Univ. Hosp., Kuopio, Finland, [5]A. I. Virtanen Inst. for Molecular Sci., Univ. of Eastern Finland, Kuopio, Finland, [6]Dept. of Med., Endocrinology and Clinical Nutrition, Kuopio Univ. Hosp., Kuopio, Finland, [7]Inst. for Precision Hlth., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Obesity induces low-grade inflammation in adipose tissue, hampering key adipose tissue functions, i.e. lipogenesis and lipolysis, and ultimately drives obesity comorbidities, such as type 2 diabetes (T2D). We hypothesized that when individuals with obesity undergo bariatric surgery, their immune cell composition in adipose tissue will change in response to the substantial weight loss. Here we leverage longitudinal bulk RNA-sequencing (RNA-seq) data of subcutaneous adipose biopsies from 168 individuals collected at the time of bariatric surgery and 12-month follow-up to identify transcriptional changes during the drastic weight loss. We performed differential expression (DE) analysis between the baseline and follow-up stratified by sex using edgeR while adjusting for key technical factors. We performed adipose single nucleus RNA-seq (n=8) and used Bisque to estimate and adjust for cell-type proportions in the bulk RNA-seq data. In both sexes, we observed a high proportion of T-cell marker genes (58.6% in males and 57.4% in females) among the DE genes up-regulated in the follow-up. We tested for pathway enrichment of these DE genes and observed 40 T-cell-related pathways. Among the top 10% most shared genes (n=20) across the pathways (FDR<5%) for both sexes, there are two T-cell marker genes, *PRKCQ* and *RASGRP1*, associated with Type 1 diabetes and T2D in genome-wide association studies, respectively. To examine whether the enrichment in immune pathways and T-cell marker genes can be explained by changes in adipose immune cell-type composition during the weight loss, we compared cell-type proportions estimated in the adipose bulk RNA-seq data between the baseline and follow-up. We observed a decrease in macrophage proportions in both males (p.adj=1.0x10-5) and females (p.adj<1.8x10-15) and a decrease in stromal proportions in females (p.adj=3.0x10-6) at the follow-up using the Wilcoxon rank-sum test. To investigate the effect of T2D, we further stratified the data by T2D in each sex. We observed a significant decrease in macrophage (p.adj<3.5x10-15) and stromal (p.adj=7.2x10-5) proportions from baseline to follow-up for non-diabetic females, and a decrease in macrophage proportions in diabetic females (p.adj=1.1x10-5), whereas there was a decrease in the macrophage proportions only in the non-diabetic males (p.adj=1.1x10-3). These longitudinal human transcriptomics findings suggest that after weight loss, males and females with obesity decrease their macrophage proportions, and when stratifying by T2D, obese males with T2D do not change their macrophage proportions, while the obese non-diabetic males and females with and without T2D do.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1438 Drug repurposing for Alzheimer's disease: targeting the genetics-enriched, neuropathology-associated SPI1 regulon in microglia

Authors:

Y. Tan[1,2], R. Chen[1,2], Q. Wang[1,2], A. Tiwari[1,2], Y. Yan[3], B. Li[1,2], X. Zhong[1,4]; [1]Vanderbilt Genetics Inst., Nashville, TN, [2]Molecular Physiology and Biophysics, Vanderbilt Univ., Nashville, TN, [3]Dept. of Biostatistics, Vanderbilt Univ., Nashville, TN, [4]Dept. of Med., Div. of Genetic Med., Vanderbilt Univ. Med. Ctr., Nashville, TN

Alzheimer's disease (AD) is characterized by progressive decline in memory and cognition and involve multiple brain cell types. Among them, microglia play a crucial role and are the major cell type implicated in AD genetics. Evidence accumulates suggesting that drugs with support from genetics are more likely to succeed to the market. Here, we aim to identify genetics-enriched, AD-relevant regulatory programs in microglia to guide the search of approved drugs for repurposing toward AD. To do this, we first applied SCENIC to single-cell RNAseq data from the prefrontal cortex of 48 individuals with varying degrees of AD pathology to infer regulons (a regulon is module of co-expressed genes composed of a transcription factor (TF) and genes the TF regulates). We detected 241 regulons, with 42 of them being significantly enriched in AD heritability based on LDSC ($p<0.05$) on the latest AD GWAS summary statistics. Most of these genetics-enriched regulons are active in microglia, as quantified by the regulon activity score based on gene expressions in the regulons. The SPI1 regulon, named by the master regulatory TF SPI1 (PU.1), ranked with the highest AD heritability. The SPI1 regulon activity score in microglia increased as the AD pathological burden increased. Specifically, increased SPI1 regulon activity is associated with an increase in neurotic plaque burden ($p=0.03$), neurofibrillary tangle burden ($p=0.02$), tangle density ($p=0.04$), global neocortical pathology ($p=0.02$), braaksc (a measure of neurofibrillary tangles, $p=0.03$) and with a worse cognitive status ($p=0.03$). The SPI1 regulon genes are enriched for GO terms including mononuclear cell differentiation, wound healing, endocytic vesicle and GTPase regulator activity etc. Several AD risk genes appear in the SPI1 regulon, including APOE, INPP5D and CD74 etc. Finally, we collected drug targets of all FDA-approved drugs (small molecules) and evaluated the proximity between the drug target(s) and the SPI1 regulon genes on a gene-gene interaction network. We identified several promising candidates including Salsalate and Baricitinib. We are currently working on validation of Salsalate in electronic medical records (EHR). In conclusion, we showed that combining single cell RNAseq, AD GWAS summary statistics and neuropathological traits of AD enabled the dissection of genetics-enriched, AD-relevant regulatory programs in human microglia, which have value in guiding the drug purposing for AD.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1439 Drug-target Mendelian randomization analysis supports lowering plasma ANGPTL4 and APOC3 but not ANGPTL3 levels as a strategy for reducing cardiovascular disease risk

Authors:

F. Landfors[1,2], S. K. Nilsson[2], S. Kersten[3,4]; [1]Dept. of Publ. Hlth.and Clinical Med., Section of Med., Umeå, Sweden, [2]Lipigon Pharmaceuticals AB, Umeå, Sweden, [3]Nutrition, Metabolism and Genomics group, Div. of Human Nutrition and Hlth., Wageningen Univ., Wageningen, Netherlands, [4]Div. of Nutritional Sci., Cornell Univ., Ithaca, NY

Aim: APOC3, ANGPTL3, and ANGPTL4 inactivation are actively pursued pharmacological strategies for the treatment of dyslipidemia and the prevention of atherosclerotic cardiovascular disease. Their key mechanism of action is inhibiting the lipases that facilitate lipolysis and removal of lipoprotein from circulation. However, which target would yield the highest clinical benefit for cardiometabolic disease and have a favorable side-effect profile in humans is still unclear. One way to approach this problem is to use human genetics. Therefore, we used drug-target Mendelian randomization (MR) methods to compare ANGPTL4, ANGPTL3, and APOC3, to determine their relative suitability as drug targets for reducing disease risk. *Methods*: MR is a genetic epidemiology method that aims to estimate causal effects in humans while limiting bias from confounding and reverse causation. We obtained exposure and outcome data on common variants in the proximity of the target genes associated with protein levels from large-scale genome-wide association studies (N=30,565-1,296,908) and corrected for linkage disequilibrium-related correlation using generalized least squares. We evaluated six key cardiometabolic endpoints and examined potential adverse effects across 2202 health registry endpoints, 53 routine laboratory tests, and 11 MRI measurements of internal organs. *Results*: Genetically reduced circulating ANGPTL4 protein levels demonstrated a beneficial profile characterized by a lower risk for coronary artery disease (CAD) (odds ratio [OR], 0.57 per s.d. protein [95%CI, 0.47-0.69]) and type 2 diabetes (T2D) (OR, 0.74 per s.d. protein [95%CI, 0.58-0.93]). Genetic APOC3 lowering had a favorable effect on CAD (OR, 0.86 per s.d. protein [95%CI, 0.80-0.92]), while ANGPTL3 lowering did not positively affect the cardiometabolic endpoints. Genetic lowering of ANGPTL3, ANGPTL4, and APOC3 levels did not raise any safety concerns. *Conclusion*: Human genetic evidence suggests that therapies reducing the amount of ANGPTL4 and APOC3 would reduce the risk of CAD. In contrast, ANGPTL3-lowering was not observed to reduce the risk of CAD.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1440 *DUSP1* and *DUSP16* are novel IBD genes implicated in the protection of the intestinal epithelial barrier integrity.

Authors:

J. Ntunzwenimana[1,2], R. Huard[1,2], G. Boucher[2], A. Alikashani[2], C. Beauchamp[2], J. Paquette[2], P. Goyette[2], J. Rioux[3]; [1]Université de Montreal, Montreal, QC, Canada, [2]Montreal Heart Inst., Montreal, QC, Canada, [3]Montreal Heart Inst. | Res. Ctr., Montreal, QC, Canada

Background: Crohn's disease and ulcerative colitis are two chronic inflammatory bowel diseases (IBD). Genome-wide association studies have identified and validated over 200 genomic regions associated with IBD. To pinpoint the causal gene within these regions, we screened 145 genes from validated IBD loci using an intestinal epithelial cell model (HT-29). The screen revealed that *DUSP1* and *DUSP16*, two phosphatases targeting the phosphorylation of MAP kinases (MAPKs), modulated the expression of 452 and 457 genes respectively, with 40.9% of targets in common, including genes crucial for the protective function of intestinal epithelial cells. To date, no coding variants in these two genes have been associated with IBD, whereas the index SNPs in these loci (or their proxies) co-localize with different regulatory elements. Thus, our hypothesis is that a decrease in *DUSP1* or *DUSP16* expression negatively impacts their protective functions in intestinal epithelial cells. **Methodology:** To understand the impact of *DUSP1* and *DUSP16* on epithelial functions, we generated stable knockdowns (KD) of these genes in Caco-2 cells; a model known for its ability to form a monolayer of polarized cells. Intestinal barrier structure in this model was evaluated via confocal immunofluorescence imaging (IF) of apical junction complexes in 2D monolayers and 3D spheroids. Intestinal barrier function was evaluated by measuring transepithelial electrical resistance (TEER) across monolayers. **Results:** In the 2D epithelial monolayers, the knockdown of *DUSP1* or *DUSP16* altered cell shape and size and increased permeability as measured by a decrease in TEER. In addition, lowering the expression of *DUSP1* or *DUSP16* led to a diminished capacity to form polarized structures in 3D cultures. Through Western Blot and IF analyses, we observed that *DUSP1* and *DUSP16* knockdown perturbed the phosphorylation patterns of MAPKs, leading to an upregulation of myosin light chain kinase (*MLCK*) expression and phosphorylation of myosin II regulatory light chain (MLC). Consequently, this affected the localization of tight junction proteins, particularly Occludin and Zo-1, which are partially controlled by MLC. Further confirmation through IF analysis revealed the deregulation of tight junction protein localization upon *DUSP1* or *DUSP16* knockdown. **Conclusion:** By identifying functional links between two genes located in independent genomic regions associated with IBD, namely *DUSP1* and *DUSP16*, our study highlights their significant roles in maintaining intestinal homeostasis and their contribution in the development of IBD.

PB1441 Effect of ABCA1-R219K polymorphism in serum lipid parameters in patients under statin therapy visiting tertiary cardiac center of Nepal.

Authors:

B. Yadav[1], S. Ghimare[2]; [1]Madhesh Inst. of Hlth.Sci., Janakpurdham, Nepal, [2]Shahid Dharma Bhakta Natl. Transplant Ctr., Bhaktpur, Nepal, Kathmandu, Nepal

Introduction:ATP-binding cassette transporter A1 (ABCA1) encoded by ABCA1 gene is one of the important protein involved in lipid metabolism. The effect of statin therapy on dyslipidemia varies among individuals and it may be due to different genetic polymorphism. The R219K polymorphism of ABCA1 gene is found to have a significant role in the response of statin. **Objective:**This study was designed to evaluate the effect of R219K polymorphism in lipid-lowering action of statin in patients with dyslipidemia.**Material and Methods**:This study was conducted in 88 patients. Blood samples were taken from patients before and at the end of 3months of statin use and were analyzed for lipid profile. Whole blood was analyzed for R219K Polymorphism using PCR-RFLP.**Results:**R219K polymorphism was associated with significant percentage reduction of serum TG/HDL ratio and TC/HDL ratio in atorvastatin users. However, there was no significant association of polymorphism with change in serum TC, HDL-C, LDL-C, TG and VLDL. Among KK genotype individuals, value of TG, VLDL, TG/HDL, and TC/HDL were significantly lower than in RR genotypes. Also TG/HDL and TC/HDL were significantly lower in RK genotype than in RR. Treatment of dyslipidemia with statin was found to be comparatively better in patients having the genotypes KK and RK.**Conclusion**:Our study demonstrated association of R219K polymorphism with the significant reduction of TG/HDL and TC/HDL and particularly the KK genotype was associated with significant improvement of lipid parameters following atorvastatin treatment. **Keywords:**ABCA1-R219K polymorphism, PCR-RFLP, Lipid Profile, Single Nucleotide Polymorphism, Dyslipidemia, Atorvastatin, statin therapy

PB1443 Effects of somatic and germline variants on coronary heart disease in Chinese population

Authors:

K. Zhao[1], X. Shen[1], H. Liu[1], J. Li[1], S. Chen[1], F. Liu[1], K. Huang[1], J. Cao[1], D. Gu[1,2], X. Lu[1], Z. Lin[1]; [1]Fuwai Hosp., Natl. Ctr. for Cardiovascular Diseases, Chinese Academy of Med. Sci. and Peking Union Med. Coll., Beijing, China, [2]Sch. of Med., Southern Univ. of Sci. and Technology, Shenzhen, China

Background: The genetic basis of coronary heart disease (CHD) has expanded from the germline genome to somatic mutations in haematopoietic cells, termed clonal haematopoiesis of indeterminate potential (CHIP). However, little is known about CHIP and its relationship with CHD development in East Asians, especially those with different genetic backgrounds. **Objective**: Here, we aimed to characterize CHIP in the general Chinese population and investigate its effect on incident CHD risk considering germline predisposition. **Methods**: This analysis included 6,181 participants (mean age, 54.15 years) from three large prospective cohorts with a median follow-up of 12.17 years. Fix-effect meta-analysis was conducted to calculate pooled results of the three cohorts. Targeted deep sequencing for 90 leukemia-related genes was used to detect CHIP mutations. A predefined CHD polygenic risk score (PRS) comprising 531 germline variants was utilized to evaluate CHD germline predisposition. We then measured the concentrations of six inflammatory cytokines using an automated enzyme-linked immunosorbent assay. **Results**: A total of 1,153 (18.65%) individuals harbored 1,555 CHIP mutations at baseline, demonstrating an increased risk of incident CHD (HR = 1.40, 95% CI: 1.16-1.70, $P = 5.00 \times 10^{-4}$). A risk gradient of CHD was observed across variant allele fraction (VAF) categories (P for trend = 3.90×10^{-4}). We found CHIP carriers had higher CHD risk in the intermediate and high PRS groups, but not in the low PRS group. Specifically, individuals with both high PRS and CHIP demonstrated a 2.16-fold increase in risk (95% CI: 1.47-3.18, $P = 1.04 \times 10^{-4}$) compared to those with low PRS and without CHIP. The concentrations of IL-6, CRP, and SAA were significantly higher in CHIP carriers than those without CHIP, and a dose-response relationship was observed between VAF and the levels of IL-6 and SAA. **Conclusion**: Our study comprehensively characterized the profile of CHIP in the general Chinese population and showed the effect of acquired somatic mutations on CHD was potentially modified by germline predisposition, providing new evidence for preventive precision approaches in CHD occurrence.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1444 Elucidating sex-specific gene expression at the single cell level in visceral fat.

Authors:

K. Gelev[1], M. Alvarez[1], R. Mancina[2], F. Tavaglione[3], S. T. Lee[1], O. Jamialahmadi[2], A. Kar[1], Z. Wang[1,4], D. Kaminska[5], J. Pihlajamäki[6], S. Romeo[2,3], P. Pajukanta[1,4,7]; [1]Dept. of Human Genetics, David Geffen Sch. of Med. at UCLA, Los Angeles, CA, [2]Dept. of Molecular and Clinical Med., Inst. of Med., Univ. of Gothenburg, Gothenburg, Sweden, [3]Clinical Med. and Hepatology Unit, Fondazione Policlinico Univ.rio Campus Bio-Med., Rome, Italy, [4]Bioinformatics InterDept.al Program, UCLA, Los Angeles, CA, [5]Div. of Cardiology, Dept. of Med., UCLA, Los Angeles, CA, [6]Inst. of Publ. Hlth.and Clinical Nutrition, Univ. of Eastern Finland, Kuopio, Finland, [7]Inst. for Precision Hlth., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abdominal obesity is a growing health problem with well-established sexual dimorphism, cardiometabolic comorbidities, and inflammatory changes in the visceral fat depot. Previous studies have shown that sex affects bulk tissue gene expression; however, it is not known whether sex affects cell-type and cell state level gene expression in human visceral fat. To address this knowledge gap, we investigated visceral fat biopsies from 11 Italians with obesity, 5 females (mean BMI 41.6; SD 2.88) and 6 males (mean BMI 43.4; SD 4.53), who underwent bariatric surgery. We performed single nucleus RNA sequencing in the visceral fat and conducted quality control to remove contaminated reads and doublets. Samples were integrated with Harmony, normalized and clustered using Seurat, and annotated with SingleR. We then performed cell-type level differential expression (DE) analysis that identified 5,166 DE genes between males and females in adipocytes, 2,567 in T cells, 2,566 in B cells, 1,840 in mesothelial cells, 1,474 in adipose stem progenitor cells (ASPCs), 755 in macrophages, 278 in natural killer cells, 180 in dendritic cells, 137 in lymphatic endothelial cells, 110 in endothelial cells, 41 in mast cells, and 20 in pericytes (padj<0.05), respectively. To find subcellular cell state differences by sex, we ran Milo and found differentially abundant cellular neighborhoods (DAs) (FDR<0.10) between males and females in ASPCs, T cells, macrophages, B cells, and adipocytes. Of these DAs, we identified 1,018 significant DE genes by sex in ASPCs, 682 in T cells, 171 in macrophages, 27 in B cells, and 10 in adipocytes (FDR<0.05). We also found GO enrichment in cardiovascular development for upregulated female DE genes in ASPC DAs (FDR<0.05). Using MAGENTA, regional variants around female upregulated macrophage DE genes were found to have significant (p=0.0075) enrichment in female-specific BMI GWAS results, suggesting that these DE genes genetically contribute to the cellular differences in obesity between sexes. To reveal transcription factors (TF) that regulate the sex DE genes, we ran HOMER which showed *de novo* motif enrichment in female downregulated T cell genes for the TF and nuclear receptor, Estrogen Related Receptor Alpha (*ESRRA*). This result suggests hormonal involvement drives some sex differences we observed in the visceral adipose tissue cell-types and subcellular cell states. Taken together, we performed cell-type-specific DE analysis between males and females in each visceral fat cell-type, followed by cell state level DA and DE by sex analyses. Our results show that obese visceral fat exhibits prominent sex-specific gene expression in multiple cell-types.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1445 Elucidating the genetic architecture of autism spectrum disorder compared to more broadly defined developmental disorder

Authors:

F. Satterstrom[1], J. Fu[2], Z. Zhang[3], D. Cutler[4], B. Devlin[5], K. Roeder[6], S. Sanders[7], P. Kruszka[3], J. Buxbaum[8], M. Talkowski[2], M. Daly[2], Autism Sequencing Consortium; [1]Broad Inst., Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]GeneDx, Gaithersburg, MD, [4]Emory Univ. Sch. of Med., Atlanta, GA, [5]Univ. of Pittsburgh, Pittsburgh, PA, [6]Carnegie Mellon Univ., Pittsburgh, PA, [7]Univ. of Oxford, Oxford, United Kingdom, [8]Icahn Sch. of Med. at Mount Sinai, New York, NY

The Autism Sequencing Consortium (ASC) recently published an analysis (Fu et al., 2022, *Nature Genetics* 54:1320) which drew from the exomes of over 20,000 individuals with autism spectrum disorder (ASD). Some samples were obtained through ASC collaborating clinicians, and others were from Simons Foundation efforts such as the Simons Simplex Collection (SSC) and SPARK. Parents were sequenced for about three-quarters of the individuals, allowing the identification of *de novo* variants. The analysis identified 72 genes associated with ASD at a false discovery rate <= 0.001. In addition, the autism data was combined with *de novo* variants from 31,058 developmental disorder trios (Kaplanis et al., 2020, *Nature* 586:757), and a mixture model was used to identify genes mutated more often in autism than in more broadly defined developmental disorder, and vice versa. The analysis identified 36 “autism-predominant” genes and 82 “DD-predominant genes.”

Currently, the ASC is working toward a data freeze for its next analysis. We have called *de novo* variants on an additional 1,100 individuals with ASD from ASC collaborators, 5,000+ individuals with ASD from SPARK, and 11,300 individuals with ASD from the genetic testing company GeneDx. (GeneDx contributed 18,783 trios to the Kaplanis et al. study, and in fact all 11,300 trios shared with us meet the inclusion criteria for that study, and 4,000 overlap.) Together, these new samples more than double the number of individuals with ASD for whom we can call *de novo* variants compared to the Fu et al. study, and they will lead to an expanded list of ASD-associated genes. In addition, they grant new power for investigating the genetic architecture of ASD compared to more general developmental disorder/delay.

Looking within the ASD sample sets ascertained by GeneDx, SPARK, and the ASC, we find that individuals with ASD+ID/DD have a similar rate of *de novo* synonymous variation compared to individuals with ASD only (~0.29 variants/person) but a nearly doubled rate of *de novo* protein-truncating variation in constrained genes (0.152 vs 0.089 variants/person in the three most-constrained LOEUF gene deciles), with both groups significantly enriched beyond control trios. This stratification allows the identification of genes mutated more often in one condition than the other; for example, across all sample sets, 15 of 20 protein-truncating *de novo* variants in *KDM5B* are found in individuals with ASD and no DD/ID. We are currently working to deepen this analysis and will show up-to-date results at the meeting.

PB1446 Elucidating the genetic architecture of type 2 diabetes in 125,000 admixed Mexican adults.

Authors:

E. Trichia[1,2], J. Berumen[3], D. Aguilar-Ramirez[1], M. Turner[1,2], F. Rivas[3], M. Hill[1,2], R. Collins[1], J. Emberson[1,2], J. Alegre-Díaz[3], P. Kuri-Morales[4,5], R. Tapia-Conyer[4], J. Torres[1,2]; [1]Clinical Trial Service Unit & Epidemiological Studies Unit, Nuffield Dept. of Population Hlth., Univ. of Oxford, Oxford, United Kingdom, [2]MRC Population Hlth.Res. Unit, Nuffield Dept. of Population Hlth., Univ. of Oxford, Oxford, United Kingdom, [3]Experimental Res. Unit from the Faculty of Med., Natl. Autonomous Univ. of Mexico, Mexico City, Mexico, [4]Faculty of Med., Natl. Autonomous Univ. of Mexico, Mexico City, Mexico, [5]Monterrey Inst. of Technology and Higher Ed., Nuevo Leon, Mexico

Type 2 diabetes (T2D) is a physiologically heterogeneous disease that is common in Mexico. In the Mexico City Prospective Study (MCPS) the excess mortality risk associated with previously-diagnosed diabetes accounted for one third of all deaths before age 75. However, Mexican participants remain underrepresented in genetic studies of T2D. To address this gap and characterise the genetic architecture of diabetes in this Mexican population with high relatedness and admixture, we conducted a genome-wide association study (GWAS) of previously-diagnosed type 2 diabetes among 125,042 adults (19,431 cases) using a generalised estimating equation based approach implemented in SUGEN to account for extended family networks. Regression models were adjusted for age, sex and admixture (first seven principal components). Conditional analyses yielded 86 independent variants, of which 21 were potentially novel: 6 were in known loci, all non-coding, and 15 were mapped in novel loci and included two missense variants (rs139343836 at the *RFX6* locus and rs35409673 at the *WDFY2* locus). The loci with the most conditionally independent signals were, in descending order, *KCNQ1* (5 signals), *CCND2* (3), *TCF7L2* (2), *CDKN2B* (2), *ANKRD55* (2), *RTL1* (2), *and MC4R* (2). Heritability was ascertained using a variety of approaches to account for relatedness, admixture and genotype imputation, and yielded estimates ranging from 22%-30%. Islet enhancer and beta-cell chromatin accessibility regions presented the highest enrichment of T2D-associated variants in an analysis of over 200 tissue and single-cell annotations. To better understand the potential mechanisms through which the 86 variants are linked to diabetes risk, their associations with metabolic traits such as glycemia, adiposity, and dyslipidemia from MCPS and from external GWAS consortia were used to perform physiological clustering of the variants. Known T2D variants were assigned to previously-specified clusters, while most of the potentially novel variants mapped within or close to clusters related to insulin secretion and/or insulin action. Our work highlights the need for genetic discovery efforts in understudied populations such as Mexico, a highly-admixed population, where diabetes is common and a major contributor to mortality.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1448 Enhancer marks and Epstein-Barr virus (EBV)-encoded transcription co-factors (TcFs) are closely related to the more dominant genetic mechanisms operating among the 330 now known risk loci for systemic lupus erythematosus (SLE) in two ancestries.

Harley[2,4]; [1]Ctr. for Autoimmune Genomics and Etiology (CAGE), Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, [2]Res. Service, US Dept. of VA Med. Ctr., Cincinnati, OH, [3]Dept. of Pediatrics, Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [4]Cincinnati Ed. and Res. for Veterans Fndn. (CERVF), Cincinnati, OH

Background: The associations of EBV infection with SLE, of anti-EBNA1 molecular mimicry with SLE autoantigens, of EBNA2 TcF binding at SLE loci of EBV-infected B cells (EBBCs), and of B-cell tropic EBV mechanisms suggest that the interaction between host and EBV is responsible for SLE autoimmunity and pathogenesis. We have identified the dominant histone mark at SLE loci in East Asian (EAS) and European (EU) ancestries in EBBCs. Methods: We identified published SLE risk loci. We curated 18,075 ChIP-seq datasets assessing DNA binding by 1,339 transcription factors and co-factors (TFs) (9,862 datasets) and 81 histone marks (HMs) (8,213 datasets), evaluated in 3,531 different "cellular sources". We modified RELI to mark DNA binding at SLE loci and assess allelic distortion with MARIO (PMID: 2966164). Results: We found 330 SLE risk loci at $p<5x10^{-8}$, published prior to 2023. Of these, 255 are reported in EAS, 106 in EU, and 30 in other ancestries, with 40 loci confirmed in both EAS & EU. KEGG analysis of 330 loci, show associations with IFNγ, IL-12, IL-23, BCR, & EBV infection ($6.1<OR<16$, $10^{-30}<p_a<10^{-8}$) and others. 200 of 1,339 tested TFs from 1,871 of the 9,862 TF ChIP-seq datasets, are associated with SLE loci at $p_c<10^{-6}$ in both ancestries. The TF dataset association ranks in EAS & EU are highly correlated ($r=0.73$, $p<0.0001$). TF DNA binding at SLE loci in EBBCs is enriched relative to other cell types in both EAS & EU ($OR>19$, $p<10^{-300}$). Removing the SLE risk loci separately in EAS & EU that are bound by the EBV-encoded EBNA2, EBNA3C, and EBNALP TcFs reduces the significantly associated human TF datasets by >95%, which is also found with many human-encoded TFs. Of the individual HM datasets, H3K27ac is the most closely associated with both the EAS & EU SLE loci ($2.43<OR<2.6$, $10^{-56}<p_a<10^{-24}$), binding a majority (>66%) of EAS & EU SLE loci. The same pattern of significant association for H3K27ac as found in EBBCs, is found in other cell types, but the proportion of significant H3K27ac EBBC datasets is far higher than any other cell type ($466<OR<882$, $10^{-12}<p<10^{-10}$), including B cells that are not EBV-infected ($121<OR<208$, $10^{-7}<p<10^{-6}$). >60% of both EAS & EU SLE loci are bound by H3K27ac more frequently in EBBCs than in B cells that are not EBV-infected. H3K27ac binding is distorted at heterozygotes for 58 EAS loci and 44 EU loci (by MARIO with score>0.4). Conclusion: TF and H3K27ac binding to SLE risk loci is relatively cell specific and highly significant in EBBCs. These results are consistent with variants influencing histone modifications and EBV-encoded TcFs in EBBCs being important for many of the mechanisms that alter genetic risk in the pathogenesis of SLE.

PB1449 Enhancing Alzheimer's disease prediction and portability through integration of transcription wide association study and polygenic risk scores in diverse populations

Authors:

M. Shivakumar, S-H. JUNG, E. Suh, J. Bao, L. Shen, D. Kim; Univ. of Pennsylvania, Philadelphia, PA

The prevalence of Alzheimer's disease (AD) is considerably higher among individuals of African ancestry compared to those of European or Asian ancestry. Despite this discrepancy, the use of polygenic risk scores (PRS) for AD prediction remains primarily applicable to individuals of European descent. However, recent research has demonstrated that combining PRS with TWAS-based PRS can enhance its applicability to other ancestries. While numerous prior TWAS studies have identified significant genes associated with AD, specific TWAS PRS studies on AD prediction have been limited. Therefore, the objective of this study was to investigate whether integrating TWAS-derived PRS with PRS can a) enhance AD prediction in the European population and b) improve its portability to the African American and South Asian populations. By exploring this integration, we aim to address the gap in understanding the potential benefits of TWAS-derived PRS in AD prediction for different populations.
We generated PRS using The International Genomics of Alzheimer's Project (IGAP) summary statistics. We imputed transcript expressions in 13 brain tissues using PrediXcan in Alzheimer's Disease Sequencing Project (ADSP) and Alzheimer's Disease Neuroimaging Initiative (ADNI) whole genome sequencing data. Using ADSP European population as training data (N = 10,121), we performed association analysis with AD to obtain effect sizes for the imputed transcripts. Subsequently, we utilized these effect sizes to calculate the TWASPRS by summarizing across all expressions weighed by effect size in ADNI dataset (N = 1,040), ADSP African American (N = 4,754) and ADSP South Asian (N = 2,628) dataset. Finally, we assessed the predictive performance by measuring the area under the receiver operating characteristic curve (AUC) using PRS, TWASPRS and PRS+TWASPRS as predictor and using AD as outcome.
The AUC for the PRS alone in the ADNI dataset was 0.727, while the AUC for TWASPRS was 0.781 in ADNI. However, after integrating TWASPRS with PRS, the AUC improved to 0.815. In the African American dataset, the AUC for PRS alone was 0.647, and for TWASPRS, it was 0.627. After integrating TWASPRS with PRS, the AUC increased to 0.649. In South Asian dataset, the AUC for PRS alone was 0.721, and for TWASPRS, it was 0.725. After integrating TWASPRS with PRS, the AUC increased to 0.729.
The findings from this study shows that integrating TWASPRS with PRS significantly enhances our ability to accurately predict an individual's susceptibility to developing AD in European ancestry and slightly increases portability of PRS to other ancestries.

PB1450 Enrichment of *AKAP11* consequential variants in bipolar disorder patients: Whole genome sequencing analysis.

Authors:

S. Chadwick, S. P. Smieszek, R. Torres, C. Xiao, E. L. Czeisler, C. M. Polymeropoulos, G. Birznieks, M. H. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC

Bipolar disorder (BD) is a heritable neuropsychiatric disorder characterized by episodes of mania and depression. It has a prevalence between 1-2% of the population, often with onset in early adulthood. Numerous twin studies estimated broad heritability of BD around 67%. GWAS meta-analysis of common SNPs have identified roughly 70 independent loci that contribute to BD susceptibility. These implicated genes encode ion channels, neurotransmitter transporters, and synaptic and calcium signaling pathways. Latest meta-analyses led to delineation of enrichment of rare consequential variants in patients with BD. *AKAP11*, which encodes A-Kinase Anchoring Protein 11 (AKAP-11), emerged as the strongest candidate and a definitive risk gene. It is highly expressed in the brain and has been shown to interact with GSK3B, the hypothesized target of lithium therapy.

In this study we investigated the frequency and type of *AKAP11* variants in a large cohort of whole genome sequencing samples obtained from patients who participated in a multicenter, randomized, double-blind, placebo-controlled, parallel-group study of iloperidone in patients with acute manic or mixed episodes associated with bipolar I disorder. We specifically tested the hypothesis of enrichment of rare MAF<5, pLOFs and missense variants in *AKAP11* in the BD cases (40 variants were tested). 456 samples were analyzed, and genetic analyses were adjusted for principal components, sex and age.

We report a significant enrichment of *AKAP11* variants. Specifically, we detect alleles: 133/456 in cases versus internal ancestry matched controls: 654/2845. This is a significant effect (p-value=0.0042), OR 1.4 (CI 1.1-1.7). Altogether we report 105 carriers of at least one *AKAP11* variant. The carriers were 60% males, mean age of 42 years old, and of multiple ancestries. On average, the age of onset was 24 years in carriers, 26 years in non-carriers, and 20 years in carriers of multiple variants within *AKAP11*.

This analysis demonstrates the role for rare coding variation as a significant risk factor in BD etiology. Importantly, *AKAP11* is known to confer risk for schizophrenia. *AKAP11* codes for AKAP-11, one of a family of scaffolding proteins that bind to the regulatory subunit of the protein kinase A. AKAP-11 binds to GSK3B and mediates PKA-dependent inhibition of GSK3B. PKA inhibits the activity of GSK3B bound to AKAP-11 more strongly than GSK3B in general, and modifications to AKAP-11 have the potential to affect downstream pathways. BD is a significant source of disease burden worldwide. Further understanding of genetic underpinnings will lead to better understanding of the etiology and optimal treatments.

PB1451 Enrichment of melanopsin genetic variants in Delayed Sleep-Wake Phase Disorder (DSWPD) patients: A whole genome sequencing analysis.

Authors:

J. Brzezynski, S. Smieszek, C. Johnson, A. Kaden, A. Goldberg, C. Miller, C. Polymeropoulos, G. Birznieks, M. Polymeropoulos; Vanda Pharmaceuticals, Washington, DC

Melanopsin (*OPN4*) is a blue light-sensitive opsin-type G-protein coupled receptor. It is highly expressed in photosensitive retinal ganglion cells which mediate responses to light, including regulation of sleep, circadian photoentrainment, and pupillary light response. Mutations in *OPN4* were shown to affect responses to light, ultimately affecting the regulation of circadian rhythm and sleep regulation. Previously, we described a male carrier of an *OPN4* missense variant diagnosed with Delayed Sleep-Wake Phase Disorder (DSWPD), with a consistent recurrent pattern of delayed sleep onset. The rs143641898 [NM_033282.4:c.502C>T p.(Arg168Cys)] variant in the *OPN4* gene was shown in a functional study to render the *OPN4* protein non-functional.

We have conducted a rigorous observational research study in suspected DSWPD patients with the aim of detecting consequential variants that may be associated with the delayed sleep phenotype. Altogether, 117 samples were collected from DSWPD patients and compared to 315 healthy controls.

We report an enrichment of *OPN4* rare coding variants (MAF<1) in DSWPD samples compared to healthy controls. This significant enrichment likely implies that other rare predicted loss-of-function variants can similarly contribute to the delayed sleep phenotype. A significant association with rs1079610, a common variant in *OPN4* with delayed bedtime in DSWPD patients, was found. This variant has been previously reported in association with altered pupillary responses. This effect is not seen in in a large set of healthy controls without DSWPD diagnoses. The discussed rare *OPN4* variants likely increase the risk of DSWPD via its direct effect on pathophysiology along the melanopsin axis.

This study offers useful insights for the differential diagnosis and ultimately treatment of DSWPD in patients that carry pathogenic variants in the *OPN4* gene.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1452 Epilepsy gene variants associated with seizure presentation in brain arteriovenous malformations.

Authors:

H. Kim[1], S. Chowdhury[2], L. Huang[1], J. Nelson[3], C. E. McCulloch[3], C. Fox[3], A. Numis[3], S. M. Weinsheimer[3]; [1]UCSF Ctr. for Cerebrovascular Res., San Francisco, CA, [2]Univ. of Toronto, Toronto, ON, Canada, [3]Univ. of California San Francisco, San Francisco, CA

Background: Brain arteriovenous malformations (BAVM) are a rare but important cause of hemorrhagic stroke in younger adults and children. The second most common presentation is seizures, which occur in 20-45% of patients and significantly impacts quality of life. While male sex and younger age have been associated with seizure onset, it is unknown whether epilepsy-related genes contribute to risk of seizure in BAVM. We hypothesized that common genetic variants in known epilepsy or epilepsy-related genes are associated with risk of seizure at initial presentation in BAVM patients. **Methods:** A total of 338 Caucasian BAVM cases were previously genotyped on the Affymetrix Genome-Wide Human SNP Array 6.0. Quality control assessment removed SNPs and samples with low genotyping call rates (<95%) and SNPs out of Hardy-Weinberg equilibrium (P<0.00001). We tested 28,312 single nucleotide polymorphisms (SNPs) mapping within 5kb of 935 genes identified as epilepsy-associated genes or genes related to epilepsy with minor allele frequency ≥1%. Using multivariable logistic regression, we tested whether the number of minor alleles was associated with seizure at presentation, adjusting for age at enrollment, sex, and the first 3 principal components to adjust for population stratification. We report odds ratio (OR) and 95% confidence interval (CI), and significance was based on Bonferroni adjustment for multiple comparisons (P=0.05/28,312 SNPs =1.8E-06). SNPs with P≤0.001 were considered *nominally* associated with seizure risk. **Results:** There were 90 BAVM patients with seizures at presentation and 248 without seizures (mean age 38.7 +/- 17.6 yrs). A total of 18 SNPs mapping to 11 epilepsy genes were nominally associated with seizure presentation in BAVM patients, although none were statistically significant after correction for multiple testing. Five of the 18 SNPs mapped to introns of the gene, teneurin transmembrane protein 2 (*TENM2)*, including rs13176788 which was the most significantly associated SNP for seizure risk (OR=2.2; CI: 1.5-3.2; P=6.3E-05). Additional SNPs associated with seizure mapped to introns of the following genes: *PRICKLE2, DLG2, SOX5, GRIN2B* and *RBFOX1*; upstream of *NALCN, SCN1A, SLC25A12* and *HERC1*; and downstream of *RBPJ*. **Conclusion:** SNPs mapping within or nearby 11 epilepsy genes including *TENM2* were associated with seizure risk at initial presentation in sporadic BAVM patients, suggesting shared genetic susceptibility. Further work is needed to confirm these findings in a larger, more diverse cohort. The identification of BAVM patients carrying epilepsy gene variants may warrant greater attention for epilepsy management.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1453 Establishing UK Biobank data augmented by electronic Medical Records for genetic association analyses on kidney function

Authors:

M. Gorski[1], T. W. Winkler[1], K. J. Stark[1], S. Wiegrebe[1,2], I. M. Heid[1]; [1]Dept. of Genetic Epidemiology, Univ. Med. Ctr., Regensburg, Germany, [2]2Statistical Consulting Unit StaBLab, Dept. of Statistics, LMU Munich, Geschwister-Scholl-Platz 1, Munich, Germany

Impaired kidney function is a substantial risk for cardiovascular disease and early mortality. Kidney function is typically assessed as estimated glomerular filtration rate (eGFR) based on serum creatinine (Scr). Hundreds of loci were identified for eGFR, including data from UK Biobank based on centralized Scr measurements (enzymatic) from baseline blood drawn in study centers (SC). Emerging electronic Medical Record (eMR) data in UK Biobank present a promising resource to augment the data on eGFR longitudinally. However, the potential of eMR-based eGFR in UK Biobank for genetic association analyses is yet unclear.

We curated a UK Biobank data set on eMR-based Scr (various labs, Jaffé or enzymatic) using a published algorithm (Denaxas et al., JAMIA Open 2020). We computed eGFR (CKD-Epi 2021) and described the resulting longitudinal information. We compared eMR-and SC-based eGFR phenotypically (selecting the eMR-Scr closest in time to SC assessment per person). We also compared genetic association effect sizes of the 634 independent variants known for eGFR (Stanzick et al., Nat Comm, 2021) on each of the two phenotypes (eMR-based, SC-based; linear regression adjusted for age, sex, 20 PC).

We obtained 1,775,433 eMR-based Scr measurements for 170,772 participants (92% European ancestry) with a median number of measurements per person of 6.0 (min=1, max=289, IQR=3.0-12.0).

When selecting the eMR-eGFR closest in time to SC assessment (n=138,362 European ancestry, unrelated), median time difference between assessments was 0.86 years (IQR= 0.27-2.63; min=0.01; max=20.46). Values of eGFR were moderately correlated and on average lower when using eMR compared to SC (Spearman r=0.67; mean eGFR =84.09 vs. 93.91 mL/min/1.73m², p<0.0001). When restricting to 55,013 persons where eMR-eGFR assessment was from the same calendar year as the SC assessment, the correlation was r=0.71.

When analyzing the 634 variants (n=138,362), we identified 206 Bonferroni-corrected significant variants for both SC- and eMR- eGFR (p<0.05/634=7.89x10-5; 296 for SC, 237 for eMR). Genetic effect estimates were highly correlated (r=0.83; similar for the n=55,013, r=0.81); standard errors were perfectly corrected and by factor 1.18 larger when using eMR- eGFR as outcome versus SC-based.

We found that the 634 variants explained a comparable proportion of the eGFR variance based on eMR- versus SC-assessment (7.0% vs. 7.4%).

Overall, we established eMR-eGFR in UK Biobank for genetic association analyses. The larger standard errors of genetic effects for eMR-eGFR might be explained by larger measurement error in eMR-Scr compared to the centralized, standardized SC-Scr measurements.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1454 † Estimating common and rare variant convergence of complex traits and diseases across diverse biological pathways

Authors:

D. Weiner, L. O'Connor; Broad Inst., Cambridge, MA

A major open question in human genetics is whether common and rare variants have mechanistically convergent effects on complex traits and common diseases. This question has critical importance for understanding disease biology and therapeutic development (Claussnitzer et al. 2020 Nature). Recently, systematic comparison of common and rare variant genetic architecture has become feasible due to biobank scale exome-sequencing resources and new analytical approaches (Karczewski et al. 2022 Cell Genomics, Weiner et al. 2022 AJHG, Weiner and Nadig et al. 2023 Nature). Recent work demonstrated convergence at the level of disease-relevant tissues and cell types (Weiner and Nadig et al. 2023 Nature). However, it remains unclear whether common and rare variants are convergent at the level of biological pathways.

To address this question, we applied recently developed tools for estimating gene set enrichments to large-scale common and rare variant association data from the UK Biobank (median GWAS/exome sample size: 382,765 individuals; rare variant analysis restricted to loss-of-function variants AF < 1e-5) and to diverse pathway annotations (n = 1,742 annotated biological pathways with at least 50 genes; Kim et al. 2019 AJHG). In a pilot analysis of 200 randomly selected pathways and 24 traits, we observed correlated common and rare enrichments (Spearman rho = 0.12 (P < 1e-10) for 4,632 trait-pathway pairs), indicating broad convergence. We observed that the relative degree of common vs. rare variant enrichment at least partially reflected inclusion in the pathway of an exome-wide significant gene. For example, filtering to lipid traits we observed rare variant enrichments 2-3x larger than common variant counterparts across a wide range of enrichments (49 < pathway size < 178), which reflected inclusion in these pathways of APOB, a gene previously shown to explain a large fraction of rare variant heritability for lipid traits. Unexpectedly, we observed many trait-pathway pairs with common-variant-specific enrichments (n = 63), such as a common variant enrichment of 46x (SE = 18x) of rheumatoid arthritis heritability in a pathway of naïve CD8+ T cells, compared to a rare variant enrichment of 0x (SE = 6x). In summary, our results are the first to systematically characterize the relationship between common and rare variant enrichments across a range of disease-relevant biological pathways for complex traits and common diseases.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1455 Evaluating a coronary artery disease polygenic risk score screening strategy in a diverse patient population at UCLA

Authors:

K. Boulier, Y. Ding, V. Venkateswaran, B. Pasaniuc; UCLA, Los Angeles, CA

Introduction: Given the existence of preventative therapies for coronary artery disease (CAD), there have been many efforts to predict and mitigate CAD risk including, more recently, incorporating polygenic risk scores (PGS). Few studies examine the clinical impact of PGS screening strategies or quantify their performance in clinical terms across a diverse patient population. Here we estimate the number needed to screen (NNS) for a PGS screening strategy for CAD based using a large and diverse electronic health record (EHR) linked biobank at UCLA Health. **Methods:** We leveraged the longitudinal EHR data to evaluate the PGS screening strategy in a synthetic manner. We assumed PGS screening to have been performed on 6/1/2013 for patients established prior to 1/1/2013 or 6 months into follow time if established after 2013. We then evaluate CAD outcomes for different strata to evaluate clinical utility (NNS). To evaluate our strategy realistically, we focused only on lower risk patients with no evidence of cardiovascular disease; patients with preexisting cardiovascular disease or strong statin indications (LDL > 190, diabetes or already on statins) are excluded. Patients with PGS scores in the top 5% of their genetic ancestry groupings (European, East Asian, African American, Hispanic) are assumed to have been started on statins for the median 6.9 years of follow up. CAD diagnosis during follow up time was determined by ICD codes. NNS to prevent one CV event is calculated from cohort size and events assuming a statin number needed to treat of 50. **Results:** Of 33,789 adults, 17,074 were low risk and eligible for PGS screening (35% male with a mean age of 44). NNS to detect one CAD diagnosis was 351, 359, 814, 159 in the European, Hispanic, East Asian and African ancestry groups and NNS to prevent one cardiovascular event was 17,550, 17,950, 40,700, 7,950 respectively. **Conclusion:** Although PGS accuracy is lower in African ancestry individuals as compared to Europeans, the clinical utility of PGS-based screening is highest in African Americans. This is due to the increased baseline rates of disease in the African American genetic ancestry grouping. Our results clearly demonstrate that PGS accuracy is distinct from clinical utility of PGS-based strategies. Evaluation of screening strategies rather than only accuracy will be required before PGS screening implementation.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1456 Evaluating integration of genetic risk into clinical risk prediction models of cardiovascular disease using polygenic risk score decomposition

Authors:

N. Larson, P. A. Decker, J. Killian, A. Batzler, S. Manemann, S. Moon, S. Bielinski; Mayo Clinic, Rochester, MN

Modern atherosclerotic cardiovascular disease (ASCVD) risk prediction models, such as the Pooled Cohort Equations (PCE), are widely used for clinical risk stratification. These models include multiple heritable risk factor phenotypes, including total and HDL cholesterol, systolic blood pressure, hypertension, diabetes, and smoking status. With the growing availability of trained PRS models across diverse phenotypes, there is increased interest in integrating PRSs into existing clinical risk prediction models. However, PRS models are typically developed from GWAS without adjustment for clinical risk factors, and thus likely include many genetic effects that are mediated through these factors via vertical pleiotropy. Thus, adding a previously trained ASCVD PRS to an existing risk prediction model may attenuate the potential benefit of integrating genetic risk information into such models, and previous studies have demonstrated only modest increases in discrimination with the addition of an ASCVD PRS. One strategy for addressing this source of redundancy is aggregating PRS model scores for disease risk itself as well as corresponding heritable clinical risk factors. For example, by linear regression we can decompose the original PRS into a residual polygenic component and complementary risk-factor-associated component. Herein, we explored this approach using data on 16,832 participants of European ancestry from the Mayo Clinic Biobank (MCB) free of ASCVD at enrollment and with available genome-wide genotyping data generated in collaboration with Regeneron Genetics Center. Representative PRS models for ASCVD risk as well as the six heritable clinical factors included in the PCE listed above were downloaded from the PGS Catalog and applied to all eligible MCB participants. Among these individuals, ASCVD risk factor PRSs explained ~13.8% of the variability in the ASCVD PRS. At a median 10.9 years of follow-up, we observed a total of 1,325 (7.9%) incident ASCVD events (i.e., myocardial infarction, CABG, PCI, stroke, CVD death). The Harrell's concordance index for the ASCVD PRS was 0.592 (95% CI = [0.577,0.608]). Cox proportional hazards regression for time-to-ASCVD was applied to fit three separate models, defined as M1: PCE risk factors alone; M2 = M1 plus the ASCVD PRS; and M3 = M2 plus the residualized ASVCD PRS. We observed statistically significant results for both the ASCVD PRS in M2 ($P<0.0001$) and the residualized PRS after adjusting for the full ASCVD PRS in M3 ($P = 0.025$). We anticipate more sophisticated methods can address heritable mediators of genetic risk and fully leverage the growing available information on polygenic risk across the phenome.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1457 Evaluating somatic mosaicism in post-mortem Parkinson's disease brains.

Authors:

Y. Heng[1], E. Chew[1], M. Lian[1], M. Tandiono[1], R. Reynolds[2], J. Foo[1]; [1]Nanyang Technological Univ. Singapore, Singapore, Singapore, [2]Imperial Coll. London, London, United Kingdom

Parkinson's disease (PD) is a common neurodegenerative movement disorder resulting from dopaminergic neuronal loss in the substantia nigra. Previous genetic studies have focused on identifying germline mutations which are present in all cells of an affected individual. However, these mutations only account for <10% of PD cases and explain a small percentage of PD risk. Beyond such heritable genetic variations, somatic mutations which are present in only a subset of cells, are gradually shown to be implicated in PD. Somatic mutations in the brain may perturb essential genes and pathways, thereby contributing to individual variation in the severity of PD. Characterizing them at high sensitivity in post-mortem brain tissues would enable us to gain biological insights into the genetic mechanisms driving PD pathogenesis.

We performed high coverage whole-exome and mitochondrial DNA sequencing on 116 well-characterized post-mortem human brain tissues, retrieved from 73 PD patients and 43 age-matched controls, to uncover genes harbouring recurrent somatic mutations that were enriched in PD patients compared to controls. The mean sequencing coverage was 176× and an average of 95.8% of bases were covered by 50 or more reads in individual samples. Using the MosaicForecast bioinformatics pipeline which was designed to identify somatic mutations from NGS data in the absence of paired samples, this study identified 22 genes that were recurrently mutated in >1 PD brain samples from between 2 to 7 PD patients. Interestingly, some of these genes were implicated in alpha-synuclein aggregation (i.e., *G3BP1* and *CAPN15*), one of the widely recognized hallmarks of PD, as well as in neuronal and axonal pathways (i.e., *DOCK7*, *DVL1* and *NAV1*). However, none of the genes identified were significantly enriched in patients compared to pathologically normal brains ($p > 0.05$) and none are known PD genes with germline variants previously identified by GWAS or family studies. Similarly, even though the control region of mitochondrial DNA was found to be enriched for genetic variants in PD patients compared to controls, none of the mutations identified in this region - which includes known mitochondrial transcription and replication regulatory sites - passed Bonferroni correction for multiple testing.

The high inter-individual genetic heterogeneity of PD noted in this present research as well as in past studies highlights the need to expand the study to include as many samples as available. This will enable characterization of the full spectrum of somatic variants and a more comprehensive assessment of their distribution in diseased vs pathologically normal, age-matched brains.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1458 Evaluating the cardiovascular impact of genetically proxied PCSK9 and HMGCR inhibition in East Asian and European populations: a drug-target Mendelian randomization study.

Authors:

L. Park[1], D. B. Rosoff[1,2], A. S. Bell[1], L. A. Mavromatis[1], A. M. Hamandi[1], J. Jung[1], J. Wagner[1], P. Pacher[1], D. Ray[2], G. Davey Smith[3], F. Lohoff[1]; [1]NIH/NIAAA, Bethesda, MD, [2]Univ. of Oxford, Oxford, United Kingdom, [3]Univ. of Bristol, Bristol, United Kingdom

Background: Lipid-lowering pharmacotherapies involving proprotein convertase subtilisin/kexin 9 (PCSK9) inhibition and/or 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMGCR) inhibition are effective in reducing cardiovascular risk; however, it remains unknown whether there are differences in long-term efficacy between cohorts of East Asian (EAS) and European (EUR) ancestries. **Methods:** Using single-nucleotide polymorphisms (SNPs) in the *PCSK9* and *HMGCR* loci from EAS and EUR genome-wide association studies (GWAS) summary-level data of low-density lipoprotein cholesterol (LDL-C), we performed drug-target Mendelian randomization (MR) analysis evaluating their cardiovascular impact in these populations and assessed potential differences of the drug target-cardiometabolic relationships, including across ancestries and drug classes. **Results:** PCSK9 and HMGCR proxied LDL-C lowering (per standard deviation decrease in circulating LDL-C) were associated with reduced coronary artery disease (CAD) risk in both EAS and EUR [PCSK9 EAS: odds ratio (OR)=0.524, [95% CI, 0.430, 0.638], P-value=1.1610^{-10}; PCSK9 EUR: OR=0.503, [95% CI, 0.413, 0.613], P-value=$8,8810^{-10}$; HMGCR EAS: OR=0.681, [95% CI, 0.557, 0.833], P-value=2.0010^{-4}; HMGCR EUR: OR=0.681, [95% CI, 0.529, 0.876], P-value=0.003]. Analysis of additional cardiovascular diseases showed genetically proxied PCSK9 inhibition was associated with reduced arrhythmia, atrial fibrillation, and congestive heart failure in EUR but not EAS while peripheral artery disease was reduced in both EUR and EAS. Interestingly, genetically proxied HMGCR inhibition had no effect on any of the additional outcomes in either population. MR estimates were generally consistent across complementary MR methods and tests for heterogeneity and pleiotropy were null, strengthening causal inference. **Conclusions:** We demonstrate similar efficacy of genetically proxied PCSK9 and HMGCR inhibition for CAD risk reduction among EAS and EUR cohorts. PCSK9 inhibition had additional beneficial effects on various cardiovascular outcomes, highlighting potential additional therapeutic value. Together, these findings underscore the utility of genetics-based drug-target analysis to compare efficacy, which might help our understanding of the impact of long-term lipid lowering therapies for cardiovascular disease in diverse populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1459 Evaluating the effects of sex chromosome dosage on ASD risk and cognitive performance

Authors:

A. Berry[1], B. Finucane[2], S. Myers[3], M. Oetjens[3]; [1]Geisinger, Danville, PA, [2]Geisinger Hlth.System, Lewisburg, PA, [3]Geisinger, Lewisburg, PA

Autism spectrum disorder (ASD) is 3.8 times as prevalent in boys as in girls, however the biological mechanism for this sex bias is unknown. To explain the large ASD sex difference, theories such as a protective effect of two X chromosomes in females compared to the single X found in males have been proposed. However, genetic studies of ASD have largely overlooked the Y chromosome. Sex chromosome aneuploidies (SCAs) are common human genetic conditions characterized by an atypical number of X or Y chromosomes and are therefore ideal candidates for the study of X and Y chromosome dosage effects on ASD. Here, we use several population-based cohorts to assess how changes in sex chromosome dosage affect ASD risk. We assembled an ASD case-control cohort by combining individuals with an ASD diagnosis from the Simons Foundation SPARK study with controls from Geisinger's MyCode, NIH's All of Us, and the UK Biobank. Sex chromosome complements were identified using genotype array data. Logistic regression was used to determine whether ASD risk differed between each SCA and 46,XX. 46,XY and 47,XXY had ~4-fold (46,XY OR [95% CI]: 3.6 [3.5-3.7]; 47,XXY: 4.7 [3.4-6.7]) increased ASD risk compared to 46,XX. 47,XYY and 45,X had the highest ASD risk relative to 46,XX (47,XYY: 9.3 [6.6-13.1]; 45,X: 11.1 [5.9-21.0]), and were also at increased ASD risk relative to 46,XY (47,XYY: 2.6 [1.9-3.7]; 45,X: 3.1 [1.6-5.9]). Next, we examined the effect of SCAs on cognitive performance measured by a fluid intelligence test taken by UK Biobank participants. Within the UK Biobank cohort, we found that only individuals with an additional sex chromosome had significantly reduced cognitive performance (47,XXX SD [95% CI]: -0.7 [-1.0- -0.5]; 47,XXY: -0.9 [-1.1- -0.7]; 47,XYY: -0.7 [-0.9- -0.5]) relative to 46,XX and 46,XY. Comparisons between SCA groups revealed that 45,X had a significantly increased risk of ASD relative to 47,XXX (OR [95% CI] 5.4 [2.1-14.0]) and yet had significantly better cognitive performance compared to 47,XXX (SD [95% CI] 0.7 [0.3-1.1]). All adjusted $P<0.05$. In summary, our results suggest that the addition of a Y chromosome, but not an X chromosome, increases ASD risk relative to a 46,XX or 46,XY background, while the addition of either an X or Y chromosome reduces cognitive performance. Despite our observation that 45,X conferred the highest ASD risk among females, we did not observe an association between 45,X and cognitive performance typical of an ASD-risk variant of large effect. The study of SCAs may provide an untapped avenue to investigate the effects of X and Y-related gene dosage on mental health conditions that differentially affect males and females in the general population.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1460 Evaluating the interaction of polygenic risk and child sexual abuse on longitudinal trajectories of posttraumatic stress disorder symptoms

Authors:

K. Passero[1], K. O'Donnell[2], C. Selin[1], J. G. Noll[1], M. A. Hall[1]; [1]The Pennsylvania State Univ., State College, PA, [2]Yale Sch. of Med., New Haven, CT

Posttraumatic stress disorder (PTSD) has a modest estimated heritability and a suspected polygenic architecture, yet is predicated on the occurrence of a traumatic event. Although most individuals will experience a potentially traumatic event, developing PTSD is relatively rare in the general population albeit elevated in high-risk groups, such as children exposed to adverse childhood events. In adolescent victims of sexual assault, the rate of PTSD is estimated above 30%. Furthermore, child sexual abuse (CSA) is hypothesized to exacerbate risk for negative outcomes when in conjunction with other risk factors. We tested whether polygenic risk of PTSD and CSA interacted to affect the developmental trajectory of PTSD in a cohort of female adolescents. Participants were stratified into African or European ancestry groups, and ancestry-specific polygenic risk scores (PRSs) of PTSD were computed. Their PTSD symptoms over three timepoints were discretized into four trajectory classes - chronic, recovering, emerging, or resilient - using growth mixture modeling. Using multinomial logistic regression, we compared how CSA, PRS, and their interaction affected trajectory classification within each ancestral group. We computed gene-environment interactions on both the additive and multiplicative scales. Within the African ancestry participants, only CSA significantly contributed to a greater odds of a chronic trajectory, even after controlling for potentially confounding psychosocial risk factors, including alternative potentially traumatic events. Among the European ancestry participants, both PRS and the PRS×CSA interaction significantly differentiated the chronic and recovering trajectories. The interaction suggested that having higher PRS alongside CSA elevated the risk of a chronic trajectory versus a recovering trajectory. Together, these results suggest that background genetic risk may play a variable role in the development of PTSD, with a greater negative effect displayed in the presence of a salient traumatic event such as child sexual abuse.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1461 Evaluation of the association between suicidality and polygenic risk scores for anorexia nervosa, suicide attempts, and suicidal ideation.

Authors:

R. Zhang[1,2], J. Termorshuizen[2], A. Birgegård[2], L. M. Thornton[1], P. Sullivan[1], C. M. Bulik[1], A. Abbaspour[2]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]Karolinska Inst.t, Stockholm, Sweden

Suicidality, including suicidal thoughts and attempts, is elevated among individuals with anorexia nervosa (AN), as evidenced by an increased risk of suicide attempts and suicide being one of the leading causes of death in this population. Twin studies suggest that shared genetic factors may underlie the co-occurrence of AN and suicide. To further explore the genetic factors that contribute to suicidality in AN, we computed three polygenic risk scores (PRS): for AN, suicide thoughts, and suicide attempts, and evaluated their associations with both ICD-based and self-reported suicidal behaviors in individuals with AN. Using data from the Swedish site of the Anorexia Nervosa Genetics Initiative (ANGI-SE) study comprising 3,189 AN cases born after 1977 with linkage to the Swedish National Registers, we examined the association of AN PRS, suicide thought PRS, and suicide attempt PRS on self-harm, suicide thoughts/plans, suicide attempts, and suicide death.

Among ANGI-SE cases, higher suicide attempt PRS was significantly associated with higher risk of ICD-based suicide attempt measured by odds ratio (OR) with 95% confidence interval (CI) (OR [95%CI]: 1.30 [1.14, 1.49]) and higher risk of self-reported self-harm (1.22 [1.08,1.38]). Higher suicide attempt PRS was also significantly associated with more frequent self-reported suicide thoughts (1.18 [1.02,1.37]), self-reported self-harm (1.19 [1.06,1.34]), and self-reported suicide attempts (1.34 [1.09,1.64]). Suicide thought PRS was significantly, albeit less strongly, associated with higher risk of ICD-based suicide attempts (1.14 [1.02,1.27]) and self-reported self-harm, both as presence/absence (1.13 [1.02,1.25]), and frequency (1.12 [1.02,1.24]). Although a moderate correlation existed between AN PRS and suicide attempts PRS (r_g=0.26), we did not observe any association between AN PRS and the suicidality measures.

These results suggest individuals with AN who have a genetic predisposition to suicide attempts are more likely to experience a range of suicide-related thoughts and behaviors. Furthermore, genetic risk factors from common variants for AN itself (i.e., AN PRS) may not directly contribute to the high risk of suicidality in individuals with AN. Risk factors including other genetic factors (e.g., rare variants) as well as environmental factors contributing to suicide risk in individuals with AN merit further investigation.

Crawford[1,2,3]; [1]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [2]Cleveland Inst. for Computational Biology, Case Western Reserve Univ., Cleveland, OH, [3]Dept. of Genetics and Genome Sci., Case Western Reserve Univ., Cleveland, OH, [4]Univ. Hosp., Cleveland Med. Ctr., Cleveland, OH, [5]John P. Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [6]Dr. John T. Macdonald Fndn. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [7]Dr. John T. Macdonald Fndn. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, Cleveland, OH

Late-onset Alzheimer disease (LOAD), a progressive neurodegenerative disease characterized by brain-related changes such as amyloid-β plaque deposition, is the most common form of dementia among adults ≥65 years of age. Known risk factors include female sex, increased age, and LOAD-associated genetic risk alleles, most notably *APOE* e4. Recent lines of evidence implicate the adaptive immune system as an important component of amyloid-β plaque clearance and suggest in limited sample sizes there are LOAD-associated immune profiles detectable in blood. Here, we characterized somatic T-cell receptor (TCR) sequence diversity profiles from DNA extracted from blood (99%) and saliva (1%) in clinically diagnosed cognitively impaired (CI; n=38), cognitively borderline (CB; n=17), and cognitively unimpaired (CU; n=32) Amish participants residing in Ohio. Participants were predominantly female (63.8%), and CI participants were on average older at last clinical exam than CU participants (85.40 vs 78.70 years; t-test, $p<0.0001$). Sequencing was performed using Adaptive Biotechnologies immunoSEQ targeting the beta chain, resulting in >160,000 productive templates and >100,000 productive rearrangements. TCR beta chain sequences were characterized using Simpson's productive clonality, which ranges from 0 to 1 representing diverse and completely even sequences (e.g., 0) to monoclonal or single dominant clone (e.g., 1). We also examined the frequency of recurrent sequences for evidence of recent clonal expansion. As hypothesized, in this relatively homogeneous population, TCR sequence diversity was lowest among CI (0.123) and highest among CU (0.083), a difference (t-test, $p=0.038$) that was no longer significant after adjusting for age ($p=0.156$). TCR diversity among CB participants was intermediate (0.1043). Overall, CI participants had more dominant clones (defined here as productive rearrangements greater ≥10% in frequency) compared with CU participants (35% versus 22%, respectively). While this pattern is suggestive of increased clonal expansion among CI compared with CU participants, the difference was not significant ($p=0.255$). Relatively few clonotypes (exact nucleotide sequences) were shared across participants; of those few shared include the Epstein Barr virus associated clonotype (CASSLGQAYEQYF), with at least one count detected in 45% and 44% of the CI and CU participants, respectively. Collectively, these data suggest that reduced TCR diversity is associated with CI, but further study in larger and additional study populations is needed to establish the association and its relationship to the development of LOAD independent of age.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1463 Evidence that GWAS-derived genetic risk scores are not associated with vitiligo in African Americans, Hispanics, or Asians drawn from a clinical population

Authors:

D. Drouet, S. Liu, D. C. Crawford; Case Western Reserve Univ., Cleveland, OH

Vitiligo is an autoimmune dermatologic condition characterized destruction of melanocytes subsequently resulting in the depigmentation of the affected skin areas. The causes of vitiligo, affecting approximately 1.9 to 2.8 million adults residing in the United States, are unknown. Risk factors include a diagnosis of autoimmune diseases such as Addison's disease, pernicious anemia, psoriasis, rheumatoid arthritis, systemic lupus, erythematosus, thyroid disease, and type 1 diabetes and well as having a family history of vitiligo. Recent genome-wide association studies (GWAS) have identified >70 common single nucleotide variants (SNVs) associated with vitiligo in mostly European-descent populations. No GWAS has been published for African Americans (AA) or Hispanics (H), and it is unclear if vitiligo GWAS-identified SNVs or risk scores derived from them are also associated with vitiligo in diverse populations. In the present study, we accessed the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) BioVU, a resource of de-identified electronic health records (EHRs) linked to Illumina Metabochip genotypes assayed on ~15,000 DNA samples extracted from clinical blood draws at a major medical center in Davidson County, Tennessee. Using International Classification of Diseases (ICD)-9 codes 709.01, 374.53, 624.8, we identified 118, 9, and 6 cases of vitiligo for (AA), Asian (A), (H) patients, respectively. Controls or non-cases (11,072 AA, 1,011 A, and 1,474 H) were defined as absence of case-defining ICD-9 codes. We queried the NHGRI-EBI GWAS Catalog for genome-wide association SNVs (at $p<5x10^{-8}$), risk alleles, and risk allele effect. Of the 79 identified SNVs, 10 were assayed directly on the Metabochip, and after tests of Hardy Weinberg Equilibrium and additional quality control, the final risk score included 7, 6, and 7 SNVs for AA, A, and H, respectively. We calculated both unweighted and weighted risk scores for each patient and tested each for an association with vitiligo using logistic regression. Mean weighted vitiligo risk score was 2.22 ± 0.45 (AA), 1.64 ± 0.44 (A), and 2.32 ± 0.52 (H) in controls and 2.15 ± 0.49 (AA), 1.55±0.21 (A), and 2.27 ± 0.62 (H) in cases. Despite previous reports of strong genetic associations for vitiligo in European-descent populations, weighted risk scores adjusted by sex risk scores not associated with vitiligo (p-values>0.05) in any of the diverse patient groups tested here (ORs = 0.70; 95% CI 0.46-1.06 (AA), 0.61; 95% CI 0.12-2.78 (A), and 0.83; 95% CI 0.18- 3.93(H)). The lack of association underscores the need for both additional resources and discovery efforts for vitiligo in diverse populations.

PB1464 Evolutionary meta-analysis of exomes identifies new Type 2 Diabetes risk genes and mechanistic pathways

Authors:

K. Wilhelm, J. K. Asmussen, K. Lee, M. Samieinasab, O. Lichtarge; Baylor Coll. of Med., Houston, TX

Type 2 Diabetes (T2D) is a leading cause of morbidity and mortality. It is characterized by impaired insulin sensitivity and production, leading to hyperglycemia and progressive metabolic, vascular, renal, and neurological complications. While environmental factors, exercise, and body mass index (BMI) are important, genetics is a major risk factor in T2D. Genome-wide association studies (GWAS) have suggested over 5,000 risk loci, yet missing heritability remains. To fill the missing heritability gap, we analyzed whole exome sequencing data from 3,273 T2D cases and 3,273 age-, sex-, and BMI-matched healthy controls from the UK Biobank. We annotated missense variants by their inferred functional impact calculated from phylogenetic distances and amino acid substitution odds. Next, genes were tested for differences in the functional burden of mutations between cases and controls. For this, we used three complementary machine learning algorithms. Finally, we combined the results by meta-analysis into a high confidence set of 178 genes hypothesized to be associated with T2D risk. These 178 genes overlapped with known risk genes (n = 6/72, p = 4.5x10^{-5}), co-localized with T2D GWAS loci (p = 0.02), and interacted with known risk genes in the STRING protein-protein interaction network (z = 5.4). In the same network, these genes were also mutually linked, grouping into clusters that discovered T2D-related pathways, such as “Glucose metabolism” (FDR = 0.003) and “Regulation of insulin secretion” (FDR = 0.009). Interestingly, we also recovered potentially novel pathways, such as “Negative regulation of stem cell proliferation” (FDR = 0.008). Additionally, when we added the 72 known risk genes into the network, we observed that many of the novel candidate genes interacted with them to augment functional clusters with annotations such as “Insulin receptor signaling pathway” (FDR = 1x10^{-10}), “Glycolysis” (FDR = 2.2x10^{-8}) and “Negative regulation of fat cell differentiation” (FDR = 0.004). Some of these novel genes also carried mutations associated (FDR < 0.1) with T2D cases, including *TNS1* and *PTCH1*. In contrast, we found other genes associated with healthy controls that may be protective, such as *PLSCR1* and *DLG1*. Finally, the 178 candidates predicted early-onset T2D in a holdout cohort (n = 988, AUROC = 0.58), on par with other genetics-only polygenic risk scores and suggesting that our results may be complementary to prior models to uncover the full genetic architecture of T2D. In summary, this study combined machine learning with evolutionary analysis of coding variants in a relatively small cohort to identify new genes contributing to risk in T2D.

Ctr., Nashville, TN, [4]Geisinger Hlth.Systems, Danville, PA, [5]Univ. of Washington Med. Ctr., Seattle, WA, [6]Mayo Clinic, Rochester, MN, [7]Galatea Bio, Inc., Hialeah, FL, [8]NIH, Bethesda, MD, [9]Columbia Univ., New York, NY, [10]Vanderbilt Univ. Med. Ctr., Div. of Epidemiology, Nashville, TN, [11]Univ. of Pennsylvania and Children's Hosp. of Philadelphia Kidney Innovation Ctr., Philadelphia, PA, [12]Vanderbilt Univ. Med. Ctr., Div. of Genetic Med., Nashville, TN

Nephrotic syndrome (NS) is a collection of disorders characterized by excess protein in the urine (>3g/day). Nephrotic syndrome has heterogeneous histopathological manifestations, including minimal change disease, focal segmental glomerulosclerosis and membranous nephropathy. Our goal was to identify loci associated with adult NS across European (EUR), African (AFR), and East and Central Asian (ASN) ancestry groups. We integrated genotype data from Vanderbilt University's BioVU and the Electronic Medical Records and Genetics (eMERGE) network with summary statistics from FinnGen, Million Veteran Program (MVP), Biobank Japan (BBJ), and UK Biobank (UKB), for a cross-ancestry total of 5,214 cases (3,060|790|1,364; EUR|AFR |ASN and 1,601,060 controls (1,279,630|135,664|185,766; EUR|AFR|ASN). Cases were identified with diagnostic codes (FinnGen) or phecodes (BioVU, eMERGE, MVP, BBJ, UKB) for NS, while controls were without renal disease diagnosis codes. Associations with NS were modeled as a function of additive genotype, sex, and the top 10 principal components, followed by inverse-variance weighted meta-analysis within and across ancestral groups. We identified 31, 15, 43, and 13 significant (r^2<0.1, >1Mb, $p<5x10^{-8}$) loci in the multi-ancestry, EUR, AFR, and ASN analyses, respectively. The strongest association in the multi-ancestry analysis was rs1265889 (class II MHC region, $p=1.4x10^{-20}$, OR=1.50 (1.43-1.57)). We significantly ($p<5x10^{-8}$) replicated loci associated with pediatric NS (*ZNF345*) and membranous nephropathy (*PLA2R1*). In the AFR analysis, we identified 16 novel non-HLA loci, as well as replicated the *APOL1* G1 variants ($p=4.5x10^{-15}$, OR=2.56). We evaluated associations between NS and transcriptome wide predicted gene expression using GTEx v8 tissue models. We identified 28 unique genes from 167 significant ($p<1.55x10^{-6}$) gene-tissue pairs in the multi-ancestry, 33 unique genes at 337 gene-tissue pairs in EUR, and one gene out of two gene-tissue pairs in AFR. We interrogated significant SNPs in these genes with the Human Kidney eQTL Atlas (susztaklab.org) and observed 1,080 kidney microstructure and bulk tissue eQTLs (FDR<0.05) in *AGPAT1, C4A, HLA-DQA1, HLA-DQB1, HLA-DQB2, NOTCH4,* and *RNF5* genes. This study provides insight into adult NS through identification of novel genetic loci and translation to predicted renal gene expression in the largest multi-ancestry meta-analyses to date.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1466 Examining Dry Eye Disease Phenotype in UK Biobank

Authors:

B. Riley-Gillis[1], M. Liu[1], J. Lee[1], A. Acevedo-Canabal[2], K. Held[2], A. Abbasi[1], N. Smaoui[1]; [1]AbbVie, North Chicago, IL, [2]AbbVie, Irvine, CA

Dry eye disease (DED) is a common, and often under-diagnosed disease, that affects five to fifty percent of the population. DED is a heterogenous disease with symptoms such as blurred vision and irritation, and treatments vary from over-the-counter artificial tears to surgical closure of the tear ducts. Symptoms of DED can be driven by multiple factors, including environmental (e.g., arid climate), behavioral (e.g., prolonged use of computers) or medication use. Twin studies have estimated the heritability of DED from 50%-80% depending on the phenotype, which implies a genetic component of the disease.

The mechanism of how these factors, individually or together, can lead to dry eye symptoms has not been well understood. Furthermore, precisely identifying DED as a phenotype is a challenge as the different causes and symptoms are often classified under one umbrella medical code.

In the current study, we utilized the UK Biobank to investigate how genetic factors may play a role in DED. First, we defined dry eye disease using a combination of medical records and prescription information to precisely define DED cases with established dry eye symptoms. Next, we limited cases to individuals of European ancestry to avoid any population confounders. In total, we identified a case cohort of 2,327 and a control cohort of 137,672 who do not have medical records or prescriptions related to dry eye. A case-control genome-wide association study (GWAS) was performed but did not identify any genome-wide significant loci. Stratification of the cohort by sex or known dry eye disease factors also did not find any genome-wide significant loci.

In conclusion, we characterized a dry eye disease cohort within a large biobank using medical records and prescription information, however GWAS analysis did not identify any genetic factors associated with dry eye disease. The heterogeneity of DED is a key challenge that may be addressed by precise phenotyping (e.g., Schirmer values) to more accurately classify DED patients for future genetic analyses.

Hosp., Edinburgh, United Kingdom, [4]Dept. of Publ. Hlth., Clinicum, Faculty of Med., Univ. of Helsinki, Helsinki, Finland, [5]Broad Inst. of the Massachusetts Inst. of Technology and Harvard Univ., Cambridge, MA, [6]Med. Res. Council Human Genetics Unit, Inst. of Genetics and Cancer, Univ. of Edinburgh, Western Gen. Hosp., Edinburgh, United Kingdom, [7]Dept. of Mathematics and Statistics, Univ. of Helsinki, Helsinki, Finland

Background: Human plasma lipidome captures risk for cardiovascular diseases and beyond. Genome-wide association studies (GWAS) of individual lipid species have identified many lipid-associated loci, however the influence of associated genetic variants on disease risk remains poorly understood.
Methods: We derived polygenic risk scores (PRS) for 131 lipid species measured in two independent Finnish cohorts, GeneRISK and FinRISK. PRS were calculated using GWAS summary statistics from the GeneRISK cohort for 7,174 individuals with PRS-CS and PLINKv1.9 and validated using the FinRISK cohort (N=1,032). Regional heritability for 179 lipid species from the GeneRISK cohort was estimated with FINEMAP. For lead variants, association analyses of 8 disease endpoints were performed in 3 independent cohorts- FinnGen (N=377,277), UK Biobank White British subset (N=408,959) and Generation Scotland (N=20,032).
Results: PRS explained >4% of variance for 25 lipid species. For each of these lipid species, we identified the locus, which when removed from the PRS calculation resulted in a drop of variance explained > 2%. There were six loci (*AL161670.1*, *CERS4*, *FADS2*, *LINC01722*, *LIPC*, *ZPR1*) for which variance explained was < 2.5% after removal of the corresponding loci. These six loci and five other loci (*ABCG8*, *APOE*, *GLTPD2*, *NTAN1*, *TMC4*) reached regional heritability values > 2%. The GWAS lead variants and top variants of credible sets identified by fine-mapping of these 11 high impact loci revealed their associations with cholelithiasis and alzheimer's disease in all 3 cohorts, ischaemic heart disease, statin medication, type 2 diabetes and pure hypercholesterolemia in 2 cohorts, and age-related macular degeneration in 1 cohort (P < 6.25e-9). Non-alcoholic fatty liver disease was nominally associated in 2 cohorts (P < 6.25e-3). We observed several distinct signals in some loci. For instance, one of five independent *LIPC* signals (missense variant rs113298164) had larger effect sizes for both age-related macular degeneration and phosphatidylethanolamines compared to another *LIPC* signal (intronic variant rs1800588).
Conclusion: PRS explained over 4% of variance for 25 lipid species. We identified 11 loci with regional heritability estimates over 2%. Lipid species associated variants within these loci revealed significant associations with 8 disease endpoints. In some loci, the effect sizes on lipids and diseases varied between independent signals. These results might help in determining the most suitable genetic instruments required to tease out causal relationships between lipid species and disease endpoints.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1468 Examining the relative predictive accuracy of polygenic scores across ancestral populations

Authors:

R. Alemu[1,2], P. Turley[3], A. Okbay[4], D. Benjamin[5,6]; [1]Univ. of California Los Angeles, Los Angeles, CA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA, [3]Univ. of Southern California, Los Angeles, CA, [4]Vrije Univ.it Amsterdam, Amsterdam, Netherlands, [5]Univ. of California Los Angeles, Santa Monica, CA, [6]NBER, Boston, MA

Genome-wide association studies (GWASs) are conducted to identify replicable genomic risk loci associated with diseases and other traits. Polygenic Scores (PRS) are genetic predictors of phenotypes computed using GWAS-generated summary statistics for the corresponding phenotype. The recent increase in the sample size of GWASs has helped improve the predictive performance of PGS. However, this improvement is unbalanced across ancestral groups due to the over-representation of European ancestry individuals in most GWASs (Martin et al., 2019). The predictive accuracy of PGS falls by an average of 37, 50, and 78 percent in individuals of South-Asian, East-Asian, and African ancestries, respectively (Martin et al., 2019). Prior studies have primarily focused on a few biological phenotypes, such as anthropometrics, blood pressure and hemoglobin levels. This paper examines the loss of predictive accuracy in behavioral traits such as educational attainment, substance use, and neuropsychiatric conditions. For such traits, we may expect the relative predictive accuracy to be lower, given the complex environmental pathways through which these PGS operate. Furthermore, we estimate what share of the PGS accuracy loss is explained by differences in minor allele frequencies (MAF), linkage disequilibrium, and heritability, closely following the decomposition approach recently developed by Wang et al. (2020). The SNP weights were generated from the largest training set containing European ancestry individuals excluding a validation set, while the PGS were computed using SBayesR, a Bayesian multiple regression method. Our preliminary results show PGS relative accuracy for educational attainment (EA) in African ancestry individuals in the HRS and Add-health cohorts are 11 and 15 percent, respectively. Moreover, we find that the share of predictive accuracy shrinkage attributable to minor allele frequency (MAF) and linkage disequilibrium (LD) is 65 percent, implying that the remaining loss is likely due to environmental factors or an imperfect cross-population correlation of causal SNPs. Quantifying the relative contribution of these factors may have behavioral, clinical, and policy implications.

PB1469 Expanded multi-ancestry genome-wide association meta-analysis of IBD identifies 85 new loci and implicates potential therapeutic drug targets

Authors:

L. Fachal, on behalf to the International IBD Genetics Consortium; Wellcome Sanger Inst., Hinxton, United Kingdom

Genome-wide association studies (GWASs) have identified 320 loci associated with inflammatory bowel disease (IBD) susceptibility and its two main subtypes, Crohn's disease (CD) and Ulcerative Colitis (UC). About 15% of these loci include genes that lie in pathways targeted by drugs currently approved to treat IBD. Identifying new loci can reveal novel therapeutic targets for IBD.

We carried out a multi-ancestry GWAS meta-analysis of 67 cohorts, from European (EUR), East Asian (EAS) and South Asian (SAS) populations. The final dataset included 105,116 IBD patients (49,625 with CD; 47,378 with UC) and more than 1.2 million population controls.

We identified 194 novel (P<5x10-8) disease associated signals, with no evidence of effect heterogeneity across populations. Out of these, 85 are located >1Mb from any previously reported loci, thus representing a more conservative estimation of new loci implicating new causal genes. To prioritise effector genes and generate therapeutic hypotheses we colocalised IBD loci with bulk and single cell QTL data from relevant tissues, cell types and environmental conditions. 154 IBD loci showed strong evidence of colocalisation (PP>0.8), including two independent new loci associated with UC and IBD that colocalised with *SIK2* and *VSIR*, respectively.

SIK2 encodes a protein kinase that helps maintain a pro-inflammatory status by inhibiting IL10 production in macrophages. The UC protective allele (OR=0.94;P=3.1E-9) is associated with decreased SIK2 expression in macrophages, monocytes, neutrophils and T-cells, which suggests that molecules inhibiting SIK2 could have a therapeutic effect on UC.

VISTA, the protein encoded by *VSIR*, is an immune checkpoint receptor. Knockout mice show increased expression of IL23 and develop chronic inflammation in multiple tissues. The IBD protective allele (OR=0.95;P=7.5E-9) is associated with increased *VSIR* expression in colon and oesophagus, indicating that compounds with an agonist effect on this protein might have therapeutic value.

For both genes, we have added genetic support for the mechanism of action of compounds (SIK2 inhibitors; VISTA agonists) in ongoing pre-clinical and clinical trials for immune-mediated traits, including IBD.

In summary, we performed the largest multi-ancestry GWAS meta-analysis of IBD to date, identifying 85 new IBD loci and providing further insights into the biology of the disease. Integrating molecular data from multiple cell types and conditions not only expands our ability to determine candidate causal genes, but it also provides additional evidence of the utility of genetics as an instrument to guide the development of new therapeutic drugs.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1470 Exploiting pleiotropy of corneal resistance factor genetic associations.

Authors:

X. Jiang[1,2], T. Boutin[1], V. Vitart[1]; [1]MRC Human Genetics Unit, Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, UK, Edinburgh, United Kingdom, [2]Ctr. for Genetics and Molecular Med., Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, UK, Edinburgh, United Kingdom

Background: Genome-wide association studies (GWAS) have identified over 100 genomic loci contributing to inter-individual variation in corneal resistance factor (CRF). Those have proved particularly useful to flag susceptibility loci for keratoconus, a postnatal ocular disease characterized by progressive thinning of the central cornea. Collagen and extracellular matrix (ECM) regulation pathways were prominently implicated by geneset enrichment analyses, based on closest genes to lead variants. Better understanding of the mechanisms underlying CRF associations promises to shed light on keratoconus poorly understood pathogenesis but also plausibly on ECM regulation in diverse tissues of the human body.
Methods: In absence of GWAS of gene expression in the cornea, we performed colocalization analysis between CRF fine-mapped GWAS signals and those affecting expression (eQTL) or splicing (sQTL) of genes in 49 diverse, non-corneal, tissues from the GTEx consortium. We assume that a subset of CRF causal variants affecting gene regulation in a GTEx tissue would also be acting in a corneal cell type in the same molecular way. To support this hypothesis, genes linked to regulatory loci by colocalization were evaluated in adult corneal single cell RNA Atlas. Conditions other than those affecting the cornea that the prioritized CRF variants might be associated with will be highlighted using phenome wide association studies (PheWAS) and multitrait colocalization harnessed to help refine causal variants and target genes.
Results: Twenty-six percent of 181 CRF independent causal signals colocalize with e/s QTLs from GTEx. This subset appears enriched in keratoconus susceptibility loci, and depleted in loci close to genes implicated in Mendelian connective tissue conditions. The shared causal signals with GTEx e/s QTLs provide many new insights into mediation of CRF genetic effects, including modulation of splicing events. All the nominated causal protein-coding genes were expressed in the adult cornea, with significant enrichment found in the stromal cells. Extra and intracellular known roles of several implicated genes products in providing tensile strength, mechano-sensing and signaling make the corresponding genes and regulatory variants prime CRF candidates to be validated and their roles and effects understood within specific contexts.
Conclusion: Although limited, the set of CRF and keratoconus associated causal variant and gene candidates exposed here presents the advantages of being relevant to more than one tissue and likely involved in maintenance of adult cornea rather than (or as well as) developmental processes.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1471 Exploring causal mechanisms of sex dimorphism at lipid associated loci.

Authors:

D. Zanetti[1], C. Carland[2], F. Busonero[1], A. Maschio[1], F. Crobu[1], J. Petrie[3], L. Lind[4], T. Assimes[5,6], S. Sanna[1,7]; [1]Inst. of Genetic and BioMed. Res. (IRGB), Natl. Res. Council (CNR), Cagliari, Italy, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Univ. of Glasgow, Glasgow, United Kingdom, [4]Uppsala Univ., Uppsala, Uppsala, Sweden, [5]Stanford Univ. Sch. of Med., Palo Alto, CA, [6]VA Palo Alto Hlth.Care System, Palo Alto, CA, [7]Univ. of Groningen, Groningen, Netherlands

Background: Large scale genetic studies on lipid traits have highlighted several loci with evident sex-heterogenous effects for which the underlying causal genes remain unknown. Intriguingly, a protein quantitative trait loci (pQTLs) mapping study recently identified 118 pQTLs associated with 48 circulating proteins showing significantly heterogeneous effects between sexes. Out of these 48 proteins, 15 are mapping loci previously associated with lipid traits. We explored the roles of such proteins in explaining the observed sex dimorphism in lipids traits. **Methods:** We searched for shared mechanisms and causal links between lipid-associated loci and proteins located at these loci using colocalization and two-sample Mendelian Randomization (MR) methods. We used sex-specific summary statistics of high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) from the Global Lipids Genetics Consortium (DOI: 10.1186/s13059-022-02837-1), and sex-specific pQTL summary statistics for 15 proteins measured using the Olink's Metabolism panel in a total of 10,885 women and 12,112 men from 12 cohorts from the SCALLOP consortium (DOI: 10.21203/rs.3.rs-2621829/v1). For MR, we used the two-sample MR package to select for each protein independently ($r2<0.001$) associated variants at $p<5x10^{-8}$, either in cis- or in trans-, and performed MR using Inverse Variance Weighted, Weighted Median and MR-Egger tests. **Results:** The colocalization analyses supported the existence of a potential shared causal variant for the proteins: COMT and LILRA5 with LDL-C; MEP1B with TG; and SEMA3F with HDL-C - all only in males. Using a Bonferroni-adjusted threshold of $p<10^{-4}$, the MR analyses in females supported evidence of a significant causal association with TG for a total of 2 proteins, TYRO3 and ANGPT2, and with HDL-C for MEP1B. In males, a significant causal association was found for the protein COMT with HDL-C, thus corroborating findings from colocalization analyses. In contrast, protein NECTIN2 showed causal links with all lipid traits in both sexes, with similar causal effect. The leave-one-out and sensitivity analyses removing outliers due to horizontal pleiotropy (MR-PRESSO) provided consistent results. **Conclusions:** Our study identified possible sex-specific causal roles of several proteins located at loci associated with lipids traits. This approach evidences the need for future genetic studies to perform sex-stratified QTL mapping and integrative analysis as a route to understanding sex dimorphism in lipid metabolism.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1472 Exploring cytokine pathways as potential determinants of multimorbidity: a Mendelian randomisation study

Authors:

N. Hukerikar[1], F. Schmidt[2,3,4,5], C. Finan[2,3,4], F. Asselbergs[1,2,4,5], A. Hingorani[2,3], S. Chopade[2,3]; [1]Inst. of Hlth.Informatics, Faculty of Population Hlth., Univ. Coll. London, London, United Kingdom, [2]Inst. of Cardiovascular Sci., Faculty of Population Hlth., Univ. Coll. London, London, United Kingdom, [3]UCL BHF Res. Accelerator Ctr., London, United Kingdom, [4]Dept. of Cardiology, Div. Heart and Lungs, Univ. Med. Ctr. Utrecht, Utrecht Univ., Utrecht, Netherlands, [5]Dept. of Cardiology, Amsterdam Cardiovascular Sci., Amsterdam Univ. Med. Ctr., Univ. of Amsterdam, Amsterdam, Netherlands

Background: Multimorbidity, the co-occurrence of two or more distinct diseases, presents a challenge in research and healthcare. Cytokines and their regulators play an important role in acute and chronic inflammatory responses. Moreover, they often influence multiple disease-causing pathways, thereby having implications for multimorbid diseases. This study aimed to characterise the role of cytokines as determinants of multimorbidity, and identify druggable cytokines and pathways relevant for therapeutic interventions in multiple diseases.
Methods: Using data from five large genome-wide association studies on the plasma proteome (between 1328 and 35559 samples), *cis*-acting genetic variants for 139 cytokines and regulatory proteins were identified. Mendelian randomisation was employed to determine the association between these immune proteins and 64 diseases and biomarkers relevant to multimorbidity. A knowledge graph was constructed from the significant protein-trait associations, which was further annotated with information on druggability, licensed indications and trait-tissue associations. This entire network was queried to identify cytokine communities and prioritise a subset of pleiotropic cytokines and pathways, representing the subset of immune-proteins strongly involved with multimorbidity.
Results: Diseases frequently implicated for cytokine involvement include inflammatory bowel disease (affected by 23 proteins), lung cancer (21 proteins), type 2 diabetes (20 proteins), Crohn's disease (20 proteins) and Asthma (19 proteins). These proteins were also frequently associated with cardiometabolic risk factors such as cholesterol and blood pressure. Based on the graph communities and graph node importance, 24 pleiotropic cytokines, associated with multiple clinically relevant traits, were prioritised. This included 23 druggable proteins, such as C4B, CX3CL1 and IL1RN.
Conclusion: This study found strong genetic support for plasma levels of immune regulatory and effector proteins acting pleiotropically and partially determining the onset of multimorbidity. Druggable proteins informing *de novo* and ongoing drug development programs against sets of diseases were also identified.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1473 Exploring Molecular Interactions between SARS-CoV-2 Infection and Diabetes: Transcriptomic Analysis of PBMCs Reveals Converging Pathways

Authors:

K. Kumar; Columbia Univ., New York, NY

Patients with diabetes and COVID-19 are at a heightened risk of developing severe complications, such as acute respiratory distress syndrome, multi-organ failure, and death. This increased susceptibility may be attributed to the underlying inflammation associated with obesity, insulin resistance, and other comorbidities typically seen in patients. Patients with hyperglycemia exhibit elevated expression of angiotensin-converting enzyme 2 (ACE2), the cellular receptor for viral entry, which further facilitates viral infection. The pre-existing chronic inflammation, augmented inflammatory response, and increased viral load in diabetic patients contribute to a systemic immune response known as the "cytokine storm," which is strongly associated with the severity of COVID-19. Moreover, SARS-CoV-2 infection can also induce dysregulation of metabolic factors and trigger the onset of diabetes. However, the molecular mechanisms underlying the bidirectional relationship between SARS-CoV-2 infection and diabetes are not fully understood. In this study, comparative transcriptomic analysis of peripheral blood mononuclear cell (PBMC) samples using publicly available scRNA-seq and bulk RNA-seq datasets from COVID-19 patients and type 1 and type 2 diabetes patients are used to elucidate the common molecular pathways that are involved in these conditions. An ensemble learning-based regression model informed by cell state, differential expression, predicted miRNA interactions, age, and sex distinguished significant features in altered metabolic signaling and immune profiles across measures of SARS-COV-2 infection severity. Further, functional assessment with gene ontology (GO) and pathway analyses revealed common mechanistic links between SARS-CoV-2 infected and type I and type II diabetes datasets paired with overlapping miRNA-mRNA-TFs regulatory networks through co-modulated genes involved in cytokine signaling. Such insights may contribute to the development of targeted therapeutic strategies and improved clinical management for patients with diabetes and COVID-19 at heightened risk of severe complications.

PB1474 Exploring SETD1A LoF models to elucidate genetic etiology in schizophrenia risk

Authors:

H. Giles[1,2], T. Sawada[2], A. S. Feltrin[2], Y. Wang[2], B. A. Torres[2], A. E. McCord[2], H. Shizhong[2,1], E. Radulescu[2], Q. Chen[2], B. Qamar[2], A. R. Barbosa[2], R. S. Jacomini[2], V. Dimitrova[3], R. Kaneva[3], V. Vladimirov[4], T. M. Hyde[2,5], D. Weinberger[2,5], A. C. Paquola[6,1], J. A. Erwin[2,1]; [1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [2]Lieber Inst. for Brain Dev., Baltimore, MD, [3]Med. Univ. of Sofia, Sofia, Bulgaria, [4]Univ. of Arizona, Phoenix, AZ, [5]Johns Hopkins Sch. of Med., Baltimore, MD, [6]Lieber Inst. for Brain Dev. / Johns Hopkins Med., Baltimore, MD

Heterozygous loss-of-function (LoF) mutations in SETD1A are rare variants presenting significantly increased risk for schizophrenia (SCZ). However, the mechanism by which SETD1A LoF leads to SCZ-associated phenotypes, and the relationship between SETD1A haploinsufficiency and common variant-associated SCZ, are unknown. We investigated possible connections using isogenic human pluripotent stem cell models engineered with SETD1A LoF variants (such as the most common pathogenic mutation: c.4582-2delAG>-) as well as human prenatal brain samples. We found that SETD1A preferentially acts at promoter regions of SCZ GWAS risk loci, with enrichment for genes regulating histone modification, DNA repair, and synaptic signaling. We also found that genes with significantly decreased expression were enriched for DNA repair pathways, especially homology directed repair. Taken together, these findings suggest that increased genomic instability and reduced DNA repair may undergird a potential mechanism of SCZ genetic risk. SETD1A LoF pluripotent stem cell models provide an important avenue to further investigate these mechanisms and identify therapeutic targets.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1475 Exploring the common genetic factors modifying the germline de novo mutation rate

Authors:

O. Garcia Salinas[1], S. Hwang[2], Q. Huang[1], A. Scally[2], R. Rahbari[3], H. Martin[4]; [1]Wellcome Sanger Inst., Cambridge, United Kingdom, [2]Univ. of Cambridge, Cambridge, United Kingdom, [3]Wellcome Trust Sanger Inst., Cambridge, United Kingdom, [4]Wellcome Sanger Inst., Hinxton, United Kingdom

Somatic mutations accumulate across all cell types during the normal ageing process. However, germline cells accumulate these mutations at a rate at least 27 times lower than somatic cells (Moore et al., 2021). Approximately 80% of the variance in germline *de novo* mutation (DNM) rate is explained by parental age and technical covariates, while the rest of the variance remains unexplained (Kaplanis et al., 2022). Previous studies suggest that genetics could contribute to DNM variance among unrelated individuals, but these studies lacked sufficient statistical power to test this hypothesis effectively (Sassani et al., 2019).

In this study, we capitalised on one of the largest DNM catalogues, consisting of approximately 11,000 trios from the Genomics England initiative, to investigate the role of common variants in modifying the DNM rate. We carried out a genome-wide association study for DNM rate in mothers and fathers separately and combined. The SNP heritability, as estimated by LD score regression, was not significantly different from zero, and no genome-wide significant hits were obtained. However, recent work has shown that a polygenic score (PGS) for age of menopause (which is linked with DNA repair and depletion of the ovarian reserve) is significantly associated with decreased DNM rate in mothers (Stankovic et al., 2022), suggesting there is a polygenic contribution at least in females, but that the heritability may just be too low to detect at this sample size. We then tested for associations between DNM counts and PGSs for 82 complex traits, including cancers, as well as other non-cancer diseases, and non-disease continuous phenotypes.

We found that both parents PGSs for reproductive tract malignancies, such as ovarian and cervical cancers, were significantly associated with total DNM counts per trio (p &lt 0.06, FDR 10%). PGSs for age at smoking initiation, were also nominally significantly associated with total DNM counts (p &lt 0.06, FDR 10%), suggesting that earlier initiation of tobacco use may contribute to an increased DNM rate.

In summary, we present exploratory analyses investigating the role of common genetics in modifying the DNM rate, finding that the SNP heritability is not significantly different from zero. However, we found suggestive evidence that PGSs for certain cancers and for smoking initiation are associated with DNM rate, which we now seek to replicate in an independent sample.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1476 Exploring the genetic basis of Leukodystrophies in resource-poor settings through an in-house targeted panel approach

Authors:

Y. Sharma[1], A. G. Saini[1], P. Bhatia[1], S. Attri[2], P. Srivastava[1], N. Sankhyan[1], R. Suthar[1], V. Bhatia[1], S. Vyas[1]; [1]Postgraduate Inst. of Med. Ed. and Res., Chandigarh, India, [2]Postgraduate Inst. of Med. Ed. & Res., Chandigarh, India

Background: Leukodystrophies are a group of genetically determined neurodegenerative disorders that affect predominantly the white matter. We aimed to study the clinical, radiological and genetic features of childhood-onset Leukodystrophies by in-house genetic testing using a targeted genetic panel. **Methods**: All children with a clinico-radiological suspicion of leukodystrophy were evaluated by an in-house Ion Torrent next-generation sequencing technology. A custom gene panel was designed with the most common causes of leukodystrophies in the given setting. Genes included in the panel were *GFAP, ASPA, EIF2B1-B5, GALC, L2HGDH, DARS2, EARS2, MLC1, HEPACAM, ARSA, PSAP, SUMF1, PLP1, GJC2, RNASET2, ALDH3A2, POLR3A, POLR3B* and *ABCD1*. **Results**: Twenty two children with suspected leukodystrophies were tested by our in-house panel. Of these, 14 patients (63%) were genetically confirmed. The most common diagnoses were: X-ALD 42.85% (n=6), Vanishing-white-matter disease 21.42% (n=3), L-2-hydroxyglutaric aciduria 14.28% (n=2), Metachromatic leukodystrophy 7.14% (n=1), Alexander disease 7.14% (n=1) and POL-III related leukodystrophy 7.14% (n=1). The pathogenic variations were detected in *ABCD1*, *EIF2B5, GFAP, L2HGDH, ARSA* and *POLR3A* genes respectively. Majority of cases were males 71.42% (n=10/14). The mean age at presentation was 7.8 years (range 0.3-15 years). The common clinical features were developmental delay (100%), increased tone (60%), gait impairment (50%) and seizure (40%). Magnetic resonance imaging showed characteristic bilateral symmetrical white matter involvement in all children. **Conclusion:** The advent of next generation sequencing has helped in the early genetic confirmation and prenatal counselling for these disorders. Use of in-house targeted genetic panels help in significant cost reduction and feasibility for the patients in resource-poor settings.

Keywords: *Leukodystrophies, neurodegenerative disorders, genetic panels, pathogenic variations, next-generation sequencing*

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1477 Exploring the genetic landscape of obesity through variant-level, gene-level, sex-specific, and pathway enrichment analyses

Authors:

N. Baya[1,2,3], F. H. Lassen[1,2], B. Hill[2], S. S. Venkatesh[1,2], T. Ferreira[2], S. R. Myers[1,3], D. S. Palmer[2], C. M. Lindgren[1,2]; [1]Wellcome Ctr. for Human Genetics, Oxford, United Kingdom, [2]Big Data Inst., Univ. of Oxford, Oxford, United Kingdom, [3]Dept. of Statistics, Univ. of Oxford, Oxford, United Kingdom

Obesity, a pervasive health challenge, demands a comprehensive understanding of its genetic underpinnings. Leveraging UK Biobank's whole exome sequencing data we performed variant and gene burden analysis for three obesity-related traits (n>377,000): body mass index (BMI), waist-to-hip ratio adjusted for BMI (WHRadjBMI), and body fat percentage (BFP). Secondary analyses included six traits derived from DXA scans (android fat percentage, gynoid fat percentage, total body fat percentage, android-gynoid fat percentage ratio) and MRI scans (abdominal fat ratio, visceral adipose tissue volume). Our goal was to unravel obesity's causal mechanisms and provide novel insights into its genetic architecture.

In our variant-level analysis, we identified 643 non-synonymous genome-wide significant (GWS: $P<5x10^{-8}$) variants associated with BMI (177 variants), WHRadjBMI (270), BFP (193), gynoid fat percentage (2), and android-gynoid fat percentage ratio (1). Known obesity loci were replicated (e.g. *MC4R*, *PDE3B*, and *PLIN1*) and possible novel associations were discovered in *TRMU* (chr22:46335792:G:T, $P_{BFP}=4.9x10^{-9}$, effect allele frequency=0.89, predicted damaging missense) and *SLC17A3* (chr6:25862238:C:T, $P_{BMI}=2.1x10^{-8}$, $P_{WHRadjBMI}=2.4x10^{-8}$, $P_{BFP}=3.6x10^{-8}$, effect allele frequency=0.76). We performed a sex-differential analysis and identified 15 non-synonymous GWS variants for WHRadjBMI. All these variants lie in genes that were also significant in our sex-combined analysis, except for one variant (chr3:101347873:T:A, $P_{diff}=1.8x10^{-8}$, effect allele frequency=0.62, $beta_{female}=-0.021$, $beta_{male}=0.006$) in *SENP7*.

Next, we performed gene burden analysis and identified 20 significant genes (Cauchy combination test $P<2.5x10^{-6}$, Bonferroni correction) for BMI (6 genes), WHRadjBMI (13), and BFP (5). Four genes were significant in multiple phenotypes (*MC4R*, *PLIN4*, *HECTD4*, and *GPM6A*). To our knowledge, *GPM6A* is a novel association for BMI and BFP. The female- and male-only analyses identified 11 and 6 significant genes, respectively, including 3 genes significant exclusively in the male-only analysis (*GIGYF1*, *HERC6*, and *PLXNA2*).

Gene set enrichment analysis using curated gene sets highlighted pathways associated with WHRadjBMI including extracellular matrix organization ($P=3.1x10^{-7}$), adipogenesis ($P=1.0x10^{-6}$), and integrin signaling ($P=1.7x10^{-6}$). BFP enrichment analysis implicated cell cycle regulation, including the mitotic metaphase and anaphase pathway ($P=1.4x10^{-6}$).

Our study furthers the understanding of the genetic architecture of obesity and provides opportunities for interventions in combating this health burden.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1478 Exploring the genotypic and phenotypic significance of Polycystic Kidney Disease-2 (PKD2) variants in the UK Biobank using REVEAL

Authors:

Z. Pitluk[1], S. Sarangi[1], J. Zahiri[1], C. Guerriero[2], J. Brodsky[2]; [1]Paradigm4, Waltham, MA, [2]Univ. of Pittsburgh, Pittsburgh, PA

Polycystic Kidney Disease (PKD) is a progressive, irreversible, genetic disorder that is characterized by the development of multiple cysts within the kidney, leading to loss of function over time. There are two main types of PKD - autosomal dominant (ADPKD) and autosomal recessive (ARPKD). The former is one of the most common genetic disorders affecting 1 in every 400 to 1000 adults, while ARPKD is relatively rare, affecting 1 in 20,000 children worldwide. Management and treatment of ADPKD comes with a significant economic and societal cost, and despite several clinical studies only one medication has been approved to slow disease progression. Instead, dialysis is the only option for patients who ultimately develop renal failure. Thus, there is a need to develop novel drug targets and elucidate risk factors that could lead to early intervention with existing treatment plans. Mutations in the gene *PKD2,* which encodes polycystin-2 (PC2), have been linked with ADPKD. PC2 is a multi-pass membrane protein that functions as a cation permeable cation channel, and is involved in calcium transport and signaling in the cilia in renal epithelial cells. Previous studies uncovered associations between *PKD2* variants and ADPKD-relevant phenotypes (e.g., serum polyuria and hypertension). In this study, we furthered previous findings by exploring associations between variants of *PKD2* in whole exome sequence data from 470K individuals in the UK Biobank (UKBB) (Application ID: 51518) and ADPKD-relevant phenotypes. We utilized REVEAL, a bioinformatics platform developed by Paradigm4, to do large scale GWAS with PLINK, SAIGE, and REGENIE algorithms. We used ADPKD-relevant phecodes for more accurate case-control cohort selection, and tested hundreds of metabolomic biomarkers from the UKBB dataset. We also performed large scale linkage disequilibrium plus a burden test analysis between *PKD2* variants and related genes (e.g., *PKD1, GANAB*) to gain insights on network effects. In a complementary approach, based on our initial results, we have begun to select polymorphisms and examine the efficiency of the corresponding proteins to mature and function in yeast and mammalian cells. Preliminary data using the yeast model indicates that one polymorphism in the PC2 sequence identified in the UK Biobank affects PC2 biogenesis and/or activity. Ultimately, the objective of this work is to identify novel targets that impact PKD by employing a strategy that combines *in silico* genomic analysis with a functional candidate-based experimental yeast screen, along with studies in higher cells, that could lead to development of therapeutic strategies for PKD.

PB1479 Exploring the Gut Microbiome, Gut Metabolites, and Metabolic Pathways in Dyslipidemia; A Metagenomic Approach

Authors:

S. Raza[1], H-L. Kim[2], Y. Chang[3], S. Ryu[4], J. Cho[1], H-N. KIM[1]; [1]Samsung Advanced Inst. for Hlth.Sci. & Technology, Sungkyunkwan Univ., Seoul, Korea, Republic of, [2]Ewha Womans Univ, Seoul, Korea, Republic of, [3]Kangbuk Samsung Hosp., Seoul, Korea, Republic of, [4]Kangbuk Samsung Hosp., Sungkyunkwan Univ., Seoul, Korea, Republic of

Dyslipidemia is a complex metabolic disorder characterized by abnormal lipid profiles and an increased risk of cardiovascular diseases. Recent evidence suggests that the gut microbiome and its metabolites play a significant role in lipid metabolism and the development of dyslipidemia. In this study, we aimed to investigate the composition of the gut microbiome, gut metabolites, and associated metabolic pathways in individuals with dyslipidemia using a metagenomic approach. This cross-sectional study included 1384 adults, with 895 individuals in the dyslipidemia group and 489 healthy controls. Stool samples were collected from each participant, and metagenome sequencing was performed. Our findings revealed that four bacterial species, including *Bacteroides plebeius* and *Bacteroides stercoris*, were more enriched in the dyslipidemia group, while four species, including *Dorea longicatena* and *Bifidobacterium pseudocatenulatum*, were more abundant in the control group. Furthermore, we found 47 significantly different metabolites and 18 metabolic pathways between the two groups. Additionally, the 4 pathways were found to be more active in dyslipidemia cases, with *Bacteroides plebeius* contributing to the pyrimidine deoxyribonucleosides salvage pathway. The results of our study highlight the potential of *Bacteroides plebeius* and *Dorea longicatena* as major indicators of a distorted lipid profile. Their association with various gut metabolites and metabolic pathways could potentially play a pivotal role in unraveling the link between dyslipidemia and cardiovascular diseases. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2023R1A2C2006416).

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1480 Expression analysis of circulating miRNAs and their target genes in the pathogenesis of chronic kidney disease patients of Pakistan.

Authors:

M. Khan[1], M. Ejaz[1], A. Liaquat[2], H. Salim[1], A. Dandare[1]; [1]COMSATS Univ. Islamabad, Islamabad, Pakistan, [2]Shifa Tameer-e-Millat Univ. Islamabad, Pakistan, Islamabad, Pakistan

Micro RNAs (miRNAs) are small non-coding sequences that play potent role in regulating the gene expression. The dysregulation of gene expression can disrupt many important biological processes and pathways fostering onset of several diseases including kidney diseases e.g., chronic kidney disease (CKD). The main aim of this research was to identify and explore the potential role of miRNAs as a biomarker in prognosis, diagnosis, and treatment of CKD during both early and late stages. The possible role of miRNA in CKD pathophysiology was explored through *in silico* analysis. Datasets of gene expression profiling by array were obtained through Gene Expression Omnibus (GEO), subjected for statistical analysis in GEO2R with threshold of $p<0.05$ to identify differentially expressed genes (DEGs). miRNA associated with CKD were acquired through an extensive literature scrutinization, followed by identification of miR-DEGs and functional enrichment analysis. miR-17-5p, miR-548c-3p, miR-132-3p, miR-145-5p, miR-143-3p and miR-21 indicated strong association with CKD regulating several genes involved in GTPase activity, cascade signalling, signal transduction and regulating transcription processes. Furthermore, we found significant association of these miRNA in several pathways promoting CKD pathogenesis. Next, the relative expression of all these miRNAs and their target genes was measured through qPCR in 100 healthy controls and 150 CKD Pakistani patients to validate the results of *in silico* analysis. The *in silico* and wet lab approaches employed in this research embodies inclusive role of ascertained miRNAs and their target genes as potential biomarkers for CKD. Further research can be carried out to develop miRNAs as biomarkers to modulate the dysregulated pathways and for diagnosis of CKD in early stages.

PB1481 Expression QTL-based phenome-wide association study identifies a link between *IL6ST* and polymyalgia rheumatica

Authors:

S. Lessard[1], F. Finngen[2], K. Klinger[1], E. de Rinaldis[1], S. Khader[1], J. Sloane Lazar[1], C. Chatelain[1]; [1]Sanofi, Cambridge, MA, [2]Univ. of Helsinki, Helsinki, Finland

Understanding the pleiotropic associations of a given therapeutic target can inform on potential indication expansion opportunities. Here, we propose to incorporate eQTL in a phenome-wide association study (PheWAS) context to identify shared associations within specific tissue and cell type contexts while informing on directionality. Focusing on genes related to the IL6 receptor (IL6-R), namely *IL6*, *IL6ST*, and *IL6R*, we performed MR and colocalization analysis between 2,405 disease GWAS from FinnGen Release 10 and eQTL from 28 datasets covering 118 tissues and cell types. For a given gene, we tested all phenotypes with at least one associated variant within 250kb (*P*-value $< 1x10^{-6}$). We report gene-disease pairs with MR q-value < 0.05 and colocalization posterior probability > 0.8. We identified putative causal links between increased *IL6* expression in CD16 monocytes and increased risk of varicose veins, ischemic heart disease, coronary atherosclerosis, and atrial fibrillation (MR beta > 0), but decreased risk of allergic asthma (MR beta < 0). Similarly, *IL6R* expression in artery, colon, and esophagus was associated with increased risk of coronary revascularization, coronary atherosclerosis, and abdominal aortic aneurysm, but lower risk of lower respiratory diseases and atopic dermatitis, Finally, increased *IL6ST* expression in T cells and whole blood is predicted to increase risk of rheumatoid arthritis, systemic connective tissue disorders, polyarthropathies, other arthritis, autoimmune diseases, and polymyalgia rheumatica. These associations were driven by rs7731626 (SuSIE fine-mapping probability >0.99). In summary, our analysis captured the known associations between the IL-6R pathway and cardiovascular and immune diseases and identified a novel association between *IL6ST* and polymyalgia rheumatica (rs7731626 $P=3x10^{-10}$, beta=-0.17). *IL6ST* encodes a protein responsible for signal transduction for the IL-6R. Sarilumab, an IL-6R inhibitor, has recently been approved in the US to treat polymyalgia rheumatica. Our results provide supporting genetic evidence that blockage of the IL6-R pathway can be beneficial to treat this condition.

PB1482 Extensive sex difference in regulatory elements in the developing human cortex and their plausible role in autism.

Authors:

D. Karunakaran[1], H. Berk-Rauch[1], K. Hennick[2], R. Leonard[2], J. Mitra[1], T. Nowakowski[3], A. Chakravarti[1]; [1]NYU Sch. of Med., New York, NY, [2]UCSF - Sch. of Med., San Francisco, CA, [3]

Autism spectrum disorder (ASD) is characterized by a sex ratio of 2-4 (male:female). Genomic studies have identified numerous genes with coding and noncoding variants contributing to ASD susceptibility, however, the causes of its sex difference are unknown. We hypothesize that ASD sex differences arise from enrichment of X-linked ASD gene variation, autosomal transcription factors (TFs) modulating X-linked ASD genes, and sex-biased cis regulatory element (CRE, enhancer) activity regulating ASD gene expression. Sex bias in the epigenome can arise in two ways: differential chromatin accessibility of CREs between sexes or interactions of ASD gene enhancers with cis acting sex hormone receptor (AR, ESR1, ESR2) binding sites. Note, that there is emerging evidence of variable and sex biased expression of AR, ESR1 and ESR2 during human fetal brain development.
In this study, we characterize sex bias in chromatin accessibility in multiple tissues of the developing fetal cortex and ganglionic eminences, brain regions which contribute to ASD phenotypes, from 18 individuals using ATAC-seq. We use machine learning methods to construct epigenomic reference maps from high-quality (post QC) data for each sex. Overall, we identified 252,099 index CREs of which 244,847 (97.1%), 6,813 (2.7%) and 459 (0.2%) were autosomal, X-linked and Y-linked, respectively. Consequently, there is a paucity of CREs on sex chromosomes relative to their size. We recognize that some, not all, Y chromosome CREs may be mapping artifacts. Within each sex, we identified 215,507 CREs in 9 females and 191,140 in 7 males, showing a small (13%) but significant excess of female CREs ($P < 10\text{-}3$), mostly autosomal. Our analyses of these sex-specific reference maps reveals that ~77.5% (157,797) of the CREs are shared between sexes but significant numbers are also sex-specific: 57,710 and 33,275 in females and males, respectively. These also demonstrate a female excess. Beyond these, we tested which CREs had significantly differential accessibility between sexes. We identified 2,181 CREs with a 4-fold difference and 21,166 CREs with a 2-fold difference (FDR <1%).
These results uncover extensive sex difference in the epigenome of the developing human cortex. We are currently identifying which specific genes these sex biased CREs modulate, the degree to which they affect gene expression and whether CRE sequence variants, in ASD families from the Simons Simplex Collection, are associated with ASD risk. Additionally, we are constructing cell type-specific sex-specific epigenome maps using 10X Chromium single cell Multiome ATAC + RNA analyses from 52 individuals ranging from mid-gestation to early childhood.

PB1483 Familial Hypobetalipoproteinemia caused by concurrent protein-truncating variants in *APOB* and *PCSK9.*

Authors:

A. Albuquerque[1], M. W. Lauria[1], C. Borlido Schuffner[1], N. K. Ribeiro de Almeida[1], E. Friedman[2], L. De Marco[3]; [1]Faculdade de Med., Univ.e Federal de Minas Gerais, Belo Horizonte, 30130-100, Brazil, Belo Horizonte, Brazil, [2]The Meirav High Risk Clinic, Sheba Med. Ctr., Ramat Gan, Israel, [3]Dept.s of Surgery and Med., Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil

Introduction: Familial hypobetalipoproteinemia (FHBL) is a rare disease characterized by low LDL-C levels, lipid and lipid-soluble vitamin malabsorption, hepatic steatosis, and apparent protection from coronary artery disease. The full phenotype is associated with protein truncating variants (PTVs) in the *APOB* gene with a milder phenotype related to less deleterious sequence variants in the *APOB* and *PCSK9* genes. Here we report a patient with FHBL caused by concomitant loss of function (LOF) sequence variants in both the *APOB* and *PCSK9* genes. Subjects and methods: The proband, an asymptomatic 25-year-old Brazilian man was diagnosed with non-alcoholic steatohepatitis and fibrosis heralded by abnormal liver function tests. His family history was noted for two maternal great-uncles who died of non-alcoholic cirrhosis. Lipid profile revealed low LDL-C, HDL-C, and vitamin E. His daughter, brother, mother, and maternal grandmother also exhibited low LDL-C. Whole Exome Sequencing (WES) was performed on peripheral blood DNA from the proband. Results: WES revealed two heterozygous PTVs; one in *APOB* (p.Q1551*) and the other in *PCSK9* (C679*). The *APOB* variant was classified as Pathogenic and had a 0% allele frequency in databanks. The *PCSK9* variant was also Pathogenic and has been associated with low LDL-C. Its allele frequency in the Brazilian databank is 0.00085% despite high prevalence (0.79%) in African population (gnomAD). Conclusion: This patient exhibits two heterozygous PTV in genes involved in cholesterol metabolism, leading to low LDL-C levels and hepatic steatosis. The pathophysiology of FBHL involves ineffective packaging of LDL-C and lipoprotein reuptake due to PTVs in APOB, the ligand of the LDL receptor (LDLR). PCSK9 is a protease that degrades LDLR, hence LOF variants increase LDLR-mediated LDL-C uptake causing hypocholesterolemia. Both variants detected seemingly and in a biologically plausible manner synergistically lower LDL-C levels, accounting for the hepatic fatty acid buildup. While his very low LDL-C is protective against atherosclerotic-related diseases, it seems to cause a not yet treatable form of hepatic steatosis.

Introduction: Genomic predispositions for inflammatory bowel disease (IBD), including ulcerative colitis (UC), may have complex patterns, including both monogenic, oligogenic and highly polygenic forms. We present our findings on: 1) the effect of four different selection strategies for choosing potentially relevant genomic positions for polygenic risk score (PRS) calculations; 2) the patterns of PRS distributions among UC affected and unaffected family members; and 3) the results of screening for potential monogenic pathogenic variants. **Material and Methods**: Whole-genome sequencing data were generated for 62 individuals, including 7 UC patients, 7 family members (three families), and 48 controls. Risk positions were extracted from GWAS Catalog. PRSs were calculated using the linear weighted sum of risk alleles. Monogenic causes were screened using a commercial annotation tool. **Results**: We proved the potential of PRSs in identifying at-risk individuals, but also in selecting patients for screening of monogenic/oligogenic UC. Considering the different variant sets tested, those obtaining the widest range of genomic positions (i.e. positions associated with traits IBD, including both UC and CD), were found to have the largest discriminatory power between patients and controls. Family members have not always increased PRSs. We also identified a novel variant/gene-phenotype association, possibly causing mono-/oligogenic UC. The significance of the identified ZBP1 variant (NM_030776.3:c.3G>A) will, however, require further studies. **Conclusion**: PRSs promise breakthroughs in prevention, diagnostics and therapy of complex diseases, especially when combined with screening for monogenic genetic causes. **Grants**: This work has been supported by the Operational Program Integrated Infrastructure within project ITMS:313021BUZ3, co-financed by the ERDF; and by the Scientific Grant Agency (VEGA_2/0146/23).

PB1485 Filtering Signal From Noise: Finding Potential lncRNA biomarkers in IBD Disease Pathogenesis

Authors:

M. Kennedy Ng[1], S. Silverstein[1], C. Beasley[2], K. Darlington[1], M. Schaner[1], A. Jain[1], M. D. Long[1], E. L. Barnes[1], J. J. Hansen[1], M. Kapadia[1], J. Guillem[1], J. Stem[1], J. Calabrese[1], S. Sheikh[1], T. Furey[1]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Emory Univ., Atlanta, GA

Background Crohn's Disease (CD) and Ulcerative Colitis (UC) are two types of inflammatory bowel disease (IBD) but with different clinical presentations; this includes location of the disease, contiguity of inflammation, and complications that arise. Overall, the molecular underpinnings that drive CD and UC are not well understood. Long non-coding RNAs (lncRNAs) have been shown to play numerous regulatory roles in modifying gene expression, making them an exciting area of study. Previous studies have identified IBD-associated lncRNAs, but the study of lncRNAs has been hampered because most lncRNAs are lowly expressed and are highly tissue and context specific, leading to an incomplete annotation and a lack of replicability. **Hypothesis** We hypothesize that by implementing a framework for lncRNA discovery and robustly quantifying both known and previously unannotated lncRNAs, we can better pinpoint lncRNAs that play a role in CD pathogenesis. Specifically, our aims are to (i) discover unannotated lncRNA transcripts; (ii) accurately quantify expression levels for previously annotated lncRNAs and novel lncRNAs; (iii) identify differential expression patterns across multiple CD patient cohorts. **Methods** We used genome-guided de-novo transcript assembly and filtration pipeline to discover and quantify well-supported unannotated lncRNAs. We then added these samples to our genome reference, and quantified these transcripts along with known lncRNAs, using RNA-seq data from uninflamed colonic mucosa tissue samples from adult CD patients and non-IBD controls across multiple cohorts. We refined these lists to target lncRNAs likely to be functionally relevant; these include lncRNAs with highly conserved promoter regions, non-spurious transcriptional activity, and nucleotide similarity to well-characterized lncRNA transcripts. **Results** We identified ~4500 well-supported unannotated lncRNAs. We also identified hundreds of unannotated and known lncRNAs that are differentially expressed between CD and compared to non-IBD patients in multiple datasets, as well as many lncRNAs that stratify patients by disease activity. Based on our refinement parameters, we have discovered a handful of lncRNAs (both known and unannotated) that are not characterized in the context of IBD and have characteristics that warrant future study. **Conclusion** This work will help us better identify and understand the molecular changes that underlie IBD.

Liao[7]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Corporal Michael Crescenz VA Med. Ctr., Philadelphia, PA, [3]Palo Alto VA Inst. for Res., VA Palo Alto Heath Care System, Palo Alto, CA, [4]MAVERIC, VA Boston Hlth.care System, Boston, MA, [5]Argonne Natl. Lab., Lemont, IL, [6]Columbia Univ.'s Mailman Sch. of Publ. Hlth., New York, NY, [7]VA Boston Hlth.care System, Boston, MA, [8]Oak Ridge Natl. Lab., Dept. of Energy, Oak Ridge, TN, [9]Harvard Med. Sch., Boston, MA, [10]Dept. of VA, Washington, DC, [11]VAPAHCS/Stanford Univ., Palo Alto, CA, [12]Children's Hosp. of Philadelphia, Philadelphia, PA

Though genome-wide association studies (GWAS) have accelerated our understanding of the phenotypic and biological consequences of genetic variation across the genome, a significant diversity gap exists in the characterization of genetic architecture due to historical overrepresentation of individuals genetically similar to European (EUR) reference populations. In contrast to most GWAS cohorts, the Department of Veteran Affairs (VA) Million Veteran Program (MVP) consists of nearly 30% representation from non-EUR populations. This study was performed as part of a larger effort to detect genetic associations across 2,070 phenotypes obtained from linked electronic health records (EHR) and questionnaires in 635,969 MVP participants genetically similar to African (AFR, n=121,177), Admixed American (AMR, n=59,048), East Asian (EAS, n=6,702), and EUR (n=449,042) reference superpopulations from the 1000 Genomes Project. Fine-mapping was performed on 1,257 phenotypes in which one or more significant loci were detected in a multi-population meta-analysis (P-value < 4.6×10^{-11}). Employing the Department of Energy's (DOE) Andes supercomputer, in-sample linkage disequilibrium (LD) reference panels, the Sum of Single Effects (SuSiE) framework, and a previously developed multi-population signal merging approach, we fine-mapped 57,601 signals, ~25% of which were fine-mapped to a single variant. Among the signals, we identified 2,069 variant-phenotype associations mapped with high confidence (posterior inclusion probability > 0.95) exclusively in non-EUR populations. These included novel variants, such as rs7338263 which associates with a lower white blood cell (WBC) count in AFR only, informing longstanding epidemiologic observations of lower WBC in AFR relative to EUR populations. We additionally observed high-confidence fine-mapped variants with different effects across populations; rs429358 at the *APOE* locus, for example, had a significantly larger effect on risk of dementia in EUR compared to the non-EUR populations, supporting findings from prior multi-population studies. Our findings represent a significant advance in understanding the genetic architecture of complex human traits in non-EUR populations and highlight the need and possible benefit of further expanding participation in GWAS efforts among these groups. Furthermore, this collaboration between the VA and DOE has significantly expanded the corpus of fine-mapped genotype-phenotype associations available to the global research community.

Coll., Jammu, Jammu and Kashmir, Jammu, India, [8]Dept. of Radiology, Chest Disease Hosp., Bakshi Nagar, Jammu, Jammu and Kashmir, Jammu, India, [9]Sch. of Biotechnology, Shri Mata Vaishno Devi Univ., Katra, Jammu and Kashmir, Katra, India, [10]Shri Mata Vaishno Devi Univ., Katra, India, [11]Ctr. for Molecular Biology, Central Univ. of Jammu, India, Samba, India

Scoliosis is the bending and twisting of the spine occurring at any age. Adolescent Idiopathic Scoliosis (AIS) is the most prevalent among all other types of scoliosis, with a worldwide prevalence of approximately 2-3%. Surprisingly, no genetic study on AIS was conducted in any Indian population.Blood/saliva samples were collected from 113 clinically confirmed (through anteroposterior X-ray) AIS cases, and 500 non-AIS controls were recruited in the study after obtaining ethical clearance from the Institutional Ethics Review Board at Shri Mata Vaishno Devi University and All India Institute of Medical Sciences in New Delhi. All the samples were genotyped in the population of North-west India using Infinium Global Screening Array-24 v3.0 chip. A total of 1163 SNPs were genotyped in 14 previously reported candidate Genes/regions (*AJAP1, MATN1, PAX3, VDR, SOX9, BCL2, DOT1L, PAX1, LBX1, COL6A3, FBN1, FBN2, COL11A2,* and *CALM1*). The Bonferroni correction threshold was set at 0.000043 based on the total number of variants. The statistical analysis was performed using PLINK v1.07, 1.09, R programming, IBM SPSS v 23, and Linux shell scripting. The functional role of the genes/variants was further evaluated using FUMA GWAS, MSigDB, and Cytoscape v 3.9.1 bioinformatic tools and databases.This genetic study has highlighted an association of newly identified variants of developmental and bone morphogenetic pathway genes, namely *AJAP1, BCL2, SOX9, COL6A3,* and *FBN2*, with AIS risk in North-west India. The present study found an association between the *SOX9* variant; rs74898711, rs9302936, and rs9900249, *AJAP1* variants; rs141899425, rs11591221, and rs7517857, *BCL2* variant; rs11591221, *COL6A3* variant rs77009782, and *FBN2* variant rs17697567, was found to pose an increased risk to AIS among the Northwest Indian population. All the associated variants followed the Hardy-Weinberg Equilibrium (HWE) within the control population dataset. The variants were found to lack functional significance at the protein or gene expression level. While the associated genes were found to play a crucial role in the musculoskeletal system. The gene enrichment analysis has demonstrated the role of *SOX9, FBN2,* and *COL6A3* in bone formation, mineralization, and endochondral ossification. The findings suggest that *AJAP1, BCL2, SOX9, COL6A3,* and *FBN2* genes are associated with increased AIS risk predisposition in the Northwest Indian population. Therefore, it can be inferred that these genes play a significant role in the pathogenesis of AIS in this population, and this study also strengthens the hypothesis of genetic heterogeneity among different populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1488 Fish oil supplementation modifies the genetic potential for blood lipids and cardiovascular disease

Authors:

Y. Sun, T. McDonald, A. Baur, H. Xu, N. Bateman, Y. Shen, K. Ye; Univ. of Georgia, Athens, GA

Dyslipidemia is well-known to be a risk factor for cardiovascular disease (CVD), which has been the leading cause of mortality worldwide. Although habitual intake of fish oil has been implicated in offering modest cardioprotective effects through triglyceride reduction, the interactions of fish oil with the genetic predisposition to dysregulated lipid profiles and CVD risk remain elusive. A total of 441,985 participants of predominantly European ancestry with genetic and complete data from the UK Biobank were included and prospectively followed up to 2023. Polygenic risk scores (PRS) were calculated in participants of diverse ancestries, and a higher PRS indicates a higher genetic susceptibility to elevated lipid levels or CVD risk. Multivariable linear regression models or multivariable Cox proportional hazards regression models were used to assess associations with adjustment for relevant risk factors. Fish oil supplementation mitigated genetic susceptibility to elevations in total cholesterol, low-density lipoprotein cholesterol (LDL-C), and triglycerides, while it amplified genetic susceptibility to increased high-density lipoprotein cholesterol (HDL-C) among 424,090 participants of European ancestry ($P_{\text{interaction}} < 0.05$). Consistent significant findings were obtained using PRS calculated based on multiple genome-wide association studies or alternative PRS methods. We also detected that fish oil significantly attenuated genetic predisposition to high triglycerides among African ancestry participants. During an average of 13.4 years of follow-up, there were 1,854 coronary artery disease (CAD) deaths, 3,577 CVD deaths, 23,327 incident CAD cases, and 28,417 incident CVD cases. Although fish oil was significantly associated with lower CAD and CVD mortality and incidence rates, it did not alter genetic predisposition to CAD and CVD mortality or incidence. In categorical analyses, the multivariable adjusted hazard ratios (HR) for CAD mortality among individuals with higher PRS (greater than/equal to the median score) were 0.71 (95% confidence interval 0.62-0.81) for those consuming fish oil versus non-users and 0.86 (0.73-1.01) among those with lower PRS; multivariable HR for CVD incidence were 0.94 (0.91-0.97) for higher PRS and 0.99 (0.95-1.03) for lower PRS. Fish oil supplementation attenuated the genetic potential for elevated blood levels of total cholesterol, LDL-C, and triglycerides, while accentuating genetic susceptibility to higher HDL-C. Moreover, we detected that there might be a more pronounced protective effect of fish oil supplementation on CAD mortality and CVD incidence in people at high genetic risk.

PB1489 Functional dissection of putative heart enhancers implicated in left ventricle function and cardiomyopathy

Authors:

Z. Weber[1], T. Monroe[2], E. McNally[3], M. Nobrega[1]; [1]Univ. of Chicago, Chicago, IL, [2]Northwestern Univ., Chicago, IL, [3]Northwestern Univ, Chicago, IL

Inherited cardiomyopathies have long been thought to be Mendelian disorders, driven by highly penetrant, rare coding mutations; albeit with variable clinical expressivity. Recently, with biobank-scale genetic cohorts, genome-wide association studies (GWAS) have suggested a more oligogenic trait liability underlying the inheritance and expressivity seen in the clinical environment. Although several novel loci have been implicated in GWAS of cardiomyopathies, most of these loci have not been experimentally validated, and the relatively rare nature of these disorders has limited the power of GWAS to further resolve candidate causal variants. As cardiomyopathies tend to manifest as extreme ends of diastolic and systolic heart dysfunction, we leveraged a well-powered cardiac MRI cohort in the UK Biobank to investigate loci implicated in inherited cardiomyopathies. To this end, we conducted GWAS in three left ventricle phenotypes: End-Diastolic Volume (LVEDV), End-Systolic Volume (LVESV), and Ejection Fraction (LVEF) and jointly meta-analyzed these trait associations using Multi-Trait Analysis of GWAS (MTAG). Results of the MTAG analysis and subsequent functionally informed fine-mapping prioritized two loci of interest, whose signals appear to result from variation in cardiac enhancers. The first signal appears to intersect a large enhancer complex downstream of WNT7a and upstream of SLC6A6 at the chr3p25.1 locus. This locus has been implicated in previous GWAS of dilated cardiomyopathy, but has yet to be validated experimentally. Furthermore, rare variants in the gene encoding taurine transporter SLC6A6 have been reported to cause childhood onset cardiomyopathy and retinal degeneration. We also identified a novel genome-wide association signal in a putative upstream enhancer of BAG3 at the chr10q26.1 locus. Rare variants in BAG3 are also known to cause inherited dilated cardiomyopathy -suggesting that this signal may be a promising candidate for further investigation. To experimentally interrogate these loci we developed a variant to function strategy for testing these enhancers for their potential effects on gene expression and myocardial function in iPSC-derived cardiomyocytes and engineered heart tissues. Using haplotype-resolved reporter assays and CRISPR engineered models, we can not only test whether enhancer variation is the likely source of these association signals, but can also probe potential epistatic effects between enhancer variants and rare-coding variants, and examine pleiotropic effects across cardiac development, contributing to our evolving understanding of complex trait liability in cardiomyopathies.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1490 Functionally informed fine-mapping of glycaemic trait loci improves fine-mapping resolution compared to an agnostic approach.

Authors:

J. Soenksen[1], J. Chen[1], A. Varshney[2], S. Martin[1], S. Parker[3], J. Asimit[4], A. Morris[5], I. Barroso[1], MAGIC; [1]Exeter Ctr. of Excellence for Diabetes Res. (EXCEED), Univ. of Exeter Med. Sch., Exeter, United Kingdom, [2]Univ. of Michigan, Canonsburg, PA, [3]Univ. of Michigan, Ann Arbor, MI, [4]MRC Biostatistics Unit, Cambridge, United Kingdom, [5]Univ. of Manchester, Manchester, United Kingdom

Introduction: Previously, the Meta-Analysis of Glucose and Insulin-related traits consortium (MAGIC) reported 242 loci associated ($P<5x10^{-8}$) with glycaemic traits 2h-Glucose (2hGlu), fasting glucose (FG), fasting insulin (FI) and glycated haemoglobin (HbA1c). However, at most locus-trait associations the underlying causal variant(s) remained unknown. To help narrow down the number of potential causal variants at these loci, we previously employed multi-trait fine-mapping with flashfm. This improved fine-mapping resolution in 99/116 locus-trait associations compared to single trait fine-mapping with FINEMAP. The median 99% credible set (99CS) size reduced from 50 to 19 SNPs ($p=2.2x10^{-16}$).
Aim: To further improve fine-mapping resolution by incorporating functional annotations.
Methods: We used fGWAS v.0.3.6 to build a model of enriched annotations by testing 28 static annotations, including conserved regions and 32 cell-type specific annotations such as stretch enhancers in islets. We used the resulting enrichments to calculate prior probability of causality for each SNP, and then used FINEMAP v1.4 to calculate posterior probabilities and credible sets accounting for 99% of the posterior probability of being causal (99CS).
Results: In agreement with previous results, we found that static annotations such as coding or conserved regions were enriched across multiple glycaemic traits (FG, 2hGlu and HbA1c) whilst cell-type specific annotations varied across traits. FG and 2hGlu results were enriched for islet stretch enhancers, while FI was enriched for adipose-specific stretch enhancers. The median 99CS size improved from 40 SNPs in functionally-agnostic fine-mapping to 30 in functionally-informed fine-mapping ($P=3.6x10^{-13}$) when looking at loci predicted to have a single causal variant. The number of locus-trait associations with 10 or less SNPs in the 99CS improved from 32 to 39, and the number of locus-traits with 1 SNP in the 99CS improved from 3 to 6.
Conclusion: Incorporating functional information into fine-mapping can reduce 99CS size compared to agnostic approaches. In the future, we will incorporate these priors and take advantage of the correlation between traits in multi-trait fine-mapping with flashfm to further improve fine-mapping resolution.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1491 *G6PD* genetic variants prevalent in British Africans and British South Asians: Under-identification of G6PD deficiency leads to delayed diagnosis of type 2 diabetes and reduced time to diabetes complications

Authors:

S. Martin, J. Chen, T. J. McKinley, K. G. Young, H. Green, G. Hawkes, R. N. Beaumont, A. R. Wood, I. Barroso; Univ. of Exeter, Exeter, United Kingdom

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked genetic disorder where a mutation of the protein produced by the *G6PD* gene causes haemolytic anaemia and leads to reduced red blood cell lifespan. The *G6PD* variant rs1050828, common in African Americans, is known to be associated with a corresponding reduction in glycated haemoglobin (HbA1c) levels independently of blood glucose. We aimed to determine how prevalent this and other *G6PD* variants are in the UK population, how many carriers are recorded as having G6PD deficiency, and the effect these variants have on age of type 2 diabetes diagnosis as well as time to diabetes complications.

We used whole-exome sequencing data from the UK Biobank to identify pathogenic variants for the *G6PD* gene, determining carrier status of these for 7394 individuals genetically identified as British African (AFR) and 9541 British South Asian (SAS), with 42% and 53% males respectively. Using electronic health records, we identified how many carriers were diagnosed with G6PD deficiency and/or haemolytic anaemia. HbA1c and fasting glucose (FG) were compared between carriers and non-carriers for individuals with no diagnosis of diabetes. Next, we identified individuals with a new diagnosis of type 2 diabetes since 2011, when HbA1c became the standard diabetes screening assay in the UK, and compared age of diagnosis and time to diabetic retinopathy and/or nephropathy between carriers and non-carriers. A dominant model was assumed in all analyses.

We identified 141 missense and 2 loss-of-function *G6PD* variants that we defined as pathogenic, 63 of which were singletons. The prevalence of carriers for at least one *G6PD* variant was 17% and 30% in AFR men and women respectively, and 4% and 7% in SAS. Despite this prevalence, 91% of AFR men and women are not diagnosed with either G6PD deficiency or haemolytic anaemia, with 100% and 96% in SAS men and women. In individuals without diabetes, HbA1c was on average 6.4mmol/mol lower in carriers compared to non-carriers in AFR and SAS ($p<5E-18$), while no difference was observed in FG. Carriers were on average diagnosed with type 2 diabetes 7.4 years later than non-carriers in AFR men ($p=0.02$), and diabetes complications arose 1.7 years earlier in SAS men ($p=0.04$). Our results were consistent when using only the rs1050828 variant in AFR.

Our results show that despite *GP6D* variants being common in British Africans and South Asians, the majority of carriers are not identified as having G6PD deficiency. Such misidentification may lead to delayed type 2 diabetes diagnosis with faster progression to diabetes complications, further increasing existing health inequities in these population groups.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1492 Genealogy-based Investigation of Epilepsy Genetics

Authors:

J. BOULBES[1], C. Moreau[1], P. Cossette[2,3], H. Vézina[1,4], S. Girard[1,5]; [1]UQAC, Chicoutimi, QC, Canada, [2]Université de Montréal, Montréal, QC, Canada, [3]Ctr. de recherche du CHUM, Montréal, QC, Canada, [4]Projet BALSAC, Chicoutimi, QC, Canada, [5]Ctr. de recherche CERVO, Québec, QC, Canada

Epilepsy is a neurological disorder characterized by temporary dysfunction of the brain, resulting in abnormal, excessive, or synchronized neuronal activity. It is estimated that 30% of epilepsies have a genetic cause, and there are over 500 potentially involved genes in the onset of epilepsy. However, a large portion of the heritability of these genes is missing or unexplained. Our objective is to develop a method for identifying and analyzing genetic changes related to the transmission and genetics of epilepsy at the scale of Quebec and to fill in this gap in information regarding heritability. We have access to a Quebec cohort of 348 epilepsy patients, their genotypes, and their deep genealogies. The current population of Quebec is the result of founder effects that have greatly influenced its genetic structure. By studying genotypes in conjunction with genealogical data, we can investigate the transmission of complex diseases with greater precision. An analysis of the number of recent common ancestors (MRCA) among pairs of patients and by region has allowed us to identify genealogical clusters. Genealogical kinship allows us to group families with affected individuals and determine the genealogical proximity between these patients which would not be possible using only 2-3 generations' pedigrees. A differential MRCA matrix of patients/controls enables us to identify a difference in population structure between the population and patient families. Finally, the genotype data will help us identify the identity-by-descent segments (IBD) transmitted within the identified family clusters. This study will enhance our understanding of the transmission of epilepsy-related genes at the individual, family, and regional levels in Quebec, thereby limiting bias related to population structures and identifying new responsible genes while furthering knowledge of the heritability of a complex disease, namely epilepsy.

PB1493 Gene-Environment Interactions and Their Impact on Nonalcoholic Fatty Liver Disease in Mexican Americans: Insights from south Texas.

Authors:

E. Manusov[1], V. P. Diego[2], X. Mao[2], M. Almeida[2], A. Leandro[2], S. Laston[2], J. Blangero[2], S. Williams-Blangero[2]; [1]One West Univ. Boulevard, Brownsville, TX, [2]Univ. of Texas Rio Grande Valley, Brownsville, TX

Background: Nonalcoholic fatty liver disease (NAFLD) is a chronic liver condition influenced by genetic, cellular, and environmental factors. Depression is associated with NAFLD, suggesting an interaction between genetic factors and depression in developing hepatic fibrosis. We investigated the association between ADAMTS7 gene variations and Beck Depression Inventory-II (BDI-II) scores, Alanine Aminotransferase (ALT), Aspartate Aminotransferase (AST), and Controlled Attenuation Parameter (CAP) values in Mexican Americans with NAFLD. Previous studies have linked ADAMTS7 gene variations to an increased risk of NAFLD and hepatic fibrosis, making it a potential genetic marker for identifying at-risk individuals, particularly among Mexican Americans. **Methods**: We included 279 Mexican American participants from a south Texas community. We measured hepatic fibrosis (Vibration Controlled Transient Elastography-VCTE), liver steatosis (Controlled Attenuation Parameter-CAP), Alanine Aminotransferase (ALT), Aspartate Aminotransferase (AST), and depression (Beck Depression Inventory-BDI-II). RNA sequencing was performed using the Illumina Novaseq 6000 platform. Gene-by-Environment (GxE) decomposition analysis was conducted to estimate heritabilities and GxE interactions. Transcript identification was made using Kallisto software against the UCSC hg19 reference transcriptome. **Results**: We found significant associations between ADAMTS7 gene variations and BDI-II scores, ALT, AST, and CAP values. These findings support the role of genetic factors interacting with depression in influencing hepatic fibrosis in Mexican Americans with NAFLD. **Discussion**: ADAMTS7, a gene involved in inflammation and Extracellular Matrix (ECM) regulation, emerges as a candidate gene implicated in liver fibrosis, lipid metabolism, coronary artery disease, and depression. The GxE interactions identified in this study provide insight into the complex interplay between NAFLD, depression, and genetic factors. **Conclusion**: Our study highlights the importance of GxE interactions in NAFLD and depression among Mexican Americans. The associations between ADAMTS7 gene variations, depression, and liver disease provide valuable insights into the inflammatory theory of depression and its impact on NAFLD. Further research is needed to elucidate the underlying molecular mechanisms and pathways and identify additional candidate genes contributing to these interactions.

PB1494 Generalizability of Alzheimer's disease plasma biomarkers of phospho-Tau and beta amyloid in individuals of diverse genetic ancestries

Authors:

A. Griswold[1], F. Rajabli[1], T. Gu[1], C. Garcia-Serje[1], J. Arvizu[1], C. Golightly[1], P. Whitehead[1], K. Hamilton-Nelson[1], L. Adams[1], K. Celis[1], J. Sanchez[1], S. Tejada[1], P. Mena[1], T. Starks[2], M. Cornejo-Olivas[3], M. Illanes-Manrique[3], C. Silva-Vergara[4], M. Cuccaro[1], J. Vance[1], B. Feliciano-Astacio[4], G. Byrd[2], G. Beecham[1], J. Haines[5], M. Pericak-Vance[1]; [1]Univ. of Miami, Miami, FL, [2]Wake Forest Sch. of Med., Winston-Salem, NC, [3]Inst. Natl. de Ciencias Neurologicas, Lima, Peru, [4]Univ. Central del Caribe, Bayamon, PR, [5]Case Western Reserve Univ, Cleveland, OH

Background: Plasma concentrations of phosphorylated threonine-181 of Tau (pTau181) and the ratio of amyloid beta isoforms Aβ42/Aβ40 are biomarkers for differential diagnosis and preclinical detection of Alzheimer disease (AD). However, measurement of these biomarkers is mostly from individuals of non-Hispanic, European ancestry. Given differences in AD risk, generalizability of these findings is not assured in individuals of diverse ancestry. Here we evaluate the utility of plasma pTau181 and Aβ42/Aβ40 in discriminating clinically diagnosed AD from cognitively intact, age-matched controls in ancestrally diverse, admixed cohorts. **Method:** We measured plasma pTau181 and Aβ42/Aβ40 with Simoa chemistry using the pTau181 AdvantageV2 and NEUROLOGY 3-PLEX A assays, respectively. Our cohorts consisted of: 642 African Americans (162 AD and 480 cognitively intact (CI)), 906 Puerto Ricans (385 AD and 521 CI), 149 Peruvians (49 AD and 100 CI), 60 Cubans (26 AD and 34 CI), and 246 non-Hispanic, European ancestry (22 AD and 224 CI). Linear mixed-effect regression models adjusted for age, sex, population substructure and relatedness followed by Bonferroni correction was applied to identify differences across AD status. Diagnostic performance and construct receiver operator characteristic (ROC) curves were created from logistic regression models. **Result:** Plasma pTau181 concentrations were increased in individuals with AD compared to CI ($p < 2x10^{-16}$) taking into account all individuals and in each cohort separately (African Americans, $p = 1.2x10^{-9}$; Puerto Ricans, $p=7.6x10^{-9}$; Peruvians, $p=0.02$), and European ancestry, $p=2.2x10^{-8}$) except for the Cubans where there was a trend. There was no significant difference in the plasma Aβ42/Aβ40 ratio, however there was a trend towards a decreasing concentration in AD. Using the area under the ROC, pTau181 was more accurate at predicting status than the Aβ42/Aβ40 ratio, but the classification improved when both biomarkers were combined. The accuracy varied widely over the individual cohorts with AUC from 0.845 for African Americans to 0.683 for Peruvians. **Conclusion:** These results suggest AD biomarkers are generalizable across ancestries, though the predictive value may differ depending on specific ancestral backgrounds. Ultimately, combining genomic and biomarker data from diverse individuals will increase understanding of genetic risk and refine clinical diagnoses in individuals of diverse ancestries

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1495 Genes and Cognition study, a recallable cohort to study Dementia/Alzheimer's disease

Authors:

M. Rahman[1], S. Hill[2], B. Tom[1], P. Chinerry[1]; [1]Univ. of Cambridge, Cambridge, United Kingdom, [2]Univ. of Manchester, Manchester, United Kingdom

Background: Decades of research have not resulted in a cure for dementia/Alzheimer's disease (AD). Most treatments have failed to benefit patients in clinical trials, potentially due to treatment being provided too late when brain damage is irreversible. There is an urgent need to understand the disease mechanism at the preclinical and prodromal stages of AD, which requires early identification of participants at risk of AD.
Method: We attempt to address this need by establishing an open cohort named Genes and Cognition (GC), nested within NIHR Bioresource (https://bioresource.nihr.ac.uk/) and comprising 21,051 healthy people aged 17-85 who consented to be recalled for follow-up studies. Participants took 11 cognitive tests (CTs) covering various domains of cognition. We examined the association between CT scores and demographic characteristics, explored phenotypic and genotypic correlations between CTs, and estimated SNP-based heritability. In addition, AD polygenic risk (high vs low) was determined in 10,038 participants using 20 single nucleotide polymorphisms (SNPs) from Lambert et al. (PMID:24162737) to identify the earliest age with a noticeable score difference in CTs.
Result: CT scores (higher score indicates poorer performance) were associated with age and gender differences were significant for each CT score. Significant linear trends were observed between CTs and educational attainment. Genetic correlations between tests were stronger than the phenotypic correlations. SNP-heritability for CTs and general cognitive ability ranged from 8-28%. We observed that three CTs (Reaction Time, Stroop Box, Stroop Ink) began deviating around age 55 between high ($\geq 96^{th}$ percentile) and low ($\leq 95^{th}$ percentile) AD polygenic risk groups, although not significant. Similar deviations in some CTs were observed among *APOE* E4 allele carriers compared to E3/E3 carriers. However, AD risk groups determined without including the *APOE* region indicated such deviation after age 65.
Conclusion: We presented preliminary findings for the GC study cohort. Our results suggest that AD polygenic risk measured with or without *APOE* region may be less beneficial than the two *APOE* SNPs (*rs429358* and *rs7412*) alone for the early identification of AD. Repeated CT measures would shed more light on this observation; therefore, we aim to investigate this with CTs repeated at two years intervals.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1496 Gene-Sleep Duration Interactions in the Genetic Architecture of Blood Pressure

Authors:

H. Wang[1], P. Nagarajan[1], R. Noordam[2], A. Bentley[3], A. Giri[4], H. Chen[5], W. Gauderman[6], A. Hung[4], T. Winkler[7], S. Redline[1], CHARGE Gene-Lifestyle Interactions Working Group; [1]Brigham and Women's Hosp., Harvard Med. Sch., Boston, MA, [2]Leiden Univ. Med. Ctr., Leiden, Netherlands, [3]NIH, Bethesda, MD, [4]Vanderbilt Univ. Med. Ctr., Nashville, TN, [5]The Univ of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [6]Univ of Southern California, Los Angeles, CA, [7]Univ. of Regensburg, Regensburg, Germany

Sleep duration may affect blood pressure traits, involving dysregulation of the sympathetic nervous system, endothelial dysfunction, or inflammation. To test the modification effect of sleep duration on the genetic variants for blood pressure, we conducted large-scale gene-by-short- and long-sleep duration interaction analyses on 3 blood pressure (BP) traits (systolic BP, diastolic BP, and pulse pressure [PP]). Analyses included a sample size of 810,724 individuals (6% African [AFR], 4% Hispanic/Latino [HIS], 6% East Asian [EAS], 83% European [EUR], 1% South Asian [SAS]) from 37 cohorts including the Million Veteran Program and the UK Biobank. Cohort-specific genome-wide interaction analyses were meta-analyzed using a 2 degree of freedom (df) joint test of main and interaction effects and a 1df interaction test within each population group. Significant BP loci were identified using genome-wide significance criteria (P_{2df} or $P_{1df} \leq$5e-9). Variants with marginal significance for the main genetic effect (P≤10e-5) were further followed up to identify significant interaction effects (Bonferroni $P_{1df} \leq 0.05$ accounting for the number of independent SNPs). Our preliminary results identify 940 previously reported BP loci and 10 novel loci, including and 8 novel loci in HIS (*HTR1F* and *SDK1* for SBP; *CTNNA3* and *CRBN* for DBP; *PAK5, KCNJ3, WWOX* and *PRMT6* for PP), 1 novel locus in AFR (*BRINP3* for PP), and 1 novel locus in EUR (*RPL39L* for PP) We expect to identify additional novel findings in the cross-population meta-analysis and will interpret findings through bioinformatics. While further work is ongoing, these preliminary results support the use of gene-by-sleep duration interactions to identify novel BP loci.

PB1497 Genetic analyses of inflammatory polyneuropathy and chronic inflammatory demyelinating polyradiculoneuropathy identified candidate genes.

Authors:

Z. Du, S. Lessard, T. Iyyanki, M. Chao, T. Hammond, D. Ofengeim, K. Klinger, E. de Rinaldis, S. Khader, C. Chatelain; Sanofi US Services Inc., Cambridge, MA

Objective: Chronic inflammatory demyelinating polyneuropathy (CIDP) is a rare, immune-mediated disorder in which an aberrant immune response causes demyelination and axonal damage of the peripheral nerves. Genetic contribution to CIDP is unclear and no genome-wide association study (GWAS) has been reported so far. In this study, we aimed to identify CIDP-related risk *loci*, genes, and pathways. Methods: To boost power, we first included all patients with a diagnosis of inflammatory polyneuropathy (IP) as cases. We performed a GWAS study using Finngen R10 individual data and combined the results with GWAS summary statistics from UK biobank (UKBB) using a fixed-effect meta-analysis. A total of 1,261 cases and 823,730 controls were included in the analysis. The second GWAS focused on CIDP patients and a total of 516 cases and 403,545 controls were included in the analysis. Stratified analyses by gender were also performed for both IP and CIDP. We performed gene-level analyses using transcriptome-wide mendelian randomization (TWMR) analysis, colocalization analysis, transcriptome-wide association study (TWAS) using S-PrediXcan and MAGMA to identify genes associated with IP and CIDP. Gene-set analyses were conducted using MAGMA to identify pathways that are related to IP and CIDP. Results: In GWAS study, we identified one genome-wide significant *loci* for CIDP risk among women. TWMR, colocalization and S-PrediXcan analyses identified four candidate pathogenic genes for IP; three candidate pathogenic genes for CIDP; three candidate pathogenic genes for IP among males; and two candidate pathogenic genes for IP among women. MAGMA gene-set analyses identified a total of 18 pathways related to IP or CIDP. Conclusion: Our study identified suggestive risk genes and pathways for IP and CIDP. Functional analysis will be conducted to further confirm these associations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1498 Genetic and embryonic transcriptomic analyses revealed the molecular basis of Mayer-Rokitansky-Küster-Hauser syndrome.

Authors:

X. Cheng[1], S. Zhao[2], N. Chen[1], H. Zhao[1], Y. Zhang[3], Z. Zhao[1], G. Li[1], K. Xu[1], J. Cai[1], Q. Li[1], N. Wu[1], L. Zhu[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]Baylor Coll. of Med., Houston, TX, [3]Wenzhou Med. Univ., Wenzhou, China

Background: Mayer-Rokitansky-Küster-Hauser syndrome (MRKHS), a congenital anomaly affecting the female reproductive system, is characterized by the aplasia of the uterus, cervix, and upper portion of the vagina. The etiology of MRKHS could be attributed to genetic perturbation during uterine development. Despite its clinical significance, a comprehensive understanding of MRKHS remains limited with the absence of single-cell transcriptomic analysis of the embryonic uterus, as well as the lack of systematic genetic association study.
Methods: Gene-level and pathway-level burden analyses were conducted based on exome sequencing/genome sequencing data from 727 probands with MRKHS and 2504 female control individuals. To gain more insight into the role of MRKHS-associated genes in the developing uterus, we performed single-cell transcriptome sequencing (scRNA-seq) on the metanephros of human and mouse embryos at different embryonic stages. Integration analyses of genetic and transcriptome data were employed to elucidate the intricate processes underlying uterine development.
Results: On the gene level, we identified five genes at an exome-wide significance (false discovery rate [FDR] < 0.05), including three previously reported genes (*PAX8*, *BMP7*, *GREB1L*) and two novel genes (*PAN2*, *AGPAT2*). In the human metanephros, scRNA-seq data indicated that the expression of MRKHS-associated genes ($P < 0.01$) was significantly enriched in the w8 uterine epithelium and the w11 Wolffian duct (WD) epithelium. Consistently, the expression in mouse metanephros was marginally enriched in the E14.5 WD and E18.5 Müllerian duct (MD) epithelium. Enrichment analysis and hierarchical clustering aided the prioritization of suboptimal genetic signals (e.g. *MT1F*). On the pathway level, two top hits were 'regulation of apoptotic process involved in development' (GO:1904748, P = 1.14E-06) and 'mesenchymal-to-epithelial transition involved in metanephros morphogenesis' (GO:0003337, P = 7.91E-06), consistent with their essential roles in the formation and morphogenesis of the female reproductive tract. Further analysis of cell type-specific driver genes revealed that dynamic driver genes of MD epithelium harbored the most significant mutational burden in patients. Notably, the digenic combination analysis identified three combinations reaching exome-wide significance, indicating potential digenic inheritance modes of MRKHS with co-expression evidence.
Conclusion: Our study uncovered the complex genetic factors associated with MRKHS and delineated their biological relevance in the context of the single-cell transcriptome of the embryonic uterus.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1499 Genetic and phenotypic association analyses of cardiometabolic traits in diverse African samples with whole-genome sequencing data.

Authors:

D. Hui[1], M. Hansen[1], D. Harris[1], M. McQuillan[1], D. Ju[1], A. Platt[1], W. Beggs[2], W. Sununguko Mpoloka[3], G. Mokone[3], G. Belay[4], T. Nyambo[5], S. Chanock[6], M. Yeager[7], TOPMed Consortium, G. Sirugo[1], M. Ritchie[8], S. Williams[9], S. Tishkoff[10]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Univ Pennsylvania, Philadelphia, PA, [3]Univ. of Botswana, Gaborone, Botswana, [4]Addis Ababa Univ., Addis Ababa, Ethiopia, [5]Muhimbili Univ. of Hlth.and Allied Sci., Dar es Salaam, Tanzania, United Republic of, [6]Natl. Cancer Inst, Rockville, MD, [7]FNLCR/NCI, Rockville, MD, [8]Univ. OF PENNSYLVANIA, Philadelphia, PA, [9]Case Western Reserve Univ, Cleveland, OH, [10]Univ. of Pennsylvania Sch. of Med., Penn Valley, PA

African populations demonstrate exceptional genetic and phenotypic diversity, due in part to their varied environments, lifestyles, and demographic history. We conducted genetic and phenotypic association analyses in 6,965 geographically and ethnically diverse Sub-Saharan African individuals (6,280 with whole-genome sequences from the NIH TOPMed consortium and 685 with genotypes from Illumina arrays), using 15 cardiometabolic phenotypes (range 686-6,854 individuals/trait). Each phenotype had at least one ethnicity with significantly differing mean values compared to the remaining cohort, such as short stature in the Baka rainforest hunter-gatherers of Cameroon, and high adiposity in the Herero pastoralists of Botswana. An analysis of ethnicity-sex interactions revealed several ethnic groups with significant sexual dimorphism for at least one cardiometabolic phenotype, such as Herero women having markedly higher body mass index than men. Comparison between the African cohort and African ancestry UK Biobank (UKBB) individuals showed the latter have higher mean values than any of the 53 African ethnic groups for multiple cardiometabolic measurements, including low density lipoprotein cholesterol (LDL), body fat percentage (BFP), and systolic blood pressure. We also found that phenotype-phenotype correlations differ between the UKBB and African cohort, as well as between African ethnicities. For example, BFP and LDL had low correlation in the UKBB (r=0.04) but showed a range of correlation among African groups, from r = 0.00 in the Maasai pastoralists of eastern Africa to r = 0.43 in the Agaw agriculturalists of Ethiopia. Genome-wide association analyses identified 76 significantly associated loci ($p<5.0x10^{-8}$), with 14 passing a more stringent empirical threshold ($p<3.0x10^{-9}$), including *APOE* and *APOC1* loci for various blood lipids, *PCSK9* for LDL, and *CETP* for high density lipoprotein cholesterol (HDL), as well as novel loci. Set-based rare variant analyses for loss-of-function variants found 12 gene-phenotype associations replicating known associations with *PCSK9* and *APOE* for LDL and total cholesterol and uncovering several novel gene-trait associations for adiposity traits and HDL. Ongoing analyses include phenotype associations with subsistence and genetically inferred ancestry, replication of genetic associations, and gene-set enrichment. In total, these results offer insights into the genetic and phenotypic landscape of cardiometabolic traits in African populations. This work was supported by grant numbers: ADA 1-19-VSN-02, NIH grants 1R35GM134957, R01DK104339, and R01AR076241, and 1X01HL139409-01.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1500 Genetic architecture of occupational creativity and extensive genetic overlap with psychiatric disorders revealed from genome-wide association analyses of 241,736 individuals.

†These individuals contributed equally to this work as co-first authors.
*These individuals contributed equally to this work as co-corresponding authors.

Although creativity is heritable and often has a familial aggregation with psychiatric disorders, its genomic basis and genetic links with psychiatric disorders are mainly unexplored. By using a machine learning-based phenotyping of creativity based on occupation, we conducted a genome-wide association study (GWAS) of occupational creativity in individuals of European ancestry from the UK Biobank (n = 241,736) and identified 25 creativity-associated loci. The genetic association, polygenic risk score, and MiXeR analyses revealed extensive genetic overlap of occupational creativity with psychiatric disorders such as schizophrenia, major depression, bipolar I disorder, attention deficit/hyperactivity disorder, and anorexia nervosa. The condFDR and conjFDR investigations discovered additional loci for occupational creativity and psychiatric disorders, as well as shared genetic loci. Our GWAS showed similar results with GWASs conducted with traditionally creative occupations and GWASs adjusted for educational achievement. Our findings elucidate the genetic architecture of occupational creativity and shed light on its polygenic associations with psychiatric illnesses.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1501 Genetic association of ubiquitin specific peptidases (USPs) with the risk of Alzheimer's disease

Authors:

A. Cheema[1], K-H. Fan[1], M. Aslam[1], V. Acharya[1], E. Feingold[2], M. Kamboh[2]; [1]Dept. of Human Genetics, Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA, [2]Dept. of Human Genetics, Sch. of Publ. Hlth., Univ of Pittsburgh, Pittsburgh, PA

Taupathy is a major pathological hallmark of Alzheimer's disease (AD). Tau aggregation and clearance are controlled by multiple post translational events, including ubiquitination, which is the final modification step that controls proteasome-mediated clearance and degradation of tau. Ubiquitination is regulated by deubiquitinase (DUB) enzymes that remove ubiquitin groups. The human genome consists of ~100 DUBs, of which 50% are USPs, and 22 of them are expressed in the brain. We hypothesized that genetic variation in the brain USPs might alter the risk of AD by directly affecting the ubiquitin-linked clearance and degradation of tau. We examined this hypothesis in the International Genomics of Alzheimer's Project (IGAP) sample comprising ~72, 000 AD cases and controls. A total of 200 variants with nominal significance ($P<0.05$) were observed. After applying the M_{eff} method (effective number of independent tests) for multiple-testing correction, 62 variants remained significant in five genes, all in non-coding regions. The greatest number of significant associations were found in the USP8 gene (n=57), with both risk and protective variants. The most significant variant was protective (β= - 0.0726; P= 1.64E-05) followed by a risk variant (β= 0.0627; P= 4.80E-05). Based on RegulomeDB functional annotation, both variants had a RegulomeDB score of 1f, indicating that both have regulatory functions as they can affect transcription binding and expression of a gene target. In addition to SNPs, we also observed seven 2-5 bp insertions associated with both AD risk (n= 3) and protection (n= 4). The two top protective insertions were TACC (β= - 0.0697; P= 7.79E-05), and AAAAC (β= - 0.0695; P= 9.14E-05), and the top risk insertion was GTA (β= 0.0574; P= 5.81E-04). In conclusion, our study indicating that genetic variation in the brain USPs may affect the risk of AD, potentially highlights a tau-linked ubiquitination-deubiquitination pathway. Future genetic and associated functional studies may help to better understand this pathway.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1502 Genetic Associations with lupus in Sundanese population

Authors:

K. Patasova[1], S. Elbagir[2], N. Mohammed[3], M. A. Nur[4], E. M. Elagib[5], A. Elshafie[2,6], I. Gunnarsson[1], E. Svenungsson[1], J. Rönnelid[2], L. Diaz-Gallo[1]; [1]Karolinska Inst.t, Stockholm, Sweden, [2]Uppsala Univ., Uppsala, Sweden, [3]Al Neelain Univ., Khartoum, Sudan, [4]Alribat Univ. Hosp., Khartoum, Sudan, [5]Military Hosp., Omdurman, Sudan, [6]Linköping Univ. Hosp., Linköping, Sweden

Background: Published genome-wide studies have identified close to ~120 loci associated with systemic lupus erythematosus (SLE). However, current genetic findings are based mainly on Europeans. Investigations of SLE in East-Asian populations revealed distinct genetic associations with SLE manifestations across ancestries. We join the growing efforts to study the SLE genetic risk factors in other ancestry groups. **Aims:** This study aimed to evaluate genetic associations with SLE in the Sundanese population. To evaluate whether the HLA alleles associated in this cohort are similar to the reported ones in SLE. **Methods:** The study sample included 494 Sundanese participants; 92 were diagnosed with SLE, classified according to the 1982 revised (ACR) criteria. Genotyping was performed using Infinium® Expanded Multi-Ethnic Genotyping Array (MEGAEX). *HLA* alleles and amino acids were imputed against a modified 1000G African panel (5) in SNP2HLA. Genetic markers with MAF < 1%, genomic missingness >5% and imputation quality < 75% were removed; following quality control procedures, 453 unrelated samples, and 1,183.339 variants were advanced for statistical analyses. Genetic associations with SLE were evaluated in logistic regression model adjusted for age, sex, and the first two principal components, using PLINK2.0 (7). Associations with HLA alleles and amino-acids were assessed in separate analyzes and were considered significant if their probabilities were below Bonferroni correction threshold of 0.001 (p-value=0.05/44) and $5.55x10^{-05}$ (p-value=0.05/900), respectively. We applied conventional genome-wide significance threshold (p-value=$5x10^{-08}$) to genetic associations outside MHC region. **Results:** The strongest association within MHC region was detected with *HLA-DRB1*03* allele (frequency=12%) conferring an increased risk of SLE (OR=1.95, 95% CI=1.19,3.20; p-value=0.008). At higher allele resolution the *HLA-DRB1*0301* allele was associated with the two-fold increased risk of SLE (OR=2.00; 95%CI: 1.21, 3.33; p=0.007). The top amino acid associated were AK at position 71 of the *HLA-DRB1* gene (OR= 1.77; 95%CI: 1.18,2.66; p= 0,006). We also identified a suggestive novel association with rs12953472 (OR= 5.64, 95% CI= 2.86,11.09; p=$5.55x10^{-07}$) marker located within intronic region of *ZNF236-DT* gene, which encodes ferroptosis-related lincRNA. **Conclusions:** We have conducted the first GWAS assessing genetic determinants of SLE in the Sundanese population. We observed that HLA-DRB1*03 is also associated in SLE in this population and we report a novel suggestive signal within *ZNF236-DT* gene which is associated with a marked increase in the risk of SLE.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1503 Genetic Basis of Dilated Cardiomyopathy in Indian population

Authors:

S. Singh[1], A. Pandey[2], N. Garg[1], A. Srivastava[3]; [1]Sanjay Gandhi Postgraduate Inst. of Med. Sci. Lucknow, Lucknow, India, [2]Sanjay Gandhi post graduate Inst. of Med. Sci.s lucknow,, Lucknow, India, [3]Sanjay Gandhi Postgraduate Inst. of Med. Sci., Lucknow, India

Introduction- Dilated cardiomyopathy (DCM) is an autosomal dominant disease characterized by enlargement and dilation of one or both the ventricles along with impaired contractility.The genetic architecture of DCM continues to evolve rapidly due to its diverse and complex nature. In the present study, we sought to determine the genetic basis of DCM in Indian population. **Methods-**. We performed whole-exome sequencing (WES) on 50 individuals presented with the clinical features of dilated cardiomyopathy.Among them, 16 (32%) were familial. Sanger sequencing validated the pathogenic variants. Minigene assay was performed to functionally characterize the novel splice variant. **Results and discussion:** We identified pathogenic variants in 6 (12%) of the DCM-affected individuals. *ACTC1* c.309C>A, *DSP* c.478C>T, *PSEN2* c.250G>A and *TNNT2* c.547C>A. were identified as known whereas *ACTN2* c.616-2A and *FLNC* c.5897C>A were identified as novel variants. Minigene reporter assay confirmed that c.616-2A variant results in the skipping of exon 7 and expression of mutant protein.While DCM exhibits a Mendelian, monogenic architecture in the families cases, our data suggests that 4 (8%) of DCM-affected individuals have a digenic basis.Variant of unknown significance was identified in 33 individuals while remaining 17 (34%) were WES negative. **Conclusion:** Our study identified genes directly related to Z disc, sarcomere, ion channel, cytoskeleton and desmosome that highlights the complex genetic scenario of DCM. Furthermore, we show the digenic basis of DCM where two rare variants from different, unlinked loci determine the clinical features and the advantage of analysing population-specific sequences variants in the underrepresented populations.

PB1504 Genetic determinants of host IgG response to COVID-19 vaccination.

Authors:

S. Bian, X. Guo, X. Yang, Y. Wei, Z. Yang, X. Du, Y. Shu, S. Liu; Sch. of Publ. Hlth.(Shenzhen), Shenzhen Campus of Sun Yat-sen Univ., Shenzhen, China

Vaccination is an effective strategy for safeguarding vulnerable populations and reducing the severity of COVID-19 infections during the ongoing pandemic. However, there is substantial variation among individuals in the duration and strength of immune response following vaccination, and the underlying reasons for this variability remain unclear. Here, we explore the extent to which host genetic predisposition may contribute to the IgG responses following COVID-19 vaccination. We conducted a genome-wide association study (GWAS) on the qualitative IgG serostatus of individuals who had received either a single dose (N=54,066) or two doses (N=46,232) of the COVID-19 vaccine which use the spike protein of virus as antigen, and had no prior SARS-CoV-2 infection from UK Biobank. We found significant associations between common variants in the *LAT* gene (16q13) and HLA class II region with serostatus following a single-dose vaccination. Notably, we identified four independent alleles, including *HLA_DRB1*13:02*, *HLA_DQA1*01:01*, *HLA_DPB1*04:01*, and *HLA_DQB1*02:01*, which were consistently associated with serostatus after a single vaccine dose. Particularly, we observed an association between the amino acid residue at position 71 on DRβ1 and its electrostatic properties of the binding pocket and the serostatus among individuals who received only one vaccine dose. These findings underscore the role of host genetic factors in influencing the responses to COVID-19 vaccines and highlight the importance of considering the impact of the genetic background when formulating and implementing vaccination strategies to maximize protection within different populations.

PB1505 Genetic Determinants of Placental Growth Factor Levels and their Association with Coronary Artery Disease Risk

Authors:

J. Hartiala[1], J. R. Hilser[1], X. Huang[1], Y. Han[1], P. Huang[1], Q. Jia[1], S. L. Hazen[2], W. Tang[2], H. Allayee[1]; [1]USC Keck Sch. of Med., Los Angeles, CA, [2]Cleveland Clinic, Cleveland, OH

Introduction: Recent studies show that elevated placental growth factor (PlGF) concentrations predicted higher risk of cardiovascular disease (CVD) independent of known risk factors and were associated with adverse cardiovascular outcomes (death or future MI) in patients with acute coronary syndromes (ACS) or with chronic kidney disease (CKD). Although PlGF is an important cytokine involved in angiogenesis, cardiac remodeling and inflammation, it is not known whether the association between PlGF levels and coronary artery disease (CAD) outcomes is causal. To address this question, we used a large-scale genome-wide association study (GWAS) approach combined with Mendelian randomization (MR) and mediation MR analyses. **Methods:** A GWAS analysis was carried out in subjects from the GeneBank (n=3,455) and UK Biobank (n=52,096), followed by a weighted Z-score meta-analysis with four additional cohorts including AGES (n=5,368), SCALLOP (n=19,188), Fenland (n=10,708), and INTERVAL (n=3,301). To investigate the causal association of PlGF levels with cardiovascular risk, we performed MR analyses for CAD and MI with our lead SNPs that were not associated with cardiovascular-related traits as instrumental variables (IVs). Additionally, we performed mediation MR analyses using systolic blood pressure (SBP) as a potential mediator. **Results:** A meta-analysis for PlGF levels with 94,166 subjects and 9,723,360 overlapping SNPs identified 1,176 genetic variants distributed across 13 loci that exceeded the genome-wide significance threshold ($P<5.0x10^{-8}$). Of these, 12 loci were novel and not previously associated with PlGF. To investigate the causal relationship between PlGF levels and CAD, we used variants near the *FLT1*, *PGF*, and *BANF2* (rs9319427, rs91144 and rs17793602) for MR analyses with risk of CAD and MI. These analyses provided evidence that PlGF levels may be causally associated with decreased risk of CAD (OR=0.75, 95% CI 0.71-0.79, $P=2.5x10^{-23}$) and MI (OR=0.80, 95% CI, 0.71-0.91, $P=6.5x10^{-4}$), and that SBP was not mediating these associations. **Conclusions:** Our results suggest that higher levels of PlGF are associated with decreased risk of CAD and MI. This observation is surprising since higher PlGF levels have been clinically associated with increased cardiovascular risk. While increased levels of PlGF may precede progression and development of CAD, it is also plausible that PlGF levels may increase as a function of CAD as a protective response. Future studies will be needed to further explore the directionality of this relationship and to better understand the underlying biological mechanisms for this apparent paradoxical causal association.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1506 Genetic etiologies of sex hormones differ between female late premenopause and postmenopause stages.

Authors:

T. Waller[1], S. S. Faubion[2,3], J. M. Biernacka[1,4], S. J. Winham[1]; [1]Dept. of Quantitative Hlth.Sci., Mayo Clinic, Rochester, MN, [2]Div. of Gen. Internal Med., Mayo Clinic, Jacksonville, FL, [3]Ctr. for Women's Hlth., Mayo Clinic, Rochester, MN, [4]Dept. of Psychiatry and Psychology, Mayo Clinic, Rochester, MN

Steroid sex hormones regulate many aspects of physiology, and the concentrations of these hormones differ between males and females and change over the lifespan. In addition to variants on the sex chromosomes, broad differences in the autosomal genetic etiologies of sex hormones regulate their respective concentrations in both females and males. We hypothesized that genetic factors might also contribute to changes in sex hormone regulation over the lifespan, especially during the menopause transition in females. Using data from the UK Biobank, which included ~500,000 males and females over the age of 40, we compared genetic etiologies of hormone levels across stages of life. We stratified data by male age (tertiles) and by female menopause stage (late-pre-, peri-, post-) and ran genome-wide association studies (GWAS) on levels of testosterone (T), bioavailable T (BT), estradiol (E), bioavailable E (BE), and sex hormone binding globulin (SHBG) with adjustment for hormone-influencing factors such as the menstrual cycle, previous full-term pregnancies, and use of hormonal therapies. Using these GWAS summary statistics, we estimated the genetic correlation (rg) for each hormone level between males and females, age tertiles in males, and menopausal stage in females; rg<1 suggests differences in the contribution of genetic variants to hormonal phenotypes between groups. Consistent with previously published findings, we observed differences (i.e. rg<1) by sex for T (**rg: 0.09; se: 0.05**), BT (**rg: -0.05; se: 0.03**), E (**rg: 0.18; se: 0.11**), BE (**rg: 0.71; se: 0.08**), and SHBG (**rg: 0.88; se: 0.03**). Between pre- and postmenopause females, we observed differences for T (**rg: 0.65; se: 0.08**), BT (**rg: 0.74; se: 0.07**), and BE (**rg: -0.17; se: 0.21**). We also observed differences for BE (**rg: 0.38; se: 0.15**) between peri- and postmenopause females. We did not observe differences across the lifespan in males or for E and SHBG in females. These results confirm that contributions of common autosomal genetic variants to steroid sex hormones differ by sex, and they also suggest that genetic contributions vary based on menopause stage in females. Female reproductive stage is an important consideration in studies of genetic predisposition for levels of steroid sex hormones.

PB1507 † Genetic Factor Structure of the Posttraumatic Stress Disorder Checklist (PCL-17) in the Million Veteran Program

Authors:

C. Overstreet[1], D. Levey[1], R. Pietrzak[2], J. Deak[3], M. Galimberti[3], K. Adhikari[1], H. Zhou[4], K. Harrington[5], R. Quaden[5], J. Gaziano[6], M. Stein[7], J. Gelernter[8]; [1]Yale Univ., West Haven, CT, [2]VA Connecticut Hlth.care Ctr., West Haven, CT, [3]Yale Univ., New Haven, CT, [4]Yale Univ., Orange, CT, [5]Massachusetts Veterans Epidemiology Res. and Information Ctr. (MAVERIC), VA Boston Hlth.care System, Boston, MA, [6]VA Boston Hlth.care System, Roxbury Crossing, MA, [7]Univ. of California San Diego, San Diego, CA, [8]Yale Univ Sch. of Med., West Haven, CT

Posttraumatic stress disorder (PTSD) is a heterogenous disorder and summing items reflecting symptoms into a single sum score may obscure our ability to discern the biological underpinnings of the disorder. Attempts have been made to refine the trait definition by parsing items into phenotypic subdomains of re-experiencing, avoidance, and hyperarousal, per the DSM-IV; however, the genetic subdomains of PTSD may vary from phenotypic subdomains. No known study has performed item-level genome-wide association studies (GWAS) of the PTSD Checklist (PCL-17) or completed genetic modeling with GWAS results. We conducted (1) item-level GWAS of the PCL-17 in veterans of European (EUR) ancestry in the Million Veteran Program (MVP) and (2) genomic structural equation modeling (gSEM) to determine the best-fitting model of PTSD symptoms.
The sample consisted of ~230,000 EUR MVP participants. GWAS were conducted on the PCL-17 items and FUMA was used for mapping and annotation. Eigenvalues were examined to determine the number of factors to extract. To complete the modeling, gSEM was used. Exploratory factor analyses (EFA) were conducted using odd chromosomes and confirmatory factor analyses (CFA) were conducted using even chromosomes. The following conventions were used to evaluate model fit, with CFI>=0.90 and SRMR<=0.08 suggesting good-to-adequate fit. Genetic correlations across the 17 items ranged from 0.68 to 0.98. The number of independently significant SNPs ranged between 1 and 19. GWAS results across multiple items revealed SNPs associated with genes previously identified in other PTSD studies (e.g., *MAD1L1*). Examination of eigenvalues demonstrated two eigenvalues > 1 so an EFA was conducted using a two-factor model. The EFA results indicated that 11 items loaded onto factor one encompassing ‘threat’ symptoms, including 5 items assessing re-experiencing (e.g., emotional reactivity to trauma cues), 3 avoidance (e.g., avoiding reminders of the trauma), and 3 hyperarousal (e.g., hypervigilance) symptoms. Factor two items included symptoms encompassing ‘dysphoric’ symptoms, including 4 assessing avoidance (e.g., loss of interest) and 2 hyper-arousal (i.e., sleep disturbance) symptoms. A CFA was then conducted and results indicated adequate fit (χ^2=639.25, p=1.48e-72, CFI=0.92, SRMR=0.027).
Although all strongly genetically correlated, there was also some genetic variability across PCL-17 items. Modeling results demonstrated that a two-factor model best fit the data. Additional analyses will be conducted using the two factors derived from gSEM to further examine genetic variability and interrogate post-GWAS findings.

PB1508 Genetic heterogeneity in type 1 diabetes risk and age-at-onset using diverse ancestry populations in the Type 1 Diabetes Genetics Consortium (T1DGC).

Authors:

D. Michalek[1], C. Tern[1], W-M. Chen[1,2], W. Zhou[3,4,5], S. Onengut-Gumuscu[1,2], S. Rich[1,2], T1DGC; [1]Ctr. for Publ. Hlth.Genomics, Univ. of Virginia, Charlottesville, VA, [2]Dept. of Publ. Hlth.Sci., Univ. of Virginia, Charlottesville, VA, [3]Analytic and Translational Genetics Unit, Dept. of Med., Massachusetts Gen. Hosp., Boston, MA, [4]Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA, [5]Program in Med. and Population Genetics, Broad Inst. of Harvard and MIT, Cambridge, MA

Background: Type 1 diabetes (T1D) is a complex autoimmune disease characterized by the destruction of the pancreatic β-cells, resulting in life-long requirement for insulin. The etiology of T1D includes both genetic and unknown environmental components. To date, GWAS meta-analyses and fine mapping studies reported over 100 loci associated with risk of T1D, with the majority of associated SNPs enriched in enhancers, although specific alleles in HLA class I and class II genes account for ~50% of T1D genetic susceptibility.
Objective: Use a multi-ancestry GWAS approach to discover novel genetic variants, HLA genes and amino acids, that are associated with T1D risk and age-at-onset.
Methods: The T1DGC data included 3,222 affected sib-pair/trio families (12,213 individuals, largely of European ancestry (EUR)), 891 unrelated African ancestry (AFR, 409 T1D cases, 482 controls) and 308 unrelated Admixed individuals (AMR, 153 T1D cases, 155 controls). All samples were genotyped using the Illumina CoreExome BeadChip array. Genotypes were imputed to the Trans-Omics for Precision Medicine (TOPMed) reference panel. HLA imputation used the multi-ancestry HLA reference panel (HLA-TAPAS). Imputation generated 13,965,323 variants (MAF > 0.01), including 20,425 HLA region variants (MAF > 0.005). T1D risk and HLA analysis was performed with logistic mixed models (SAIGE), while age-at-onset of T1D used survival models (GATE).
Results: In meta-analysis, seven T1D-associated loci attained genome-wide significance: 1p13.2 (*PTPN22*), 6p21.32 (*HLA-DQA1*), 10p15.1 (*IL2RA*), 10q23.31 (*RNLS*), 11p15.5 (*INS*), 12q13.2 (*IKZF4-RPS26-ERBB3*), and 12q24.12 (*SH2B3*), all known. Four of these loci were associated with age-at-onset of T1D (*PTPN22*, *HLA-DQB1*, *INS* and *ERBB3*). In meta-analysis of AFR and AMR, the *NRP1* locus (rs722988, OR = 1.61, P = 1.10×10^{-8}) was associated with both T1D risk and age-at-onset, *NRP1* was not significant in EUR; *PTPN22* was only significant in EUR. Fine mapping in the HLA region revealed *HLA-DRB1*03:01-DQA1*05:01-DQB1*02:01* as the most significant haplotype in AFR and AMR and *HLA-DRB1*04:01-DQA1*03:01-DQB1*03:02* in EUR. In conditional analysis, *HLA-DRB1*08:02-DQA1*04:01-DQB1*04:02* was protective in AMR population (OR = 0.39, P = 2.9×10^{-2}); in EUR, *HLA-DRB1*08:01-DQA1*04:01-DQB1*04:02* was associated with increased risk for T1D (OR = 1.81, P = 5.5×10^{-5}).
Conclusions: The inclusion of subjects with diverse genetic ancestry identified NRP1 with a stronger effect on T1D risk and age-at onset in non-EUR populations. The *NRP1* locus and specific HLA haplotypes, in addition to *PTPN22* distinguish T1D risk in EUR and non-EUR ancestries.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1509 Genetic Identification of New Chronic Pain Associations with the Central and Peripheral Nervous System.

Authors:

E. UZOCHUKWU[1], Z. Cader[2], C. Sandor[3], C. Webber[4]; [1]CARDIFF Univ., CARDIFF, United Kingdom, [2]Univ. of Oxford, Oxford, United Kingdom, [3]Univ Oxford, Oxford, United Kingdom, [4]Cardiff Univ., Cardiff, United Kingdom

Chronic pain, defined as pain persisting or reoccurring for 3 months or longer, is a leading cause of disability and represents a significant unmet medical need. Hence, there is an urgent need to identify novel drug targets for chronic pain, especially non-opioid analgesics, to support the development of new analgesic therapies and improved long-term pain outcomes. Current -omic studies of chronic pain often focus on clinical diagnoses of specific pain disorders. We hypothesize that there are genetic mechanisms that are shared across chronic pain disorders that are not specific to any single disease. To identify 'chronic pain', we utilized recurring analgesic prescription usage, defined as a minimum duration of 3-months of continuous use, (in lieu of specific pain diagnosis) to identify chronic pain phenotypes in the UK Biobank that we could then leverage in novel genome-wide association studies (GWAS). We generated n=13 phenotypes and conducted n=39 individual GWAS (both sexes combined and sex-stratified) to understand the genetic architecture of chronic pain. Subsequently, we identified cell specific pathways specific associated with these genetic pain traits by integrating the information of multiple PNS and CNS single-cell RNA sequencing atlases. We found that the cell/pathway varied according to type of analgesic, gender, and time on/off prescription. The identification of these distinct pathway is critical in the future development of successful therapeutic strategies for chronic pain.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1511 Genetic insights into platelet counts and Gestational Thrombocytopenia during pregnancy: A Genome-wide association study of 100,186 Chinese pregnancies.

Authors:

Z. Yang, Y. Gu, Y. Wei, Y. Liu, H. Zheng, X. Guo, S. Liu; Sch. of Publ. Hlth.(Shenzhen), Sun Yat-sen Univ., Shenzhen, China

Platelet counts decrease throughout pregnancy, and 5-12% of pregnant women are diagnosed with gestational thrombocytopenia (GT), characterized by a reduced platelet count during pregnancy. However, the biological mechanism of altered platelet counts and GT during pregnancy is still unclear. Here, we employed the human genetics approach and performed the first genome-wide association studies (GWAS) to investigate genetic factors for platelet counts at five stages of pregnancy (the first, second, and third trimesters, delivery, and the postpartum period), as well as two statuses of GT (GT: platelet count $< 150 \times 10^9$/L and severe GT: platelet count $< 100 \times 10^9$/L), using whole-genome sequencing data from non-invasive prenatal sequencing (NIPT) among 100,186 Chinese pregnancies. We identified 138 loci that showed genome-wide associations ($P < 5\times10^{-8}$), accounting for 3.2% of the phenotypic variation, and eight loci were newly discovered. Notably, we observed two loci in *PEAR1* and *CBL* with changing genetic effects in the five pregnancy periods. In the time-dependent GWAS across pregnancy, *PEAR1* was associated with platelet count variation during pregnancy.
Furthermore, *PEAR1* and *TUBB1* were found to be the most significant loci associated with GT and severe GT. We provided the first insights into the genetic basis of platelet counts and GT in pregnancy, and our findings indicate that *PEAR1* is the most crucial gene in the decrease of platelet counts and GT during pregnancy. We further propose the hypothesis that women carrying specific variants associated with a decrease in platelet count during pregnancy experience a more pronounced decline in platelet count during pregnancy, thereby contributing to the occurrence of GT. Our research provides insights for subsequent exploration of the biological mechanisms of GT.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1512 Genetic loci implicated in a meta-analysis of body shape in Africans

Authors:

M. Nakabuye, TACG Research Group; MRC/UVRI & LSHTM Uganda Res. Unit, Entebbe, Uganda

Background & Significance: Obesity is one of the leading causes of non-communicable diseases (NCD). Thus, NCD risk varies in obese individuals based on the location of their fat depots; while subcutaneous adiposity is protective, visceral adiposity increases NCD risk. Although, previously, anthropometric traits have been used to quantify body shape in low-income settings, there is no consensus on how it should be assessed. Hence, there is a growing interest to evaluate body shape derived from the principal component analysis (PCA) of anthropometric traits; however, this is yet to be explored in individuals of African ancestry whose body shape is different from those of Europeans. We set out to capture body shape in its multidimensional structure and examine the association between genetic variants and body shape in individuals of African ancestry. **Methods:** We performed a genome-wide association study (GWAS) for body shape derived from a PCA analysis of anthropometric traits in the Ugandan General Population Cohort (GPC, n = 6407) and the South African Zulu Cohort (SZC, n = 2595), which was followed by a GWAS meta-analysis to assess the genetic variants associated with body shape. **Results:** We identified variants in *FGF12*, *GRM8*, *TLX1NB* and *TRAP1* to be associated with body shape. These genes were different from the genes that have been associated with BMI, height, weight, WC and waist-hip ratio in continental Africans. Notably, we also observed that a standard deviation change in body shape was associated with an increase in blood pressure and blood lipids. **Conclusion:** Variants associated with body shape, as a composite variable might be different for those of individual anthropometric traits. Larger studies are required to further explore these phenomena.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1513 Genetic pleiotropy for kidney function and soluble receptor for advanced glycation end-products (sRAGE) using correlated meta-analysis in genome-wide association study and genome-wide transcriptome analysis: The Long Life Family Study (LLFS).

Authors:

M. Feitosa[1], B. Thyagarajan[2], S. J. Lin[1], S. Acharya[3], M. Wojczynski[1], A. Kuipers[4], A. Kulminski[5], G. Patti[6], K. Christensen[7], J. Zmuda[4], M. Brent[3], M. Province[1]; [1]Div. of Statistical Genomics, Dept. of Genetics, Washington Univ. Sch. of Med., St. Louis, MO, [2]Dept. of Lab. Med. and Pathology, Sch. of Med., Univ. of Minnesota, Minneapolis, MN, [3]Dept. of Computer Sci. and Engineering, Washington Univ., St. Louis, MO, [4]Dept. of Epidemiology, Graduate Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA, [5]Biodemography of Aging Res. Unit, Social Sci. Res. Inst., Duke Univ., Durham, NC, [6]Dept. of Chemistry, Washington Univ. in St. Louis, St. Louis, MO, [7]Unit of Epidemiology, Biostatistics and Biodemography, Dept. of Publ. Hlth., Southern Denmark Univ., Odense, Denmark

The estimated glomerular filtration rate (eGFR) is used for detecting and managing kidney disease. Patients with chronic kidney disease (CKD) present increased oxidative stress and chronic inflammation, which may escalate the production of advanced glycation end-products (AGE). Low eGFR measured by creatinine (eGFRcr) and cystatin C (eGFRcys) and high circulating soluble receptor for AGE (sRAGE) are associated with aging and CKD. In the LLFS, eGFRcr and eGFRcys correlated negatively with sRAGE (r= -0.25, p= $1.4x10^{-37}$ and r= -0.30, p= $2.7x10^{-53}$, respectively). To identify whether pleiotropic genetic variants share effects on kidney function and sRAGE, we conducted GWAS for eGFRcr, eGFRcys, and sRAGE, adjusting for age, sex, relatedness, and principal components, followed by correlated meta-analysis (CMA) on GWAS p-values from whole-genome sequence variants in 4182 subjects. Of the 59 loci identified (p< $5x10^{-8}$), 42 were novel discoveries, and 17 were previously reported for eGFR. Several novel locus variants (e.g., *CDKN2C*, *ZNF326 / SNORD3G*, *STK32B*, *LINC01987*) were reported with CKD, urea nitrogen, and creatinine levels but not with eGFR. Four locus variants have minor alleles with eGFRcys protective effects. For example, the *CASC17 / ROCR* rs528757227-A frequency is ~4.2 times higher in LLFS (A= 0.0131, β= 0.105 ± 0.029) than in ALFA-Europeans (A=0.003), suggesting better kidney function in the health-aging LLFS members than the general population. In addition, several variants (e.g., in *SH3GLB1 / SELENOF* and *CENPP*) are eQTLs in the glomeruli and tubule kidney (Human Kidney eQTL Atlas), and different tissues (GTEx), and promoter and enhancer histone marks, DNAse hypersensitive sites, and protein regulatory binding sites (HaploReg). To identify signatures of kidney function with expression protein-coding genes and lincRNAs, we performed TWAS for eGFRcr, eGFRcys, and sRAGE on blood RNA-seq and then CMA in a 1209 subsample. We identified 4 genes from TWAS eGFR and 13 genes from CMA between eGFR and sRAGE (Bonferroni p< $2.73x10^{-6}$). Among the 17 genes, the Kidney eQTL Atlas reports eQTLs for *DAAM2*, *TOPORS*, and *LSP* from meta-analyses. From kidney samples, the Atlas indicates that *TEC*, *CCN1*, *ERGIC1*, *SNTB1*, *LSP1*, and *TOPORS* harbor eQTLs with expression levels in the glomeruli or tubule kidney. Our findings demonstrate that the CMA enhances the association significance by combining GWAS or TWAS, allowing the discovery of novel variants and genes and replicating others for eGFR traits. Adding, genomic, transcriptomic, and bioinformatics results demonstrate compelling evidence that some novel variants and genes have functional regulatory features in the kidney.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1514 Genetic predictors of Venous Thromboembolism in Europeans

Authors:

F. Thibord, INVENT consortium, Million Veteran Program; NIH/NHLBI, Jamaica Plain, MA

Background: Venous thromboembolism (VTE) is a cardiovascular event resulting from an imbalance of hemostasis toward coagulation, and presents clinically as deep vein thrombosis or pulmonary embolism. In order to better characterize VTE etiology at the molecular level, two independent large-scale efforts recently performed VTE genome-wide association studies (GWAS) meta-analyses: Ghouse *et al.* (N=81,190 VTE cases of European ancestry) and Thibord *et al.* (N=81,669 VTE cases, including 71,771 Europeans).
Aims: To validate novel findings from both studies by cross-replication, and to perform an expanded meta-analysis to discover additional novel gene loci influencing VTE risk.
Methods: The Ghouse *et al.* meta-analysis involved only participants of European ancestry, thus only European ancestry individuals from the Thibord *et al.* study were included in this work. For the cross-replication analysis, novel loci that were significantly associated with VTE risk in only one study were investigated in the other study, after removal of cohorts shared between the two meta-analyses. Associations from a one-tailed test reaching a Bonferroni-corrected P-value threshold were deemed successfully replicated. We then performed a meta-analysis of all cohorts from the two studies which included a total of (71,771 + 37,250 =) 109,021 cases and over a million controls. Variants that exceeded the significance threshold ($P < 5 \times 10^{-8}$) were called significant.
Results: Out of 23 significant novel loci in the Ghouse *et al.* study, signals at the *F2RL3* and *PTPRR* loci were successfully replicated ($P < 0.0043$) in the Thibord *et al.* study after removal of overlapping cohorts (N=25,258 cases). Reciprocally, out of 28 novel loci from the Thibord *et al.* study, associations at the *AK5* and *RGS18* loci were replicated ($P < 0.0036$) in the Ghouse *et al.* meta-analysis, shared cohorts excluded (N=37,250 cases). Finally, the meta-analysis of the two studies revealed significant associations at 129 genetic loci, of which 21 have not been reported by previous efforts, including notably a missense variant (rs61749613, p.K349E) in *VCAN*, a gene encoding an extracellular matrix protein with suggested roles in wound healing and inflammation.
Conclusion: With this work, we added four loci to the list of 68 VTE loci replicated in independent studies that were identified by previous efforts. These four loci were part of 129 signals significantly associated with VTE risk in our meta-analysis, which also included 21 novel genetic variants influencing VTE risk. These results will offer novel insights in the mechanisms involved in VTE progression as well as potential opportunities for new therapeutic approaches.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1515 Genetic Predisposition of DRD4 and Associated Metabolic Enzymes with Psychiatric Felonies in Pakistani Prison Inmates

Authors:

R. Qadeer[1], S. Hasnain[1], J. J. Mann[2]; [1]Inst. of microbiology and Molecular Genetics., Lahore, Pakistan, [2]Molecular Imaging and Neuropathology Div., Columbia Univ./New York State Psychiatric Inst., New York, NY

The postsynaptic action of monoamine dopamine is known to be influenced by DRD4 and its metabolising enzyme genes. These are the most studied genes in connection with the pathogenesis of aggression and criminal delinquency. A total of 729 subjects were recruited, comprising 370 violent prison inmates convicted of first-degree murder(s) from different prisons in Punjab, Pakistan, and 359 control men without any history of aggression or criminal tendency from the general population. All the subjects were genotyped for six genetic polymorphisms in genes of dopaminergic 48 bp VNTR polymorphism of the *DRD4* gene, genetic variants of TPH1 (rs1800532), *TPH2* (rs7305115), neurotrophic (*BDNF* rs6265), and neurotransmitter metabolism (*COMT* rs4680, and *MAOA* VNTR polymorphisms) systems. The overall study results demonstrate a significant association of dopaminergic DRD4 (OR = 3.62, p = <0.0005 and OR = 11.02, p = <0.0005, respectively), and no association was evident for TPH genetic variants or genetic variants of neurotransmitter metabolism system genes (BDNF, COMT, and MAOA) genetic variants with aggression and criminal behaviour. In addition, some of these candidate genetic variants were also significantly associated with verbal abuse (*BDNF* polymorphisms) and physical abuse (*COMT* and *BDNF* polymorphisms) Also, the carriers of risk genotypes /alleles of *DRD4* polymorphisms had significantly higher mean aggression scores on the STAXI subscale as compared to wild-type genotypes/alleles in murderers. Taken together, these results suggest a major role for dopaminergic (*DRD4*) polymorphism and a modest contribution of neurotransmitter metabolism (*COMT*) and neurotrophic (*BDNF*) genetic variants in determining susceptibility to self-reported aggression and criminal behaviour in this sample subset of violent murderers. Using the Braineac and GTEx databases, significant eQTL-based functional effects for 48 bp VNTR in DRD4 and other neurotransmitter metabolism polymorphisms were analysed in different brain regions and peripheral tissues. In conclusion, these findings implicate the 48-bp VNTR of DRD4 as a major genetic determinant associated with criminal aggression. Future studies are needed to replicate these findings in other populations of murderers and extend them to other forms of violence and lesser degrees of aggression.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1516 Genetic profiling and polygenic risk score performance evaluation in the multi-ethnic population of the Kahn-Sagol-Maccabi Biobank.

Authors:

O. Sabik[1], W. Kim[1], A. Madar[1], B. Peterson[1], M. Cohn Adulamy[1], W. Gordon[1], A. Peretz[2], T. Patalon[2]; [1]Valo Hlth., Boston, MA, [2]Kahn Sagol Maccabi (KSM) Res. & Innovation Ctr., Maccabi Hlth.care Services, Tel Aviv, Israel

Coupling rich electronic health record data with the ability to sequence patients of interest is key to the identification of molecular signatures of specific populations and their application to drug discovery. The collaboration between Valo Health and Kahn-Sagol-Maccabi (KSM), the Research and Innovation Center of Maccabi Healthcare Services, Israel's leading HMO, unifies Valo's Opal Computational Platform with KSM's Biobank, one of the most comprehensive and rich biomedical datasets globally. Containing more densely measured medical history, driven by Israel's adoption of universal socialized healthcare, linked pharmacy claims, and more frequent measures of a broader panel of laboratory tests than comparable biobanks, such as the UK Biobank or FinnGen, KSM's Biobank provides an unparalleled opportunity to identify patient cohorts using deep longitudinal data and leverage Israel's unique population history to drive genetic discovery. Beginning with tens of thousands of sequenced patients, this collaboration is uniquely positioned to combine clinical and genetic data for drug discovery. As an example, computing genome-wide polygenic risk scores (PRS) for diseases of interest and mediating endophenotypes in conjunction with rich longitudinal clinical data can help in the identification of high-risk populations (Khera et al, Nat Gen, 2018) and may indicate new drug target hypotheses. In the pilot study, population ancestry was evaluated, identifying predominantly individuals of Ashkenazi ancestry (~60%), but also representation from Eastern Mediterranean, Middle Eastern, and Eastern European ancestry, including many admixed individuals. This ancestry structure poses some challenges; most human genetics tools and data are biased towards western European ancestry and suffer reduced performance in admixed individuals (Ding et al, Nature, 2023). To calibrate the extent of performance degradation and identify effective analysis approaches in non-European populations, PRS performance was evaluated for the prediction of gross phenotypes and endophenotypes, as was the portability of predominantly European-derived PRS weights to this diverse and admixed population. Future work will include tuning PRS using transfer learning (Zhao et al, AJHG, 2022) for more effective application of existing PRS weights to the cohort. Additionally, the bottlenecked nature of the Israeli population is uniquely positioned to have increased rare variant discovery power due to higher local frequencies of globally rare genetic variants. Measures of identify by descent will be used to identify cohorts for rare genetic discovery.

PB1517 † Genetic risk and changes in metabolomic risk over repeated measures.

Authors:

S. Kerminen, Nightingale Health Biobank Collaborative Group; Nightingale Hlth.Plc, Helsinki, Finland

Polygenic scores (PGS) are shown to improve risk prediction of complex diseases and could be used as a tool to motivate interventions and lifestyle changes. As genetic risk stays the same throughout life, it will also be important to complement genetic risk prediction with measures responsive to changes in lifestyle to encourage positive behavior. Metabolomic scores, measured from blood and analogous to PGS, have recently been shown to provide impressive risk prediction for many diseases. However, there is yet little understanding on how changes in metabolomic risk are associated with genetic and overall future risk. Here, we measure blood biomarkers using nuclear magnetic resonance for 255,000 individuals from UK Biobank. For 15,000 participants, we also measured a second blood sample 5 years after the baseline visit. Using half of the baseline samples without repeat sample and Cox proportional hazards model with Lasso and 5-fold cross validation, we developed metabolic risk scores for type 2 diabetes (T2D), myocardial infarction (MI) and chronic obstructive pulmonary disease (COPD). We calculated genetic risk for T2D, MI and COPD using previously published PGS. First, by fitting a joint risk model with baseline and follow-up metabolomic scores, we show that both time points were significantly associated with 10-year risk suggesting that both person's current metabolomic risk, and how long they have lived in a state of elevated risk, contribute information about future risk. Furthermore, we found that leaving the highest risk decile showed a dramatic reduction in future risk of diabetes (HR 3.1, p=3e-6) and COPD (HR 2.4, p=0.002), and consistent but non-significant difference for MI (HR 1.5, p=0.2). We replicated the results in 5000 Estonian Biobank participants with two metabolomic measurements for T2D (HR 4.5, p=0.002) which was the only disease with enough cases to test. Second, we tested associations of change in metabolomic score with PGS. For T2D, we observed that individuals with PGS at the highest decile were 1.3 times more likely (p=0.004) to switch from average metabolomic risk group into the highest decile 5 years later than other participants who started with average metabolomic risk. Analogously for COPD, we observed that among individuals who started with high metabolomic risk, individuals with high PGS were 0.51 times less likely (p=0.003) to reduce their metabolomic risk than the rest. Our results demonstrate that metabolomic risk scores dynamically capture risk over time and can track changes in an individual's risk profile. We also show it is more difficult to maintain good metabolomic risk profiles over time for individuals with high genetic risk.

PB1518 Genetic Risk for Body Mass and Mortality in Chronic Obstructive Pulmonary Disease

Authors:

J. Zhang[1], M. Moll[2], B. Hobbs[2], P. Bakke[3], E. Regan[4], H. Xu[5], J. Dupuis[6], E. Silverman[2], G. O'Connor[1], M. Cho[2]; [1]Boston Univ. Sch. of Med., Boston, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Univ. of Bergen, Bergen, Norway, [4]Natl. Jewish Hlth., Denver, CO, [5]Boston Univ. Sch. of Publ. Hlth., Boston, MA, [6]McGill Univ., Montreal, QC, Canada

Background: Low body mass index (BMI) is associated with increased COPD mortality, but the underlying mechanism is unclear. BMI is partially determined by genetics. We hypothesized that BMI genetic risk is associated with COPD mortality and has differential effects on respiratory and cardiovascular death in COPD. Methods: To obtain a summative measure of genetic risk for BMI, we developed a polygenic risk score (PRS_{BMI}, with higher scores associated with higher BMI) using lassosum based on the summary statistics from the largest BMI GWAS to date (~700,000 general population participants of European ancestry). We calculated the PRS_{BMI} for COPDGene non-Hispanic white (NHW) and African American (AA), ECLIPSE, and Framingham Heart Study (FHS) participants who had moderate-to-severe COPD (FEV_1/FVC <0.7 and FEV_1 % predicted <80%). We used penalized splines to test for non-linear effects of the PRS_{BMI} on mortality. We used Cox proportional hazards models to examine the association between the PRS_{BMI} and all-cause mortality. For respiratory and cardiovascular mortality, we used cause-specific hazard models to account for competing risks. Models were adjusted for age, sex, current smoking, pack-years of smoking, genetic ancestry, and FEV_1 % predicted. We conducted meta-analysis to combine effect estimates among cohorts. Results: We included 2811 COPDGene NHW, 753 COPDGene AA, 1708 ECLIPSE, and 751 FHS participants with moderate-to-severe COPD. The PRS_{BMI} contained approximately 439,000 variants, and accounted for 9.9% of the BMI in COPDGene NHW, 1.0% in COPDGene AA, 7.5% in ECLIPSE, and 18.3% in FHS participants. We did not observe a significant non-linear effect of the PRS_{BMI} on all-cause, respiratory, or cardiovascular mortality. In meta-analysis, a one standard deviation increase in the PRS_{BMI} was associated with an increased hazard for cardiovascular mortality (HR=1.30, 95% CI=1.12-1.51), but not with respiratory mortality (HR=1.01, p=0.80) or all-cause mortality (HR=1.04, p=0.052). We did not observe significant heterogeneity in effects of the PRS_{BMI} among cohorts (I^2=0%, p for the Q statistic >0.60 for all outcomes). Conclusions: In individuals with COPD from smoker-enriched cohorts and a population-based cohort, higher BMI genetic risk is associated with higher cardiovascular mortality, but not with respiratory mortality.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1519 Genetic risk stratification for primary open-angle glaucoma in Japanese individuals

Authors:

M. Akiyama[1], G. Tamiya[2], K. Fujiwara[1], K. Sato[2], Y. Kamatani[3], T. Ninomiya[1], K-H. Sonoda[1], T. Nakawaza[2]; [1]Kyushu Univ., Fukuoka, Japan, [2]Tohoku Univ., Sendai, Japan, [3]The Univ. of Tokyo, Minato-ku, Japan

Primary open-angle glaucoma (POAG) is a complex disease. Although the recent studies suggested that genetic risk scores (GRSs) could estimate the susceptibility of POAG, the most studies had been conducted in non-East Asian populations. To assess the utility of genetic risk stratification for POAG in Japanese individuals, we generated GRSs based on the summary statistics of the genome-wide association study (GWAS) of Japanese POAG (3,979 cases vs 30,278 controls). Three types of GRSs were constructed: 1) polygenic risk scores (PRSs) using pruning and thresholding (P+T) procedure (N = 24), 2) PRSs constructed by LDpred software (N = 4), and 3) GRS using variants significantly associated with POAG in the GWAS of International Glaucoma Genetics Consortium (IGGC; Gharahkhani et al. *Nat Commun* 2021). A total of 3,535 Japanese individuals including 1,191 POAG cases and 2,344 controls were analyzed to select the model with highest discriminative accuracy based on area under the receiver operative characteristics curves (AUCs). Among the 29 constructed models, the GRS based on 98 variants which were reported by IGGC showed the best discriminative accuracy (AUC = 0.65). In this case-control dataset, the proportion of POAG in individuals at the top decile of GRS was significantly higher than that at bottom decile (54.4% vs16.2%, odds ratio = 6.15, 95% confidence interval = 4.35-8.71). Associations of the selected GRS with prevalence of POAG was investigated in a dataset of general Japanese population (Hisayama study; N = 1,900). In the Hisayama study, we confirmed that the GRS was significantly associated with the prevalence of POAG (*P* for trend = 0.01). In conclusion, GRS showed moderate discriminative accuracy for POAG in the Japanese population which was in line with those in the European and African populations.

Drugs inhibiting interleukin-1 cytokines are a promising new treatment option for recurrent pericarditis, but their use is based on scarce biological evidence and clinical trials of modest sizes. Our aim was to use human genetics and multiomics to study the pathogenesis of pericarditis. We performed a GWAS meta-analysis of 4,894 pericarditis cases and 1,457,822 controls from five countries; Iceland (deCODE genetics), Denmark (Copenhagen Hospital Biobank Cardiovascular Study/Danish Blood Donor Study, CHB/DBDS), the UK (UK Biobank), the USA (Intermountain), and Finland (FinnGen). We identified two independent sequence variants at the interleukin-1 locus on chromosome 2q14 that associate with pericarditis; rs12992780[T] (effect allele frequency, EAF = 31-40%, OR = 0.83, $P = 6.7\times10^{-16}$) and rs7575402[A or T] (EAF = 45-55%, adjusted OR = 0.89, adjusted $P = 9.6\times10^{-8}$). Rs12992780 has a stronger effect on recurrent pericarditis than the acute form (OR = 0.76 vs 0.86, *P*-het = 0.030). Available transcriptomics and proteomics datasets did not reveal plausible causative genes for the associations. Rs7575402 associates with CpG methylation overlapping binding sites of four transcription factors known to regulate interleukin-1 production, PU.1 (encoded by *SPI1*), STAT1, STAT3, and CCAAT/enhancer-binding protein beta (encoded by *CEBPB*). The genetic associations substantiate the involvement of interleukin-1 in the pathogenesis of pericarditis and have the potential to solidify the use of interleukin-1 inhibitors in the treatment of the disease.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1521 Genetic variants associated with premature peripheral artery disease and surgical revascularization.

Authors:

j. hu[1], D. Alameddine[2], C. I. Ochoa Chaar[2], A. Dewan[1]; [1]Yale Sch. of Publ. Hlth., New Haven, CT, [2]Yale Sch. of Med., New Haven, CT

Peripheral artery disease (PAD) affects over 200 million people worldwide and impacts mostly the elderly. Even though advanced stages of the disease can lead to major lower extremity amputations, most patients are asymptomatic. Identification of patients at risk of progression is crucial to develop strategies for early treatment and risk factor modification. Multiple lines of evidence have suggested that there is a significant genetic component contributing to the development of PAD, and a recent genome-wide association study (GWAS) has identified and replicated 19 independent single nucleotide polymorphisms (SNPs) associated with the diagnosis of PAD, but the relationship between these variants and PAD severity has not been established. This study explored the association between these 19 variants and PAD severity using 6,815 PAD patients and 401,872 controls of White European ancestry from the UK Biobank. We have demonstrated in prior work that the common age for patients to present for surgical lower extremity revascularization was 60-80, and that patients with premature PAD were at increased risk of major amputation. Thus, early age of onset (<55) and surgical revascularization for PAD are indicators of increased severity. We classified PAD cases into 4 groups with increasing levels of severity: non-premature (>=55), non-surgical PAD (N=3,589); non-premature, surgical PAD (N=2,115); premature (<55), non-surgical PAD (N=710); and premature, surgical PAD (N=401). Genetic association analysis was conducted using REGENIE, to compare each severity group with the common control subjects. Each analysis was adjusted for age, sex and 10 principal components. Association results were then extracted for the 19 variants. A linear test for trend was conducted to test whether the effect of each SNP increased or decreased with severity. Three variants (rs6025, rs11066301, and rs10851907) showed increasing odds ratios (ORs) with increasing severity and each had a significant trend test ($p<0.0026$ [0.05/19]). Among them, rs6025 had the clearest trend: OR=1.13 (95% CI: 0.89, 1.32) for non-premature, non-surgical PAD, 1.22 (95% CI: 0.83, 1.48) for non-premature, surgical PAD, 1.36 (95% CI: 0.74, 1.93) for premature, non-surgical PAD, and 1.45 (95% CI: 0.7, 2.33) for premature, surgical PAD. Ten of the 19 SNPs showed larger ORs for surgical compared to non-surgical PAD in both premature and non-premature PAD suggesting that these SNPs are associated with surgical intervention regardless of age of onset. Our findings demonstrate that SNPs associated with PAD development may also be associated with PAD severity as assessed by surgical intervention and prematurity.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1522 Genetic variants associated with type 2 diabetes mellitus among Filipinos

Authors:

E. Cutiongco De La Paz[1,2], J. Nevado[1], E. Paz-Pacheco[3], G. Jasul[3], A. Aman[1,4], D. Francisco[3]; [1]Inst. of Human Genetics, NIH, Univ. of the Philippines Manila, Manila, Philippines, [2]Philippine Genome Ctr., Univ. of the Philippines, Quezon City, Philippines, [3]Section of Endocrinology, Dept. of Med., Philippine Gen. Hosp., Univ. of the Philippines Manila, Manila, Philippines, [4]Philippine Council for Hlth.Res. and Dev., Dept. of Sci. and Technology, Taguig City, Philippines

Background: Type 2 diabetes mellitus (T2DM) affects a significant number of Filipinos and leads to debilitating complications and poor quality of life. Genetic variability contributes to as much as 30% to70% of T2DM risk. The determination of genomic variants related to susceptibility to T2DM can help in early identification of at-risk individuals. However, it has been recognized that interethnic variability in T2DM genetic susceptibility exists. This study aimed to identify the variants that may be associated with type 2 diabetes mellitus in the Filipino population.**Methodology:** Using a case-control design frequency matched for age and sex, and compared 66 adult, unrelated Filipinos with T2DM with 188 without T2DM. Genotyping was done using a candidate gene approach derived from various literature and database sources in relation to T2DM and related conditions. Analyses involved allelic association and genotypic association studies with correction for multiple testing.**Results:** The study found eight (8) significant variants associated with T2DM in Filipinos (implicated gene): rs7119 (*HMG20A*), rs7766070 (*CDKAL1*), rs708272 (*CETP*), rs12150053 (*SERPINF1*), rs2383208 (*CDKN2B-AS1*), rs391300 (*SRR*), rs659366 (*UCP2*), and rs10497721 (*TMEFF2*). In particular, the highest ORs were rs7119, rs7766070, and rs708272 at 31.06 (95% CI: 4.18, 230.52), 20.03 (95% CI: 6.15, 65.26), and 12.80 (95% CI: 3.87, 42.34), respectively. Notably, both rs7119 and rs708272 had high risk allele frequency at 0.77 and 0.66, making them potentially good markers for screening for T2DM. As expected, most variants are from genes related to glucose and/or energy metabolism.**Conclusion:** The study found eight significant SNPs associated with T2DM susceptibility, with a variant of HMG20A (rs7119) conferring the highest level of risk. The data generated from this study can be valuable towards the development of genetic prediction models for type 2 diabetes relevant to the prevention and diagnosis of T2DM among Filipinos.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1523 Genetic Variants Impacting Brain Structure Changes in Cognitive Decline: A Genome-wide Association Study.

Authors:

Y. Jin[1], A. Scott[1], C. Rochet[1], P. Drineas[2], P. Paschou[1]; [1]Purdue Univ., West Lafayette, IN, [2]Purdue Univeristy, West Lafayette, IN

Individuals with cognitive decline exhibit distinct brain structure changes, highlighting the importance of understanding the genetic factors that may influence these alterations. We performed the first genome-wide association study aiming to identify common genetic variants that are associated with rates of brain change in the context of cognitive decline. We analyzed longitudinal magnetic resonance imaging (MRI) data from three cohorts, including the ADNI, AddNeuroMed, and NACC (1627 individuals). We initially assessed correlations between the rate of change in the Mini-Mental State Examination and changes in different brain structures. Subsequently, we performed a genome-wide association study (GWAS) and discovered common genetic variants that had a significant impact on the rates of brain change associated with cognitive decline. The identified variants were found to influence the rates of change in 16 distinct brain regions, including the bilateral hippocampus, lateral ventricles, temporal lobe, frontal lobe, occipital lobe, parietal lobe, left inferior lateral ventricles, left putamen, right cerebellum cortex and white matter hyperintensities. Notably, our study revealed a noteworthy association between the IRS1 gene and changes in the left temporal lobe in our gene-based GWAS. Previous research has linked IRS1 to anti-amyloid effects in mouse models of Alzheimer's disease. We also investigated the pleiotropy and concordance of genetic risk factors associated with changes in brain structure in the context of cognitive decline, examining the influence of various factors such as smoking, drinking, obesity, diabetes, high cholesterol, and head injuries on alterations in brain structure. Our findings revealed that all these risk factors could affect the rate of brain change in cognitive decline through genetic pleiotropy, concordance, or a combination of both mechanisms. Gene-set analysis highlighted the involvement of vascular dilation, inflammation, and nucleus protein stabilization processes specifically in the rates of brain changes associated with cognitive decline. To further explore the genetic findings, we performed exploratory Transcriptome-wide Association Studies (TWAS) and phenome-wide association studies (pheWAS), which allowed us to systematically identify mRNA expression of genome-wide significant genes and analyze their associations with various phenotypes. By identifying genetic variants associated with structural brain changes in individuals with cognitive decline, our study sheds light on the biological pathways underlying dysfunctional brain development in this population.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1524 Genetically elevated abdominal fat and non-fasting triglycerides: implications for cardiovascular risk.

Authors:

M. R. Christiansen[1], G. D. Carrasquilla[1], T. O. Kilpeläinen[1,2]; [1]Novo Nordisk Fndn. Ctr. for Basic Metabolic Res., Univ. of Copenhagen, Copenhagen, Denmark, [2]Novo Nordisk Fndn. Ctr. for Genomic Mechanisms of Disease, Broad Inst. of MIT and Harvard, Cambridge, MA

Background: Elevated fasting triglyceride (TG) levels are a risk factor for cardiovascular disease (CVD). While most previous studies have focused on the association between fasting TG levels and CVD risk, non-fasting TG levels may be more predictive of CVD, as they reflect changes in remnant cholesterol levels. Recently, we showed that abdominal obesity is associated with increased postprandial TG levels after a high-fat meal, independent of fasting TG levels. These differences may reflect the relatively high lipolytic activity of visceral fat, compared to lower-body fat that stores excess fatty acids after a meal, acting as a "metabolic sink". However, it is unclear whether these findings are generalizable to the broader population and whether they have implications for CVD risk.
Objective: Using the UK Biobank, we aimed to study how abdominal obesity affects non-fasting and fasting TG levels and assess the impact on incident CVD risk.
Methods: We utilized data from the UK Biobank, including TG levels for 382,203 non-fasting individuals (<8 hours since last meal) and 15,175 fasting individuals (≥8 hours since last meal). A genetic risk score for waist-hip ratio adjusted for BMI (WHR_{adjBMI}) was used to determine the effect of abdominal obesity on non-fasting and fasting TG levels to minimize the influence of confounding and reverse causation. Furthermore, the association between the WHR_{adjBMI} GRS and incident CVD in non-fasting and fasting individuals was assessed by Cox regression models, controlling for age, sex, hypertriglyceridemia treatment, assessment center, genotype chip, and 15 genetic principal components.
Results: The genetic score for WHR_{adjBMI} showed a 25% greater effect on non-fasting TG levels (beta = 0.005 SD per allele) than fasting TG levels (beta = 0.004 SD per allele). For every SD unit increase in the WHR_{adjBMI} genetic score, there was an increased CVD risk in the non-fasting group (Hazard Ratio = 1.003, 95% CI 1.002; 1.004), but not in the fasting group (Hazard Ratio = 1.000, 95% CI 0.995; 1.006). The effect of the WHR_{adjBMI} score on CVD was reduced after adjusting for non-fasting TG levels.
Conclusion: Genetic predisposition to abdominal obesity increases non-fasting TG levels more than fasting TG levels. Furthermore, the association between the genetics of abdominal obesity and incident CVD is stronger in the non-fasting than in the fasting state.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1525 Genetically informed type 2 diabetes risk prediction: leveraging machine learning for personalized approaches

Authors:

A. Khattab[1,2], S-F. Chen[1,2], A. Torkamani[2,1]; [1]Scripps Res., La Jolla, CA, [2]Scripps Res. Translational Inst., La Jolla, CA

Background: Early detection and prevention of type 2 diabetes (T2D) are crucial considering its global prevalence. This study proposes comprehensive person-centered risk prediction models for T2D, integrating environmental, clinical, and genetic factors using machine learning (ML) techniques. Methods: Utilizing data from the UK Biobank, we identified a prevalent T2D group at baseline (8,969 cases and 107,981 controls) and an incident T2D group over a 10-year follow-up (21,470 cases and 258,485 controls). Our models incorporated three types of risk factors: environmental, clinical (including biomarkers and diseases with known diabetes risk like CVD), and genetic factors in the form of polygenic risk scores (PRS) related to both clinical risk factors and T2D pathogenesis. Decision-tree-based ensemble ML algorithms were employed to train separate models for each group. The importance of features was assessed using SHAP values, and the top predictors were selected to build the final model. Results: Serving as a baseline model, the T2D prevalence model, consisting of 395 features, exhibited an ROC-AUC of 0.99, an area under the precision-recall curve (PR AUC) of 0.96, and an F1 score of 0.9. The T2D incidence model, incorporating the same 395 features, achieved an ROC-AUC of 0.97, a PR AUC of 0.87, and an F1 score of 0.78. Conclusions: While this study is still in progress, our interim results highlight the potential of ML in identifying relevant risk factors. The metrics of our comprehensive ML models, including the ROC-AUC, PR AUC, and F1 score, indicate their higher performance compared to existing literature. These models have the capacity to assist clinicians in making more precise and individualized decisions regarding T2D screening and treatment, ultimately aiming to prevent the onset of T2D. Future validation will be conducted on the All of Us dataset, which is known for its greater diversity, to further solidify our findings.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1526 Genetically predicted telomere length is associated with adverse clinical and pathological outcomes of Alzheimer's disease and dementia

Authors:

M. Lynch[1], J. Jin[1], M. Taub[2], J. Farfel[3], J. Yang[3], N. Chatterjee[4], D. Bennett[3], R. Mathias[5]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins, Baltimore, MD, [3]Rush Med. Coll., Chicago, IL, [4]Johns Hopkins Univ., Gaithersburg, MD, [5]Johns Hopkins Univ, Baltimore, MD

Telomere Length (TL) attrition is an established hallmark of aging and shorter TL has been associated with aging-related phenotypes including Alzheimer's disease (AD) and mild cognitive impairment (MCI). However, the interplay between TL and pathologic measures of AD has not been as well established. This study examined the association of genetically predicted TL (gTL) with dementia, MCI, level of and change in cognition, and AD-related pathologies. We leveraged existing genotype array data on N=2057 European ancestry samples from the Religious Orders Study (ROS) and the Rush Memory and Aging Project (MAP). In the combined ROSMAP sample, 37.6.% were diagnosed with clinical dementia, 22.9% with MCI, and 64.9% were diagnosed with pathologic AD among the n that came to postmortem. The mean age was 78.8 years old at blood draw. The polygenic risk score (PRS) previously derived for TL based on multi-ancestry TOPMed data using a ME-Bayes SL approach was used to compute gTL in ROSMAP. The approach uses a Bayesian framework to first model the genetic correlation in SNP effect size across ancestries, followed by a super learning step to combine PRS across various tuning parameter settings and all ancestries. Next, we tested for associations between gTL and four clinical outcomes and 12 neuropathologies, adjusting for age at death and sex. Education was also included as a covariate when assessing clinical outcomes. In ROSMAP, higher gTL is associated with lower odds of dementia (OR= 0.86, p=0.0034) and MCI (OR=0.86, p=0.0036), higher global cognition (Beta=0.32, p=0.0100), less severe cognitive decline (Beta=0.02, p=0.0332), and less global AD pathology (Beta=-0.17, p=0.0268) and tau tangle density (Beta=-0.44, p=0.0061).Our findings provide evidence linking shorter telomere length with adverse clinical and pathological outcomes of AD. We are currently extending this research to include a more diverse ancestral representation, utilizing data from both the Alzheimer's Disease Sequencing Project and the Health and Retirement Study cohorts.

PB1527 Genetically regulated gene expression influences chronotype and sleep duration in diverse populations.

Authors:

G. Chilton[1], K. Bozeman[1], M. Patel[1], H. Wheeler[2]; [1]Loyola Univ. Chicago, Chicago, IL, [2]Loyola Univ Chicago, Chicago, IL

Sleeping habits are integral components of daily life and circadian misalignment can increase cardiometabolic disease risk. Two important sleeping traits are chronotype, defined as the inclination to be a morning person, and sleep duration. Heritability estimates are 50% for chronotype and 46% for sleep duration. Populations with African genetic ancestries benefit from more genetic variation and smaller linkage blocks, increasing potential to discover new underlying mechanisms of complex traits. However, around 80% of GWAS are done on European populations, resulting in very little diversity of results and insufficient predictive power across diverse populations. Here, we focused on how genetically regulated gene expression may affect sleep phenotypes in diverse populations. We used Pan-UK Biobank GWAS summary statistics and Genotype Tissue Expression (GTEx) Project multivariate adaptive shrinkage gene expression prediction models implemented in S-PrediXcan to perform transcriptome-wide association studies (TWAS) on the chronotype and sleep duration phenotypes. For chronotype, there were 498,781 total participants from 6 diverse populations (META) and 5,561 participants from the African ancestries population (AFR). For sleep duration, there were 501,504 META participants with 6,382 participants from AFR. We performed S-PrediXcan on the META and AFR populations for each phenotype for 13 brain tissues. In the META analysis, 89 genes significantly associated with chronotype and 63 were significant in more than one tissue ($p < 5.0e-8$). Additionally, of the 22 genome-wide significant genes for sleep duration, 10 were significant across several tissues. The most significant association was increased *RGS16* expression with the “morning person” chronotype in hypothalamus and 8 other tissues (P = 4.7e-46) in the META analysis. *RGS16* (regulator of G protein signaling 16) is a highly plausible association because the protein is involved in the formation and functioning of retinal ganglion cells by sending external light signals to the circadian clock region of the hypothalamus known as the suprachiasmatic nucleus. In the AFR analysis, the most significant associations were decreased *DOK5* expression with the “morning person” chronotype in 6 tissues (P = 9.0e-5) and increased *ATP1A3* expression with increased sleep duration in 13 tissues (P = 6.6E-6), both including hypothalamus, potentially implicating these genes in sleep phenotypes for the first time. These results are important in determining how an individual’s genotype may affect their sleeping habits and demonstrating how expanding the diversity of genetic research can increase discovery.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1528 Genetically-predicted gene expression identifies novel candidate genes for Polycystic Ovary Syndrome

Authors:

H. Rao[1], N. Josyula[2], L. Fernandez-Rhodes[3], A. Justice[4]; [1]Pennsylvania State Univ., State College, PA, [2]Geisinger Hlth.System, Danville, PA, [3]Penn State Univ., State College, PA, [4]Geisinger, Danville, PA

Polycystic Ovary Syndrome (PCOS) is a multifactorial and polygenic condition that affects metabolism, endocrine function, adiposity, menstrual cycle, fertility, and mental illness. Genome wide association studies have found single nucleotide polymorphisms (SNPs) associated with PCOS, most of which are located in non-coding regions and with limited knowledge on any functional role in PCOS pathogenesis. To identify the genes that may be relevant for PCOS-associated genetic loci, we conducted a Transcriptome-wide Association study (TWAS) for PCOS in female participants of the Geisinger MyCode Community Health Initiative Study (MyCode). Our analyses included 63,806 females with genetically-linked electronic health record data. Ninety percent of the study self-identified as of white/European American, 3% as black/African American, 4% as Hispanic/Latino, and <1% as Asian/Asian American. There were 2,466 females with PCOS in our study (prevalence= 3.82%), based on ICD billing codes and Rotterdam criteria to diagnose PCOS. Genetically regulated gene expression was estimated for PCOS-relevant tissues (ovary, uterus, brain, adipose, pancreas, whole blood, pituitary, and thyroid) using PrediXcan software and GTEx v8 reference data and used in subsequent TWAS analyses. Analyses were adjusted for age, self-identified ancestry, and first 10 genetic ancestry principal components. TWAS identified a significant ($P< 0.05/22,077$ genes tested, 2.26×10^{-6}) association for a long non-coding RNA (lncRNA), Lnc-APOL1-16 (Ensemble id: ENSG00000279652), on chromosome 22 with PCOS in 5 tissues (Adipose Subcutaneous, Adipose Visceral Omentum, Pituitary, Uterus, and Testes). LncRNAs can affect chromatin structure, RNA splicing, stability, and translation; however, there is no prior evidence linking this lncRNA to PCOS. Genes *IL4R* and *RBFOX2* achieved suggestive significance ($p<2.26 \times 10^{-5}$), in visceral omentum adipose tissue, and thyroid gland, respectively. *IL4R*, interleukin 4 receptor gene, is a protein coding gene that regulates IgE and TH2 cell production and is implicated in the insulin resistance pathway. *RBFOX2* (also known as *RBM9*) is an RNA binding protein known to regulate estrogen-receptor-1 transcriptional activity. We identified tissue-specific expression of two candidate genes (*IL4R* and *RBFOX2*) with strong evidence of a relationship with PCOS risk and comorbidities. Additionally, we identify a novel association between *Lnc-APOL1-16* and PCOS in several relevant tissues. Future analyses are needed to evaluate the utility of these newly identified genes as potential biomarkers or therapeutic targets for PCOS.

Genome Wide Association Studies (GWAS) have identified more than 100 loci associated with Parkinson Disease (PD). However, previous studies were mostly focused on European and Asian populations, leading to limited understanding of the genetic architecture of PD in Latin Americans. Recently we performed the first GWAS of PD in Latin Americans using 1,502 samples from Brazil, Chile, Colombia, Peru and Uruguay in the Latin American Research consortium on the GEnetics of Parkinson's Disease (LARGE-PD). To evaluate the impact of admixture in LARGE-PD GWAS, we performed local ancestry-based analysis (TRACTOR) using 1,450 unrelated LARGE-PD samples. LARGE-PD samples were imputed using TOPMed imputation server and local ancestry was inferred using RFMix v1. We identified 19 PD risk intergenic variants near *NRROS, SNCA, CTNND2, YTHDF1P1, SLC15A1, and ZNF264* and variants in *MAML3*, *SBSPON*, and *TRAV27*. Importantly, we replicated the association in *SNCA* (rs356182), which is one the most common genes implicated in Parkinson's disease. Additionally, the *NRROS* was found to be suggestively associated in our previous LARGE-PD GWAS, but significantly associated in our analysis accounting for local ancestry. The *NRROS* signal is Native-American ancestry specific and it is the only statistical significant p-value when we calculate the p-value based in a single ancestry. According FUMA analysis, our dataset has variants associated or linked with variants reported on GWAS catalog, which we found variants associated Schizophrenia (*SNCA*) and PD (*SNCA*), and in linkage with Educational attainment (*SNCA*) and Smoking initiation (*MAML3*). Notably, Mendelian Randomization analysis showed that Educational attainment is a risk factor while smoke is a protective factor for PD. Overall, after accounting for local ancestry, we discovered new ancestry specific loci associated with PD (*NRROS*) while confirming loci from previous conventional GWAS (*SNCA*). These results highlight the importance of account for local ancestry in GWAS using admixed populations such as Latin Americans.

Campus, Denver, CO, [13]Boston Univ. SPH, Boston, MA, [14]Johns Hopkins Univ, Baltimore, MD, [15]Univ North Carolina, Chapel Hill, NC

Severe obesity (SevO; BMI≥40kg/m^2) is an understudied global health issue, limiting knowledge about its mechanisms and impacts. To provide novel insights into the genetic architecture and mechanisms of SevO, we performed GWAS in 120,676 individuals across 11 ancestrally diverse population-based studies, generated a polygenic score (PRS) to quantify susceptibility to SevO, and assessed PRS applicability in phenome-wide association studies (PheWAS) to assess associations with chronic conditions. Ancestry and sex specific GWAS and meta-analysis were conducted with three different classes of SevO traits; 95th percentile [cases defined as the upper 5th percentile and controls as the 5th-50th percentile], Obesity Class 3 ([BMI≥40kg/m^2] vs. BMI≤25 kg/m^2) and Obesity Class 4 ([BMI≥50kg/m^2] vs. BMI≤25 kg/m^2). All analyses were adjusted for age, age^2, 10 principal components of ancestry and study specific covariates. We assessed replication of our novel findings in a follow-up sample of 479,213 individuals across 6 ancestrally diverse studies. We derived a weighted class 3 SevO PRS in the UK BioBank (UKBB) and performed a PheWAS of 19 clinical conditions. Participants were stratified according to PRS deciles and lifestyle behaviors including physical activity, diet, alcohol, and sleep were compared for those in the bottom (<10th percentile) with the top (>90th percentile) deciles. Across the three SevO traits we mapped 12 independent variants (P<5×10^{-8}) not previously associated with obesity related traits. Six variants located in *UBXN4, BHLHE40-AS1, TENM2, PLCL2, ZNF184, PSMD9* were replicated (Bonferroni P<0.004). Over 200 (21%) known signals for BMI were significantly associated with SevO, demonstrating a strong overlap in their genetic architecture. The class 3 SevO PRS in UKBB explained 11.4%, 6.0% and 14.4% of the phenotypic variance for Europeans, Africans, and South Asian participants, respectively and was associated with 37% of phenotypes considered (max 1668); many are known biological sequalae of obesity and some are novel (reticulocyte traits). SevO was present in 4.9% of those >90th percentile for PRS compared to 0.55% of those in <10th percentile, corresponding to a 10-fold increased risk of SevO. Within the 90th percentile, 20% of individuals had BMI<25kg/m^2 and reported significantly healthier lifestyle behaviors when compared to those with SevO. Our study expands the number of identified SevO signals, demonstrates a strong overlap in the genetic architecture of SevO and BMI, and reveals a remarkable impact of SevO on the clinical phenome, affording new opportunities for clinical prevention and mechanistic insights.

PB1531 Genome wide association study of Vitamin D deficiency in the Middle East with a relevant characterization of the novel*SDR42E1*gene

Authors:

N. Hindi[1], O. Albagha[2], P. M. Ericsson[1], G. M. Nemer[2]; [1]HBKU, Doha, Qatar, [2]Hamad Bin Khalifa Univ., Doha, Qatar

Vitamin D deficiency is highly prevalent in Middle Eastern countries, yet studies on Vitamin D polymorphisms and polygenic models have primarily focused on European populations. Interestingly, genomic research has identified a nonsense variant in the *SDR42E1* gene as a potential contributor to Vitamin D deficiency, but its role in Vitamin D metabolism remains understood.Here, we conducted the first genome-wide association study (GWAS) on Middle Eastern populations to identify genetic determinants of Vitamin D levels using genome and exome sequencing approaches on 6,047 and 199 Qatari and Lebanese subjects, respectively. We also functionally and structurally characterized the *SDR42E1* through CRISPR/Cas9 genome editing technique on cutaneous HaCat and intestinal HCT116 human cells.We discovered a novel variant, rs2298850 (*P* value = 1.71×10^{-08}), in the *GC* gene among Qataris. We further identified two novel suggestive variants, rs141064014 in *MGAM* (*P* value = 4.40×10^{-06}) and rs7036592 in *PHF2* (*P* value = 8.43×10^{-06}), in Lebanese individuals. A meta-analysis combining our Middle Eastern with the largest European GWAS confirmed the replication of numerous known variants. We also demonstrated that European-derived polygenic scores for Vitamin D exhibited lower performance than European estimations yet effectively predicted hypovitaminosis D.Significant associations between *SDR42E1* and genes involved in Vitamin D pathways were identified, including *ALPP*, *ABCC1*, and *SLC7A5*. Gene regulators of steroid and lipid biosynthesis, cellular senescence, and cancer prognosis were significantly affected in *SDR42E1* HaCat and HCT116 knockout models. We observed significant alterations in Vitamin D metabolites, including 24R,24,25 Dihydroxyvitamin D, in the *SDR42E1* HaCat knockout cells. In conclusion, our research underscores the diversity in genetic architecture and its impact on precision medicine across different populations. The study of the novel *SDR42E1* gene contributes to a comprehensive understanding of Vitamin D metabolism and related health conditions, laying a foundation for future research and clinical precision medicine applications.

PB1532 Genome-wide analyses of machine-learning predicted brain aging identifies new genomic loci and causal cross-phenotype associations

Authors:

P. Jansen[1,2], H. E. M. Abaddy[2], S. C. de Lange[2], T. A. Gausvik[2], I. A. Dekkers[3], J. E. Savage[2], M. van den Heuvel[2], D. Posthuma[2]; [1]Amsterdam UMC, Amsterdam, Netherlands, [2]VU Univ., Amsterdam, Netherlands, [3]Leiden Univ. Med. Ctr., Leiden, Netherlands

Introduction: Brain aging is a complex multifaceted process with profound implications on health, impacting cognitive function, neurological disorders, and overall lifespan. The specific genetic factors and biological mechanisms that influence this complex process remain to be fully understood. Here, we conduct a genome-wide association study (GWAS) on brain-age derived from machine learning in the largest single-site imaging dataset of the UK Biobank.
Methods: In UK Biobank we ran multiple ML algorithms to predict brain-age and calculate brain-age gaps (difference between predicted and actual brain-age), using structural and diffusion tensor magnetic resonance imaging (DTI) data. We perform GWAS analyses of brain-age in N=29,030 individuals to map genetic variants to brain aging, and extensive follow-up analyses using FUMA and other bioinformatic tools. We explore genetic overlap, and causality with possible risk factors of accelerated brain aging using LD score regression (LDSC) and Mendelian Randomization (MR).**Results:** XGBoost performed well in predicting brain age (mean gap: ~4.5 years). We observe a high SNP heritability (~25%) of BAG, with enrichment in conserved regions. We discover 9 lead variants in 7 genomic loci, and 153 mapped genes. We show significant genetic overlap in LDSC analyses with various phenotypes (depression, alcohol use). Mapped genes contain previously involved in (monogenic) neurodegenerative disease (MAPT, GFAP). Causality analyses using inverse-variance weighted MR highlights lifestyle factors (smoking) and chronic disease (type 2 diabetes) as causal factors for brain aging.
Conclusions: Our results illustrate the possibilities of advanced machine learning algorithms to derive novel, heritable brain phenotypes from multimodal brain MRI datasets. Combined with large-scale genetic data, we uncover the cross-trait association of brain-age with risk factors that shed new light on the causes of brain aging.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1533 Genome-wide analysis identifies genetic associations for multiple deep-learning-derived brain imaging endophenotypes.

Authors:

B. Guo[1], Z. Xie[2], S. Islam[1], A. Gottlieb[3], H. Chen[4], D. Zhi[5]; [1]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [3]UTHlth., Houston, TX, [4]The Univ of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [5]U Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Investigating the genetic architecture of brain structure from imaging data can be challenging, partly because of the difficulties involved in developing accurate and impartial brain morphology descriptors. Previously, we have created a 128-dimensional brain imaging endophenotype (ENDOs) using an unsupervised deep representation learning approach, and identified multiple loci from single-phenotype genome-wide association studies (GWAS) for each of the ENDO dimensions, using data from the UK Biobank. However, this approach may miss genetic associations where one single nucleotide polymorphism (SNP) is weakly or moderately associated with multiple ENDO dimensions. Here we develop a computationally efficient method, Joint Analysis of multiple GWAS (JAGWAS), and applied it on those ENDOs. Compared to existing multi-phenotype GWAS methods, JAGWAS can take related individuals and is free of the need for reference panels or permutations. Multi-phenotype GWAS of the ENDOs in discovery (n = 22,948 T1/T2) and replication cohorts (n = 12,839/11,708 for T1/T2) identified 22,552/21,109 significant replicated variants from 215/183 independent loci, respectively for T1 and T2. Out of the loci discovered, 51/39 cannot be found by taking the minimum p-value across single-phenotype GWAS of 128 ENDOs. Out of the genes mapped, 27 out of 46 T1 genes and 23 out of 34 T2 genes had significant transcription factor-expression associations in at least one of 47 tissues from the GTEx database. Out of those, 9 genes from T1 and 9 genes from T2 were from brain tissues, 3 of them came from both. Meta-analysis of the discovery and replication cohorts identified 159,769/150,076 variants which clustered into 906/848 independent association loci for T1/T2, at the genome-wide significance threshold of 5×10^{-8}, and 516/471 loci overlapped with expression quantitative trait loci from brain tissues in the GTEx database. We identified the optimal linear combination of ENDO dimensions that was most significantly associated with each SNP, and used a perturbation-based decoder interpretation (Eigen-PerDI) approach to identify brain signatures corresponding to the SNP. We showed that Eigen-PerDI identified relevant brain regions of a SNP more interpretable than individual ENDO dimensions. Our results showed that multivariate GWAS using unsupervised deep learning derived ENDOs, can boost the discovery of new genetic markers relevant to Alzheimer's disease (AD) which may provide insights into the genetic architecture of the brain.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1534 Genome-wide association analysis and construction of polygenic risk score model for predicting paroxysmal atrial fibrillation using machine learning models.

Hosp. Organization Disaster Med. Ctr., Tokyo, Japan, [9]Cardiovascular Ctr., Tsuchiura Kyodo Hosp., Ibaraki, Japan, [10]Div. of Clinical Pharmacology, Dept. of Pharmacology, Jichi Med. Univ., Tochigi, Japan, [11]Div. of Cardiovascular Med., Saitama Med. Ctr., Jichi Med. Univ., Saitama, Japan, [12]Dept. of Cardiovascular Med., Tokyo Med. and Dental Univ., Tokyo, Japan

Atrial fibrillation (AF) is one of the most common heart rhythm disorders, often developing as paroxysmal atrial fibrillation (PAF) and progressing to persistent AF. Diagnosis of PAF is challenging due to its intermittent occurrence. It is important to design a method to stratify the risk of PAF. Polygenic risk scores (PRS) facilitate the identification of individuals at high risk of a disease and can be clinically used for risk stratification. This study aimed to construct PRS-based models to predict PAF by conducting a comparative analysis of the genomic DNA isolated from patients with and without PAF. For model construction, we conducted a genome-wide association study (GWAS) of 1,208 subjects, and the results were used as summary statistics. We tested the constructed models using the data of 600 subjects who were not in part of the GWAS. Based on several parameters, including PRS and clinical factors, the Light Gradient Boosting Machine framework, an ensemble model based on decision trees for classification and regression prediction, was used to construct PAF-predicting models. We performed 5-fold cross-validation and evaluated model performance by determining the area under the curve (AUC). This study identified 57 significant PAF-associated SNPs by GWAS ($P < 5 \times 10\text{-}8$). To obtain the optimal model, SNPs were selected per the associated resultant *p*-values of the GWAS, and multiple R2 and *p*-value thresholds were considered to obtain candidate models that could predict PRS. The performance of these models was evaluated using test and validation datasets with a randomly split cohort of 600 subjects, and models with AUCs greater than 0.7 were selected. The investigation of the utility of clinical factors in identifying patients at risk of PAF revealed that AUC further increased upon including risk factors of PAF and other clinical factors in the model. These results suggest that predictive models including PRS and clinical factors may help in identifying PAF cases.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1535 Genome-wide association analysis and Evolutionary Action Equation for the Fitness Effect of Missense Mutations of Systemic Sclerosis identifies new susceptibility locus and mechanistic pathway genes

Authors:

S. Ketkar[1], H. Dai[1], B. Dawson[1], L. Burrage[1], D. Murdock[2], J. Asmussen[1], K. Wilhelm[1], O. Lichtarge[1], B. Skaug[3], M. Kerick[4], J. Martin[4], S. Assassi[3], M. Mayes[3], B. Lee[1]; [1]Baylor Coll. of Med., Houston, TX, [2]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [3]Univ. of Texas McGovern Med. Sch., Houston, TX, [4]Inst. of Parasitology and Biomedicine López-Neyra, CSIC, Granada, Spain

Systemic Sclerosis (SSc) has considerable morbidity and the highest mortality of all the systemic autoimmune diseases. SSc is a chronic, autoimmune connective tissue disorder that is primarily characterized by fibrosis of the skin and internal organs associated with a vasculopathy and exhibiting wide clinical heterogeneity. The causes of SSc are unknown and it is generally considered to result from a combination of external triggers operating in the context of genetic susceptibility. Several genome-wide association studies (GWAS) have shed light on the genetic component and estimated that it contributes 30% to the risk of developing SSc.

We conducted an extensive study using the exome sequencing (ES (performed by Regeneron in an academic-industry partnership)) from the participants of SSc Registry to elucidate etiology and pathogenesis of SSc, to identify novel SSc susceptibility loci, and to identify causative pathways and prioritize variants that stratify disease severity by examining the genotype-phenotype relationships which shape health and population fitness.

We first performed GWAS of 2,865 Caucasian cases and 1,043 controls. Genotype imputation of ES data with the 1,000 Genome Project Phase 3 panel yielded 5,522,961 variants for the analysis. Case-control association analysis was done using PLINK v1.9 logistic regression model of additive effects, including gender and first two principal components as covariates.

We identified a novel susceptibility locus at *MICB* (rs2516497, $P = 8.42 \times 10^{15}$) within the HLA region. Additionally, we confirmed and firmly established the role of *HLA-DQA1* (rs1048372, $P = 2.95 \times 10^{21}$) and *HLA-DQB1* (rs2647032, $P = 1.32 \times 10^{16}$) gene regions as SSc genetic risk factors. Replication testing in an independent case-control set of European ancestry (949 SSc patients, 998 controls) validated association of *MICB* SNP (rs2516497, $P = 7.17 \times 10^{9}$) to SSc and confirmed it as an independent event, i.e., not in linkage disequilibrium with other HLA class genes.

Next, we applied an evolutionary action method which predicts the impact of missense variants on protein function by measuring the fitness effect based on phylogenetic distances and substitution odds in homologous gene sequences. Using the missense variants from the ES data, this method corroborated genes associated with SSc and identified additional genes in the interferon pathway among others. *IFI44L* and *IFIT5* are interferon genes and are shown to be dysregulated in SSc blood and skin.

Using a GWAS analysis and evolutionary action method, we have identified a novel locus and missense mutations in the interferon pathway that may contribute to SSc pathogenesis.

Inc, Montreal, QC, Canada, [8]Dept. of Epidemiology, Biostatistics and Occupational Hlth., McGill Univ., Montreal, QC, Canada, [9]Dept. of Twin Res., King's Coll. London, London, United Kingdom

Background: Growing attention has been focused on sarcopenia, an aging-related disease of skeletal muscle characterized by low muscle mass, low muscle strength, and low physical performance. Although it is a common disease in the elderly which is associated with various comorbidities and mortality, the mechanisms underlying its development are not well understood. **Aim:** To elucidate the genetic drivers of sarcopenia, we performed genome-wide association studies (GWASs) using data from the Canadian Longitudinal Study on Aging (CLSA) cohort, in which data of grip strength, skeletal muscle index, a parameter of lean mass, and gait speed, a parameter of physical performance, are all available. **Results:** We assessed 24,655 subjects of European ancestry, with a mean age of 63.0 years where 50.3% were females. We first performed a GWAS of grip strength and identified three genome-wide significant variants: *EFCAB8* (rs2377735) and *CABLES1* (rs28589524) are novel loci for grip strength, and *UQCC1* (rs2425063) is close to *GDF5* which was reported to be associated with low grip strength and lean mass. We also performed a GWAS of skeletal muscle index, identifying three loci: *FTO* (rs1558902) and *RNU4-17p*/*MC4R* (rs35361355) are close to those which were reported to be associated with lean mass and grip strength, and *CCDC26* (rs4568584) is a novel locus for lean mass. No genome-wide significant findings were found for gait speed. Moreover, we performed a principal component (PC) analysis of the three traits and found that just a single variant showed a significant association with the first PC, a locus near *GDF5-AS1*/*GDF5* (rs224329) which is close to *GDF5* mentioned above. Regression analyses of the first PC showed that the first PC was associated with type 2 diabetes, osteoporosis, osteoporotic fracture, Alzheimer's disease, and other aging-related diseases. **Conclusions:** This is the first study to examine the genetic determinants of the three sarcopenia-related traits to the best of our knowledge, in contrast with previous reports to focus on just one of them. Further analysis of the data is expected to provide insights into mechanisms underlying the development of sarcopenia, which could lead to the identification of potential therapeutic targets and biomarkers.

PB1537 Genome-wide association and HLA fine-mapping analysis of Hunner-type interstitial cystitis identify predisposing class II HLA variants.

Authors:

K. Sonehara[1,2,3], Y. Akiyama[1], D. Maeda[4], H. Katoh[1], T. Naito[2,3], K. Yamamoto[2,5], Biobank Japan, T. Morisaki[6], S. Ishikawa[1], T. Ushiku[1], H. Kume[1], Y. Homma[7], Y. Okada[1,2,3,5]; [1]Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [2]Osaka Univ. Graduate Sch. of Med., Suita, Japan, [3]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [4]Graduate Sch. of Med. Sci., Kanazawa Univ., Kanazawa, Japan, [5]Immunology Frontier Res. Ctr. (WPI-IFReC), Osaka Univ., Suita, Japan, [6]The Univ. of Tokyo, Inst Med Sci, Tokyo, Japan, [7]Faculty of Med., Kyorin Univ., Tokyo, Japan

Hunner-type interstitial cystitis (HIC) is a rare, chronic inflammatory disease of the urinary bladder, with an extremely low prevalence of 10-50 cases per million population worldwide. HIC is among the most intractable, devastating bladder disorders, with severe impacts on patients' quality of life. Although recently generated evidence suggests its nature of the immune-mediated disease, the etiology and genetic background of HIC remain still enigmatic. Here, employing approximately 10% of the estimated HIC cases in Japan, we perform an initial genome-wide association study of 144 patients with HIC and 41,516 control participants, both of Japanese ancestry. Thanks to the largest case sample size ever reported for this rare disease, we identify a genome-wide significant association in the major histocompatibility complex (MHC) region on chromosome 6 (lead variant, rs1794275; risk allele frequency = 0.27; $P = 3.4 \times 10^{-9}$; odds ratio = 2.32 [95% CI 1.75-3.06]). The association is replicated in an independent dataset of 26 cases and 1,026 controls ($P = 0.014$). To fine-map the association, we perform an HLA imputation analysis using a high-resolution population-specific reference panel, pinpointing HLA-DQβ1 amino acid positions 71, 74, and 75 as the most significant associations ($P = 5.0 \times 10^{-8}$; OR, 1.94; 95%CI, 1.53-2.44). These amino acid variants are in complete linkage disequilibrium in the Japanese population ($r^2 = 1.00$). The completely linked haplotype of Thr71-Glu74-Leu75 shows a protective effect against HIC. Other than HLA-DQβ1 variants, we identify HLA-DPβ1 amino acid position 178 surpassing the region-wide significance threshold, which perfectly tags HLA-DPB1*04:02 ($P = 7.5 \times 10^{-8}$; OR, 2.35; 95%CI, 1.77-3.12). The three HLA-DQβ1 amino acid positions of 71, 74, and 75 are located together at the peptide binding groove, suggesting their functional importance in antigen-presentation. Our study provides the first evidence of genetic determinants of HIC risk, which may be attributed to class II MHC molecule antigen-presentation.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1538 Genome-wide association studies for alloimmunization among patients with sickle cell disease.

Authors:

Q. Sun[1], M. S. Karafin[1], M. Garrett[2], M. Telen[2], A. Ashley-Koch[2], Y. Li[1]; [1]UNC-Chapel Hill, Chapel Hill, NC, [2]Duke Univ., Durham, NC

Sickle cell disease (SCD) is a severe inherited blood disorder affecting about 100K US individuals, and blood transfusion is a key component in the clinical management of SCD patients. However, 8-76% SCD patients unfortunately become alloimmunized, many of which cause accelerated donor red blood cell destruction. Patients show substantial variability in their predisposition to alloimmunization, where genetic variability is one proposed component. Although several genetic association studies have been conducted for alloimmunization, the results have been inconsistent, and the genetic determinants of alloimmunization remain largely unknown. In an effort to advance genetic studies of alloimmunization, we performed a genome-wide association study (GWAS) in 236 African American (AA) SCD patients from the Duke OMG-SCD cohort, which is part of TOPMed, with whole genome sequencing data available. We applied logistic mixed models adjusting for sample relationship matrix and covariates, including presence of autoantibodies, hemoglobin genotype categories and sex. Despite the small sample size, we identified one genome-wide significant locus on chr12 ($p = 3.1e-9$) with no evidence of genomic inflation (lambda = 1.003). We also performed sensitivity analyses adjusting for additional covariates (Fy^b antigen and the amount of blood transfusion) and applying different sample grouping strategies based on the number of alloantibodies patients developed (>=2 v.s. 0 and >=2 v.s. <=1). These analyses consistently revealed several additional suggestive loci. Furthermore, these suggestive loci are supported by both eQTL evidence from GTEx whole blood and/or Jackson Heart Study PBMC RNA-seq data, and 3D chromatin conformation information derived from HiC data in spleen and/or K562 cells. In conclusion, we identified several novel genetic variants that are significantly associated with alloimmunization among SCD patients and linked those variants to genes leveraging functional annotation information. We call for the community to collect additional alloantibody information within SCD cohorts to further the understanding of the genetic basis of alloimmunization in order to improve transfusion outcomes.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1539 Genome-wide association studies identify a susceptibility locus to pelvic organ prolapse in the Japanese

Authors:

M. Matsunami[1], M. Imamura[2], A. Ashikari[1], X. Liu[3], N. Miyagawa[4], K. Tomizuka[4], K. Hikino[5], P. The Biobank Japan[6], K. Matsuda[6], C. Terao[7], M. Miyazato[1], S. Maeda[8]; [1]Univ. of the Ryukyus, Nishihara-cho, Japan, [2]Univ. of the Ryukyus, Nishihara, Okinawa, Japan, [3]RIKEN, Kawasaki, Japan, [4]RIKEN, Yokohama, Japan, [5]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [6]The Univ. of tokyo, Tokyo, Japan, [7]RIKEN IMS, Yokohama, Japan, [8]Univ. of the Ryukyus, Nishihara, Japan

Pelvic organ prolapse (POP) is a one of *common female health* issues, characterized by a descent of pelvic organs into the vaginal cavity. Although contribution of genetic factors is suggested by a twin study, its genetic predisposition has been poorly understood. While a few genome-wide association studies (GWAS) for POP have been conducted in European populations, there is no report of GWAS for POP using Asian populations, including the Japanese. To identify genetic loci associated with susceptibility to POP in the Japanese, we performed GWAS for POP using two Japanese datasets, Okinawa Bioinformation Bank (OBi) 324 POP cases and 2,733 controls and BioBank Japan (BBJ) 447 POP cases and 74,561controls. Genotypings were performed using Illumina Asian Screening Array for OBi participants, or Illumina Infinium Omni Express, Human Exome, Infinium Omni Express Exome v1.0, and Infinium Omni Express Exome v1.2, for BBJ participants. Genotype imputation was performed by minimac4 using 1KGP3+JEWEL_3k_v1.2 (1000 genomes phase 3 + 3k Japanese) as a reference. It has been known that there are two distinct genetic groups in the Japanese based on the results of principal component analysis (PCA), namely Hondo and Ryukyu. The former is a major Japanese group and the later includes individuals originally from the Ryukyu Archipelago, southernmost islands of Japan. Considering these genetic backgrounds, we divided participants of each dataset into these two groups, and analyzed the association of ~9.6 million imputed SNP dosages (RSQ > 0.3) with POP by SAIGE for each study group (OBi-Ryukyu, OBi-Hondo, BBJ-Ryukyu and BBJ-Hondo). A Meta-analysis of GWAS for OBi-Hondo and BBJ-Hondo identified *WT1* locus as susceptibility to POP (rs10742277, Chromosome 11, $p = 2.43 \times 10^{-8}$, Odds ratio (OR) = 1.54, 95% Confidence Interval (CI) 1.32-1.80, n = 68,973). A same trend of association of this locus was also observed in a meta-analysis of GWAS for OBi-Ryukyu and BBJ-Ryukyu ($p = 5.92 \times 10^{-2}$, OR = 1.29, 95% CI 0.99 - 1.68, n = 9,092), and integration of all 4 studies further strengthen the association of this locus with POP ($p = 7.67 \times 10^{-9}$, OR = 1.47, 95% CI = 1.29-1.68, n = 78,065). In conclusion, we have identified *WT1* as a genetic locus susceptible to POP in Japanese women.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1540 Genome-wide association studies of blood pressure phenotypes in 4,819 participants from Samoa and American Samoa.

Authors:

T-A. Yapp[1], J. Z. Zhang[1], M. Krishnan[1], S. Liu[1], B. M. Blobner[1], H. Cheng[2], T. Naseri[3], M. S. Reupena[4], S. Viali[5], J. Tuitele[6], R. Deka[2], N. L. Hawley[7], S. T. McGarvey[3], D. E. Weeks[1], R. L. Minster[1], J. C. Carlson[1]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of Cincinnati, Cincinnati, OH, [3]Brown Univ., Providence, RI, [4]Lutia i Puava ʻae Mapu i Fagalele, Apia, Samoa, [5]Natl. Univ. of Samoa, Apia, Samoa, [6]Government of American Samoa, Pago Pago, American Samoa, [7]Yale Sch. of Publ. Hlth., New Haven, CT

Exploring the genetic determinants of blood pressure (BP) phenotypes in Polynesian individuals could help address inequity in research with marginalized populations and has the potential to provide additional insight to what is known from other populations around the globe about the biological foundations of such traits. In the current study, we performed genome-wide associations studies of five traits—systolic blood pressure (SBP), diastolic blood pressure (DBP), mean arterial pressure (MAP), pulse pressure (PP), and hypertension (HTN)—in 4,819 research participants across five subsamples from Samoa and American Samoa. Genotypes were measured via two methods: 895,103 variants were genotyped in a subsample of 3,053 individuals from Samoa with the Affymetrix 6.0 array and 669,569 variants were genotyped in a subsample of 1,766 individuals from Samoa and American Samoa with the Illumina Global Screening Array. We then imputed up to 7,408,897 variants using a haplotype reference panel based on 1,285 participants from Samoa that were whole-genome sequenced by the TOPMed Program. We performed association testing of inverse-normally transformed traits in each subsample separately using linear or logistic mixed models, adjusting for fixed effects of age, sex, polity, principal components of ancestry and a kinship random effect. The subsamples were meta-analyzed using the *p* values and effect direction with weighting by the subsample size. No variants were observed to be genome-wide significant; variants at fourteen unique loci associated with BP phenotypes were observed at $p < 1 \times 10^{-7}$. Several of these loci have been associated with BP phenotypes before: *FGF5*, associated here with SBP and MAP, has been associated with HTN previously; *KIF15*, associated with SBP here, has been associated with PP; *KCNK3*, here with SBP, with SBP, DBP, and MAP; *DOT1L*, here with DBP and MAP, with SBP and PP previously; and *PDILT*, here with HTN, has been associated with SBP, DBP, and HTN. *PLPPR2*, associated in this study with SBP and MAP, however, has not been, to our knowledge, been associated with BP phenotypes before. Little is known about the function of *PLPPR2*; it is predicted to be involved in phospholipid processing and signal transduction. In this analysis, both known and novel genetic loci associated with BP phenotypes were observed, suggesting that the genetic architecture of blood pressure and hypertension in individuals from Samoa and American Samoa is affected by both universal and unique genetic determinants. Further investigation and validation of these results will be necessary to determine the biological mechanisms of these associations in cardiovascular health.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1541 Genome-Wide Association Study (GWAS) of Sepsis in BioMe Cohort

Authors:

M. Stapylton[1,2], A. Biji[3,2], S. Cullina[4,2], E. Kenny[3,2,5,6], S. Asgari[3,2,5,6]; [1]Mount Sinai, New York, NY, [2]Inst. for Genomic Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Icahn Sch. of Med. at Mt. Sinai, New York, NY, [5]Dept. of Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [6]Dept. of Genetics and Genomics, Icahn Sch. of Med. at Mount Sinai, New York, NY

Background: Sepsis is a life-threatening dysregulation of immune response to infections. Susceptibility to sepsis is partly explained by human genetic factors. Most previous genetic studies of sepsis have used relatively small patient populations with European ancestry, been poorly replicated and their relevance for non-European ancestry populations remains unclear. To fill this gap, we conduct a large, multi-ancestry genome-wide association study (GWAS) of sepsis that can identify the full spectrum of sepsis-associated genetic risk variants.
Methods: We identified 944 individuals in BioMe biobank (ages 18-95, median=62) with the sepsis ICD codes: A40, A41, R65.20, R65.21. Following imputation, we filtered out variants with a minor allele frequency (MAF) < 0.01, genotyping rate < 0.02, minor allele count (MAC) < 20, or Hardy-Weinberg p-value < 1e-8. Individuals with a genotyping rate < 0.1 were also excluded. BioMe participants were divided using self-reported ancestry into: Europeans N=8771, African-American/Africans N=7136, Hispanic/Latin-Americans N=10679 and Others N=4357. We then performed a GWAS of the sepsis phenotype in each subgroup using SAIGE after accounting for genetic-relatedness, population structure, age, sex, and 5 genotyping principal components. Lastly, we meta-analyzed results from each population along with results from UK Biobank (UKBB) A41 sepsis GWAS using the inverse-variance method implemented in METAL.
Results: In the meta-analysis, 242 variants reached the suggestive genome-wide association threshold (p < 10e-5). We did not observe any inflation in our meta-analysis results, (genomic inflation factor = 1.007). The odds ratio and MAF was consistent between BioMe Europeans and UKBB Europeans (1.19 (18%) vs 1.15 (18%)). The loci with the lowest p-value (p=6.5e-8) overlapped chr1:168951141 (1q24.2). This locus included four SNPs in high linkage disequilibrium (r2 > 0.7), with rs12030460 as the top associated SNP. All SNPs overlap the intronic region of LINC00970. Common SNPs in LINC00970 have been associated with several complex conditions with the strongest associations (p<10e-55) being venous thromboembolism and different clotting factors levels.
Conclusion: We ran the largest and first multi-ancestry GWAS of sepsis. At our current sample size, the locus with the strongest association overlaps LINC00970, a gene that has been implicated in coagulation disorders. Coagulation disorders are common in sepsis patients which may underlie the association between LINC00970 and sepsis risk. We are currently performing further investigation and replication of results in other biobanks to confirm this hypothesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1542 Genome-wide association study for metabolic syndrome reveals *APOA5* SNPs with multilayered effects in Koreans

Authors:

Y. Park[1,2], S. Moon[1], J. Choi[1], J. Kim[1], S-H. Im[3], H-Y. Son[1], J-I. Kim[1,2]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Med. Res. Ctr., Genomic Med. Inst., Seoul, Korea, Republic of, [3]Kangwon Natl. Univ., Gangwon, Korea, Republic of

Background and Purpose: Genome wide association studies(GWAS) regarding metabolic syndrome(MetS) have mainly been reported in non-Asian populations, and relatively small populations in Koreans. The interpretation of GWAS usually focuses on the top SNPs, but the specific explanation for other non-leading SNP signals is lacking. This study aimed to identify the interaction between rs2266788 and rs651821, major variants of apolipoprotein A5, and how they collectively influence plasma triglyceride concentrations. **Methods:** Based on the Korean Genome and Epidemiology Study cohort, a total of 58,600 Korean subjects with available biochemical information and demographic variables for MetS were included. These subjects were genotyped with the Korean Biobank Array and imputed with the Northeast Asian Reference Database 2 panel. We performed GWAS on MetS and its five diagnostic components (triglycerides, high-density-lipoprotein cholesterol, blood pressure, fasting blood glucose and waist circumference). **Results:** We conducted GWAS on MetS and its diagnostic components and discovered that APOA5 SNP rs651821 (risk allele C) was the top SNP in both MetS (p-value 1.21E-98, odds ratio (OR) 1.33) and triglyceride (p-value 2.80E-287, OR 1.67) phenotypes. rs2266788 (risk allele G, p-value 6.87E-113, OR 1.45) was another statistically significant SNP in APOA5, regarding the triglyceride phenotype. However, when a conditional analysis was done by rs651821, statistical significance was maintained but the OR direction was reversed. (Conditioned p-value 1.09E-26, Conditioned OR=0.76). Regarding SNP rs2266788, the G allele switched from the risk allele to the protective allele after conditioning. Rs2266788 was previously known to be a causal SNP with enhancer activities via the luciferase assay experiments. Thus, rs651821 and rs2266788 were independent signals but with opposite directions in the extended GWAS analysis. The conspicuous association pattern persisted in subgroup analyses regarding alcohol consumption, exercise frequency, and smoking status. **Conclusions:** Even though an allele might seem to be a risk allele, when the lead SNP's influence is removed, the particular SNP could portray an independent protective signal, indicating a multilayered effect of two SNPs. Both SNPs rs651821 and rs2266788 are independent SNPs with separate functional and enhancer activities. Hence, a new direction for future GWAS research was suggested.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1543 Genome-wide association study identifies candidate genetic variants associated with postoperative nausea and/or vomiting

Authors:

D. Nishizawa[1], R. Morino[2], M. Yokota[3,4], S. Ohka[1], S. Kasai[1], J. Hasegawa[1], Y. Ebata[1], K. Nakayama[1], K. Ikeda[1]; [1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan, [2]Koujinkai Daiichi Hosp., Tokyo, Japan, [3]Cancer Inst. Hosp., Tokyo, Japan, [4]East Hokkaido Hosp., Hokkaido, Japan

Purpose: General anesthesia is commonly conducted in surgeries for the treatment of cancer or other diseases. Whereas postoperative nausea and/or vomiting (PONV) is known as the most frequent side effect following anesthesia, considerable individual differences have been widely observed in incidence of PONV. We conducted genome-wide association study (GWAS) in patients who underwent general anesthesia to identify potential genetic variants that may significantly contribute to individual differences in PONV. **Methods**: The subjects recruited were a total of 806 patients with written informed consent who underwent general anesthesia by total intravenous anesthesia (TIVA) with propofol and/or desflurane at The Cancer Institute Hospital of Japanese Foundation for Cancer Research (JFCR). The study protocol was approved by the Institutional Review Board at each related institute. Total genomic DNA was extracted from peripheral blood samples and genotyping was conducted using whole-genome genotyping arrays with more than 900,000 markers and iScan System (Illumina, San Diego, CA, USA). GWAS was conducted in the entire 806 patient subjects to identify single nucleotide polymorphisms (SNPs) associated with frequency of nausea and presence/absence of nausea, vomiting, and both of nausea and vomiting (PONV) in trend/additive, dominant, and recessive genetic models. Genome-wide associations were also investigated only in patients with propofol. **Results**: As a result of GWAS in all patients, several two SNPs, rs2776262 SNP and exm2274524 SNP in the *CNTN5* gene region were significantly associated with frequency of nausea in additive or recessive and dominant models, respectively ($P < 7.812 \times 10^{-8}$). In another GWAS only in patients with propofol, rs7212072 and rs12444143 SNPs in the *SHISA6* and *RBFOX1* gene regions, respectively, were significantly associated with frequency of nausea in additive model as well as the rs2776262 SNP in additive and recessive models, and rs1752136 SNP and exm1401859 SNP in the *ATP8B3* gene region were significantly associated with vomiting in trend model. **Conclusions**: The results indicate that the SNPs identified could serve as markers that predict PONV. Our findings will provide valuable information for achieving satisfactory PONV control.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1544 Genome-wide Association Study Identifies Genetic Variants for Blood Sugar Regulation in a Taiwan population.

Authors:

C-L. Tsai, W-C. Chang, M-R. Lin, W-H. Chou; Taipei Med. Univ., Taipei, Taiwan

Type 2 diabetes (T2D) is a metabolic disease characterized by chronically elevated blood sugar. In the past, genome-wide association study (GWAS) studies on diabetes in the Taiwanese population only involved comparisons between cases and controls. However, our study primarily focused on analyzing glycemic indicators as continuous phenotypes in GWAS analysis. We investigated whether potential genes could be identified that would affect the regulation of blood glucose in the Taiwanese population. We combined the single nucleotide polymorphisms (SNPs) from the Taiwan Biobank (TWB) chip with the SNPs from 1000G for imputation, and underwent QC filtering. Ultimately, we obtained a total of 3,636,444 SNPs. We performed GWAS to identify associations of these SNPs with fasting glucose and glycated hemoglobin (HbA1c) in 59,448 samples from TWB. The results showed that 39 SNPs were significantly associated with fasting glucose, and 35 SNPs with HbA1c. After conducting a meta-analysis and comparing our results with previously published GWAS literature on fasting glucose and HbA1c, we identified seven overlapping SNPs associated with fasting glucose and three SNPs associated with HbA1c. Through pathway enrichment analysis, we discovered that the significant SNPs we found collectively affected the pathway related to Maturity Onset Diabetes of the Young (MODY). This further confirmed the reliability of our GWAS results. Among all, we found four novel genome-wide significant fasting glucose-associated SNPs (*rs34874677*, *rs2074489*, *rs12922649* and *rs11650716*), and one novel HbA1c-associated SNP (*rs2074489*). This study presented that in the Taiwanese population, not only identified genes that were commonly involved in regulating blood glucose levels across different populations but also discovered novel genes specific to Taiwan could be associated with the modulation of blood glucose.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1545 Genome-wide association study identifies multiple novel loci associated with circulating metabolite phenotypes involved in energy metabolism and inflammation in type 2 diabetes: results from the Asian Indian Diabetic Heart Study (AIDHS)

Authors:

M. Rout[1], G. Tung[1], D. Sanghera[2]; [1]OUHSC, Oklahoma City, OK, [2]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK

Despite the success of genome-wide association studies (GWAS), the genetic mechanisms that predispose people to type 2 diabetes (T2D) remain poorly understood. The high throughput metabolite profiling techniques have rapidly progressed from a single-gene/single-metabolite association to a genome-wide/metabolome-wide approach. However, limited data are available on non-white populations. Here we have performed global lipidomic profiling and a targeted genetic association study to understand the genetic influences of T2D-associated variants on circulating lipid metabolites using a T2D cohort of Punjabi Sikhs from India as part of the AIDHS. Untargeted lipidomic analysis was performed on blood samples of 3000 individuals (1723 T2D cases and 1277 controls) using liquid chromatography and high-resolution mass spectrophotometry (LC-MS). Of the 1863 identified analytes, including 417 known and 1446 unknown compounds, we identified 354 metabolites associated with T2D using multivariate mixed regression modeling. We further analyzed the association of 243 metabolites (with known structures) by conducting a genome-wide association study (GWAS) using genotyped and imputed at up to 14,959,825 million SNPs as part of discovery and replication cohorts. Our study identified 14 significant associations (p ranging from 3.1×10^{-8} to $3.5x10^{-18}$), including six robust signals in the genes involved in transient receptor potential (TRP) channel, and calcium signaling pathways with the metabolites connected with energy metabolism, fatty acid transport, inflammation, and glucose metabolism. No previous studies have reported the associations between these loci and metabolic traits. In our first metabolome-GWAS in Asian Indians, we have identified novel molecular signatures and pathways associated with T2D. If validated, these results can potentially contribute to developing new therapeutic strategies to improve the prediction and treatment of T2D.**Funding:** The Sikh Diabetes Study/ Asian Indian Diabetic Heart Study was supported by NIH grants R01DK082766 and R01DK118427 (NIDDK) and grants from the Presbyterian Health Foundation of Oklahoma.

PB1546 † Genome-wide association study of 30000 samples with bone mineral density in UK Biobank

Authors:

Y. Qian, H-f. Zheng; westlake Univ., Hangzhou, China

Osteoporosis, a prevalent aging-related disease, is characterized by decreased bone mineral density (BMD). Here, we conducted genome-wide association studies (GWAS) of BMD phenotypes at eleven skeletal sites, which were measured by dual-energy X-ray absorptiometry (the gold standard technology, referred to as DXA-BMD), in over 30,000 European individuals from the UK Biobank. We identified 91 unique and independent loci across 11 DXA-BMD phenotypes, including six novel loci and two sex-specific loci. By integrating multi-omics datasets, we prioritized six candidate genes for these novel loci (i.e., *ABCA1*, *CHSY1*, *CYP24A1*, *SWAP70*, *ZIC4*, and *PAX1*), providing insights into molecular mechanisms underlying osteoporosis. The annotated candidate genes of two sex-specific loci (i.e., *CYP19A1* and *CYP3A7*) were involved in steroid hormone biosynthesis. Our results demonstrated that the predictive accuracy of fracture risk using DXA-BMD phenotypic values or genetic risk scores (GRSs) outperformed those using BMD measured by quantitative ultrasound, suggesting the use of DXA assessment as a screening tool. We subsequently developed joint models that incorporated multiple GRSs, improving fracture genetic risk stratification and highlighting the utility of combining GWAS of the predicted trait with GWASs of relevant traits for enhancing genetic predictions of complex disorders. In the joint model, we identified eight DXA-BMD specific signals (five of which were novel), which were considered as novel candidate signals for fracture. Additionally, we uncovered shared polygenicity between head BMD and intracranial aneurysms (IA). Mapped genes of shared loci, especially for *SOX6* and *PLCE1* genes (with mixed effect direction on these two phenotypes), provide distinct genetic insights into the interplay between head BMD and IA. Finally, by integrating the druggable genome, gene expression, and GWAS datasets, we identified three genetically-supported drug targets (i.e., *SEBF1*, *CCR1*, and *NCOR1* druggable genes) as priority candidates for evaluation in osteoporosis treatment. This comprehensive investigation provides valuable information for understanding the genetic architecture of BMD and its relationship with aging-related diseases, as well as identifying potential therapeutic targets for osteoporosis.

PB1547 Genome-wide association study of apolipoprotein A and B and lipoprotein (a) in the China Health and Nutrition Survey

Authors:

C. Zhao, C. Spracklen; Univ. of Massachusetts, Amherst, MA

Lipids are important biomarkers and modifiable risk factors for cardiovascular diseases. The genetic determinants of total cholesterol (TC), high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), and triglyceride (TG) levels have been extensively studied in genome-wide association studies (GWAS); however, GWAS for apolipoprotein A and B (ApoA and ApoB) and lipoprotein (a) [Lp(a)] are very limited and primarily investigated populations of European ancestry, limiting the discovery of genetic variants that impact lipid-level variations in other ancestral groups. Using imputed genotypes (1000 Genomes phase 3) from up to 7,632 East Asian-ancestry individuals from the China Health and Nutrition Survey (CHNS), we performed a GWAS of seven lipid traits, including ApoA, ApoB, and Lp(a). Analysis of ApoA identified three genome-wide significant (*P* &lt 5e-8; EPACTS) loci: *LIPC* (rs1077835, $P = 1.66x10^{-14}$), *CETP* (rs72786786, $P = 1.14x10^{-11}$), and *LIPG* (rs9953437, $P = 4.37x10^{-8}$). Sequential conditional analyses identified two additional signals at the *LIPC* locus (rs261291, $P_{cond} = 9.13x10^{-11}$; rs145857216, $P_{cond} = 8.72x10^{-6}$). Analysis of ApoB identified four significant associations near *PCSK9* (rs151193009, $P=1.24x10^{-9}$), *CELSR2* (rs611917, $P = 1.47x10^{-10}$), *LDLR* (rs147540853, $P = 3.18x0^{-10}$), and *APOE* (rs7412, $P = 3.42 \times 10^{-63}$). Sequential conditional analyses identified one additional signal at the *APOE* locus (rs429358, $P_{cond} = 3.55x10^{-10}$). Results were similar for models that included BMI as a covariate. While the ApoA and ApoB loci are well-established for the traditional lipid traits, 6 of the 10 index variants have not previously been associated with ApoA or ApoB. For Lp(a), the initial analysis identified two associated loci: *TOMM40/APOE* (rs61679753, $P = 5.43x10^{-14}$) and *LPA* (rs7770628, $P = 2.78x10^{-204}$). Conditional analyses at *LPA* identified fourteen distinct association signals, of which nine have not been previously reported for association with Lp(a). Within Biobank Japan, we observed a positive correlation between the effect estimates of our lead *LPA* variants and the risk for coronary artery disease ($r^2 = 0.77$, $P = 0.0019$), providing support for the relationship between Lp(a) and coronary artery disease. Our findings provide new insights into the genetic architecture of apolipoproteins and lipoproteins and further highlight the importance of conducting genetic studies across diverse ancestry populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1548 Genome-wide association study of blood pressure traits in 140 000 Mexican adults

Authors:

M. Turner[1], J. Alegre-Díaz[2], J. M. Torres[1], F. Rivas[2], D. Aguilar-Ramírez[1], R. Haynes[1], N. Staplin[1], M. Hill[1], R. Collins[1], J. Emberson[1], J. Berumen[2], P. Kuri-Morales[2], R. Tapia-Conyer[2]; [1]Univ. of Oxford, Oxford, United Kingdom, [2]Univ. Natl. Autónoma de México, Mexico City, Mexico

Background: Genome-wide association studies (GWAS) in diverse ancestries have elucidated the genetic architecture of complex traits and diseases, but <0.5% of participants in previous GWAS are of Latin American ancestry. Using data from the Mexico City Prospective Study (MCPS), we aimed to identify potentially-novel blood pressure-influencing genetic variants in an admixed Mexican population.
Methods: We ran GWAS of systolic blood pressure (SBP), diastolic blood pressure (DBP), mean arterial pressure (MAP) and pulse pressure (PP) in 140,559 MCPS participants genotyped with version 2 of the Illumina Global Screening Array. Participants on antihypertensive drugs (16%) had their SBP/DBP increased by 6/3mmHg. Variants with imputation r^2>0.4 and N_{eff}>30 were analysed using SUGEN adjusted for age, age^2, sex, body mass index (BMI), and ancestry principal components. Forwards-selection-backwards-elimination fine-mapping identified conditionally-independent signals. We assessed tissue-specific enrichment with GARFIELD and molecular epigenome annotations from the Common Metabolic Diseases Genome Atlas. Sensitivity analyses included antihypertensive adjustment of 15/10mmHg and no BMI adjustment.
Results: Associations were tested at 42,121,163 variants. Covariate-adjusted LD score regression intercepts were 1.03, 1.03, 1.04 and 0.99, and heritability estimates were 0.10, 0.08, 0.10 and 0.06, for SBP, DBP, MAP and PP respectively. Fine-mapping identified 68 independent signals at 63 loci associated with SBP, of which 15 were considered 'novel'. For DBP, MAP and PP these were, respectively, 53 signals at 51 loci (11 novel), 74 signals at 70 loci (28 novel) and 22 signals at 22 loci (1 novel). After false discovery rate correction, 7 novel SBP variants replicated in a combined meta-analysis of PAGE, pan-UKB and Biobank Japan, including rs1561477 at *ACOXL*, rs7213811 near *YWHAE*, and rs9606885 at *YWHAH-AS1*. Sensitivity analyses gave similar results, but the larger antihypertensive correction yielded additional associations. Novel loci had larger MAFs in Indigenous Mexican-ancestry DNA segments. GARFIELD showed enrichment in blood vessel, kidney and adrenal tissue.
Conclusions: This GWAS of a previously under-studied population offers additional insights into the genetics of blood pressure.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1549 Genome-wide Association Study of Diabetic Retinopathy Identified with an Electronic Health Record Algorithm in the Million Veteran Program

Ctr., Atlanta, GA, [5]Emory Univ., Atlanta, GA, [6]Providence VA Med. Ctr., Providence, RI, [7]Phoenix VA Hlth.Care System, Phoenix, AZ, [8]Univ. of Arizona, Phoenix, AZ, [9]Massachusetts Gen Hosp, Boston, MA, [10]Harvard Med. Sch., Boston, MA, [11]Broad Inst., Cambridge, MA, [12]Stanford Univ., Palo Alto, CA, [13]VA Northeast Ohio Hlth.care System, Cleveland, OH, [14]Case Western Reserve Univ., Cleveland, OH, [15]Cole Eye Inst., Cleveland Clinic, Cleveland, OH, [16]Emory Univ., Johns Creek, GA

Diabetic retinopathy (DR) is the leading cause of vision loss and preventable blindness in adults. The course of diabetes and severity of complications vary substantially among individuals, and this variability is not fully explained by known risk factors. While statistically significant loci have been reported from several GWAS of DR, few have been replicated. To address this gap in knowledge, we developed and validated an electronic health record (EHR) algorithm to identify DR cases and controls with diabetes in three independent EHR systems: Vanderbilt University Medical Center, VA Northeast Ohio Healthcare System, and Massachusetts General Brigham, with positive predictive values ranging from 0.840 - 0.953. We applied the DR algorithm in the Million Veteran Program, which identified European (38,944 cases | 69,416 controls) and African (17,221 cases | 26,607 controls) ancestry individuals, identified with the HARE method. GWASs of TOPMed imputed SNPs stratified by ancestry were conducted using logistic regression adjusting for age, sex, duration of diabetes, HbA1c, and first ten principal components. We identified genome-wide significant loci in the European analysis, *TCF7L2* (rs7903146, (OR = 1.12 (95% CI 1.04 - 1.30), $p = 8.57 \times 10^{-24}$)), and *L3MBTL1* (rs6130396, (OR = 0.94 (0.93 - 0.95)), $p = 7.41 \times 10^{-9}$). The African analysis identified one significant locus, *G6PD* (rs1050828 (V68M), (OR = 1.19 (1.14 - 1.24), $p = 7.14 \times 10^{-17}$)). Investigation of genetically predicted gene expression with S-PrediXcan, using GTEx v8 followed by colocalization (>0.85), identified two and one genes significantly associated with DR in the European (*TCF7L2* and *L3MBTL1*) and African (*PSMB4*) analyses, respectively. Based on results from the European analysis, we investigated the association between a published T2D PRS and DR (OR = 1.14 (1.04 - 1.25), $p < 0.05$, per SD increase in PRS) in a European ancestry cohort (905 cases | 1,120 controls), adjusted for age, sex, duration of diabetes, and HbA1c. Our results suggest that those with a higher genetic risk for diabetes are subsequently at a higher risk for DR. The identified *G6PD* missense variant has been previously shown to be under positive evolutionary selection due to a protective effect against *Plasmodium falciparum* infections (i.e., malaria). While a *G6PD* deficiency confers protection from malaria and risk for hemolytic anemia, these results suggest it increases risk for DR as well. With an EHR-based algorithm for DR and the resources of the Million Veteran Program, we were able to identify novel DR-SNP associations that suggest an adaptive variant increases risk for DR and may contribute to ancestral disparities.

Among veterans deployed to the Gulf War (1990-1991), Gulf War Illness (GWI) is a chronic multisymptomatic illness characterized by complex and uncertain causes and pathophysiology. To gain new insights into the disease's origin and understand its complex genetic factors, we conducted the first genome-wide association study (GWAS) on GWI in 33,523 veterans of diverse ancestries (African American, Admixed American, and European) from the Million Veteran Program. This study considered GWI definitions based on Kansas and CDC criteria, as recommended by the US Institute of Medicine.

We performed GWAS on four GWI case definitions: i) Kansas GWI symptom and exclusionary condition criteria [KS Sym+/Dx−], ii) Kansas GWI symptom only criteria [KS Sym+], iii) CDC GWI criteria, iv) CDC GWI severe criteria. Transcriptome-wide association study (TWAS) was conducted using PrediXcan and gene expression weights from 49 tissues in GTEx-v8. Polygenic scores (PGS) of 31 complex traits were tested with GWI definitions using PRS-CS. All associations were adjusted for age, sex, and the top ten principal components of within-ancestry population structure and survived the multiple testing threshold.

Overall, eight independent variants were identified ($p<5\times10\text{-}8$), with two of them supported by independent transcriptomic and phenome-wide analyses. Rs4675853 was associated with KS Sym+ and was found to be an expression quantitative trait locus (eQTL) for *AGXT*, *MAB21L4*, and *ATG4B* in several tissues. It has also been reported to be associated with sex hormone-binding globulin levels. Rs138168412, associated with KS Sym+, is a multi-tissue eQTL for *AOPEP* previously linked to respiratory function and physical strength. The TWAS identified five additional GWI-gene associations, including *CEMIP* in the cerebellum and *SNCG* in the adrenal gland. PGS analysis revealed pleiotropy between GWI and several traits, with the strongest evidence observed for type-2 diabetes (T2D), anxiety, and depression. While the PGS of T2D showed a stronger association with GWI in deployed veterans, PGS of anxiety and depression was more strongly associated with GWI in non-deployed veterans. No significant association was found between GWI candidate genes (*ACHE* rs1799805, *BCHE* rs1799807, and *PON1* rs662) and GWI in the single-variant, gene-based, and genetically regulated transcriptome analyses. This study provides the first comprehensive assessment of GWI's polygenic architecture, identifying several risk loci implicated in biological functions potentially relevant to GWI pathogenesis. The pleiotropy analysis suggests that genetic liability to GWI is likely shared with several health outcomes.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1551 Genome-wide association study of hip dysplasia in two Norwegian cohorts.

Authors:

K. Kvarme Jacobsen[1], S. Børthe[2,3,4], L. Bjerke Laborie[5,6], H. Kristiansen[1,6], T. Gundersen[5,6], K. Rosendahl[7,8], B. Winsvold[9,4], T. Hosp., Oslo, Norway, [3]Univ. of Oslo, Oslo, Norway, [4]Norwegian Univ. of Sci. and Technology, Trondheim, Norway, [5]Haukeland Univ. Hosp., Bergen, Norway, [6]Univ. of Bergen, Bergen, Norway, [7]Univ. Hosp. of Northern Norway, Tromsø, Norway, [8]Univ. of Tromsø, Tromsø, Norway, [9]Oslo Univ. Hosp. HF, Ullevål, Oslo, Oslo, Norway, [10]Massachusetts Gen. Hosp., Boston, MA, [11]Broad Insitute, Boston, MA

Introduction:Developmental dysplasia of the hip (DDH) is a congenital disorder, resulting in a shallow hip socket where the hip joint may be incongruent, subluxated or completely dislocated. If diagnosed in infancy, non-invasive treatment is available but with an increased risk of early osteoarthritis. Despite a known heritability of about 70 percent in twin studies, little is known about the genetic underpinnings of DDH. Here, we aim to investigate the genetic background of DDH to aid our understanding of the disorder and improve diagnostics and treatment strategies. Methods:We used two established cohort studies: The Norwegian Mother-Father-Child Study (MoBa), and the Trøndelag Health Study (HUNT). In MoBa, the phenotype of DDH diagnosis was derived from a parent-reported question “Does the child have hip dysplasia?”. The HUNT phenotype was based on ICD-9 and ICD-10 diagnoses of DDH and secondary osteoarthritis. The samples have undergone standard quality control and imputation. A total of 32,988 children were available for analyses from MoBa and 69,500 adults from HUNT. For MoBa, we used plink 2.0s glm model for genome wide association analysis, with a 1:4 ratio of cases and controls where excess controls were excluded at random. All analyses were adjusted for sex and the first five principal components. HUNT was analysed using SAIGE, with sex and the first 10 principal components as covariates. Meta-analysis was done in METAL software. Results: From MoBa, a total of 1,362,062 SNPs and 1,340 children were included after quality control and ratio adjustment , of which 268 children had DDH. No SNPs reached genome-wide significance in this initial analysis. The most significant finding was a SNP close to *XPNPEP1* with $P = 1.01 \times 10^{-5}$, a peptidase gene that is putatively involved in collagen assembly. In HUNT, a total of 8,531,386 SNPs were available, and 408 individuals had DDH or secondary osteoarthritis. Rs713162 near *COL11A1* reached genome-wide significance at $P = 8.4 \times 10^{-9}$. *COL11A1* encodes a collagen XI subunit. This finding was not replicated in MoBa, and in the meta-analysis, the P-value of rs713162 was no longer genome-wide significant, as there was a small but opposite direction of effect in MoBa. Discussion:We found a genome-wide significant associations between SNPs and DDH in the HUNT cohort study, that was not replicated in the smaller MoBa study. However, both top hits in the MoBa and HUNT studies point to collagen and its metabolism as important factors in DDH. As the full MoBa sample becomes available, we believe that the increased sample size and power will more likely result in detection of genome-wide significant associations in the MoBa cohort as well.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1552 Genome-wide association study of Long COVID in the Million Veteran Program

Authors:

A. Rodriguez[1], D. Posner[2], M. Murray[3], J. N. Minnier[4], F. Xia[1], N. J. Getty[1], L. Gao[5], T. Cai[6], S. Iyengar[7], S-W. Luoh[8], K. Cho[2], R. Madduri[1]; [1]Argonne Natl. Lab., Lemont, IL, [2]VA Boston Hlth.care System, Boston, MA, [3]VA Boston Hlth.care System, Boston, MA, [4]Dept. of Publ. Hlth.& Preventive Med., Oregon Hlth.& Sci. Univ., Portland, OR, [5]Oregon Hlth.and Sci. Univ., Portland, OR, [6]Dept. of Med., Brigham & Women's Hosp. and Harvard Med. Sch., Boston, MA, [7]Case Western Reserve Univ., Cleveland, OH, [8]VA Portland Hlth.Care System, Portland, OR

Long COVID, also known as post-acute sequelae of SARS-CoV-2 infection (PASC), is a debilitating condition that affects up to 43% of individuals recovering from acute COVID-19. To unravel the genetic basis of PASC, the Department of Energy conducted a genome-wide association study (GWAS) in collaboration with the Million Veteran Program (MVP), a diverse cohort study of US veterans with nearly 30% representation of non-European populations.

All controls and cases had a documented history of SARS-CoV-2 infection. Cases were defined using the International Classification of Diseases (ICD)-10 code (U09.9) for PASC. Controls were individuals who previously had acute COVID-19 but did not have PASC. MVP samples were genotyped on the Thermo Fisher MVP 1.0 Axiom array and imputed with the TOPMed reference panel (version R2). GWAS was conducted for each ancestry group using PLINK2 software for logistic regression, adjusting for age, sex, and the top 10 principal components of ancestry.

The cohort included 3,779 PASC cases and 68,411 controls from MVP participants in European American, Admixed American, African American and Hispanic American ancestral groups. Of 11 million variants, we identified 2 novel loci associated with PASC at genome-wide significance (p-value < 5x10^-8) in MVP and with PASC-related traits. One locus, significant only in participants of African ancestry, contained two intronic variants of *CDH23*, rs10999901 (OR=1.39, p=3.6x10^-8) and rs1868001 (OR=1.40, p=6.7x10^-9). The association between rs10999901 and PASC may be mediated by smoking (per C-allele effect on cigarettes smoked per day in an external European cohort = 0.56, p=7.8x10^-7) or other immune-related traits such as ratio of natural killer cells to lymphocytes (beta=0.23, p=1.3x10^-4). Dysfunction of natural killer cells has been implicated in the pathogenesis of PASC-linked diseases, most notably severe COVID-19 and myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS). The other locus was rs3759084, significant in Admixed American (AMR) ancestry participants (OR=1.34, p=9.7x10^-9). rs3759084 is an eQTL for *LIN7A* in blood, which also harbors an independent risk variant for severe COVID-19, rs10862191 (R^2 with rs3759084 in AMR = 0.06). The involvement of *LIN7A* in neurotransmitter secretion and other neuronal pathways may mediate the association between rs3759084 and PASC. In summary, we identified two novel loci for PASC in the MVP providing the first evidence for genetic involvement. Refinements using a validated PASC phenotypic algorithm using natural language processing and machine learning approaches, as well as additional genetic analyses are underway.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1553 Genome-wide association study of modulators of glucocerebrosidase.

Authors:

E. Somerville[1], L. Krohn[1], K. Senkevich[1], E. Yu[1], J. Ahmad[1], F. Asayesh[1], J. A. Ruskey[1], D. Spiegelman[1], S. Fahn[2], C. Waters[2], S. P. Sardi[3], R. N. Alcalay[2,4], Z. Gan-Or[1]; [1]Montreal Neurological Inst., McGill Univ., Montreal, QC, Canada, [2]Columbia Univ. Med. Ctr., New York, NY, [3]Sanofi, Framingham, MA, [4]Tel Aviv Sourasky Med. Ctr., Tel Aviv, Israel

Parkinson's disease (PD) is a debilitating neurodegenerative disorder characterized by alpha-synuclein deposits and a progressive loss of dopaminergic neurons in the substantia nigra. *GBA1*, responsible for producing the lysosomal hydrolase enzyme glucocerebrosidase (GCase), contains some of the most common pathogenic PD variants. Although deficiencies in GCase are associated with PD risk, not all individuals with low GCase activity carry *GBA1* mutations, suggesting that other genetic variants may be influencing enzyme activity. In the present study, we aimed to uncover additional loci modulating GCase by performing the first GWAS of GCase activity on two independent cohorts: 697 PD cases and 347 controls from Columbia University and 357 PD cases and 163 controls from the Parkinson's Progression Markers Initiative. Meta-analysis revealed the strongest signal to be the *GBA1* locus, as expected, driven by p.N370S (rs76763715, beta = -4.5 se = 0.3, p = 1.6E-41). A novel association in the *GAA* locus was also observed (17:78056851:C:T, beta = -1.0, se = 0.2, p = 1.4e-8). We further investigated this locus by creating an interaction plot of GCase and acid alpha-glucosidase (GAA) enzyme activities in Columbia, which supported the top *GAA* genotype having an effect on the correlation of the enzymes. Additionally, when adding *GAA* genotype and GAA enzyme activity interaction to the linear model for GCase activity, the interaction of homozygous status for the same variant with GAA activity was associated with decreased GCase activity (beta = -0.3, se = 0.1, p = 0.03). We then investigated various PD risk genes and found multiple to be potential modulators of GCase activity. We confirmed a previously reported association of *LRRK2* p.M1646T with GCase activity in our analyses (rs35303786, beta = 1.1, se = 0.4, p = 0.003), but did not find associations with other pathogenic *LRRK2* or *TMEM175* variants. Our results present a novel locus associated with GCase activity, and provide genetic targets to be considered when conducting research and clinical trials involving GCase. Given that GAA is also a lysosomal hydrolase enzyme, an interaction between GAA and GCase may support the idea that overall lysosomal homeostasis can be disrupted by enzyme activity deficiencies. More research will be required to confidently determine the mechanisms behind this relationship.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1554 Genome-wide association study of Myasthenia Gravis uncovers new loci and gives first insights into the performance of polygenic prediction.

Authors:

A. Braun[1], F. Stascheit[1], J. Kraft[1], G. M. Panagiotaropoulou[1], M. G. M. Huijbers[2], G. Kuhlenbäumer[3], F. Leypoldt[3], A. Meisel[4], S. Ripke[1]; [1]Charité – Univ.smedizin Berlin, Dept. of Psychiatry and Psychotherapy, Berlin, Germany, [2]Dept. of Human Genetics, Leiden Univ. Med. Ctr., Leiden, Netherlands, [3]Dept. of Neurology, Univ. Med. Ctr. Schleswig Holstein, Christian-Albrechts-Univ., Kiel, Germany, [4]Charité – Univ.smedizin Berlin, Dept. of Neurology with Experimental Neurology, Berlin, Germany

Background: Myasthenia Gravis (MG) is an autoimmune disease of the neuromuscular junction that affects 14-20 per 100,00 individuals and is characterized by fluctuating weakness of the voluntary muscles. It is frequently categorized by age of onset and autoantibody profiles, as variations in symptom spectrums have been observed between these groups. About 80% of cases test positive for antibodies against the nicotinic acetylcholine receptor. While some cases exhibit other antibodies directed against skeletal muscle receptors, a fraction of patients lack any previously described biomarkers.
Methods: We performed a genome-wide association study (GWAS) of MG cases and unaffected controls of European ancestry from 13 cohorts. Subsequently, we split the sample into early-onset (diagnosed under 50 years of age) and late-onset (diagnosed aged ≥50) and ran separate GWASs. We further conducted association and conditional analyses on imputed human leukocyte antigen (HLA) class I and II alleles for combined, early, and late-onset MG. Finally, we assessed the performance of polygenic risk scores (PRS) by splitting our sample into training and test datasets. PRS were constructed using the clumping and p-value thresholding method.
Results: The GWAS of 5,708 MG cases and 432,028 controls identified 9 genome-wide significant hits ($p<5.0e^{-08}$) and 24 index SNPs below a p-value of $1.0e^{-06}$. Onset-specific analyses revealed 4 additional loci significantly associated with early and 3 with late-onset MG. Imputation of HLA types identified *HLA-B*08:01* as the top risk-conferring allele in MG (OR=2.35, $p=1.15e^{-52}$, SE=0.06) and early-onset MG (OR=4.68, $p=2.18e^{-94}$, SE=0.08) and *HLA-DRB1*03:01* as the top overall allele in a late-onset sub-sample that implied a protective effect (OR=0.48, $p=2.37e^{-9}$, SE=0.12). We observed opposite directional effects for several associated HLA types between early- and late-onset MG subtypes. PRS significantly predicted MG in an independent unstratified target sample, explaining up to 4.21% ($p=5.12e^{-9}$) of variance between cases and controls at multiple p-value thresholds.
Discussion: To our best knowledge, this represents the largest GWAS of MG to date and the first to assess polygenic risk prediction, which has yielded promising first results. Notably, the associated HLA types are part of the 8.1 haplotype which has previously been linked to MG other autoimmune diseases. In this context, the opposite direction of HLA effects between onset subtypes could imply a moderating effect on the age of symptom onset. In the next step, we aim to further expand the sample size, conduct autoantibody-specific analyses, and include non-European samples.

PB1555 Genome-wide Association Study of Orofacial Clefts in Filipinos Identifies Novel Locus

Authors:

D. Maher[1], N. Mukhopadhyay[2], S. Curtis[3], J. Carlson[1], E. Feingold[4], S. Weinberg[4], C. Padilla[5], J. Murray[6], M. Marazita[7], E. Leslie[8], J. Shaffer[1]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ Pittsburgh/Sch Dental Med, Pittsburgh, PA, [3]Emory Univ., Tucker, GA, [4]Univ of Pittsburgh, Pittsburgh, PA, [5]Univ. of the Philippines Manila, Manila, Philippines, [6]U of Iowa, Iowa City, IA, [7]Univ Pittsburgh, Ctr. for Craniofacial and Dental Genetics, Pittsburgh, PA, [8]Emory Univ., Atlanta, GA

Cleft lip with or without cleft palate (CL/P) is among the most common congenital anomalies, with an estimated incidence of approximately 1 in 500 live births in the Philippines. The etiology of CL/P is complex, manifesting in both syndromic and non-syndromic forms, with the majority of cases being non-syndromic, i.e., occurring in the absence of any other signs or symptoms. Despite advances in understanding the genetic basis of CL/P, genes identified to date cumulatively only account for part of the trait heritability. Additionally, as is broadly the case for genetic research, non-European populations have been underrepresented, contributing to health disparities and leading to generalizability issues. We performed a genome-wide association study (GWAS) on 1,399 individuals (cases/controls: 882/517) recruited from the Philippines. The participants were genotyped on the Infinium Global Diversity Array-8v1.0 and imputation was conducted using the TOPMed reference. To mitigate the risk of confounding due to population structure, principal component analysis was conducted and the first five principal components, as well as sex, were included as covariates. SNPs were filtered for imputation quality (R^2 >= 0.8), and minor allele frequency of 1%. Quantile-quantile plots were assessed visually to rule out remaining genomic inflation. One genome-wide significant association was observed near the gene KCNQ5 (rs9446804, p=3.874e-08, minor allele frequency=23.7%). The frequency of the lead variant was similar as has been reported in East Asian populations, though the association of this locus with orofacial clefting has not been reported previously. Independent replication in a cohort of 419 Filipino trios with CL/P from the Gabriella Miller Kids First Research Program did not find that this specific SNP was associated (p = 0.76), but did find two other SNPs within KCNQ5 (>5kb upstream) that were suggestive (chr6:72714789:A:G: p = 0.00029; rs12208063: p = 0.00025). Associations with several known cleft loci (e.g., ARHGAP29, IRF6, SHROOM3) were observed at the suggestive (p<10e-06) threshold and some (e.g., IRF6) were replicated in the Filipino trios. Overall, these results suggest that Filipinos share many of the known common risk variants for CL/P with other populations and additionally have nominated a novel candidate gene for follow-up. This study also showcases the benefit of performing GWAS in diverse populations.

PB1556 Genome-wide association study reveals novel genetic signals that differentiates neuromyelitis optica spectrum disorder from multiple sclerosis

Authors:

S. Liu[1], E. Misicka[1], D. Crawford[1,2,3], F. Briggs[1,2]; [1]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [2]Cleveland Inst. for Computational Biology, Cleveland, OH, [3]Genetics and Genome Sci., Case Western Reserve Univ., Cleveland, OH

Neuromyelitis optica spectrum disorder (NMOSD) is a rare demyelinating autoimmune disease (AD) affecting the optic nerve and spinal cord, with a prevalence of <1/10,000 that varies across populations. In contrast to multiple sclerosis (MS), a relatively common AD of the central nervous disease, NMOSD exhibits unique immunopathological mechanisms suggesting distinct genetic architectures. Here, we conducted genome-wide association studies (GWAS) to identify variants associated exclusively with NMOSD. The study population included 337 NMOSD cases (68% AQP4-Ab+), 718 healthy controls (HCs), and 1,547 MS cases (82% were non-Hispanic White and of European ancestry). The following GWAS for 8.9 million SNPs were conducted adjusting for age at enrollment, sex, and 1st five multidimensional scaling components: 1) NMOSD vs HC+MS, 2) NMOSD vs HC, and 3) NMOSD vs MS. In NMOSD vs HC+MS, the most significant association was rs2858866 (OR=2.0, $p=8x10^{-15}$). Located between *HLA-DRB1* and *-DQA1*, rs2858866 is an eQTL ($p<5x10^{-8}$) for *HLA-DRB1*, *-DQA1*, & *-DRB5* across tissues, including the brain. Similar associations ($p<5x10^{-8}$) were observed across all GWAS comparisons. In the major histocompatibility complex (MHC), there were several other signals with consistent associations ($p<5x10^{-8}$) across GWAS. Outside the MHC, there were also promising suggestive associations on chromosomes 2 (rs10207044-*STAT4*: OR=1.9, $p=2x10^{-7}$) and 5 (rs79272149-*LINC02147*: OR=4.1, $p=2x10^{-7}$) in NMOSD vs HC+MS. Focusing on HLA alleles in those of European ancestry, *HLA-DQA1*05:01* (OR=1.9, $p=2x10^{-9}$) and *HLA-DRB1*03:01* (OR=2.1, $p=2x10^{-8}$) were the most significant associations in NMOSD vs HC+MS and they were genome-wide significant in nearly all other comparisons. Similar results were observed when restricting to AQP4-Ab+ cases. In summary, this is the largest NMOSD sample investigated in a GWAS, including the largest study of AQP4-Ab+ cases. This is also the first GWAS to contrast NMOSD to MS, which enhanced the power to detect novel NMOSD-specific associations for this rare disease. Further investigation of the identified genetic variants targeting their functions and a more sophisticated characterization of the MHC region will offer valuable insights into the mechanisms driving NMOSD pathogenesis, and such analyses are ongoing (i.e., genetic instrument variables and metabolomic/proteomic QTL analyses). Our findings contribute novel insights into the complex genetic architecture underlying NMOSD and shed light on the distinct genetic underpinnings that differentiate NMOSD from MS.

Würzner[2]; [1]Inst. for Biomedicine (affiliated to the Univ. of Lübeck), Eurac Res., Bolzano, Italy, [2]Inst. of Hygiene & Med. Microbiol., Dept. of Hygiene, Microbiol. and Publ. Hlth., Med. Univ. of Innsbruck, Innsbruck, Austria, [3]MB-LAB – Clinical Microbiol. Lab., Innsbruck, Austria, [4]Dept. of NeuroSci.s, Biomedicine and Movement Sci., Univ. of Verona, Verona, Italy, [5]Computational Med., Berlin Inst. of Hlth.(BIH) at Charité – Univ.smedizin Berlin, Berlin, Germany, [6]MRC Epidemiology Unit, Univ. of Cambridge, Cambridge, United Kingdom, [7]Inst. of Genetic Epidemiology, Med. Univ. of Innsbruck, Innsbruck, Austria

The complement system (CS) is a fundamental part of the innate immune response. Alterations of CS activation are associated with several human diseases of both syndromic and complex nature. CS activation occurs via three distinct pathways: the classical pathway (CP), the mannose-binding lectin pathway (LP) and the alternative pathway (AP). Given no hypothesis-free genome-wide screen of the three CS pathways has been conducted so far, to identify the CS's genetic basis, we conducted genome-wide association studies of the functional activity of CP, LP, and AP in the Cooperative Health Research in South Tyrol (CHRIS) study (n=4990). We identified 7 loci, including 13 independent and pathway-specific variants (P-value<5e-08) located in or near *CFHR4*, *C7*, *C2*, and *MBL2* (known CS genes) and *PDE3A*, *TNXB*, and *ABO* (novel genes).Variants were associated with inflammatory, autoimmune and coagulation disorders and >400 proteins. We conducted transcriptome- and proteome-wide colocalization analyses based on state-of-the-art datasets, in combination with two-sample Mendelian randomization analysis. We identified three types of results: (1) confirmation of known causal pathways (e.g.: causal role of MBL2 on LP); (2) identification of within-CS feedback loops (e.g.: between AP and complement 7); and (3) identification of novel causal pathways, including: the causal role of ABO protein levels on LP (P-value=1.1e-10; MR-Egger intercept not significant); a causal effect of LP on collectin-11 (P-value=6.3e-44; heterogeneity P-value, P_{het}=0.46) and KAAG1 (P-value=9.0e-25; P_{het}=0.27) levels; a causal effect of LP on mouth ulcers' risk (P-value=9.5e-6; P_{het}=0.71). Overall, these results depict a first, comprehensive and unbiased map of the role of CS on human health.

PB1558 Genome-wide associations of multi-organ biological age gaps in humans

Authors:

J. WEN[1], Y. Tian[2], I. Skampardoni[1], Z. Yang[1], E. Mamourian[1], A. Toga[3], A. Zaleskey[2], C. Davatzikos[1]; [1]Univ. of Pennsylvania, philadelphia, PA, [2]The Univ. of Melbourne, Melbourne, Australia, [3]Univ. of Southern California, Los Angeles, CA

Introduction: Human aging is evident across multiple organ systems. Machine learning (ML) can be used to determine an individual-level phenotype known as the biological age gap (BAG), which reflects the difference between an individual's ML-derived age and chronological age. To comprehensively depict the genetic heterogeneity of the BAG within nine human organ systems, we performed genome-wide association studies (GWAS) utilizing a large cohort of 30,108 to 111,543 Caucasian participants from the UK Biobank study. **Methods**: We used a linear support vector regressor (SVR) and a 20-fold cross-validation to derive the nine BAGs. We then ran a linear regression using Plink for the brain, cardiovascular, eye, hepatic, immune, metabolic, musculoskeletal, pulmonary, and renal BAG, controlling for confounders of age, dataset status (training/validation/test or independent test dataset), age x squared, sex, age x sex interaction, age-squared x sex interaction, and the first 40 genetic principal components. Additional covariates for total intracranial volume and the brain position in the scanner were included for the brain BAG. We adopted the genome-wide P-value threshold (5x10-8) to determine significant signals. FUMA was used to define the genomic loci considering linkage disequilibrium. **Results**: GWAS identified 11, 44, 17, 41, 61, 76, 24, 67, and 52 genomic loci linked to the brain, cardiovascular, eye, hepatic, immune, metabolic, musculoskeletal, pulmonary, and renal BAGs, respectively. 143 loci are novel - their top lead SNP was never associated with any clinical traits in the EMBL-EBI GWAS Catalog. Specifically, 7, 18, 7, 11, 27, 14, 11, 26, and 22 novel loci were found for the abovementioned nine BAGs. As illustrative examples, we showed the results from two loci. First, we observed that a well-known genetic risk factor (APOE4) for sporadic Alzheimer's disease, located on chromosome 19 (rs429358), was associated with the hepatic BAG. Furthermore, we discovered a novel locus on chromosome 1 (rs76560665) that was associated with the brain BAG. **Conclusions**: In the present GWAS, we identified 394 genomic loci linked to the nine BAGs. These findings provide valuable insights into the genetic architecture underlying the biological age of human organ systems. Further investigations are warranted to elucidate the genetic correlations between the nine BAGs and other clinical traits, particularly chronic diseases.

PB1559 Genome-wide meta-analyses of cognitive decline across neurocognitive domains in older adults stratified by *APOE* genotype.

Authors:

V. Acharya[1], K-H. Fan[1], B. E. Snitz[2], M. Ganguli[3], S. T. DeKosky[4], O. Lopez[2], E. Feingold[1], M. Kamboh[1]; [1]Dept. of Human Genetics, Univ. of Pittsburgh Sch. of Publ. Hlth., Pittsburgh, PA, [2]Dept. of Neurology, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA, [3]Dept. of Psychiatry, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA, [4]McKnight Brain Inst. and Dept. of Neurology, Coll. of Med., Univ. of Florida, Gainesville, FL

Cognitive decline has a substantial heritability as shown by twin and population-based studies. *APOE*, one of the robust genetic risk factor for AD, has also been associated with cognitive decline, especially with the decline of memory, executive function, and global cognitive function. *APOE* genotype stratified analysis can help to identify other genetic loci which might be masked due to strong effect of *APOE* 4. Hence, we conducted *APOE* genotype stratified (*APOE*23/22, *APOE*33, *APOE*34/44) genome-wide meta-analyses using slopes across five cognitive domains (attention, language, executive function, memory, and visuospatial function) and global cognitive function . We derived domain slopes for ~3,000 individuals aged 65 and above coming from three longitudinal cohorts: Gingko Evaluation of Memory (GEM), Monongahela-Youghiogheny Heathy Aging Team (MYHAT), and Monongahela Valley Independent Elders Survey (MoVIES). A linear mixed effect model was used to determine the individual cognitive domain change across time by using baseline age, education, and sex as covariates. *APOE* genotype stratified genome-wide association analyses were then conducted using common and low frequency variants (≤1 % minor allele frequency) for each cognitive phenotype adjusting for four genetic principal components in each cohort and later meta-analyzed using inverse-variance method in METAL software. In the *APOE* 33 genotype group, we identified a novel genome-wide significant (GWS) signal for decline of global cognitive function on Chr6q12 (β= -0.507; P=1.44E-09). The same signal was also observed at a nominal significance in the *APOE* 23/22 group, but in the opposite direction (β= 0.57; P= 2.75E-03). A previously described novel signal for decline of attention on Chr9q21.32 in this sample without *APOE* genotype stratification (PMID: 37089073) was found to be confined in the *APOE* 33 group at GWS level (β= -0.288; P=9.95E-09). In the *APOE* 34/44 individuals, we observed a second novel signal for decline of language on Chr5q23.1 (β= 0.693; P=3.79E-08). In addition, we observed three sub-threshold GWS signals, including one for decline of executive function on Chr8p23.2 (β= 0.32; P= 8.49E-08) in the *APOE* 34/44 group, and for the decline of attention and language on Chr2q12.1 (β= 0.86; P=8.64E-08) and Chr5q22.3 (β= 1.41; P=5.66E-08) respectively in the *APOE* 23/22 individuals. In conclusion, the *APOE* genotype stratified GWAS analyses have enabled us to identify additional novel signals associated with cognitive decline in older adults. Our work provides improved understanding of the genetic architecture of cognitive aging.

Hlth., Boston, MA, [9]Ctr. for Applied Genomics, Dept. of Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA, [10]Dept. of Med., Div. of Nephrology, Columbia Univ., Coll. of Physicians & Surgeons, Dept. of Surgery, New York, NY, [11]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL, [12]Ctr. for Autoimmune Genomics and Etiology, Cincinnati Children's Hosp. Med. Ctr., Dept. of Pediatrics, Univ. of Cincinnati, Cincinnati, OH, [13]Dept. of BioMed. Informatics, Vanderbilt Univ. Med. Ctr., Nashville, TN, [14]Div. of Epidemiology, Dept. of Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [15]Div. of Genetic Med., Dept. of Med., Vanderbilt Univ. Med. Ctr., Nashville, TN

Uterine leiomyomata (fibroids) are common benign tumors of the uterus with poorly understood etiology. The prevalence of fibroids ranges between 20 to 80% across reproductive ages. Cost estimates for the United States due to fibroids range from $5.9 to $34.4 billion.

Previous genome-wide association studies (GWAS) have reported 72 associated loci but featured limited sample sizes for non-European populations. Our objective of this study is to identify novel genetic variants associated with fibroids across and within ancestry groups.

We conducted a meta-analysis of fibroid GWAS summary statistics from adult female participants with 74,294 cases and 465,810 controls across European (EUR), African (AFR), East Asian (EAS), and Central South Asian (CSA) ancestry groups from eight datasets. We meta-analyzed the data using METAL: cross-ancestry (all data), EUR, AFR, and EAS/CSA ancestry. Gene and pathway annotation used Functional Mapping and Annotation (FUMA). S-PrediXcan was used to evaluate associations with predicted gene expression in all GTEx v8 tissues, including the uterus.

We identified 371 sentinel SNPs, including 9 novel loci and 15 loci not previously discussed in literature but detected in publicly available biobank summary statistics. Functional analysis identified significant gene-set tissue enrichment in the uterus, cervix, esophagus, fallopian tube, ovary, bladder, and sigmoid colon tissues. These genes were also enriched in DNA damage and cell cycle biological pathways.

The predicted expression of 568 gene-tissue pairs at 180 unique genes were significantly associated with fibroids. Of those, 131 were previously unreported gene associations with fibroids. Within uterine tissue analyses, we observed six significant novel gene associations. There was an association with increased risk for fibroids with increased expression of: *SHMT1* (Odds Ratio (OR) = 1.24, p = 6.1e-7), *RPS26* (OR = 1.04, p = 1.4e-6), and *CD59* (OR = 1.14, p = 1.4e-5). There was an association with decreased risk for fibroids with decreased expression of: *SULT1E1* (OR = 0.72, p = 5.2e-18), *TSGA10* (OR = 0.90, p = 2.9e-10), and *SLC25A17* (OR = 0.84, p = 5.0e-6).

We identified consistent and unique associations at SNPs across populations and tissues in predicted uterine gene expression. There was enrichment in both hormone responsive tissues and tumorigenesis-related pathways. These new genetic loci and uterine expression factors may provide translational opportunities for novel fibroid treatments.

Orofacial clefts, notably clefts of the lip with or without the palate (CL/P), carry a large public health burden, ranking among the most common congenital abnormalities worldwide. Understanding the etiology of CL/P is challenging, because causality is multifactorial - with numerous genetic and environmental influences - and because phenotypes are extremely heterogeneous. Thus while genome-wide association studies (GWAS) have led to functional validation of risk loci, genetic architecture remains poorly understood.

The “subclinical phenotype” paradigm, an epidemiologically supported hypothesis, suggests that cleft lip may exist on a spectrum of severity ranging from subtle, ultrasound-detectable defects in the lip’s orbicularis oris muscle (OOM) to overt clefts. If true, OOM defects and cleft lip may share genetic and non-genetic risk factors. Therefore studying the genetics of OOM defects will improve our understanding of CL/P genetics.

Here we performed the first GWAS and meta-analysis of OOM defects in two cohorts: One GWAS cohort consisted of the individuals without CL/P but with affected close relatives (n≈3800), a cohort expected to be enriched for CL/P risk factors; another consisted of the individuals with no CL/P and no family history (n≈3400). By systematically comparing OOM defect rates, genetic associations, and their overlap with known clefting risk loci, we aimed to clarify the genetic relationship between OOM defects and CL/P.

While our study design does not enable us to formally test whether OOM defects are mild expressions of the processes leading to CL/P, we here interpret our results in the context of the subclinical phenotype framework. There are similar rates of OOM defects observed in families with and without history of CL/P (4.49% and 4.98% respectively, p=0.35, $\chi 2$=0.86). Moreover, there is limited overlap in OOM GWAS signals across the two groups, and also limited overlap between OOM and CL/P GWAS signals. These results appear most consistent with a conclusion OOM defects and CL/P are etiologically distinct phenotypes.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1562 Genome-wide polygenic score for inflammatory bowel disease is associated with diarrheal outcomes in Bangladeshi infants

Authors:

R. Munday[1], R. Haque[2], P. Korpe[3], U. Nayak[4], B. D. Kirkpatrick[5], W. A. Petri, Jr.[4], G. L. Wojcik[3], P. Duggal[3]; [1]Johns Hopkins Sch. of Med., Baltimore, MD, [2]Intl. Ctr. for Diarrhoeal Disease Res., Bangladesh, Dhaka, Bangladesh, [3]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [4]Univ. of Virginia Sch. of Med., Charlottesville, VA, [5]Univ. of Vermont Coll. of Med. and Vaccine Testing Ctr., Burlington, VT

Diarrhea is the second leading cause of death among children under 5 years of age worldwide. In addition to mortality, diarrhea also contributes to malnutrition, cognitive deficits, and linear growth faltering. In previous genome-wide association studies (GWAS) of host genetic susceptibility to enteric pathogens including *Cryptosporidium*, *Campylobacter*, and *Entamoeba histolytica*, we identified shared risk variants with inflammatory bowel disease (IBD) that were different for each pathogen suggesting a relationship between infection and autoimmunity. Children in these cohorts reported an average 3.8 independent episodes of diarrhea (range 0-19) per child and a median of 14 days of diarrhea (range 0-117) per child in the first year of life. The strong environmental risk of diarrheal infection from poor sanitation and overcrowding provides high rates of diarrhea, which represent the extreme cases of diarrhea not present among children in other studies. For this study, we aimed to identify a shared genetic architecture between inflammatory bowel disease and diarrheal outcomes. We included children in the first year of life from three independent birth cohorts in Dhaka, Bangladesh: the Dhaka Birth Cohort, the Performance of Rotavirus and Oral Polio Vaccines in Developing Countries study, and the Cryptosporidiosis Birth Cohort. All three studies prospectively enrolled children from a poor, urban community in Dhaka, Bangladesh and followed them biweekly for diarrhea episodes, infection, and general health. We used 5.37 million SNPs from a publicly available genome-wide polygenic score for inflammatory bowel disease (PGS000017) to derive a score for each participant. We performed logistic regression with 2 severe diarrheal phenotypes, each spanning the first year of life adjusted for sex, genotyping array, and the first principal component: (1) no diarrhea vs 6 or more episodes of diarrhea, indicating frequency, and (2) no diarrhea vs 25 or more days of diarrhea, indicating duration. In the analysis of diarrheal episodes, as the polygenic score increased, individuals were more likely to be cases (per SD OR = 1.31, 95% CI 1.02-1.68, p = 0.03). Similarly, in the analysis of days of diarrhea, the IBD polygenic score was associated with case status (per SD OR = 1.33, 95% CI 1.02-1.72, p = 0.03). These findings provide evidence for a link between the pathogenesis of inflammatory bowel disease and extreme diarrhea in early childhood, both in terms of frequency and duration, and may provide insights into preventative or therapeutic approaches.

Orofacial clefts (OFCs) are the most common congenital craniofacial anomalies and the second most common birth defect worldwide. OFCs can be categorized into non-syndromic malformations, which occur in isolation, and syndromic malformations, which are associated with another malformation or as part of a recognized malformation syndrome. Non-syndromic OFCs, including cleft lip, cleft palate, and cleft lip with cleft palate vary between the sexes and birth prevalence rates differ across populations. To elucidate the underlying mechanisms for differential risk to OFCs between the sexes we analyzed whole genome sequences from case-parent trios generated through the Gabriella Miller Kids First (GMKF) Consortium. Our study comprised a total of 890 OFC trios from multiple ethnicities (European (N=371), Latin American (N=265), African (N=130), and Asian (N=124)). We performed genotypic transmission disequilibrium tests (gTDTs) using our in-house Bioconductor package 'trio' to test for the interactions between autosomal SNPs and sex within each ethnic group, followed by a fixed-effects inverse-variance weighted meta-analysis using METAL. We identified one genome-wide significant locus on chromosome 3 where female carriers of variant alleles had a significantly lower OFC risk than male carriers ($p=6.1x10^{-11}$). This chromosome 3 SNP (rs74520055) has an average minor allele frequency (MAF) of 11% and maps to the intronic region of *RFTN1* gene. Its RegulomeDB score of 3a and its chromatin state assignment of 4 show biological evidence as a regulatory element and is associated with a transcription site. In addition, the SNP is also a chromatin signature of three protein-coding genes *BTD, HACL1,* and *ANKRD28,* two long intergenic non-coding RNA genes *LINC00690* and *RP11-194G10.3* and one miRNA gene *MIR563*. We further identified 8 more candidate loci on chromosomes 2, 5, 8, 9, and 10, with average MAF above 9%, where sex-specific effects achieved p-values less than $1x10^{-5}$: rs11693354 (*AGAP1*), rs28799100 (*TMEM161B*), rs1924005650 (*EIF3KP1*), rs2588209 (*SLC7A2*), rs55663336 (*RP11-586K2.1*), rs2456245 (*RP11-122C21.1*), rs78756981 (*CNTFR*), and rs11258513 (*FRMD4A*). Our inference corroborates the finding from an independent case-control study, which previously reported suggestive evidence for *RFTN1* as a sex-specific effect on risk toward non-syndromic OFCs.

PB1564 Genome-wide survival study identifies three novel assocations between non-HLA donor-recipient mismatches and kidney graft failure

Authors:

V. Mauduit[1], A. Durand[1], M. Morin[1], O. Rousseau[1], P-A. Gourraud[1], N. Vince[2], G. Blancho[3], M. Giral[3], G. Jean[4], M. Ribatet[5], S. Limou[1]; [1]CR2TI, Nantes, France, [2]Inserm, Nantes Université, Nantes Cedex 01, France, [3]CHU de Nantes, Nantes, France, [4]LS2N, Nantes, France, [5]Ecole Centrale de Nantes, Nantes, France

***Purpose**: Kidney transplantation is the best treatment of end stage kidney disease, a pathology affecting a growing proportion of the population. Donor-recipient (D-R) mismatches in HLA genes have been associated with a poorer kidney graft survival. However, HLA mismatches alone do not explain long-term graft function decline. We ran a genome-wide survival study (GWSS) on a large monocentric cohort of kidney transplant pairs in order to characterize D-R mismatches associated with kidney graft loss beyond HLA.
***Methods**: The KiT-GENIE genetic cohort comprises 1482 complete D-R pairs of European ancestry for kidney transplants performed in Nantes since 2000. After imputation with the TopMed reference panel, we performed a genetic association study on >8.2M polymorphism (SNP) mismatches for time-to-kidney graft failure (defined as return to dialysis or preemptive retransplantation). A D-R SNP mismatch was defined by the presence of a donor allele not shared by the recipient. We then tested association between mismatches and time-to-graft failure using multivariate Cox proportional hazards models adjusted for HLA mismatches. P-values below the multiple testing Bonferroni correction threshold (5x10-8) were considered significant.
***Results**: We identified three statistically significant associations: one chromosome 10 intronic mismatch near the promotor of a gene encoding a protein with structural similarities to complement component C9 (p=3.1x10-8, HR=3.5) , a chromosome 17 intergenic mismatch (p=1.0x10-8, HR=4.0) near a gene highly expressed in kidneys and playing a role in signal transduction and protein transport, and a chromosome 21 intronic mismatch of a gene encoding a type I membrane protein expressed in kidney (p=2.0x10-8, HR=5.2).
***Conclusions**: Our genome-wide analysis in a large homogeneous monocentric cohort revealed three novel non-HLA D-R mismatches associated with kidney graft failure. Further validation in external cohorts and non-European pairs is ongoing. In addition, we are constructing risk scores using the GWSS summary statistics for stratifying patients.

PB1565 Genomic Analysis of Plasmodium falciparum isolates across different altitudinal zones along the slope of Mount Cameroon.

Authors:

M. Ajonina[1,2], T. Apinjoh[1]; [1]Univ. of Buea, Buea, Cameroon, [2]Charisma Univ., Providenciales, Turks and Caicos Islands

Malaria elimination is threatened by the emergence and rapid spread of drug resistance. Understanding the demographic history of *Plasmodium falciparum* and the genetic basis of adaptation to antimalarial treatment and host immunity is critical to elimination efforts. This study sought to characterize the diversity of *P. falciparum* isolates across different altitudes along the slope of Mount Cameroon, genotyped using the Illumina next-generation sequencing platform. A total of 77,253 quality single-nucleotide polymorphisms were identified from 220 *P. falciparum* clinical isolates from high (24,214), intermediate (24,426), and low (28,613) altitude. About 49%, 48.2% and 30% of the parasite isolates from high, intermediate, and low altitudes, respectively had F_{WS} values &gt 0.95 indicative of dominant mixed genotype infections and low population sub-structure with high potential for out-crossing. No significant difference was observed in within-host diversity while population structure analysis did not separate the isolates in the three major altitudinal groups by PCA, F_{ST} and admixtures, suggesting bidirectional gene flow among the populations. A total of 94 antigenic genes under balancing selection were detected in the area including vaccine candidate gene *ama1, eba175, msp1, trap, dblmsp* and *clag2*. Moreover, 17 of these genes were identified to be under both recent positive directional and positive balancing selection including the prominent host immune target genes *surfin 8.2, trap,* and *ama1*. Recent directional selection analysis using integrated standardized haplotype score (iHS) did not detect any selection signatures in the *Pfcrt, Pfdhfr, Pfdhps, Pfmdr1,* and *PfK13* genes. Furthermore, no *PfKelch13* validated mutation associated with artemisinin resistance was identified in this study and no structural divergence was noticed among the *P. falciparum* parasite populations across different altitudes around the Mount Cameroon region.

PB1566 Genomic and transcriptomic influences on obesity-related traits in a high obesity-risk Hispanic/Latino population

Authors:

D. Kim[1], H. G. Polikowsky[2], H. M. Highland[1], H-H. Chen[2], Y. Wang[1], M. Graff[1], K. L. Young[1], M. Y. Anwar[1], X. Zhang[1], W. Zhu[2], P. Sharma[1], S. Berndt[3], J. D. Arias[3], A. D. Gutierrez[4], M. Lee[5], J. B. McCormick[5], S. P. Fisher-Hoch[5], J. E. Below[2], K. E. North[1]; [1]UNC-Chapel Hill, Chapel Hill, NC, [2]Vanderbilt Univ., Nashville, TN, [3]Natl. Cancer Inst., Rockville, MD, [4]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [5]UTH SPH Brownsville, Brownsville, TX

Approximately 66% of American adults are overweight or obese, fueling a public health crisis with financial costs projected to double every decade. Obesity-related genome-wide association studies (GWAS) have identified >1000 loci to date; however, most studies focus on crude measures like body mass index (BMI), and functional interpretation of GWAS findings remains incomplete. Thus, it is important to investigate precision obesity phenotypes coupled with additional omics data so that we can link genetic variants to causal genes and underlying pathways, in particular for historically marginalized populations. We aimed to discover causal relationships and reveal molecular mechanisms of obesity-related traits in Mexican American participants of the Cameron County Hispanic Cohort (CCHC). We performed GWAS of 13 obesity-related traits, including anthropometric traits, DEXA regional fat measures, and adipokine levels among CCHC study participants (N_{max} for GWAS = 4,271). Using directly measured transcripts in whole blood among the same CCHC participants (N_{max} = 866), we conducted two transcriptomic analyses - i) eQTL and ii) differential expression (DE) analysis. Among suggestive GWAS loci ($p < 5 \times 10^{-6}$), we identified transcripts in the 1 MB region that were significantly associated with the GWAS SNP ($p <$ 0.05 /number of transcripts tested) and for which DE was associated with the given obesity-related trait. We identified five significant SNP-transcript-trait associations from directly measured transcript levels - 1) rs74471501 - *FAXDC2* - BMI; 2) rs2774424 - *ARHGEF7* - visceral adipose tissue (VAT) to subcutaneous adipose tissue (SAT) ratio; 3) rs6810075 - *EIF4A2* - adiponectin-resistin index (ARI); 4) rs3743541 - *RP11-830F9.7* - VAT_{male}; 5) rs543314376 - *MAPK11* - SAT_{female}. We additionally performed colocalization analysis between our five genome-wide significant ($p < 5 \times 10^{-8}$) loci and GTEx gene expression data using fastENLOC. Two GWAS locus-transcript pairs demonstrated the locus-level colocalization posterior probability of ≥ 0.5 - 1) rs7171408 region (SAT and BFP) - *ANKDD1A* in multiple tissues, and 2) rs6810075 region (ARI adjusted for BMI) - *MCF2L2 pseudogene* in Brain). Many of these identified genes are relevant to obesity-related metabolism; for example, the *MAPK* pathway (with respect to SAT - *MAPK11)* plays a crucial role in appetite regulation, adipogenesis, and glucose homeostasis. In conclusion, we provide compelling evidence for novel associations between genetic variants, obesity-related traits, and genes mediating these relationships among Hispanic/Latino populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1567 Genomic heterozygosity is associated with a lower risk of osteoarthritis.

Authors:

G. Zhai[1], R. Gill[1], M. Liu[2], G. Sun[2], A. Furey[1], P. Rahman[2]; [1]Fac Med, Mem. Univ Newfoundland, St John's, NL, Canada, [2]Fac Med, Mem. Univ Newfoundland, St. John's, NL, Canada

Objective: Osteoarthritis (OA) is a chronic heterogeneous disease affecting over 500 million people worldwide. Genomic heterozygosity has been shown to confer a health advantage in humans and play a protective role in complex diseases. Given OA is a highly polygenic disease, we set out to determine if an association existed between OA and genomic heterozygosity. **Methods:** A case-control study design was utilized. End-stage knee and hip OA patients and healthy controls were recruited from the Newfoundland and Labrador (NL) population. DNA was extracted from their blood samples and genotyped by the Illumina GWAS microarray genotyping platforms. Directly genotyped GWAS data was imputed by Sanger Imputation Server and individual rates of observed heterozygosity (HetRate) and heterozygosity excess (HetExcess) relative to the expected were mathematically derived, and then standardized to a z-score. Logistic regression modelling was used to examine the association between OA and HetRate or HetExcess with adjustment for age, sex, and BMI. The Arthritis Research UK Osteoarthritis Genetics (arcOGEN) consortium database which contained end-stage OA (knee or hip) and control patients was utilized as a replication cohort to validate our results. **Results:** A total of 559 knee and hip OA patients (mean age 66.5 years, BMI 33.7 kg/m2, and 55% females) and 118 healthy controls (mean age 56.4 years, BMI 29.5 kg/m2, and 59% female) were included in the analysis as a discovery cohort. We found that OA had an inverse relationship with HetRate and HetExcess with an odds ratio of 0.64 (95% CI: 0.45-0.91) and 0.65 (95% CI: 0.45-0.93) per standard deviation (SD), respectively, after adjustment for age, sex, and BMI. This association remained unchanged for knee and hip joint-specific analyses. The findings were validated with the arcOGEN database which showed HetRate and HetExcess were associated with OA with odds ratios of 0.60 (95% CI: 0.56-0.64) and 0.44 (95% CI: 0.40-0.47) per standard deviation (SD), respectively. **Conclusions:** Our results were the first to clearly demonstrate that genomic heterozygosity plays an important role in the risk of OA, which could be used for early identification of individuals with a predisposition for OA.

PB1568 Genomic rare variant mechanisms for congenital cardiac laterality defect: A digenic model approach.

Authors:

A. Rai[1], B. Yuan[2], P. Lupo[3], C. Lo[4], R. Gibbs[2,5], J. Posey[2], J. Lupski[2,3,5], S. Morris[3], Z. Coban Akdemir[1,2]; [1]Human Genetics Ctr., Dept. of Epidemiology, Human Genetics, and Environmental Sci., Sch. of Publ. Hlth., The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [2]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [3]Div. of Pediatric Cardiology, Dept. of Pediatrics, Texas Children's Hosp. and Baylor Coll. of Med., Houston, TX, [4]Dept. of Dev.al Biology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA, [5]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX

Laterality developmental abnormalities are defined by perturbations in the usual left-right (LR) asymmetry of organs in the body. They involve a spectrum of disorders that range from cardiac D-transposition of the great arteries affecting only the heart to complex conditions including situs inversus totalis and heterotaxy which affect the entire thorax and abdomen. The heart is often affected in laterality defects as cardiac formation in early embryo requires proper LR axis signaling cues. Laterality defects show extensive anatomic heterogeneity in their genetic origins (AD, AR, XL, multigenic, etc.) and phenotypic presentation and result from heterogeneous underlying genetic etiology. The majority of their underlying molecular causes remain elusive due to its rarity, genetic and phenotypic heterogeneity, indicating that additional mechanisms remain to be elucidated. Several recent studies suggest that digenic/oligogenic inheritance models may contribute to the complex genetics of these defects. We investigated a digenic model, focusing our analysis on genes with known laterality defect associations. We analyzed a cohort of 271 "unsolved" proband-only exomes from individuals with clinically diagnosed laterality defects using family-based segregation analysis. Exonic and splicing variants with MAF <= 0.01% in gnomAD and CADD score of >=10 were used as a filtering criteria for rare and deleterious variants in 112 proposed laterality defect genes. Thirty probands were found to have >=2 rare and damaging variants, segregation analysis was performed in 21 probands for whom both parental samples were available. Variant allele confirmation and segregation analysis indicated likely damaging trans-heterozygous digenic variants in 7 probands, in genes previously associated with primary ciliary dyskinesia (PCD) such as *DNAH1/DNAH6*, *RSPH4A/DNAH6*, *DNAH6/DNAH9*, *DNAH9/TTC12*, *DNAH1/DNAH11*, *DRC1/GAS8*, and *CCDC40/DNAH1*- consistent with a digenic and or triallelic inheritance ciliopathy model. Parents of all probands were unaffected. In an extended family of 8 members, the female proband was found to have *DNAAF2/DNAH5* digenic variants, with both alleles inherited from the affected father. Of note, both of the variants were not found together in other unaffected 6 family members. These data provide further evidence that digenic epistatic interaction can contribute to the complex genetics of laterality defects. Functional studies for these identified variants and in other PCD genes in patients with laterality defects may provide further insights into the developmental biology and biological perturbations underlying birth defects.

PB1570 GWAS of Torus Palatinus Reveals Several Suggestive Loci

Authors:

M. Lee[1], A. M. El Sergani[1], C. D. Padilla[2], C. J. Buxó-Martínez[3], R. E. Long, Jr[4], L. M. Moreno Uribe[5], W. L. Adeyemo[6], A. Butali[5], M. L. Marazita[1], J. R. Shaffer[1], S. M. Weinberg[1]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of the Philippines, Manila, Philippines, [3]Univ. of Puerto Rico, San Juan, Puerto Rico, [4]Lancaster Cleft Palate Ctr., Lancaster, PA, [5]Univ. of Iowa, Iowa city, IA, [6]Univ. of Lagos, Lagos, Nigeria

Torus Palatinus (TP) is a midline bony projection located on the oral surface of the hard palate. It is generally considered benign, although when very large it can interfere with oral function. TP is common with reported incidence varying widely by both sex and ancestry. Early family-based studies have suggested autosomal dominant inheritance with reduced penetrance. Several studies have identified rare mutations associated with TP, but these can only explain a small fraction of cases. Thus, the genetics of TP remains largely unclear. In this study we performed GWAS of TP in a diverse cohort of 829 adults genotyped on the Illumina Infinium Global Diversity Array and imputed to the TOPMed reference. TP was evaluated from 3D digital impressions of the palate. In total, 41.1M SNPs were tested in GENESIS while adjusting for 5 ancestry principal components and sex as covariates. Thirteen SNPs showed suggestive associations. We highlight intronic SNP rs4704136(beta(se)=-0.86(0.17), p-value=7.37 x 10^{-7}), rs17013053(beta(se)=1.62 (0.33), p-value=8.28 x 10^{-7}) and rs1859400(beta(se)=1.25(0.25), p-value=9.51 x 10^{-7}), which are located near facial development genes (e.g., *LRRTM4, HEXB, SUPT4H1*). These results suggest that TP may be an oligogenic or polygenic trait.Results await confirmation via independent replication.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1571 Hemophagocytic lymphohistiocytosis gene variants in severe aplastic anemia and their impact on post hematopoietic cell transplantation outcomes.

Authors:

M. Rafati[1], L. McReynolds[1], Y. Wang[1], K. Jones[1], C. Dagnall[2], B. Hicks[3], S. Spellman[4], M. He[4], Y-T. Bolon[4], S. J. Lee[5], S. Savage[1], S. Gadalla[1]; [1]Natl. Cancer Inst., NIH, Rockville, MD, [2]Natl. Cancer Inst. /Leido, Bethesda, MD, [3]Leidos Biomed/DCEG/NCI/NIH, Bethesda, MD, [4]Ctr. for Intl. Blood and Marrow Transplant Res., Minneapolis, MN, [5]Clinical Res. Div., Fred Hutchinson Cancer Ctr., Seattle, WA

Severe aplastic anemia (SAA) is most frequently immune-mediated, but a subset of patients has a germline genetic predisposition including rare variants in hemophagocytic lymphohistiocytosis-associated (HLH) genes. Germline genetic testing for patients with SAA is important to guide their treatment plan and adjust hematopoietic cell transplantation (HCT) modalities. HLH is predominantly autosomal recessive (AR) or X-linked recessive (XLR). The frequency of monoallelic HLH gene variants and whether they are associated with SAA HCT outcomes are not known. The Transplant Outcomes in Aplastic Anemia project is a collaboration between the NCI and the Center for International Blood and Marrow Transplant Research and consists of genomic and clinical data from 824 patients with SAA of which 140 have an inherited marrow failure syndrome. We used exome sequencing data from the 684 patients with acquired SAA who underwent HCT between 1989-2015 to identify variants in 14 HLH-associated genes (11 AR, 3 XLR) which were curated using ACMG/AMP criteria. Deleterious variants of uncertain significance (dVUS) were defined as those with damaging predictions in => 3/5 meta-predictors (BayesDel, REVEL, CADD, MetaSVM and EIGEN). Patients with potentially causal variants fitting XLR or AR inheritance patterns were deemed unrecognized HLH (UHLH). The Kaplan-Meier estimator was used to calculate the probability of overall survival (OS) after HCT. There were 77 HLH variants in 49 patients; 24 were pathogenic or likely pathogenic variants (PLPVs) identified in 19 patients (2.8%) and 53 were dVUS. Monoallelic PLPVs in *PRF1* were the most frequent, present in 8/19 patients. Three patients fit the criteria for probable UHLH, including a male with a hemizygous PLPV in *SH2D1*, and two patients with dVUSs (one biallelic in *UNC13D*and one homozygous in *AP3B1*). Two UHLH patients survived until last follow-up and the third died one month post-HCT. HCT outcomes in patients with monoallelic PLPVs were statistically comparable to those of patients without variants. The 5-year OS probability in patients with PLPVs was 89% (95% CI=72-99) compared with 66% (95% CI=63-70) in those without variants (p=0.06). No statistically significant associations between HLH variants and other HCT outcomes were noted. We found that 7.2% of patients undergoing HCT for SAA carry potentially deleterious variants in HLH genes, with 2.8% carrying a PLPV. Patients with heterozygous PLPVs did not have different HCT outcomes compared with those without variants. Our data suggest that identification of monoallelic variants in HLH genes does not influence HCT outcomes and no special treatment consideration is warranted.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1572 Hepatic steatosis is reduced in PNPLA3 carriers on the WELL program: a very low carbohydrate diet, mindful eating, and positive affect online intervention

Authors:

E. Speliotes[1], J. Krinock[1], A. O'Brien[1], K. Raymond[1], J. Moskowitz[2], J. Daubenmier[3], H. Bayandorian[4], D. J. Isaman[1], D. H. Griauzde[1], L. R. Saslow[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Northwestern Univ., Chicago, IL, [3]San Francisco State Univ., San Francisco, CA, [4]none, San Francisco, CA

Background: Nonalcoholic fatty liver disease (NAFLD) affects about 25% of individuals. No effective medications are currently available to treat NAFLD. Our preliminary data suggests that insulin resistance and the G allele of rs738409 interact to amplify risk of developing NAFLD. One effective way to reduce insulin resistance is using a very low-carbohydrate (VLC) eating pattern which is a moderate protein, higher fat eating pattern. Mindfulness and positive affect teachings may also increase adherence to behavioral changes. **Methods:** We carried out a single-arm, online trial in adults with rs738409-GG or -CG. Participants completed measures on intervention feasibility, acceptability, and physical and patient-reported outcomes. Participants were taught to follow an ad libitum very low-carbohydrate eating pattern (20-35 net or non-fiber grams) of carbohydrates per day for 4 months. They were given supplementary psychological tools on mindfulness and positive affect. **Results:** Eleven participants were enrolled, 9/11 (82%) completed study outcomes, and 8/11 (73%) attended at least half of the sessions. In the intention-to-treat analyses we found: body weight decreased 10.9% ($p < 0.001$), HbA1c reduced 9.4% ($p = 0.001$), insulin reduced 30.7% ($p = 0.020$), insulin resistance reduced 36.8% ($p = 0.007$), triglycerides reduced 14.3% ($p = 0.021$), abdominal symptoms reduced 33.2% ($p = 0.044$), emotional function improved 22.6% ($p = 0.16$) and fatigue reduced 27.1% ($p = 0.024$). Six participants adhered to the eating pattern (defined based on their 4-month 24-hour dietary recalls), 3 participants were not adherent, and 2 had no 4-month 24-hour dietary recall. Adherent participants decreased body weight by 12.0% ($p < 0.001$), decreased liver lobe fat percent by 53.1% ($p = 0.001$), reduced AST by 33.9% ($p = 0.006$), reduced ALT by 47.5% ($p = 0.003$), reduced HbA1c by 7.7% ($p = 0.014$), reduced insulin by 40.5% ($p = 0.023$), and reduced insulin resistance by 44.0% ($p = 0.019$); LDL-cholesterol levels were not significantly changed. Nine participants provided 4-month self-report information. These nine were highly satisfied with the program (mean 6.22, 95% CI 5.58 to 6.85), with 5/9 (56%) giving the intervention the top score. Only 11% reported that they would stop the assigned eating pattern as soon as `the study was over, and 44% stated that they did not plan to ever stop following it. **Conclusion**: These results support the feasibility, acceptability, and preliminary efficacy of the VLC intervention in adults with high genetic risk for NAFLD. The results of this pilot study suggest that a VLC eating pattern is safe and efficacious approach for reducing hepatic steatosis in this population.

Hussman Inst. for Human Genomics, Univ. of Miami Miller Sch. of Med., Miami, FL, [4]The Dr. John T. Macdonald Fndn. Dept. of Human Genetics, Univ. of Miami Miller Sch. of Med., Miami, FL, [5]Dept. of Nutrition, Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [6]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [7]Dept. of Neurology, Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH, [8]Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Alzheimer Disease (AD) is the most common cause of dementia with a strong genetic component. Emerging studies have found a correlation between various plasma biomarkers and AD pathology, cognitive function, and neurodegeneration. However, limited research has been done to explore the influence of genetic variation on these plasma biomarkers, including the 42- and 40-amino acid forms of amyloid beta (Aβ40, Aβ42), total tau (tTau), phosphorylated tau 181 (pTau181), neurofilament light chain (NfL), and glial fibrillary acidic protein (GFAP).
We recruited 920 individuals from 16 extended, multigenerational Amish families in Ohio and Indiana to estimate the pedigree-based heritability of each biomarker. Genome-wide array data was employed to assess the SNP-based heritability for each biomarker. Plasma Aβ40, Aβ42, tTau, pTau181, NfL, and GFAP concentrations were measured using the Simoa™ Neuro-3Plex, 4Plex, and pTau181 Advantage V2 assays. Genotyping was performed using the Illumina Expanded Multi-Ethnic Genotyping Array and Global Screening Array. All plasma biomarkers were inverse-normalized before analysis. Pedigree-based heritability was estimated using a variance component model, adjusting for study center, age, sex, and diagnosis. *ApoE* e4 dosage was assessed as an additional covariate. SNP-based heritability was estimated using the Genomic Relatedness Restricted Maximum Likelihood model, stratifying SNPs based on linkage disequilibrium and adjusting for the same covariates above.
Pedigree-based heritability estimates were: Aβ40 = 14.8%, Aβ42 = 12.9%, Aβ42/40 = 5.3%, tTau = 38.0%, pTau181 = 25.8%, NfL = 60.3%, GFAP = 79.0%. Including *ApoE* e4 dosage as a covariate significantly affected the heritability of four biomarkers. It increased the heritability of plasma Aβ42 (13.7%, $p = 0.04$) and pTau (27.3%, $p < 0.0001$) but decreased that of Aβ42/40 (2.53%, $p < 0.0001$) and GFAP (29.7%, $p = 0.02$). SNP-based heritability estimates for plasma Aβ40, NfL, and GFAP (4.5%, 38.8%, and 66.2%) were lower than pedigree-based estimates; however, for Aβ42/40, SNP-based approach yielded a higher heritability of 48.4%.
We found that plasma biomarkers, such as Aβ42/40, tTau, pTau181, NfL, and GFAP, are highly heritable in the Amish population. These findings suggest a strong genetic determinant of plasma biomarkers associated with AD in the Amish population. Given plasma biomarkers are more objective than heterogeneous AD diagnosis and easier to measure, they may serve as surrogate markers to study the genetics of AD.

PB1574 Hidden protein-altering variants influence diverse human phenotypes

Authors:

M. Hujoel[1], R. Handsaker[2], M. Sherman[3], N. Kamitaki[4], A. Barton[5], R. Mukamel[6], C. Terao[7], S. McCarroll[6], P-R. Loh[8]; [1]Brigham & Women s Hosp./Harvard Med. Sch., Boston, MA, [2]Broad Inst., Charlemont, MA, [3]Massachusetts Inst. of Technology, Marblehead, MA, [4]Brigham and Women's Hosp., Boston, MA, [5]Harvard Univ., Cambridge, MA, [6]Harvard Med. Sch., Boston, MA, [7]RIKEN IMS, Yokohama, Japan, [8]Brigham and Women s Hosp. / Harvard Med. Sch, Boston, MA

Structural variants (SVs) comprise the largest genetic variants, altering from 50 base pairs to megabases of DNA. However, SVs have not been effectively ascertained in most genetic association studies, leaving a key gap in our understanding of human complex trait genetics. We identified protein-altering SVs from UK Biobank (UKB) whole-exome sequencing data (*n*=468,570) using haplotype-informed methods capable of detecting sub-exonic SVs and variation within segmental duplications. Subsequent association and fine-mapping analyses identified hundreds of protein-altering SVs that appeared to influence health-related traits in UKB.

Rare CNVs predicted to cause gene loss-of-function (pLoF) enabled new insights into effects of gene inactivation. A partial deletion of *RGL3* exon 6 conferred one of the strongest protective effects on hypertension of all coding variants in the human genome (OR = 0.86 [0.82-0.90], $P = 6.3 \times 10^{-10}$), replicating in *All of Us* (AoU; OR = 0.83 [0.75-0.92], *P*= 0.00026). Knockout of *RGL3* appeared to be well-tolerated based on 37 homozygotes in UKB, suggesting RGL3, or a pathway in which it functions, as a potential drug target. Incorporating pLoF CNVs into gene-level burden analyses of 57 quantitative traits identified 100 pLoF gene-trait associations undetectable from analyses of SNVs and indels alone, representing a 20% increase in power. Several associations implicated new gene-trait relationships, even for well-studied traits such as height for which common-variant GWAS have reached saturation. Replication analyses in BioBank Japan demonstrated consistent effect sizes for five new height genes with adequate replication power.

Common protein-coding variation in rapidly-evolving gene families within segmental duplications—previously invisible to most analysis methods—appeared to generate some of the human genome's largest contributions to variation in type 2 diabetes (T2D) risk, chronotype, and blood cell traits. In a highly polymorphic 99kb segmental duplication at 7q22.1 (1-7 copies per allele), copy number of a common missense variant in *RASA4* appeared to strongly influence T2D risk (1.3-fold [1.2-1.4] range, $P = 1.3 \times 10^{-25}$ in UKB; replication $P = 2.8 \times 10^{-5}$ in AoU). The same paralogous sequence variant in *RASA4* appeared to drive the strongest association genome-wide with chronotype ($P = 2.6 \times 10^{-72}$). Additionally, variation at the immune-related *FCGR2/3* (Fcγ receptor) and *DEFA1/A3* (α-defensin) segmental duplication loci generated two of the top five associations with basophil count. These results illustrate the potential for new genetic insights from genomic variation that has escaped large-scale analysis to date.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1575 Higher genetic risk for type 2 diabetes is associated with progressive decline of beta cell function.

Authors:

H. Lee[1], J. Choi[1], K. Park[1], N. Cho[2], S. Kwak[3]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Ajou Univ., Incheon, Korea, Republic of, [3]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Objective
While the association between the polygenic risk score (PRS) for type 2 diabetes (T2D) and static beta cell function is known, the relationship between T2D PRS and the progressive deterioration of beta cell function remains largely unknown. We aimed to evaluate the association of PRS and the trajectory of beta cell function in a community based prospective cohort.
Method
We analyzed 6,311 participants without T2D at baseline from the Ansan-Ansung cohort with 75-g 2-hour oral glucose tolerance tests taken biennially for 14 years. Disposition index (DI), derived from insulinogenic index at 60 minutes and Matsuda index, was used as a marker for beta cell function. PRS was calculated using 1.0 million variants derived from T2D genome-wide association studies from multiple ancestries using Bayesian regression (PRS-CSx). Participants were stratified into low (1^{st} quintile), intermediate (2^{nd} to 4^{th} quintiles) and high genetic risk (5^{th} quintile). Lifestyle was categorized as unfavorable, intermediate and favorable lifestyle according to Life's Essential 8. Linear mixed model was applied.
Result
During a median follow-up of 13 years, 369 (29.4%), 872 (23.2%) and 172 (13.3%) participants developed T2D in high, intermediate and low genetic risk group, respectively. Participants in high genetic risk group, compared to low genetic risk group, had a 27% lower DI at baseline (53 [95% CI 50, 57] *vs* 73 [68, 78]; $P = 7.6x10^{-10}$), and a 2.3-fold faster rate of decline in log_2(DI) per year (-0.037 [-0.043, -0.030] *vs* -0.016 [-0.022, -0.0090]; $P = 1.8x10^{-5}$). Notably, we found significant interaction between the rate of decline in DI and T2D PRS ($P = 1.4x10^{-4}$). Of the 161 known lead variants associated with T2D in East Asians, a variant near SLC30A8 (rs13266634) was significantly associated with the progressive decline in disposition index ($P = 0.000153$, <0.05/161). PRSs of other T2D-related traits (Homeostasis Model Assessment of Beta-cell function (HOMA-B), fasting glucose, fasting insulin, waist hip ratio adjusted by body mass index) did not perform better than T2D PRS. Healthy lifestyle was associated with attenuated rate of decline in DI across all genetic risk group.
Conclusion
Individuals with a high genetic risk for T2D not only exhibit a lower baseline DI, but also experience a more rapid decline in DI over time. Genetic information could be used to identify those at risk for faster decline of beta cell function, enabling a focus on lifestyle intervention.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1576 Higher levels of chronic illness in the Australian Genetics of Bipolar Disorder Study are associated with genetic risk for reduced lifespan, increased BMI, and increased sites of chronic pain: a polygenic risk score analysis

Authors:

P. Lind, B. Mitchell, N. Martin, S. Medland; QIMR Berghofer Med. Res. Inst., Brisbane, Australia

There are extensive research findings that individuals with bipolar disorder (BD) experience high levels of comorbid chronic illness and reduced life expectancy. We examined multimorbidity data in the Australian Genetics of Bipolar Disorder Study using unweighted and weighted Rx-Risk Comorbidity Index scores derived from prescription records. We then investigated, for the first time, whether individual differences in these Rx-Risk Comorbidity Index scores could be predicted by polygenic risk scores (PRS) calculated from genome-wide association studies for lifespan (Timmers et al 2019), chronic pain (Johnston et al 2019) and BMI (leave out QIMR; Yengo et al 2018). Prescription and genotyping data were available for 3,562 unrelated participants (67% female; 64.9% BD-I, 22.5% BD-II and 12.6% sub-threshold BD). Record linkage was available for prescription data from 30/06/2014-30/06/2019 for all dispensed medications listed on the Australian Pharmaceutical Benefits Scheme schedule. The unweighted Rx-Risk score was calculated as the total number of 46 comorbidities mapped to prescriptions using Anatomical Therapeutic Chemical Classification System codes. A weighted score was calculated using mortality-related Rx-Risk weights for 43 comorbidities. PRS were calculated using the PLINK profile score method for clumped SNPs. Linear regression on the profile scores were performed, controlling for ancestry, sex, age and age^2 at survey time, and sex*age. Almost all participants had one or more prescription-based comorbidities, with an average unweighted Rx-Risk score of 6.7. After correcting for multiple testing, genetic predisposition for lifespan, BMI and chronic pain all significantly ($p<2E-06$) predicted the unweighted and weighted Rx-Risk scores (explaining 0.7-2.0% of variance) with effects going in the expected direction. In summary, we confirm individuals with lived experience of BD have high rates of comorbid conditions which are observable from electronic prescription records. We have also shown that the Rx-Risk Comorbidity Index can be predicted by polygenic risk scores.

PB1577 High-throughput measurement of regulatory SNPs with biased allelic enhancer activity effect for osteoporosis

Authors:

X-F. Chen, Y-Y. Duan, Y-Y. Jia, Y. Guo, T-L. Yang; Xi'an Jiaotong Univ., Xi'an City, China

Osteoporosis is a common age-related skeletal disease characterized by low bone mineral density (BMD) and increased fragility and fracture risk. Recent studies have uncovered crucial roles of chromatin loop in controlling osteogenesis. However, the precise roles of 3D chromatin organization at osteoporosis risk loci remains largely elusive. Here, we firstly integrated GWAS fine-mapping across multiple osteoporosis-relevant traits, including BMD at 6 different sites (forearm, femoral neck, lumbar spine, heel, total body and total-body less head) and fracture from the GEFOS portal, and 3D chromatin interaction analysis in human mesenchymal stem cells (hMSCs) induced osteoblasts to systematically prioritize candidate osteoporosis-associated functional SNPs. We prioritized 5,642 candidate osteoporosis-associated functional SNPs with promoter chromatin interactions. We then utilized an adapted self-transcribing active regulatory region sequencing (STARR-seq) to assess their allelic enhancer regulatory activities in human osteoblast-like cell line U2OS and identified 505 SNPs with biased allelic enhancer activity effect (baaSNPs) from 165 loci (FDR<0.05 by Fisher's exact test). Functional characterization revealed significant enrichment for open chromatin region and active epigenetic markers in osteoblasts for identified baaSNPs. Further functional analysis suggested significant enrichment for biological pathways relevant to skeletal growth and osteoblast differentiation on their chromatin interacted genes on baaSNPs. Collectively, our results highlighted potential important regulatory roles of 3D chromatin organization at osteoporosis risk loci and provided a valuable enhancer-promoter genetic regulatory atlas for osteoporosis, which may help better understand molecular mechanisms underlying osteoporosis-risk loci.

PB1578 HOMA-B/-IR GWIS using fasting glucose and insulin suggests causal role of inflammation in insulin resistance

Authors:

Z. Balkhiyarova[1,2,3], I. O. Fedko[4,5], L. Zudina[1,3], Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) Investigators, O. Yelizarova[6], R. Mägi[7], M. Kaakinen[1,2,3], D. I. Boomsma[4,5], I. Prokopenko[1,2]; [1]Univ. of Surrey, Guilford, United Kingdom, [2]People-Ctr.d Artificial Intelligence Inst., Univ. of Surrey, Guildford, United Kingdom, [3]Imperial Coll. London, London, United Kingdom, [4]VU Univ. Amsterdam, Amsterdam, Netherlands, [5]Amsterdam Publ. Hlth.Res. Inst., Amsterdam, Netherlands, [6]Inst. for Publ. Hlth.O.M. Marzieiev, Natl. Academy of Med. Sci. of Ukraine, Kyiv, Ukraine, [7]Univ. of Tartu, Tartu, Estonia

Introduction: Studying the development and manifestation of negative effects of obesity, type 2 diabetes (T2D) is a priority for science today. Insulin resistance is one of the predictors of metabolic disorders related to above-mentioned conditions. The aim of this study was to obtain new knowledge about the genetic relationships between insulin resistances, disorders of glucose metabolism, dyslipidemia, fibrinolytic activity (or coagulation markers), and inflammation.**Materials and Methods**: We implemented a Genome-Wide Inferred Statistics (GWIS) approach for homeostasis Model Assessment of β-cell function and insulin resistance (HOMA-B/-IR, N_{GWIS}=75,240). We dissected the effects of glycaemic trait/T2D loci effects on HOMA-B/-IR; genetic relationships between HOMA-B/-IR and 36 inflammatory and cardiometabolic phenotypes. We evaluated causal relationships between PAI-1 and HOMA-IR using two-sample Mendelian randomization approach.**Results**: We identified one novel HOMA-B (*FOXA2*) and three novel HOMA-IR (*LYPLAL1, PER4, PPP1R3B*) loci. We explored and defined a large group of T2D loci influencing insulin resistance. We detected novel strong genetic correlations between HOMA-IR/-B and Plasminogen Activator Inhibitor-1 (PAI-1, r_g=0.92/0.78, P=2.13×10^{-4}/2.54×10^{-3}). HOMA-IR/-B were correlated with C-Reactive Protein (r_g=0.33/0.28, P=4.67×10^{-3}/3.65×10^{-3}) and HOMA-IR was correlated with adiponectin (r_g=-0.30, P=0.012) among others. We detected a causal effect of increased levels of PAI-1 on HOMA-IR (beta = 0.070 ln (ng/mL), 95%CI [0.033, 0.11], P = 2.13×10^{-4}).**Conclusions**: We found support for the role of inflammation in the pathogenesis of metabolic disorders through their genetic relationships improving our understanding of the genetic mechanism underlying development and pathophysiology of complications related to metabolic disorders, including obesity and T2D.**Funding:** LongITools H2020-SC1-2019-874739, Diabetes UK 20/0006307, PreciDIAB ANR-18-IBHU-0001

PB1579 Host genetics and gut microbiota in asthma among US Hispanics/Latinos: The Hispanic Community Study / Study of Latinos.

Authors:

M. Stanislawski[1], E. Litkowski[2], C. Arehart[3], N. Gilmore[4], L. Lange[5], E. Lange[4], A. Christy[6], M. A. Katie[6], F. Holguin[4], K. North[7], R. Burk[8], R. Kaplan[9]; [1]Univ. of Colorado Sch. of Med. 1, Aurora, CO, [2]Univ. of Colorado, Aurora, CO, [3]Univ. of Colorado, Boulder, CO, [4]Univ. of Colorado Sch. of Med., Aurora, CO, [5]Univ Colorado Denver, Aurora, CO, [6]Univ. of North Carolina, Chapel Hill, NC, [7]Univ North Carolina, Wake Forest, NC, [8]Albert Einstein Col Med., Bronx, NY, [9]Albert Einstein Coll. of Med., Bronx, NY

Rationale: Asthma is a heterogeneous condition influenced by diverse factors that is often comorbid with obesity. Defining the contribution of genetic and gut microbial factors could improve our understanding of the pathophysiology of these interrelated conditions. **Objectives**: To quantify associations between gut microbiota characteristics and asthma/obesity status among US Hispanic/Latinos, and to integrate genetic and microbiota information to assess their relative contributions to these conditions. **Methods**: We used data from shotgun metagenomic sequencing of stool DNA from N=2404 participants of the Hispanic Community Health Study/Study of Latinos and assessed associations of microbiota characteristics with current asthma and obesity status, defining obesity as body mass index$\geq$30kg/m^2: non-obese asthma (N=86); obese asthma (N=105); and non-asthmatic obesity (N=920) versus non-obese with no history of asthma (N=1293). We used multivariable-adjusted regression-based methods, including permutational ANOVA of overall microbiota composition (beta diversity) and ANCOM-BC of species-level taxa with the Holm method to adjust for multiple comparisons. Based on literature-supported genetic variants, we derived an asthma polygenic risk score (PRS) using host genetic data. We split the data into training (N=1353) and testing (N=1051) sets for taxonomic analyses and to assess the classification accuracy of genetic and microbial risk factors for asthma/obesity status compared to baseline risk factors alone, using a sequential adjustment approach and likelihood ratio tests to compare models. **Measurements and Main Results**: We observed significant associations of overall gut microbiota composition with non-obese asthma, asthmatic obesity, and non-asthmatic obesity versus non-obese non-asthmatic (all $p<0.002$). We observed distinct taxonomic associations with non-obese and obese asthma, such as *Acidaminococcus intestini* with increased risk of non-obese asthma and *Fournierella massiliensis* with decreased risk of obese asthma. The asthma PRS improved models of non-obese ($p=0.02$; AUC=0.79) and obese asthma ($p=0.0008$; AUC=0.83) above baseline risk factors (AUC=0.78 and AUC=0.81, respectively); the addition of microbial factors further improved models of obese asthma (non-obese asthma: $p=0.65$; AUC=0.79; obese asthma $p=0.002$; AUC=0.86). **Conclusions**: Our results support that genetic and microbiota characteristics are independently associated with obese asthma in adults. While we observed some microbiota characteristics associated with non-obese asthma, the associations were strongest in asthma comorbid with obesity.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1580 Human body fat distribution genes affect adipocyte function via Wnt signaling and mitochondrial activity: a systems genetics analysis.

Authors:

J. Reed[1], J. Huang[2], Y. Li[2], L. Ma[3], D. Banka[1], T. Wang[2], W. Ding[2], J. L. Bjorkegren[3,4], M. Civelek[1]; [1]Univ. of Virginia, Charlottesville, VA, [2]Novo Nordisk Res. Ctr. China, Beijing, China, [3]Icahn Sch. of Med. at Mount Sinai, New York, NY, [4]Karolinska Inst.t, Stockholm, Sweden

BACKGROUND: Excess fat in the abdomen is a sexually dimorphic risk factor for cardio-metabolic disease. The relative storage between abdominal and lower-body subcutaneous adipose tissue depots is approximated by the waist-to-hip ratio adjusted for body mass index (WHRadj). Genome-wide association studies (GWAS) have identified ~495 genes (346 loci) associated with WHRadj. Most of these genes have unknown roles, but many are expressed and putatively act in adipose tissue. We aimed to identify novel sex- and depot-specific drivers of WHRadj using a systems genetics approach.
METHODS: We used two independent cohorts of adipose tissue gene expression data (STARNET, GTEx) with 362 - 444 males and 147 - 219 females, primarily of European ancestry. Sex- and depot-specific Bayesian networks were used to model the gene-gene interactions from 8,492 adipose tissue genes. Key driver analysis identified genes that, *in silico* and putatively *in vitro*, regulate many others. Key driver gene function was determined by perturbing their expression in human subcutaneous pre-adipocytes.
RESULTS: A total of 51 - 119 key drivers in each network were replicated in both cohorts. We used single-cell expression data to select replicated key drivers expressed in adipocytes, prioritized genes unstudied in adipose tissue, and integrated public datasets to nominate 53 novel key driver genes (10 - 21 from each network) that may regulate fat distribution by altering adipocyte function. In other cell types, 23 of these genes are found in crucial adipocyte pathways - Wnt signaling or mitochondrial function. We selected eight genes whose expression is highly correlated with WHRadj to study their effects on adipogenesis/Wnt signaling (*ANAPC2, ANTXR1, PSME3, RSPO1, TYRO3*) or mitochondrial function (*C1QTNF3, MIGA1, PSME3, UBR1*).
Adipogenesis was inhibited in cells overexpressing *ANAPC2* and *RSPO1* compared to controls, consistent with a third cohort (METSIM) that shows higher expression is associated with higher WHRadj, and thus lower relative storage in the subcutaneous depot. *RSPO1* inhibited adipogenesis by increasing β-catenin activation and Wnt-related transcription, repressing *PPARG* and *CEBPA*. *PSME3* overexpression led to more adipogenesis than controls, inconsistent with association data. In mature adipocytes, *MIGA1* and *UBR1* downregulation led to mitochondrial dysfunction, with lower oxygen consumption than controls; additional research (e.g., deeper phenotyping of cells from both depots) is needed to support that lower expression is associated with higher WHRadj.
SUMMARY: *ANAPC2, MIGA1, PSME3, RSPO1,* and *UBR1* affect adipocyte function and may drive body fat distribution.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1581 Identification and functional characterization of rare mutations of the SYNGR family genes associated with schizophrenia.

Authors:

M-C. Cheng, S-H. Hsu, H-Y. Tsai; Yuli Branch, Taipei Veterans Gen. Hosp., Hualient Country, Taiwan

Schizophrenia is a severe psychiatric illness experienced by approximately 1% of individuals worldwide and has a debilitating impact on perception, cognition, and social function. The heritability of schizophrenia is estimated at 80% on average. Synaptic vesicle-related genes significantly regulate synaptic transmission and play a critical role in various psychiatric diseases. Synaptogyrin (SYNGR) gene family are the transmembrane protein genes of presynaptic vesicles that warrant genetic and functional analysis for the pathogenesis of schizophrenia. For pathogenic mutation identification, we sequenced the exonic regions of the *SYNGR* family genes in 516 unrelated patients with schizophrenia from Taiwan. We analyzed the Synaptogyrin protein functions of the identified protein-altering mutants via bioinformatic analysis, immunoblotting, exocytosis assay, and mass spectrometry analysis. After the resequencing, 17 protein-altering variants were identified, including 5 in the *SYNGR1* gene, 4 in the *SYNGR2* gene, 3 in the *SYNGR3* gene, and 5 in the *SYNGR4* gene. Among these mutations, 15 had minor allele frequencies (MAFs) less than 0.5% in the gnomAD and Taiwan BioBank database. Two mutations (*SYNGR1*$^{p.Tyr196Ter}$ and *SYNGR3*$^{p.Pro197Thr}$) were not observed among 1,517 healthy controls from Taiwan BioBank and the gnomAD database. The immunoblot assay demonstrated that the *SYNGR1*$^{p.Tyr196Ter}$ mutant as a loss-of-function mutant in the cultured cells. In the exocytosis assay, we found that overexpressing *SYGRN1*^{WT} and *SYNGR3*^{WT} inhibited Human growth hormone 1 (hGH1) secretion in PC12 cells, whereas two mutations (*SYNGR1*$^{p.Thr144Met}$ and *SYNGR1*$^{p.Tyr196Ter}$) did not inhibit hGH1 secretion. Mass spectrometry assay showed that the phosphorylated serine^{210} site of SYNGR3 protein was identified in wild-type (*SYNGR3*^{WT}) but not in three mutant-types (*SYNGR3*$^{p.Ser190Arg}$, *SYNGR3*$^{p.Pro197Thr}$, and *SYNGR3*$^{p.Ser210Asn}$). The results suggest that the SYNGR family genes, especially two neuronal genes (*SYNGR*1 and *SYNGR3*), harbor rare and functional disrupting mutations in some patients with schizophrenia, supporting contributing rare coding variants to the genetic architecture of schizophrenia. Of particular interest is that *SYNGR1* gene mutations might be associated with exocytosis, while *SYNGR3* gene mutations might be involved in regulating protein kinase C function.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1582 Identification of 39 Gene-Lifestyle interaction Loci for cardio-metabolic traits in Sub-Saharan African populations: An AWI-Gen study

Authors:

P. Boua[1,2], J-T. Brandenburg[2], S. Singh[2], H. Sorgho[1], A. Choudhury[2], H. Tinto[1], M. Ramsay[2], as members of AWI-Gen, and the H3Africa Consortium; [1]Clinical Res. Unit of Nanoro (CRUN), Inst. de Recherche en Sci. de la Santé (IRSS), Nanoro, Burkina Faso, [2]Sydney Brenner Inst. for Molecular BioSci., Faculty of Hlth.Sci., Univ. of the Witwatersrand, Johannesburg, South Africa

Gene-environment (GxE) interaction refers both to the modification of genetic risk factors by environmental risk and protective factors and to the role of specific genetic risk factors in determining individual differences in vulnerability to environmental risk factors. Gene-environment interactions affect cardiometabolic traits and can help identify novel pathways of diseases susceptibility. Several studies have identified environmental or behavioural factors that influence the genetic risk associated to cardiometabolic traits, with few conducted in Africa. In a sub-Saharan African population cohort (AWI-Gen study), we investigated the gene-lifestyle interaction of smoking and alcohol consumption on lipid and blood pressure traits. Participants were genotyped using the H3Africa genotyping array (2.3M SNPs), followed by imputation using the Sanger Imputation Server (African panel). GxE analyses were performed, using LinGxEScanR v1.0 (https://github.com/USCbiostats/LinGxEScanR/tree/CHARGE), in this resident African population-based cohort of over 9000 middle-aged adults. Exposure to smoking tobacco was defined by current smoking status and intensity (cigarette pack years and cigarettes per day), and alcohol consumption was defined by current drinking and intensity (heavy, light, never and the number of standard drinks). We found 39 significant loci for gene-alcohol interaction for blood pressure traits (3 Loci), gene-alcohol interactions for lipid (6 loci) and gene-smoking interaction for blood pressure traits (21 Loci). The identified loci were associated with exposure to alcohol and smoking, but also to the intensity of the exposure (standard drinks, heavy drinker, and cigarettes per year). There were also shared loci for blood pressure traits and lipid traits. The post-GWAS analysis revealed that some of the genes involved in the interaction were previously reported as markers of exposure, showing differential methylation in smoking. Most variants were population-specific and had very low allele frequencies in non-African populations. Inclusion of under-represented populations in medical genomics research is essential for advancing an understanding of complex trait genetics.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1583 Identification of an East Asian-specific variant associated with Lewy bodies dementia by genome-wide association study in Japanese subjects.

Authors:

R. Mitsumori[1], Y. Asanomi[2], D. Shigemizu[3,4], S. Akiyama[1], T. Morizono[1], S. Niida[1], K. Ozaki[5,4]; [1]Natl. Ctr. for Geriatrics and Gerontology, Obu, Japan, [2]Natl. Ctr. for Geriatrics and Gerontology, Obu City, Aichi Prefecture, Japan, [3]Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan, [4]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [5]The Natl. Ctr. for Geriatrics and Gerontology, Obu, Aichi, Japan

Dementia with Lewy bodies (DLB) is the second most common clinically neurocognitive disorder among the elderly, following Alzheimer's disease (AD). The current therapy is limited to symptomatic and supportive care. The hallmarks of DLB are α-synuclein neuronal inclusions (Lewy bodies and Lewy neurites) that induce neuronal loss and deposit in the brain cortex and limbic system. DLB results from interactions among multiple genetic and environmental risk factor, none of which can cause disease solely by each of themselves. Recent large-scale genetic analysis such as genome-wide association study (GWAS) and genome sequencing analysis with Caucasian descent have identified several susceptibility loci for DLB. Whereas reports of large-scale genetic analysis with Asian are relatively modest. To clarify genetic architecture in the pathogenesis of DLB, we conducted GWAS in the Japanese population comprising of 221 DLB and 6,113 controls recruited at the National Center for Geriatrics and Gerontology (NCGG) biobank using ethnicity-specific genotyping array, Asia screening array. We identified a new East Asian-specific genetic risk variant for DLB with GWAS significance ($P < 5.0\times10^{-8}$) in the Japanese GWAS. We also replicated *APOE* locus, a known risk locus for DLB and AD in Caucasians. We found that the East Asian specific DLB associated variant affected the expression of the closest gene by assessing the expression quantitative trait loci analysis in whole blood. We performed trans-ethnic meta-analysis with the GWAS data from the NCGG biobank, UK biobank and another Caucasian cohort described elsewhere (Chia et al. Nat. Genet. 2021). In the meta-analysis, *APOE* and *SNCA* loci were successfully replicated with GWAS significance. We are further conducting the transcriptome-wide association analysis (TWAS), mendelian randomization analysis, construction of polygenic risk score (PRS) and genetic correlation analysis, which could contribute to better understanding of the polygenic mechanism for DLB.

PB1584 Identification of cells, genes, and regulatory elements affecting human kidney function.

Authors:

G. Loeb[1], P. Kathail[2], R. Shuai[2], R. Chung[2], R. Grona[1], S. Peddada[1], S. Volkan[3], S. Federman[1], K. Mader[1], A. Chu[4], J. Davitte[5], S. Shafer[3], L. Przybyla[1], R. Rapiteanu[6], J. Reiter[1]; [1]UCSF, San Francisco, CA, [2]UC Berkeley, Berkeley, CA, [3]GSK, San Francisco, CA, [4]GSK, Jamaica Plain, MA, [5]GSK, Exton, PA, [6]GSK, Stevenage, United Kingdom

Background The molecular mechanisms underlying human kidney disease remain largely unknown. Genome-wide association studies (GWAS) have identified hundreds of genomic loci associated with kidney function and disease. However, the genetic variants and genes mediating the effect of most of these loci remain unclear. **Methods** We performed a GWAS of kidney function estimated using multiple biomarkers in the UK Biobank and used functionally informed fine-mapping to identify putative causal kidney function variants. To determine the effect of genetic variants implicated in kidney function, we used scATAC-seq in human kidneys, genome-wide measurements of H3K27 acetylation (CUT&RUN), and measured the effect of CRISPR-mediated perturbation of regulatory elements on gene expression.
Results We found that 58% of kidney function SNP-heritability localized to candidate regulatory elements of kidney tubule epithelial cell types, 10% localized to podocyte-specific regulatory elements, and <1% localized within endothelial, stromal, or immune cell-specific regulatory elements. We identified putative causal kidney function variants using functionally-informed fine-mapping and used these variants to identify regulatory elements and genes involved in kidney function. In human kidneys and primary tubule epithelial cells, we assessed how kidney function variants affect chromatin accessibility, enhancer activation, and enhancer function. We found that kidney function variants alter chromatin accessibility and regulatory element function within tubule epithelial regulatory elements. A pooled screen targeting kidney function noncoding regulatory elements with CRISPR interference (CRISPRi) identified novel genes involved in human kidney function. **Conclusion** By integrating human genetics and studies of enhancer function, this work provides a framework for identifying variants, regulatory elements, and genes involved in human kidney disease. The combination of fine-mapping of GWAS-nominated variants, regulatory element identification, and mapping enhancers to regulated genes provides a framework for moving from GWAS to molecular mechanisms of disease.

PB1585 Identification of circulating protein biomarkers for childhood obesity using Mendelian randomization

Authors:

R. AVOCEGAMOU[1], N. Yazdanpanah[2], M. Yazdanpanah[2], D. Manousaki[3]; [1]Univ. of Montreal, Montreal, QC, Canada, [2]CHU Sainte-Justine, Montréal, QC, Canada, [3]Sainte Justine Hosp. Univ. of Montreal, Montreal, QC, Canada

BACKGROUND: Childhood obesity is a major public health problem affecting one in 10 youth and is associated with several short and long term cardiometabolic complications. Characterisation of early biomarkers for pediatric obesity is necessary to develop screening tools, to prioritize children at risk for preventive interventions, while these biomarkers represent potential therapeutic targets. Here, our goal was to identify circulating proteins with causal effects on childhood obesity, leveraging proteomic and pediatric body mass index (BMI) GWAS data, in a two-sample Mendelian randomization (MR) study.**METHODS**: We identified genome-wide significant (P < 5x10-8) polymorphisms (SNPs) associated with circulating levels of 1,297 proteins in 5 large European GWAS (Sun et al, Emilsson et al, Folkersen et al, Yao et al , Suhre et al). We obtained the effects of SNPs on the level of each protein from these GWAS and their effects on pediatric BMI from a European GWAS by Vogelezang et al. (N=61,111 children). Subsequently, we estimated the causal effect of circulating proteins on BMI by calculating the Wald ratio for proteins with a single SNP-instrument or by meta-analyzing the effects of multiple SNP-instruments per protein on pediatric BMI using the Inverse Variance Weighted (IVW) approach. We next applied genetic colocalization for the proteins prioritized by our MR study.**RESULTS**: Among 1068 proteins tested (with SNPs available in Suhre et al, Sun et al, Folkersen et al, Yao et al et Emilsson et al GWAS), we identified two proteins whose MR effect (Wald ratio) had a P-value below the Bonferroni-corrected threshold (<2.4 x10-4). These are the ENG (endoglin; MR beta: -0.07, 95% CI= -0.10, -0.05, P= 4.4 x10-5) and the FABP4 (fatty acid binding protein 4, MR beta: - 0.33 95% CI -0.5, -0.16, P=1.3 x10-4), both having a negative effect on BMI per standard deviation increase in their serum level. Both proteins colocalized with childhood BMI (posterior probabilities for shared causal variant 95.9% for ENG and 75.9% for FABP4). ENG is expressed in the vascular wall, while FABP4 has a known role in fatty acid transport and metabolism. Neither ENG nor FABP4 have been previously associated with adult or pediatric BMI in GWAS.**CONCLUSION**: We identified two circulating proteins as candidate causal biomarkers of pediatric obesity. MR studies are ongoing to test specific proteins prioritized by previous MR studies as biomarkers of adult BMI for causal effects on pediatric BMI. Upon the number of identified proteins, we will use the candidate proteins to identify protein-protein interaction networks that will point to predominant pathophysiological pathways in pediatric obesity.

PB1586 † Identification of insulin trafficking and secretion genes by a targeted prime editing screen

Authors:

V. Parsons, S. Vadlamudi, A. S. Moxley, A. Etheridge, J. D. Rosen, K. A. Broadaway, K. Mohlke; UNC Chapel Hill, Chapel Hill, NC

Altered proinsulin secretion due to incomplete insulin processing has been linked to pancreatic islet beta-cell stress, but the genes involved are incompletely understood. A recent genome-wide association study (GWAS) meta-analysis of plasma proinsulin levels identified 36 independent signals at 30 loci. To elucidate the underlying genes and variants driving association signals, we are performing a targeted CRISPR prime editing screen. We selected 11 genes at eight loci to knock out in INS1 832/13 rat insulinoma cells; genes were selected based on pancreatic islet expression, colocalized islet eQTL, and putative function. We also chose to edit the lead GWAS variants at two of these loci (*TBC1D30, SGSM2*) because these variants encode amino acid substitutions. For each target, we designed six to eight prime editing and secondary nicking guide combinations. We observed editing efficiencies of ~50-80% for four genes (K*ank1, Madd, Sgsm2 knockout, and Lrrc49*), ~20% for one gene (*Dlc1*), and <2% for one gene (*Larp6*) and the *Sgsm2* substitution; editing of four additional targets and repeated targeting of *Larp6* and the *Sgsm2* variant are underway. For targets with ≥30% editing efficiency, we will isolate clonal lines and assay proinsulin secretion. The first target we investigated was a proinsulin-associated locus on chr12 for which the lead variant rs150781447 encodes an Arg279Cys substitution in *TBC1D30* that is predicted to damage protein function. We generated 14 clonal lines with 47% *Tbc1d30* expression and compared them to 14 mock-edited control lines. When stimulated with glucose to induce proinsulin secretion, *Tbc1d30* knockdown cells secreted 1.6-fold more proinsulin ($p=2.1x10^{-3}$) compared to mock-edited controls. These results validate effects on proinsulin secretion of two sets of mutant lines created by CRISPR editing with double strand breaks. For the *Tbc1d30* Arg279Cys variant, we generated seven Arg/Cys and four Cys/Cys lines and compared them to mock-edited Arg/Arg lines. The Arg/Cys lines secreted 2.3-fold more (p=0.034) and Cys/Cys lines secreted 2.2-fold more (p=0.037) proinsulin, respectively, than mock-edited lines. These data are concordant with the GWAS direction of effect, support the hypothesis that rs150781447 may be the causal variant at this locus, and the similar effect size of for Arg/Cys and Cys/Cys lines on proinsulin secretion highlights the challenges of modeling variants with modest effects. In summary, we have established a prime editing strategy to functionally identify genes and variants at GWAS loci and demonstrated a role for *TBC1D30* in proinsulin secretion, suggesting it is responsible for the chr12 GWAS locus.

PB1587 Identification of microbiota features correlated with host lifestyle and molecular, biochemical, and immunophenotypic measurements in a deeply phenotyped Sardinian cohort.

Authors:

M. Diana[1,2], M. Pitzalis[2], M. Masala[2], A. Maschio[2], F. Busonero[2], M. Lobina[2], M. Devoto[2,3], M. Gorospe[4], D. Schlessinger[4], V. Orrù[2], E. Fiorillo[5], F. Santoni[6,2], F. Cucca[2,1], M. Pala[2]; [1]Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy, [2]Istituto di ricerca genetica e biomedica (IRGB), CNR, Monserrato, Italy, [3]Dipartimento di medicina traslazionale e di precisione, Università Sapienza, Roma, Italy, [4]Lab. of genetics and genomics, NIH, Baltimore, MD, [5]Istituto di ricerca genetica e biomedica (IRGB), CNR, Lanusei, Italy, [6]Ctr. Hosp.ier Univ.ire Vaudois (CHUV), lausanne, Switzerland

Extensive literature exists on the association between the microbiota and various host phenotypic traits, lifestyles, and diseases. These studies have limitations including small sample sizes, reliance on non-whole-genome technologies (e.g., 16S rRNA), limited capacity to correlate metagenomic data with a large number of concurrently measured characteristics in the same individuals, and predominant use of observational or case-control experimental designs, which are susceptible to experimental confounders and reverse causality effects. To address these limitations, we propose leveraging metagenomic data obtained through whole-genome shotgun sequencing of fecal microbiota from 2,700 volunteers in the ProgeNIA cohort. Our objective is to establish correlations between these data and a diverse range of quantitative, qualitative, and genetic measurements available within the same cohort. These measurements encompass biochemical blood markers, anthropometric traits, disease status, lifestyle factors (such as alcohol consumption, coffee intake, cigarette smoking, and physical activity), immunophenotypic measurements (including cellular composition and protein expression of surface markers), leukocyte transcriptional profiling, and high-resolution genetic characterization (involving approximately 25 million variants, including SNPs and INDELs). The ProgeNIA cohort uniquely facilitates the study of the microbiota's impact on a broad spectrum of host characteristics. Thus far, we have quantified 5,566 taxonomic levels, encompassing 22 phyla, 139 classes, 173 orders, 227 forms, 895 genera, 1,724 species, and 2,317 taxa. Preliminary findings have identified more than 100 taxonomic levels displaying significant correlations with factors such as alcohol consumption (padj<1.7E-14), smoking (padj=4.2E-08), Proton Pump Inhibitors (PPI) (padj=1.7E-09), BMI (padj=2.9E-06), anti-diabetics intake (padj=2.2E-07), cancer (padj=7E-04), diabetes (padj=8.7E-07), glycemia (padj=1.4E-03), sex (padj=3E-09) and age (padj=5.8E-09). Our study demonstrates both agreement and disagreement with existing literature, providing a better resolution of the taxa involved.

PB1588 Identification of rare functional genetic variants and cell-type gene regulatory networks in Progressive Supranuclear Palsy

Authors:

J. Grundman[1], T. Chang[1], R. Kawaguchi[1], L. Qi[1], L. Chen[1], K. Gao[1], J. Ou[1], J. Nguyen[1], M. DeTure[2], B. Rawlinson[2], C. L. Dalgard[3], H. Morris[4], D. Dickson[2], T. Li[5], A. Battle[5], W-P. Lee[6], H. Wang[6], Y. Leung[6], L-S. Wang[6], G. Schellenberg[6], D. Geschwind[1]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Mayo Clinic, Jacksonville, FL, [3]Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD, [4]UCL Inst. of Neurology, London, United Kingdom, [5]Johns Hopkins Univ., Baltimore, MD, [6]Univ. of Pennsylvania, Philadelphia, PA

Progressive supranuclear palsy (PSP) is a rare, relatively homogeneous neurodegenerative tauopathy with some known common and rare genetic risk factors and proposed cell type and regional vulnerability patterns. Here, we aimed to use paired RNA-sequencing to inform interpretation of whole genome sequencing (WGS) based on outlier calls across both gene expression and alternative splicing. Specifically, we employ a recently developed framework, Watershed (Ferraro et al., 2020), that leverages transcriptomic outliers and genomic annotations to construct a Bayesian model that scores the likelihood of rare functional genetic variants within +/- 10 kb of outlier genes. Our cohort is comprised of over 300 European-ancestry PSP patients and age- and sex-matched controls who have undergone both WGS and bulk RNA-sequencing across prefrontal cortex and caudate nucleus. All samples have identity by descent (IBD) < 0.25. We additionally examine the association of common and rare genetic risk variants in the context of cell-type gene regulatory networks through the use of single-nucleus RNA-sequencing and ATAC-sequencing across both prefrontal cortex and caudate nucleus in a subset of our samples (N=23 per region). Identifying additional genetic risk variants and specific cell type-specific mechanisms related to PSP will further our understanding of causative disease mechanisms and provide new avenues for therapeutic developments. More broadly, such integration of transcriptome data with rare variant data is a potentially powerful means identify new risk variants and genes.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1589 Identifying causal genes modulated by rare regulatory variants in Alzheimer's disease.

Authors:

T. Patel; Icahn Sch. of Med. at Mount Sinai, New York, NY

Genetic studies have identified more than 75 loci associated with Alzheimer's disease (AD) risk to date, however most are localized to non-coding regions of the genome, making it difficult to pinpoint the causal genes and pathways. We have previously shown that common AD risk variants are enriched in active enhancers of myeloid cells, which likely modify disease risk by regulating gene expression and, in turn, function of these cells. However, the impact of rare non-coding variation on myeloid gene expression and function remains to be elucidated. We intersected whole-genome sequencing (WGS) data from 6,161 AD cases and 6,502 controls with microglial epigenomic annotations (H3k27Ac ChIP-seq) and chromatin interactions (PLAC-seq) (from Nott et al., 2019) to identify rare variants (MAF < 1%) that fell within these cell-type-specific regulatory elements. Using GENESIS, we performed single variant and set-based association tests by aggregating variants to the gene regulatory elements (GRE) they were located in, and GRE-target genes based on the chromatin interactions. Variants were assigned weights using functional impact scores (e.g. disruption to transcription factor binding sites, DNase hypersensitivity sites) from various databases including RegulomeDB. Preliminary analyses identified several rare variants significantly associated with AD, including variants that were in GREs interacting with known myeloid expressed gene promoters CX3CR1 ($P=3.2x10^{-10}$) and IL4R ($P=7.5x10^{-10}$), and potentially novel genes of interest such as RIPK2 ($P=3.8x10^{-8}$). Aggregating variants to GRE-target gene level identified clusters of significant genes in the VEGFA-TMEM63B locus ($P=1.6x10^{-7}$) that appear to be regulated by the same GREs. We plan to replicate our analyses using the larger AD case-control 36k WGS data to increase power to detect additional disease-relevant regulatory variants and their target genes in microglia. Integrative approaches have already nominated candidate AD risk genes whose expression may be modulated by common AD risk variants in myeloid cells. By investigating the contribution of rare regulatory variation in AD, we can better understand the mechanisms through which these rare variants regulate gene expression and disrupt gene regulatory networks in disease-relevant cell types.

Hosp., Boston, MA, [9]Univ. of Louisville, Louisville, KY, [10]Boston Children's Hosp., Boston, MA, [11]Univ Nevada Sch Med, Las Vegas, NV, [12]Univ Toronto, Toronto, ON, Canada, [13]NIH, Bethesda, MD

Introduction: Supravalvar aortic stenosis (SVAS), a narrowing of the aorta above the aortic valve, is a characteristic feature of Williams-Beuren syndrome (WBS). SVAS is present in about two-thirds of those with WBS, but severity varies; ~20% of people with WBS have SVAS requiring surgical intervention in their early childhood, while ~35% have no appreciable SVAS and ~45% have mild or intermediate narrowing. Recently, we reported a new method for identifying genetic modifiers of SVAS outcomes. However, until now a clinically usable scoring system for early identification of children with WBS at risk of surgical SVAS has not been available. **Methods:** In our previous modifier study evaluating 217 individuals with WBS (87 surgical SVAS and 130 no SVAS), we identified 360 genes (containing a total of 427 common non-synonymous variants; [hereafter variants]) in 13 pathways that were associated with extreme SVAS outcomes: surgical SVAS *vs.* no SVAS. These pathways include innate/adaptive immune and matrisome. We first assessed whether the polygenic score (PGS) calculated using 361 of the variants (after clumping) in the extreme phenotype subgroups (87 surgical SVAS and 130 no SVAS) could be useful for classification of SVAS severity. We further assessed whether the same set of variants was also able to distinguish surgical SVAS (n=87) from mild/intermediate stenosis (n=184) by the PGS. **Results:** When 90% of the samples are used for training, and 10% of the samples for testing, the classification accuracy of the PGS measured by the area under the curve (AUC) is 0.97 for surgical SVAS vs no SVAS and is 0.89 for surgical SVAS vs mild/intermediate stenosis. **Conclusion:** The variants from 13 pathways described here not only provide insight into the molecular underpinnings of SVAS but can also be used to calculate a highly predictive PGS. Together, the combination of a strongly predictive PGS and the identification of key modifier pathways offers the previously inconceivable possibility of molecularly targeting the most severe form of SVAS before it becomes life threatening.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1591 Identifying the best performing Alzheimer's disease PRS with the aim of risk prediction and the role of age in the genetic architecture.

Authors:

Y. Abakkouy[1], E. Luckett[1], S. Becelaere[1], R. Vandenberghe[1,2], I. Cleynen[1]; [1]KU Leuven, Leuven, Belgium, [2]UZ Leuven, Leuven, Belgium

Polygenic risk scores (PRS) combining the effect of disease-associated variants offer possibilities for risk prediction, also in Alzheimer's disease (AD). However, there are many PRS tools available and there is no consensus on how to model a PRS for AD in terms of f.e. p-value threshold (pT) settings for SNP inclusion and how to best deal with the strong *APOE* effect.

We designed a PRS-pipeline comparing PRSice and Lassosum for different parameter settings and PRS models: PRS_{AD} (incl all SNPs), PRS_{noAPOE} and PRS_{APOE} (excl and only incl *APOE*), $APOE_{\varepsilon2+\varepsilon4}$ (incl the two major *APOE* variants), and the weighted sum of PRS_{noAPOE}+$APOE_{\varepsilon2+\varepsilon4}$. Scores were built from summary statistics of Kunkle et al (Nat Genet 2019) and Bellenguez et al (Nat Genet 2022) to test the effect of the inclusion of proxy cases in the latter. PRS were derived from and standardized against the 1000G European dataset, and built on a publicly available test dataset (ADNI, N_{case}=241, $N_{control}$=256) from which we selected the best performing PRS model for each summary statistic based on variance explained (R2). This best model was then validated on an in-house AD case-control dataset (N_{case}=179, $N_{control}$=98).

We found that PRSice and the PRS_{noAPOE}+$APOE_{\varepsilon2+\varepsilon4}$ model performed best for both the Kunkle- and Bellenguez-based scores (R2=25.1%, AUC=0.64, pval=2.7e-19; R2=21.9%, AUC=0.65, pval=1.7e-17 respectively). The pT for SNP inclusion for the best Kunkle-based score was 1; while the pT for the best Bellenguez-based score was 1e-05. The best Kunkle score had an accuracy of 70.4% (sensitivity=67.0%, specificity=76.5%). The best Bellenguez score had an accuracy of 73.7% (sensitivity=69.3%, specificity=81.6%). The two scores showed a correlation coefficient of 77% (p<2.2e-16) but performed poorly in identifying the same individuals in the top/bottom 5% PRS (28.6% overlap). The best Kunkle score was correlated with age at diagnosis (R=0.17, p=0.02), while the best Bellenguez score was not (R=0.11, p=0.2). Considering the known association between APOE and age at onset, we also tested the PRS_{noAPOE} for correlation with age, and found no significant correlations. *APOE4* carriers however had a higher Kunkle-based PRS_{noAPOE} with pT=1 than non-carriers (p=0.03, b=0.56, se=0.25), which was not the case for a Bellenguez-based PRS_{noAPOE} with pT=1e-05 (p=0.9).

Our analyses confirm that a PRS in which the two major APOE variants are modeled separately outperforms any other PRS model tested, irrespective of GWAS base set used. Other analyses however show inconsistent results depending on GWAS base set used, with fe Kunkle scores suggesting a polygenic architecture, and Bellenguez scores an oligogenic architecture.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1592 Identifying the Genes Responsible for Natural Genetic Resistance to Type 1 Diabetes in a Middle Eastern Cohort

Authors:

A. Akil[1], I. Ahmed[1], B. Ajaz[1], K. Fakhro[2], W. Hagopian[3], R. Oram[4]; [1]Sidra Med., Doha, Qatar, [2]Sidra Med., Doha, Qatar, Qatar, [3]Pacific Northwest Res. Inst., Seattle, WA, [4]Univ. of Exeter, Exeter, United Kingdom

Background: Specific HLA alleles have been linked to autoimmune diseases including susceptibility to type 1 diabetes (T1D). The T1D risk has been shown high for certain HLA class II genes while others provide protection from disease development. Defining the underlying mechanisms of DQB1*06:02-mediated protection will help identify the molecular, metabolic, and immunologic pathways responsible for T1D pathogenicity.
Aim: Fine mapping of the HLA alleles and haplotypes from 15k whole genomes of Qatar Genome subjects. Assessment of the risk and protective HLA alleles that exist in Qatari population associating with an increased or a lower risk of T1D development.
Methods: HLA type inference was performed using multiple independent typing methods with high accuracy on the WGS data and association with clinical traits of T1D was performed using linear regression models.
Results: We found a high diversity of rare alleles among class II HLA genes in our population. We further tested the association of observed HLA alleles with five clinically relevant traits of T1D and identified several potentially protective and risk alleles for the disease. We particularly analyzed the associations of the HLA-DQB1*06:02 allele and found that the protective effects of DQB1*06:02 could be gender specific in our population. Compared to males, homozygous females for DQB1*06:02 allele are likely to have greater levels of hemoglobin A1c (HbA1c), glucose and thyroid stimulating hormone (TSH), some of the clinical traits that are associated with an increased risk for T1D. Conversely, homozygous males have significantly higher levels of Insulin and C-peptide, the clinical traits that are associated with a lower risk for T1D.
Conclusion: Multiple alleles from genes DRB1, DQA1 and DQB1 which are known to segregate with T1D predisposition showed a significant association with clinical phenotypes of T1D suggesting a greater genetic susceptibility for T1D in the general population.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1593 Impact of genome-wide rare copy number variants on autism spectrum disorders.

Authors:

Z. He[1,2], K. S. Benke[2,3], J. Daniels[2,3], V. Morrill[1,2], M. Fallin[4], H. Volk[2,3], C. Ladd-Acosta[1,2,3]; [1]Dept. of Epidemiology, Bloomberg Sch. of Publ. Hlth., Johns Hopkins Univ., Baltimore, MD, [2]Wendy Klag Ctr. for Autism and Dev.al Disabilities, Bloomberg Sch. of Publ. Hlth., Johns Hopkins Univ., Baltimore, MD, [3]Dept. of Mental Hlth., Bloomberg Sch. of Publ. Hlth., Johns Hopkins Univ., Baltimore, MD, [4]Rollins Sch. of Publ. Hlth., Emory Univ., Atlanta, GA

Background: Rare single nucleotide variants have been identified and common single nucleotide polymorphisms (SNPs) from genome-wide association studies continue to emerge as autism spectrum disorder (ASD) risk factors. Rare copy number variants (CNVs) have also been implicated in the genetic etiology of neurodevelopmental disorders but further discovery and characterization in US ASD populations is needed. Thus, we leveraged 1005 participants in Study to Explore Early Development (SEED) 1 and 3 to examine the association of rare CNVs with ASD. **Methods:** Genotyping was performed on Illumina Infinium HumanOmni1-Quad BeadChip, with over 1.1 million probes among a subset of SEED participants. We generated raw autosomal CNV calls using PennCNV (v1.0.5) and QuantiSNP (v2.3) and retained consensus CNV calls detected by both algorithms. Extensive sample and CNV level quality control was performed. We filtered CNV calls with minor allele frequency <1%, length ≥10 kilobases and <10 megabases, spanning ≥10 consecutive probes as confidence rare CNVs. We performed functional annotation using ANNOVAR. We examined CNV burden measures of total number/length of CNVs at four levels: genome-wide, genes, exons of 470 autistic genes, and functional categories. We used logistic regression to examine associations of CNV burden with ASD, adjusting for maternal and child characteristics, study site, wave, and principal components 1-10. **Results:** We identified 5804 rare CNVs: 2192 in 337 ASD cases (CASE), 3068 in 513 general population controls (POP), and 544 in 155 non-ASD developmental delay controls (DD). Genome-wide CNV burden combining copy number (CN) gain and loss was greater among ASD cases (CASE vs POP, odds ratio (OR) = 1.18, 95% confidence interval (CI): 1.01-1.39, P = 0.043; CASE vs POP & DD, OR = 1.16, 95% CI: 1.003-1.35, P = 0.045), measured as total length of CNVs. ASD cases had a higher burden of CNVs spanning exons of autistic genes for CN gain and loss combined (CASE vs POP, OR = 1.32, 95% CI: 1.01-1.73, P = 0.042; CASE vs POP & DD, OR = 1.34, 95% CI: 1.05-1.72, P = 0.019), and for CN loss (CASE vs POP & DD, OR = 1.93, 95% CI: 1.14-3.30, P = 0.015), measured as total length of CNVs. Functional annotation suggested a higher burden of exonic CNVs among ASD cases (CASE vs POP, OR = 1.20, 95% CI: 1.01-1.42, P = 0.041), measured as total length of CNVs. SNPs associated with ASD were enriched in CNVs in ASD cases compared to POP/DD. **Conclusion:** These results contribute to the growing evidence that rare CNVs, both genome-wide and at specific loci, contribute to risk of ASD. Rare CNVs are essential for understanding the genetic architecture of ASD and may provide novel genetic testing or therapeutic targets.

Ethics and Hlth.Policy, Baylor Coll. of Med., Houston, TX, [5]Section of Diabetes, Endocrinology and Metabolism, Baylor Coll. of Med., Houston, TX, [6]DHR Hlth.Heart Inst., McAllen and Edinburg, TX, [7]Diabetes and Endocrinology Inst., DHR Hlth., Edinburg, TX, [8]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [9]DHR Hlth.Inst. for Res. and Dev., Edinburg, TX

Background: Cardiometabolic diseases are the leading cause of mortality worldwide. The genetic etiology has been extensively studied, ranging from high-penetrance monogenic conditions to polygenic traits. However, genetic testing uptake in community settings has been low and notably lower in Hispanic populations, an underrepresented minority in genomic research.
Methods: We developed a genome sequencing (GS) based testing panel, targeting a majority Hispanic population in community-based cardiology and endocrinology clinics in the Rio Grande Valley, Texas, that interrogated 177 genes related to monogenic cardiometabolic conditions, two *LPA* polymorphisms (rs3798220 and rs10455872), and specific pharmacogenomic (PGx) alleles of *SLCO1B1* and *G6PD* related to simvastatin and rasburicase metabolism. Results were returned to referring physicians and reviewed during a virtual multi-disciplinary sign-out conference.
Results: As of April 2023, testing was completed for 694 individuals (291 females, 403 males, 18-92 years old, 92% Hispanic). 24 individuals (3.5%) were positive for a pathogenic or likely pathogenic variant in a monogenic disease gene, including 8 also positive for an LPA risk allele, conferring increased risk of comorbidities. 11 findings were considered diagnostic, whereas6 were nondiagnostic but provided valuable disease risk information. The remaining 7 findings were pending review with referring physicians. Most diagnostic findings were related to cardiomyopathies (*TTN* n=5, *MYH7* n=1, *MYL2* n=1, *TNNI3* n=1), followed by *LDLR*, *HNF1A* and *FBN1* (n=1, respectively). The nondiagnostic findings included *ABCC8* (n=2), *SDHA* (n=2), *MYH7* (n=1), and *SCN5A* (n=1), suggesting subclinical traits or incomplete penetrance. Additionally, 252 individuals (36.3%) were positive for at least one *LPA* risk allele, and 159 (22.9%) individuals were positive for at least one PGx allele.
Discussion: Implementation of a diagnostic and pharmacogenomic cardiometabolic gene panel signifies clinical utility in disease diagnosis, intervention, and preventative care for historically underserved populations in community settings. The diagnostic rate of this study (3.5%) is lower than the previous HeartCare project (9%) (PMID:34363016), potentially due to different clinical spectrums and settings (community-based vs academic), and underrepresentation of Hispanic populations in present genomic knowledgebases. Expanded GS analysis may increase diagnostic yield. Developing and implementing population-specific *LPA* risk alleles and polygenic risk scores may improve individual-level risk assessment and management.

Polygenic scores (PGS) estimate the cumulative genetic risk for common diseases but are mostly developed in Europeans leading to limited global clinical utility. Within the INTERnational consortium of integratiVE geNomics prEdiction (INTERVENE), we developed a novel framework to estimate country-, age- and sex-specific absolute lifetime risk across ancestries. We leveraged 9 biobanks, including 2 Asian biobanks (East and South Asian) and estimated absolute lifetime risks across PGS strata for 18 high global burden diseases. We integrated population-specific metrics from the Global Burden of Disease (GBD) and harmonized disease outcomes across biobanks. PGSs were computed with MegaPRS, using available GWAS summary statistics. Overall, we had a combined sample size of 1.38M (7.6% non-European), with extensive (up to 50 years) follow-up within health registries. We employed Cox proportional hazards models and GBD baseline risks to estimate overall, age- and sex-stratified PGS effects by ancestry per disease. We observed high variability in several diseases' prevalence. Overall cancer prevalence was >20% among Europeans and East-Asians but lower in South Asians (3.15%). Prevalence of type 2 diabetes (T2D) was 11.8% in Europeans, but twice as high in South-Asians and three times higher in East Asians. All PGSs were associated with the diseases in the European ancestry but only a fraction remained significant in the other ancestries. Similar to Europeans, PGS had a larger effect for coronary heart disease (CHD in South-Asian men compared to women (HR_{male} = 1.34 (95% CI: 1.29 - 1.39) vs HR_{female} = 1.20 (95% CI: 1.14 - 1.27), $PGS*Sex_{Interaction}$ P-value = $7.92x10^{-4}$), whereas for T2D the effect was larger in East Asian women compared to men (HR_{male} = 1.53 (95% CI: 1.50 - 1.55) vs HR_{female} = 1.62 (95% CI: 1.59 - 1.66), $PGS*Sex_{Interaction}$ P-value = $1.76x10^{-5}$). Varying effect sizes by age were detected for CHD, type 1 diabetes and T2D in South Asians, whereas T2D and prostate cancer exhibited age-specific effects in East Asians. We also observed a reduced cumulative incidence of T2D in East-Asians relative to Europeans; at age 80, cumulative incidence for men and women in the top 5% PGS was 37.46% (95% CI: 34.55% - 40.27%) and 28.37% (95% CI: 25.89% - 31.11%), respectively. The variability by ancestry in cumulative incidence was driven by baseline hazard variation. Our results demonstrate variable sex- and age-specific PGS associations across ancestries and emphasize the importance of calibrating lifetime risk estimates.

We aim to further improve PGS accuracy in non-Europeans by including primary care data and additional global biobanks for better cumulative risk assessment.

PB1596 Incorporating genetic and environmental variables to understand disease risk in The Biobank at the Colorado Center for Personalized Medicine.

Authors:

J. Shortt, M. Lin, M. Fisher, H. Smith, S. Chavan, N. Pozdeyev, N. Rafaels, K. Crooks, C. Gignoux; Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Prediction of complex disease risk promises to be another important milestone in personalized medicine and population health but accurate prediction depends on sufficient knowledge of both genetic and non-genetic factors. Although environmental information is typically difficult to gather in contrast to genetics, as we build more complex models and try to capture more trait variance environmental information, and any interactions between, population-scale biobanks with linked electronic health records (EHR) provide opportunities to test how this can be accomplished. Here, we build a multi-modal dataset comprised of over 1500 phecodes derived from EHR data, over 2500 polygenic risk scores (PRS) calculated from dense genotyping, and both direct environmental variables (e.g., altitude) and indirect environmental variables (neighborhood social vulnerability and urban-rural commuting areas) in 73,346 participants in the Colorado Center for Personalized Medicine (CCPM) biobank. We identify hundreds of associations between phecodes and environmental variables at an FDR of 0.05, including known associations between elevation and carcinoma of skin (OR per elevation quantile [95% CI] = 1.19 [1.08-1.31], p ~ 0.0003). Additionally, we find associations between altitude and cardiovascular symptoms (OR = 1.35 [1.30-1.40], p ~ 1.46e-58), socioeconomic status and alcohol-related disorders (OR=6.3 [3.28-12.01], p ~ 2.65e-8), and urban-rural commuting areas and upper respiratory infections (OR = 0.86 [0.84-0.89], p ~ 6.71e-27). We then evaluate how including environmental variables and polygenic risk scores affects prediction of complex disease across diverse genetic similarity groups and test for gene-environment interactions. Future efforts will focus on identifying additional environmental variables and other factors to better characterize their contributions to health.

PB1597 Infectious disease as a trigger: The relationship between infection and immunological disease.

Authors:

L. Howell[1], M. Davis[2]; [1]Brigham Young Univ., Provo, UT, [2]Brigham Young Univ, Provo, UT

Infectious disease and genetic or immunological diseases have long been considered separate entities with completely distinct etiologies and no overlap in causality. However, some evidence suggests that there is a link between infection and diseases like multiple sclerosis (MS) and Alzheimer's disease (AD), or even that infection could act as a trigger for such conditions as well as causing acute infection. Preliminary analysis in the All of Us database compared the rates of encephalitis in individuals with dementia against the greater population, using multivariate logistic regression, and found significantly higher rates of infection among individuals with dementia even after correcting for age ($p < 2 \times 10^{-16}$). The same procedure was done for rates of meningitis, again showing significantly higher rates of infection among individuals with dementia ($p < 2 \times 10^{-16}$). In order to continue to unravel the multifaceted association between infection and other complex diseases, we will perform a PheWAS on two pathogens, focusing on herpesvirus infections (HSV1 and HHV6) and *Mycobacterium tuberculosis* infections, with the goal of identifying associated diseases. We will also perform a GWAS on infection with these two pathogens to screen for genetic variants that could contribute to infection. Our research will be performed in the All of Us database, using the substantial genomic data and EHR data available there, including approximately 24,000 cases of herpesvirus infection and approximately 2,000 cases of tuberculosis. We anticipate that the results will suggest that the relationship between infectious disease and chronic immune conditions is complex and deserving of further study.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1598 Influence of autozygosity on complex disease risk across the phenotypic spectrum

Authors:

NHS Trust, Leeds, United Kingdom, [8]Waltham Forest Council, London, United Kingdom, [9]Congenica Limited, Hinxton, United Kingdom, [10]Dept. of Complex Trait Genetics, Ctr. for Neurogenomics and Cognitive Res., Amsterdam NeuroSci., VU Amsterdam, Amsterdam, Netherlands, [11]Univ. of Manchester, Manchester, United Kingdom, [12]Wolfson Inst. of Population Hlth., Queen Mary Univ. of London, London, United Kingdom, [13]23andMe Inc, Sunnyvale, CA

Consanguinity increases autozygosity, which is associated with rare Mendelian disorders and various quantitative traits. Previous studies investigating its impact on complex disease have been plagued by confounding by socioeconomic and cultural factors. We investigated patterns of consanguinity and associations between autozygosity and complex disease in unrelated individuals from the Genes & Health cohort (G&H; N=23,978 with genetically-inferred Pakistani or Bangladeshi ancestries) and UK Biobank (UKB; N=397,184 with genetically-inferred European or South Asian ancestries), using a new strategy to reduce confounding. Based on their distribution of runs of homozygosity (ROHs), we inferred that 33% of G&H individuals are offspring of second cousins or closer, versus 2% of European-ancestry UKB individuals. We found significant changes in rates of consanguinity with age that differ between ancestry groups.

We examined associations between F_{ROH} (fraction of the genome in ROHs) and traits using only individuals inferred to be offspring of first cousins or closer, reasoning that, within this group, variation in F_{ROH} is primarily driven by stochastic recombination events and Mendelian segregation. We showed that subsetting to this highly consanguineous group greatly attenuates confounding that hampered previous studies. We tested associations between 61 common diseases and F_{ROH} amongst highly consanguineous individuals from G&H and UKB, and found significant associations (FDR<5%) with twelve of them, including type 2 diabetes (T2D) and stress-/anxiety-related disorders. We attempted to replicate seven of these in a within-sibling analysis in 23andMe (median N=478,590). All seven showed concordant directions of effect and we replicated two, T2D and post-traumatic stress disorder (p<0.05/7), despite having only 43% power to do so. We estimated that autozygosity due to consanguinity accounts for 5-18% of T2D cases in British Pakistanis, in which T2D is particularly common. We show through simulations that although in theory, autozygosity can influence risk of binary traits with a purely additive genetic architecture by increasing the variance in polygenic risk, in practice non-additive genetic effects are more likely to be driving our observed signals.

Our work quantifies, for the first time, the impact of autozygosity on dozens of common diseases using a novel approach to control for confounding (i.e. restricting to offspring of first cousins). It has important implications for global populations with high rates of consanguinity, and highlights the possibility of widespread non-additive effects on several diseases.

PB1599 Influence of germline variants of *IGHV3-53* and *IGHV3-66* genes on antibody responses to BNT162b2 mRNA COVID-19 vaccine

Authors:

Y. Mashimo[1], K. Yamazaki[1], T. Kageyama[2], S. Tanaka[2], T. Taniguchi[3,4], K. Matsushita[5], H. Igari[3,4], H. Hanaoka[6], K. Yokote[7], H. Nakajima[2,4], Y. Onouchi[1]; [1]Dept. of Publ. Hlth., Chiba Univ. Graduate Sch. of Med., Chiba, Japan, [2]Dept. of Allergy and Clinical Immunology, Chiba Univ. Graduate Sch. of Med., Chiba, Japan, [3]Dept. of Infectious Diseases, Chiba Univ. Hosp., Chiba, Japan, [4]Chiba Univ. Hosp. COVID-19 Vaccine Ctr., Chiba, Japan, [5]Div. of Lab. Med., Chiba Univ. Hosp., Chiba, Japan, [6]Clinical Res. Ctr., Chiba Univ. Hosp., Chiba, Japan, [7]Dept. of Endocrinology, Hematology and Gerontology, Chiba Univ. Graduate Sch. of Med., Chiba, Japan

Understanding the factors affecting acquisition of neutralizing antibodies (nAbs) after COVID-19 vaccination may be useful to lead better prevention of COVID-19. Multiple reports have suggested the unique and central role of two paralogous immunoglobulin heavy variable (*IGHV*) genes (*IGHV3-53* and *IGHV3-66*) in protection against SARS-CoV-2 as the components of nAbs. We hypothesized that germline variants affecting the function or expression of these genes may influence antibody acquisition in recipients of COVID-19 vaccines designed to induce nAbs. To validate this hypothesis, we investigated the relationship between post-vaccination antibody titers of 1,773 Japanese healthcare workers who received two doses of BNT162b2 mRNA COVID-19 vaccine and the germline variants of *IGHV3-53* and *IGHV3-66*. Based on the existing information on expression quantitative trait loci (eQTL) and linkage disequilibrium of the surrounding variants and data in our previous study, two single nucleotide variants rs11623191 and rs6423677 within *IGHV3-53* and *IGHV3-66*, respectively were selected as the promising candidates for the predictors of the post-vaccination antibody titer. Significant impacts of rs11623191-T and rs6423677-C alleles on the increasing usage of *IGHV3-53* and *IGHV3-66*, respectively in *IGH* transcripts were confirmed by analyses of genotypes and *IGHV* repertoire in peripheral blood mononuclear cells of 96 participants. Linear regression showed significant effect of the number of rs6423677-C allele on log2-transformed antibody titers (coefficient [B] = 0.08, 95% confidence interval [CI], 0.0085-0.15). Although this relationship was not observed for rs11623191 (B = 0.0021, 95% CI, -0.071-0.075), the sum of the numbers of rs6423677-C and rs11623191-T alleles appeared to predict a larger titer increase than rs6423677 alone (B = 0.095, 95% CI, 0.018-0.17). In addition, an independent effect of these two alleles on the antibody titer was also found in a multivariate linear regression analysis additionally using previously reported predictors as explanatory variables, including age, sex, and several factors such as medication and drinking behavior (n = 1,511, standardized coefficient [β] = 0.056, 95% CI, 0.0088-0.10). Interestingly, the effect of the two SNVs was not uniform among the participant subpopulations stratified by sex and/or age. Our study is the first to reveal the influence of the germline variants of two *IGHV* genes on the antibody response against SARS-CoV-2 after BNT126b2 vaccination. This result might provide an important clue to future optimization of COVID-19 prevention strategies.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1600 Insights into genetics affecting brain morphology and the endocrine system using image-derived phenotypes from large-scale magnetic resonance imaging.

Authors:

Ctr. for Protein Res., Univ. of Copenhagen, Copenhagen, Denmark, [2]Oxford Ctr. for Functional MRI of the Brain, Oxford Univ., Oxford, United Kingdom, [3]Big Data Inst., Oxford Univ., Oxford, United Kingdom, [4]Wellcome Ctr. for Human Genetics, Oxford Univ., Oxford, United Kingdom, [5]Univ. of Heidelberg, Heidelberg, Germany, [6]Reproductive Endocrine Unit, Massachusetts Gen. Hosp., Boston, MA, [7]Harvard Ctr. for Reproductive Med., Massachusetts Gen. Hosp., Boston, MA, [8]Boston Children's Hosp., Boston, MA

Background: Several brain structures are involved in regulating the endocrine system, and their dysmorphology predicts function: pituitary gland volume correlates with sex-steroid concentrations and hypoplasia of olfactory bulbs is a phenotype of Kallmann syndrome which causes infertility. Magnetic resonance imaging (MRI) provides a tool for acquiring rich phenotypes that reflect brain morphology. Here we conduct genetic association analyses at different phenotypic scales to elucidate the biology underlying brain morphology and explore its link to endocrinology.

Methods: We performed genome-wide association studies utilising image-derived phenotypes from UK Biobank brain MRI (n=34,834, 53% female) representing the volume of endocrine-related brain structures: the hypothalamus, pituitary gland and olfactory bulbs. We identified sexually dimorphic loci and performed phenome-wide association studies (PheWAS). To elucidate links between brain morphology and reproductive hormone levels, we calculated genetic correlation, performed Mendelian Randomisation (MR) and constructed genotype-stratified hormone trajectories. We further expanded phenotypic resolution by supplementing the original phenotypes with detailed spatial maps of the genetic association between loci of interest and voxel-level volume changes across the entire brain.

Results: We discovered 48 loci ($p<5\times10^{-8}$) associated with the volume of the hypothalamus, pituitary and olfactory bulbs, two of which were sexually dimorphic ($pdiff<5.5\times10^{-4}$). PheWAS identified associations with endocrine conditions including diabetes mellitus ($p<1.69\times10^{-5}$). There was evidence of genetic correlation of pituitary gland volume with follicle stimulating hormone (FSH) and testosterone levels ($p<0.05$). MR further identified a possible bidirectional link between brain structure volumes and FSH and testosterone levels. Analysis of primary care data identified age-dependent differences in sex hormone levels when stratified by genotype at identified loci. Voxel-wise modelling found additional associations between loci associated with the three brain structures and finer-grain brain morphology that reinforce the relationship between these brain structures in regulating the endocrine system. These include a genetic variant associated with pituitary gland volume that also showed associations with the volume of parts of the olfactory cortex.

Conclusions: Empowered by its unparalleled size and high-resolution of phenotype, our project furthers our understanding of the genetics underlying brain structure, and the interaction of these effects with the endocrine system.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1601 Integrate RNAseq gene expression and genome-wide genetic data to identify genes modifying age-at-onset of Alzheimer's disease

Authors:

Y-J. Li[1,2], M-F. Hsueh[1,2], J. La[1,2], E. Martin[3,4]; [1]Duke Univ., Durham, NC, [2]Duke Molecular Physiology Inst., Durham, NC, [3]Univ. of Miami Miller Sch. of Med., Miami, FL, [4]John P. Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL

Objective: Genetic effects on age-at-onset (AAO) of Alzheimer's disease (AD) are supported by high heritability (e.g., 42%). In recent years, several large genome-wide association studies (GWAS) have identified genes for AAO of AD, including known AD-risk genes and novel ones. However, GWAS may not capture all AAO genes. Here, we sought to use RNAseq data to identify additional genes for AAO of AD and genetic variants with pleiotropic effects on both gene expression and AAO of AD.
Methods: RNAseq data from dorsolateral prefrontal cortex tissues were available for 636 participants from ROSMAP cohort, of which 249 Non-Hispanic White (NHW) AD cases with AAO data were analyzed. Fragments per kilobase exon per million (FPKM) were used as expression measures. Excluding genes with > 10% missing expression data, 19,173 genes were tested. Multivariable linear regression models regressed log10(FPKM) on AAO, disease duration, sex, postmortem interval, RNA integrity number, and the first principal component derived from expression data. This model allows us to identify genes associated with AAO and disease duration, respectively. Qvalues were computed to correct for multiple testing, and genes with qvalue < 0.05 were considered genome-wide significant. Suggestive genes were defined by $p < 5x10^{-4}$. eQTLs for the top AAO genes were queried from GTEx and crossed checked for their association with AAO of AD from our AAO GWAS results. To investigate genetic variants with pleiotropic effects on both gene expression and AAO of AD, we performed fastQTL analysis for each gene expression using variants within 5KB of the gene and will follow with colocalization and SMR analyses using results of fastQTL and AAO GWAS.
Results: Among 249 NHW AD cases, the median (Q1, Q3) was 87.29 (83.4, 91.3) years for AAO and 2.8 (1.2, 5.0) years for AD duration with moderate correlation between them (r=-0.37). *MSLNL* reached genome-wide significance (beta (95% CI) =0.02 (0.01, 0.03), $p=1.1x10^{-6}$, qvalue=0.019) for AAO and 14 suggestive genes were identified ($p< 5x10^{-4}$) with *ITM2A* gene ranked at the second (p=9.83x10-5). On the other hand, *WDR55* was significantly associated with disease duration ($p=2.84x10^{-6}$, qvalue=0.026). The best eQTLs for *MSLNL* were in *MIR662* (in the overlapping region). These eQTLs also showed association with AAO of AD (e.g., rs9927150, p=0.003).
Conclusion: Gene-based expression association analysis for AAO demonstrated the utility to discover novel AAO gene such as *MSLNL*. We also identified *WDR55* associated with AD disease duration. More analysis is underway to understanding these findings further.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1602 Integrated analysis of rare exonic variants provides additional insights into alcohol use disorder risk.

Authors:

T-H. Nguyen[1], A. Gentry[1], H. Vy[2], M. Ahangari[1], R. Peterson[3], K. Kendler[4], B. Riley[4], S-A. Bacanu[4], B. Webb[5]; [1]Virginia Commonwealth Univ., Richmond, VA, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]SUNY Downstate Hlth.Sci. Univ., Brooklyn, NY, [4]Virginia Commonwealth Univ, Richmond, VA, [5]RTI Intl., Research Triangle Park, NC

Alcohol use disorder (AUD) is common and affects millions of people in the United States. Twin and family studies show that this disorder is heritable, and genome wide association studies (GWASs) report multiple loci associated with AUD. Post-GWAS analyses of GWAS signals yield enrichment in several gene-sets that show nominal enrichment in brain tissues. Unfortunately, only a handful of genes have been reported from rare-variant studies. However, recent studies strongly imply that for many complex disorders, common and rare variant findings, while not converging at gene level, converge at gene-set level. In addition, recent studies have showed that using phenotypic information predicted from biobanks can increase genetic discoveries. These suggest that using different approaches for rare variant analyses can improve detection power for genes associated with AUD.
Here, we explore integrative approaches to prioritize genes associated with a proxy phenotype of AUD, the Alcohol Use Disorder Identification Test-Problems (AUDIT-P) phenotype. We analyzed the whole-exome-sequencing (WES) datasets of 500K people from the UK Biobank. First, we conducted WES analyses for individuals whose AUDIT scores are available. Second, we developed a pipeline to jointly model rare variants and gene-sets to improve statistical power. Finally, we used a machine learning approach developed by our group to predict AUDIT scores for all the 500K people, and re-analyzed their WES datasets.
We first analyzed loss-of-function and missense variants from WES sequencing datasets of 133,914 people with AUDIT scores available. Three significant genes (*ADH1C, FPR1, VPS29*) were observed. The most significant signal was for *ADH1C* (adjusted p-value = 0.4×10^{-5}). Next, to prioritize additional genes, we jointly analyzed gene-level statistics and 181 gene sets curated from previous studies. We prioritized several genes (max posterior probability > 0.8) including *ADH1C*. Finally, to see if the prediction of phenotypic information can help prioritize genes, we conducted WES analysis for all 414,508 samples of European descent with full predicted AUDIT scores. Statistical power for *ADH1C* was substantially improved (adjusted p-value = 3.3×10^{-21}). Our results present top significant genes for AUD obtained by analyzing rare variants from a large-scale WES dataset. The results also include 1) the additional biological information into AUD, and 2) integrative approaches for incorporating functional genomics and health care record datasets to improve genetic discoveries. This research has been conducted using the UK Biobank Resource application number 30782.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1603 Integrated Illumina and PacBio genome sequencing of Middle Eastern families identifies novel pathogenic variants underlying neuro-developmental disorders

Authors:

Z. Siddig[1], M. Ghorbani[1], R. Abouelhassan[1], S. Hassan[1], H. Naeem[1], R. Farhad[1], I. Diboun[1], S. Moosa[1], M. Tauro[1], A. El Khouly[1], S. Poolat[1], S. Tomei[1], S. Lorenz[1], D. Love[1], K. Fakhro[1,2,3], A. Satti[1], R. Benini[1], Y. Mokrab[1,2,3]; [1]Sidra Med., Doha, Qatar, [2]Weill Cornell Med., New York, U.S.A, NY, [3]Hamad Bin Khalifa Univ., Doha, Qatar

Establishing genotype-phenotype correlations for neurodevelopmental disorders (NDDs) is a substantial challenge, especially amongst Middle Eastern populations enriched for these conditions due to high level of consanguinity. We implemented a platform integrating data from Illumina WGS, PacBio long-read sequencing, and EHRs to diagnose and characterize unresolved pediatric cases with NDDs in Qatar. In a pilot project, we recruited a cohort with intractable epilepsy or GDD, consisting of 168 families of patients. Family segregation genomic analysis was done using Congenica©, and variants were annotated with allele frequency from Qatar Genome Project and other public datasets. Candidate variants were prioritized using ACMG guidelines. Using this approach, we analyzed a set of 15 families leading to a positive genetic diagnosis yield of 40%. We identified 4 novel variants within previously reported disease genes using Illumina HiSeq, in addition to a likely pathogenic homozygous deletion identified using PacBio HiFi in two patients. Through deploying family segregation analysis on Congenica©, we identified a likely pathogenic missense mutation (NM_004113.5:c.155G>A, chr3:192335434 based on GRCh38, p. R52H) in *FGF12* in a 2-year-old boy who exhibits early-onset epileptic encephalopathy and global developmental delay. This gene encodes a cytosolic neuronal sodium channel binding protein and increases their voltage-dependent fast inactivation. The reported protein-altering variant has a change of amino acid from arginine to histidine, and the affected arginine residue is part of the highly conserved surface region that binds voltage-gated sodium channels which is necessary for *FGF12* modulation of sodium channels' fast inactivation gating. The mutation was predicted to be damaging by in silico prediction scores, including CADD (>25) and SIFT (<0.05). This gene is reported to have a definitive association with neonatal onset epileptic encephalopathy and intellectual disability in the Decipher Gene2Phenotype database, matching the reported patient's phenotype. Functional studies reported in the literature have shown that mutant *FGF12* proteins have a strong gain-of-function phenotype, increasing neuronal excitability in zebrafish. Currently results are being analyzed for the rest of the cohort, the results of which will have significance impact on precision diagnosis and understanding of NDDs in the Middle East and worldwide.

PB1604 † Integrating COVID-19 severity genetics with single-cell omics implicates alveolar type II cells and CD14 monocytes

Authors:

D. Chang, H. Shi, D. Garfield, C. M. Rosenberger, M. Reyes, S. Kapadia, M. I. McCarthy, B. L. Yaspan; Genentech, South San Francisco, CA

Large-scale efforts to characterize host genetic factors underlying COVID-19 severity have associated over 40 loci (The COVID-19 Host Genetics Initiative, 2022), highlighting genes involved in innate immunity and type 1 interferon response. Single-cell studies have also associated monocyte transcriptional states with severity in COVID-19 patients (Schulte-Schrepping et al, 2020), providing further support for the role of innate immunity in the pathogenesis of COVID-19. Beyond peripheral blood, alveolar type II (ATII) cells in the lung have been implicated from observations of ATII hyperplasia and loss in COVID-19 patients, and the genetic association with hospitalized risk at the SFTPD locus. To investigate whether additional cell types play a role in COVID-19 severity and identify pathogenic cell functions, we integrated a genome-wide association study (GWAS) of hospitalized COVID-19 risk (release 7 COVID-19 HGI) with studies measuring the transcriptional and chromatin accessibility landscape across single cells in the blood and the lung. First, we used the LD-score regression framework to investigate whether hospitalized COVID-19 genetic risk was enriched in regions of open chromatin in >200 cell types captured across 30 tissues (Zhang et al 2021, Wilk et al 2022). We found nominal evidence for enriched heritability in open chromatin of ATII cells (P=0.016) and CD14 monocytes (P=0.030). We next applied the scDRS method to integrate polygenic signals from hospitalized COVID19 risk GWAS with single cell transcriptomic data from the Human Lung Cell Atlas (Sikkema et al, 2022) and a study of PBMCs from COVID19 participants and healthy controls (Wilk et al, 2020). Similar to the partitioned heritability results above, we found that in the lung, ATII cells were enriched for higher scDRS scores ($P=1.00x10^{-3}$, FDR=0.058), while in the blood, activated granulocytes, CD14 monocytes and dendritic cells from COVID-19 patients were enriched (P<0.010, FDR<0.1). In ATII cells, gene expression correlating with the scDRS score mapped to several pathways including fatty acid metabolism and response to IL6 (FDR<0.029). In contrast, gene expression correlating with the scDRS score in COVID-19 patient derived CD14 monocytes mapped to inflammation associated pathways such as type 1 interferon response, and granulocyte activation ($FDR<2.20x10^{-16}$). Together these results provide support for the causal roles of ATII and CD14 monocytes in the pathogenesis of severe COVID-19, and highlight key pathogenic pathways in these cells.

PB1605 Integrating metabolomics with proteomics identifies novel drug targets for heart failure and atrial fibrillation.

Authors:

M. van Vugt[1,2,3], C. Finan[3,1,4], S. Chopade[3,4], F. W. Asselbergs[2,3], J. van Setten[1], F. Schmidt[2,3]; [1]UMC Utrecht, Utrecht, Netherlands, [2]Amsterdam UMC, Amsterdam, Netherlands, [3]Univ. Coll. London, London, United Kingdom, [4]UCL BHF Res. Accelerator Ctr., London, United Kingdom

Background. Altered metabolism plays a role in the pathophysiology of heart diseases, such as atrial fibrillation (AF) and heart failure (HF). Aside from NT-pro-BNP, which is used for HF diagnosis and prognosis, there is a paucity of plasma metabolites for patient monitoring and potential therapeutic targets. We aimed to identify plasma metabolites and biological pathways associated with the onset of cardiac disease, and subsequently prioritized plasma proteins that affect these metabolites and are potentially relevant for therapeutic intervention. **Methods.** Mendelian randomization (MR) was used to assess the causal association of 174 metabolites measured in up to 86,507 participants, spanning seven distinct metabolic classes, on the following cardiac outcomes: AF, HF, dilated cardiomyopathy (DCM), and non-ischemic cardiomyopathy. Subsequently, we sourced data on 1,567 plasma proteins and performed *cis* MR to identify proteins affecting the identified metabolites as well as the cardiac diseases. Results were subsequently mapped to biological pathways and prioritized for cardiac tissue expression and druggability. **Results.** Of the 174 metabolites spanning seven metabolic classes, 34 metabolites belonging to six metabolite classes were prioritized for involvement with cardiac disease. While most metabolite classes affected multiple cardiac outcomes, phosphatidylcholines were enriched for HF (p=0.029) and acylcarnitines for DCM (p=0.001). A total of 87 proteins affected these metabolites and cardiac diseases, including APOC3 and PLA2R for HF, and RET and DPEP1 for AF. Furthermore, 38 proteins were drugged or druggable, of which eight (ACES, AT1B2, DPEP1, FA10, IL6RA, KPCA, PCSK9, and RET) were targeted by drugs with cardiovascular indications, side-effects, or both. **Conclusion.** This study identified plasma metabolites involved with cardiac diseases, providing information on potential diagnostic markers. By linking these metabolites to druggable proteins with a concordant effect on cardiac disease, we provide actionable leads to facilitate the development of novel treatments for AF and HF.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1606 Integrating phenome and gene level approaches to identify genetic associations with glaucoma

Authors:

A. Scalici[1,2,3], T. Miller-Fleming[4,2,5], J. Hirbo[6,2,5], N. Cox[4,2,5]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Genetics Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Div. of Genetic Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [4]Vanderbilt Univ Med Ctr., Nashville, TN, [5]Div. of Genetic Med., Dept. of Med., Vanderbilt Univ. Med. Ctr., Nashville, TN, [6]Vanderbilt Univ. Sch. of Med., Nashville, TN

Glaucoma is a highly heritable progressive eye disorder defined by optic nerve degeneration. While age and biological sex are major risk factors for developing glaucoma, recent studies have shown that there are significant disparities in glaucoma prevalence, severity of disease, and age of onset between individuals of African and European ancestry. Despite this disparity, the majority of genome-wide association studies (GWAS) of glaucoma are conducted among individuals of European ancestry. Leveraging electronic health record (EHR) based studies that integrate genetically predicted gene expression (GPGE) and glaucoma comorbidities have the potential to shed greater insight into disease mechanisms and expand the known genes and pathways associated with glaucoma pathogenesis. We identified glaucoma cases (N=11,888) and age matched controls (N=59,440) within Vanderbilt's EHR that had at least three visits in five years and had an EHR-reported race as white. We conducted a phenome-wide association study (PheWAS) to identify glaucoma comorbidities. Known glaucoma comorbidities such as radiotherapy (p=5.30x10-241), and diabetes (p=5.05x10-72) were significantly enriched among glaucoma cases. Using the beta estimates from the significantly associated comorbidities as weights, we constructed a phenotypic risk score (PheRS) in an independent population (BioVU, N=70,493 participants with European genetic ancestry). This PheRS represents a weighted sum of an individual's glaucoma comorbidities. To test whether the PheRS was associated with changes in GPGE, we conducted a transcriptome-wide association study (TWAS) in BioVU. We identified several genes (NEU2, TDRKH, TPP1) (p<8x10-5) that have previously been associated with neurological phenotypes, but not glaucoma. In future studies, we will apply this phenome-based approach to individuals of African ancestry to identify ancestry-specific genetic factors that may be involved in glaucoma pathogenesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1607 Integration of 3D human stem cell models derived from post-mortem tissue and statistical genomics to guide schizophrenia therapeutic development

Authors:

J. Erwin[1,2], T. Sawada[1], K. Benjamin[1], A. Barbosa[1], B. Araujo[1], A. McCord[1], L. D'Ignazio[1], B. Sheehan[3], M. Zabolocki[4], J. Kleinman[1], T. Hyde[1], C. Bardy[5], D. Weinberger[3], A. Paquola[6]; [1]Lieber Inst., Baltimore, MD, [2]Johns Hopkins Sch. of Med., Baltimore, MD, [3]Lieber Inst. for Brain Dev., Baltimore, MD, [4]South Australian Hlth.and Med. Res. Inst. (SAHMRI), Adelaide, Australia, [5]South Australian Hlth.and Med. Res. Inst., Adelaide, Australia, [6]Lieber Inst. for Brain Dev. / Johns Hopkins Med., Baltimore, MD

Schizophrenia is a neuropsychiatric disorder characterized by positive symptoms (such as hallucinations and delusions), negative symptoms. Schizophrenia is highly heritable, and genetic studies are playing a pivotal role in identifying potential biomarkers and causal disease mechanisms with the hope of informing new treatments. Genome-wide association studies (GWAS) identified nearly 270 loci with a high statistical association with schizophrenia risk; however each locus confers only a small increase in risk therefore it is difficult to translate these findings into understanding disease biology that can lead to treatments. Induced pluripotent stem cell (iPSC) models are a tractable system to translate genetic findings and interrogate mechanisms of pathogenesis. Mounting research with patient-derived iPSCs has proposed several neurodevelopmental pathways altered in SCZ. However, it is unclear what exactly these iPS models recapitulate, how potential perturbations of early brain development translates into illness in adults and how iPS models that represent fetal stages can be utilized to further drug development efforts to treat adult illness. I will present the largest transcriptome analysis of post-mortem caudate nucleus in schizophrenia where we discovered that decreased presynaptic DRD2 autoregulation is the causal dopamine risk factor for schizophrenia. We developed stem cell models from a subset of the postmortem cohort to better understand the molecular underpinnings of human psychiatric disorders. We established a method for the differentiation of iPS cells into ventral forebrain organoids and performed single cell RNAseq and cellular phenotyping. To our knowledge, this is the first study to evaluate iPSC models of SZ from the same individuals with postmortem tissue. Our study establishes that striatal neurons in the patients with SCZ carry abnormalities that originated during early brain development. Differentiation of inhibitory neurons is accelerated whereas excitatory neuronal development is delayed, implicating an excitation and inhibition (E-I) imbalance during early brain development in SCZ. We found a significant overlap of genes upregulated in the inhibitory neurons in SCZ organoids with upregulated genes in postmortem caudate tissues from the same patients with SCZ compared with control individuals. Altogether, we demonstrate that ventral forebrain organoids derived from postmortem tissue of individuals with schizophrenia recapitulate perturbed striatal gene expression dynamics of the donors' brains.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1608 † Integration of protein-disease associations with Mendelian randomization reveals potential drug targets and disease biomarkers in UK Biobank Pharma Proteomics Project (UKB-PPP)

Authors:

L. Hou[1], A. Li[1], Y. Zhang[1], E. Baugh[1], A. Doostparast Torshizi[1], S. Guo[2], A. Hart[1], J. Molineros[1], D. Waterworth[1], T. Mansi[3], C. Whelan[4], S. Li[1]; [1]Janssen R&D, Spring House, PA, [2]Janssen R&D, San Francisco, CA, [3]Janssen R&D, Titusville, NJ, [4]Janssen R&D, Boston, MA

The UK Biobank Pharma Proteomics Project (UKB-PPP) collected plasma proteomics data of 2,923 proteins across 54,219 participants. The proteomics data along with extensive phenotypic and genetic data offers unprecedented opportunity for human omics-driven drug discovery. In this study, we developed a framework for biomarker and target identification by integrating: 1) cross-sectional association analysis between plasma protein levels with prevalent and incident cases of ~1,500 diseases defined by combined ICD codes (PheCODEs); 2) protein-change trajectory estimation for patients before and after disease onset; 3) systematic Mendelian randomization (MR) analysis for ~800 traits using UKB-PPP cis-pQTL as instrumental variables. Our analysis revealed 241,501 significant ($p < 6.0\times10^{-8}$) associations between 2,389 proteins with 860 diseases. Protein-disease pairs were further classified into different categories based on 1) whether the protein is casually related with the diseases from MR analysis, 2) whether the protein is significantly up/downregulated in prevalent, incident cases or both, 3) trajectory of protein-change before/after disease onset. Our results confirmed some well-known causal relationships (e.g., ANGPTL3 for hypercholesterolemia and coronary artery disease) and revealed novel causal risk factors (e.g., IL4R for type 1 diabetes, UMOD for hypertension). Among non-causal protein-disease pairs, protein association and change trajectory analysis replicated diagnostic biomarkers established previously (e.g., prostate-specific antigen for prostate cancer) and revealed novel insights into candidate biomarkers: glial fibrillary acidic protein (GFAP), for example, is a more neurodegeneration-specific biomarker elevated in Alzheimer's disease (AD) and dementia cases at least 5 years prior to diagnosis, compared to neurofilament light-chain (NfL), which is a more non-specific marker associated with >200 diseases, including AD and other neurological, metabolic, and respiratory diseases. Our work demonstrates that integrating large-scale human omics analyses has great potential to identify therapeutic targets and potential biomarkers for disease prediction, diagnosis, or subtyping, especially with the public release of UKB-PPP data and the growth of diverse biobanks.

PB1609 Integrative Analysis of Cell-Specific Human Endogenous Retrovirus Expression and Host Gene Expression Identifies Associations with Clinical Phenotypes in Systemic Lupus Erythematosus.

Authors:

M. Sirota[1], C. Lanata[2], Z. Cutts[1], S. Patterson[1], L. Maliskova[1], K. Taylor[1], C. Ye[1], M. Dall'Era[1], J. Yazdany[1], L. Criswell[3], G. Fragiadakis[1], C. Langelier[1], T. Capra[1]; [1]UCSF, San Francisco, CA, [2]NHGRI, Bethesda, MD, [3]Natl. Human Genome Res. Inst., Bethesda, MD

Introduction: Transposable elements (TEs) consist of human endogenous retroviruses (HERVs) and long interspersed nuclear elements (LINEs). Their expression may contribute to production of type I IFN and the generation of autoantibodies. The objective of this study was to detect TEs in 4 cell-types in systemic lupus erythematosus (SLE) patients and characterize their relationship to SLE phenotypes and host gene expression.
Methods: We profiled cell-sorted RNA-seq data (CD4+ T cells, CD14+ monocytes, CD19+ B cells, and NK cells) from PBMCs of 119 SLE patients from the California Lupus Epidemiology Study. We performed cell specific differential expression analysis of TEs across 11 SLE clinical phenotypes adjusting for sex, age, genetic principal components 1-10 and medication use. TE family and viral gene enrichment was performed. We explored which genes and pathways were differentially expressed with SLE phenotypes associated TEs.
Results: After standard quality control, we quantified TEs in 4 cell-types using Telescope resulting in a total of 27,135 TEs. TE expression was cell specific as observed by dimensionality reduction clustering. Differential expression analysis on SLE subphenotypes identified a moderate number of significant differentially expressed TEs in different cell types and SLE subphenotypes (adj $p < 0.05$). For example, 53 TEs were differentially expressed in CD19 cells by disease severity. Some commonly positively associated TEs across phenotypes include MER4B, MER101, ERVLB4, ERVLE and HERVH. Viral protein enrichment analysis found protease (Pro), integrase, reverse transcriptase (RT) enriched in the CD4 cells, dutpase enriched in CD14, Pro and RT enriched in CD19, and Ribonuclease H, Pro, and RT enriched in NK cells. We then performed differential expression analysis of host gene expression with SLE phenotype associated TEs across cell types. There was an upregulation of the IFN signaling pathway in CD4, CD19 and CD14 cells (FDR <0.05). CD19 cells had upregulation of genes in pathways related to BCR signaling, NF-kB activation, and DNA repair. CD4 cells revealed a downregulation of metabolic pathways and viral influenza pathways. CD14 showed upregulation of OAS antiviral response, and NK cells had downregulation of transcription pathways.
Conclusion: We have described differentially expressed TEs in 4 cell types according to several SLE subphenotypes. Furthermore, these TEs correlate with differential gene expression in SLE relevant pathways, in particular in CD19 cells. These findings suggest that expression of TEs might be contributing to activation of SLE-related mechanisms in a cell-specific manner.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1610 Integrative analysis of the colonic transcriptome and colonoscopy-based diverticula enumeration unveils diverticulosis-specific causal genes

Authors:

J. Seo, H. Liu, K. Young, X. Zhang, T. O. Keku, C. D. Jones, K. E. North, S. S. Robert, A. F. Peery; Univ. of North Carolina, Chapel Hill, NC

Colonic diverticulosis is a prevalent condition among older adults, marked by the presence of thin-walled pockets in the colon wall that can become inflamed, infected, hemorrhage, and rupture. The genetic factors that contribute to the pathogenesis of the disease, including the transcriptome, remain understudied. Here, we report the first large colonoscopy-based transcriptomic study that investigates variations in the colonic transcriptome from well-characterized patients with (N=172) and without (N=232) diverticulosis. Between patient groups, 38 genes were differentially expressed, and 17 genes showed evidence of differential transcript usage. These genes suggested tissue remodeling as a potential mechanism of diverticula formation. In addition, expression quantitative trait loci (eQTL) mapping identified a total of 6,143 genes that exhibited at least one *cis*-eQTLs at a false discovery rate (FDR) of less than 1%. Mendelian randomization combining GWAS and colonic *cis*-eQTLs identified potential causal genes at five loci, three of which had been previously implicated in diverticulosis GWAS (*ENTPD7*, *CRISPLD2*, and *PHGR1*). Notably, the *ENTPD7* gene was upregulated in diverticulosis patients. Furthermore, polygenic risk score analysis revealed that a higher prevalence of diverticula is associated with elevated genetic risk for developing diverticulitis. These discoveries shed light on the underlying gene regulation contributing to diverticulosis and provide insights into the potential molecular pathways involved in its pathogenesis.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1611 Interplay between Polygenic Risk Score and Solar Radiation Exposure: Implication for Systemic Lupus Erythematosus Onset and Pathogenesis

Authors:

Y-M. Chen[1], T-C. Chen[2], H-W. Yang[1], Y-J. Chen[1], I-C. Chen[1]; [1]Taichung Veterans Gen. Hosp., Taiwan, Taichung, Taiwan, [2]Academia Sinica, Taiwan, Taipei, Taiwan

Objectives: This research elucidates the correlation between solar radiation exposure, polygenic risk score (PRS), and systemic lupus erythematosus (SLE) onset, utilizing genomic, environmental, and clinical data.
Methods: We included 1,800 SLE participants and 1,800 controls from the Taiwan Precision Medicine Initiative, genotyped via the Affymetrix Genome-Wide TWB 2.0 SNP Array. The SLE PRS, a sum of weighted genetic variants encompassing 27 SNPs, was calculated. QGIS computed solar radiation exposure from participants' residences. We utilized logistic regression and mediation effect analyses to explore connections between SLE PRS, solar insolation susceptibility, and SLE.
Results: SLE patients showed decreased solar insolation ($p<0.001$). The highest decile of SLE-PRS had lower solar insolation before 1, 3, 6, and 12 months compared to the lowest decile, with statistical significance for 1 and 12 months ($p=0.025$, $p=0.004$, respectively). An inverse association between SLE prevalence and solar insolation was found. Solar insolation didn't mediate the SLE-PRS effect on SLE in the high insolation group. A substantial direct effect of SLE-PRS on SLE (0.44, 95% CI: 0.23-0.68, $p<0.001$) was observed in the high solar insolation group. Compared to the lowest decile, the highest SLE-PRS decile showed a 10.98-fold SLE risk increase (95% CI, 3.773-31.952, $p<0.001$). High SLE-PRS and high solar insolation exposure significantly raised SLE risk.
Conclusions: Our study unveils the intertwined nature of UV exposure and polygenic risks in SLE. Future studies should explore the preventative potential of robust solar radiation protection for high-risk individuals before the disease onset.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1612 Interrogating aging-associated transcriptional changes in the murine enteric nervous system

Authors:

J. Slosberg[1], S. Kulkarni[2,3], L. Goff[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Beth Israel Deaconess Med. Ctr., Boston, MA, [3]Harvard Med. Sch., Boston, MA

Diverse gut functions, including intestinal motility, absorption, and immunity, are regulated by the cells of the enteric nervous system (ENS) which resides entirely within the gut wall. These processes change significantly during maturation and are increasingly dysregulated with aging - suggesting that the ENS changes structurally and functionally during these phases. However, the molecular factors that contribute to ENS maturation and aging are unknown. Identifying these will provide a more complete understanding of the etiology of age-associated ENS disorders and will yield putative targets for therapies against diseases, for which incidence is increasing in aging populations.

To this goal, we investigated how the motility-regulating enteric neurons and their local environment, the longitudinal muscle-contained myenteric plexus (LM-MP) of the gut wall, changes at a molecular level over the course of aging. We performed RNA-sequencing to profile the transcriptome of the ileal LM-MP tissue of male and female C57BL/6J mice of 3 different ages: juvenile (1 month-old), mature adult (6 month-old), and aging (17 month-old). Using a DESeq2 analysis framework, 809 genes were identified as varying with age (388 genes upregulated, 411 genes downregulated, and 10 genes with inconsistent direction of effect). Between tissues from juvenile and aging mice, a gene set enrichment analysis highlighted the downregulation of the TGF-beta signaling pathway and of genes involved in extracellular matrix (ECM) organization. Specifically, we observe decreased expression in diverse collagen subunits, elastin (Eln), and matrix metalloproteinases (Mmp2, Mmp11, Mmp15), suggesting aging-associated decreased rates of ECM turnover and remodeling. We also found significant changes in genes involved in synapse organization, notably a decrease in the neuronally-expressed proteoglycan Agrin (Agrn). Aging was further associated with increased expression of Ric3 (resistance to inhibition of cholinesterase 3) and Vsnl1 (visinin-like 1), which are known to modulate neuronal signaling.

Our observations suggest important aging-associated changes in gene regulatory networks that are important for normal ENS and gut function. These data provide us with important putative targets for therapeutic interventions to provide treatment for aging-associated gut dysfunction.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1613 Investigating alternative splice variants as potential biomarkers in Parkinson's disease: Insights from targeted sequencing of plasma extracellular vesicles

Authors:

T. Cole[1], D. L. Miller[2], S. K. Chakrabortty[2], K. Babcock[2], S. Xing[2], J. J. Ray[2], B. C. Haynes[1], S. Yu[2], J. Skog[2]; [1]Bio-techne, AUSTIN, TX, [2]Bio-techne, Waltham, MA

Introduction: Parkinson's disease (PD) is a neurodegenerative disorder with rapidly expanding global prevalence, ranking as the second most common neurodegenerative disorder worldwide. Dysregulation of RNA splicing has emerged as a hallmark of neurodegenerative diseases, including PD, underscoring the importance of investigating alternative splice variants. The use of minimally invasive plasma liquid biopsies provides an opportunity to monitor neuronal-origin cell-free RNA (cfRNA) and holds promise for surveillance purposes in the context of PD. While the low abundance of neuronal extracellular vesicles in hematopoietic-rich plasma poses challenges, leveraging targeted profiling of brain-derived transcripts can unveil rare splice variants and enhance their detection.
Methods: We conducted whole transcriptome sequencing (WTS), whole exome sequencing (WES), and brain-specific exosomal RNA profiling on a cohort of 20 plasma samples from PD patients and 20 healthy controls. We performed differential splice variant analysis to examine the influence of each RNA-Seq enrichment platform on the resolution of gene expression and the detection of isoforms.
Results: The brain-specific exosomal RNA profiling exhibited remarkable performance in terms of coverage and detection of brain-specific transcripts compared to the WTS and WES panels. We observed orders of magnitude deeper coverage of transcripts specific to the brain tissue using brain-specific exosomal RNA profiling and identified a substantial number of transcripts that were not detected by the other panels. Notably, our analysis unveiled a set of 37 genes that demonstrated robust evidence of differential splice variant usage across all three panels. Furthermore, the brain-specific panel revealed an additional 30 genes that were exclusively identified.
Conclusions: Our findings underscore the significance of leveraging brain-specific exosomal RNA profiling for a more comprehensive understanding of the transcriptomic landscape in the context of PD. The identification of genes exhibiting significant alternative splice usage across multiple panels emphasizes their potential as robust biomarker candidates for PD. Moreover, the discovery of additional genes exclusively captured by the brain-specific panel adds to the richness of the transcriptomic landscape and further expands the repertoire of potential PD biomarkers. These findings underscore the value of integrating multiple profiling approaches and provide valuable insights for future investigations in larger clinical cohorts.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1614 Investigating ancestry-specific genetic variation in apolipoprotein L genes associated with electronic health record phenotypes in diverse patient biobanks

Authors:

D. Zhang[1], M. Levin[1], S. Damrauer[2], M. Ritchie[1], D. Rader[1]; [1]Perelman Sch. of Med., Philadelphia, PA, [2]Corporal Michael J. Crescenz VA Med. Ctr., Philadelphia, PA

Health care disparities between people of different ancestries and ethnicities are well-documented in every field of medicine. As a poignant example, African Americans are more than 3 times as likely to have kidney failure compared to White Americans per the National Kidney Foundation. A major contributor to this disparity is the sample bias underlying existing genomic studies. Of the ~6,401 studies compiled in the genome-wide association studies (GWAS) catalog, ~95% of all GWAS participants are of European (EUR) ancestry with less than 1% of participants being of African American (AFR) ancestry. Using the Penn Medicine Biobank (PMBB) and adopting a genome-first approach, we investigated 572 protein-altering variants in the apolipoprotein L gene family, including 69 predicted loss-of-function (pLOF) and 503 missense variants, with a specific interest in those more common in non-European populations. We performed phenome-wide association studies (PheWAS) on 48 variants with a MAF > 0.1% in the PMBB AFR population (n = 11,198) against 1,236 binary phenotypes derived from electronic health records data with at least 20 cases. In addition to confirming the known AFR-specific rs73885319 and rs60910145 *APOL1* variants as strong positive controls for their association with end-stage renal disease (ESRD), our results identified a stop-gain variant rs11089781 (p.Gln58*) in the *APOL3* gene also found to be significantly associated with increased risk for ESRD (OR = 1.38, p = 3.64e-08). This variant has a gnomAD minor allele frequency of 0.22 in AFR compared to 3.97e-04 in EUR. It is also in linkage equilibrium (r^2 < 0.05) with the *APOL1* G1 and G2 known risk alleles for renal disease. Furthermore, the association between rs11089781 under a recessive model and ESRD is strongest in individuals who have low *APOL1* risk and carry either 0 or 1 copy of the risk alleles (OR = 1.79, p = 2.48e-03) compared to those who carry 2 copies of the risk alleles (OR = 0.98, p = 0.914). Using laboratory values for creatinine and estimated glomerular filtration rate (eGFR), we found that rs11089781 is also significantly associated with increased levels of max creatinine (beta = 0.07, p = 2.96e-05) and decreased levels of max eGFR (beta = -0.08, p = 2.36e-06). Replication of this association in up to 121,790 AFR individuals from the Million Veterans Program also yielded significant associations, both with ESRD (OR = 1.16, p = 1.01e-08) and mean eGFR (beta = -0.04, p = 2.42e-13). Initial hypotheses suggest that *APOL3* may play a protective role against *APOL1* and loss-of-function in *APOL3* increases susceptibility to *APOL1*-induced kidney dysfunction, though further functional characterization is still required.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1615 Investigating genetic architecture of cognitive functioning in correlation to metabolic traits in the Indian population

Authors:

S. CHAKRABORTY[1,2], SANSCOG Study Team, J. S. Sundarakumar[2], B. Kahali[3]; [1]Indian Inst. of Sci., Bangalore, India, [2]Ctr. for Brain Res., Bangalore, India, [3]Ctr. for Brain Res., Indian Inst. of Sci., Bangalore, India

Several large-scale genome-wide studies on general intelligence and common executive function phenotypes have established association of hundreds of independent genomic loci with cognition. Such large-scale association studies on either general cognition or domain-specific cognitive measures based entirely on the Indian population has not yet been conducted. Through our ongoing study on healthy individuals (aged 45 years and above) residing in south India, we aim to study the genetic landscape of normal cognitive functioning in a population-specific manner. In our study of ~3000 individuals, we have imputed ~400,00 (post quality check) genetic variants to three reference imputation panels - the haplotype reference consortium (HRC), TOPMed and our in-house panel based on whole-genome sequencing of Indian samples. The imputation accuracy of our in-house panel is higher than that of TOPMed and HRC panel for rare, low-frequency and common variants. With these imputed genotypes from our in-house panel scanning ~13 million markers, we carry out genome-wide association analysis (GWAS) for Hindi Mini Mental State Examination (HMSE) scores which assess general cognitive functioning and COGNITO (Computerized assessment of adult information processing) scores which report scores for diverse cognition domains adapted to rural settings. We also carry out GWAS for anthropometric and metabolic traits, namely body mass index, waist-hip ratio adjusted for BMI, waist-height ratio adjusted for BMI, fasting blood sugar, fasting insulin, HbA1c, HDL, LDL, triglycerides, and total cholesterol, since evidence from a multitude of studies highlight that age-associated metabolic risks affect cognitive functioning and could contribute to cognitive decline in ageing. We report association signals for each of the phenotypes and assess novelty by comparing with variants in the proximity (±500kbp and LD R^2>0.8) listed in EBI-GWAS catalogue associated with cognition and related neurological traits. Our initial analysis for HMSE has yielded one novel genome-wide UTR variant in chr 7(p11.2) and several suggestive novel associations in intronic and UTR regions of genes, a few of which are brain-specific eQTLs, and have been implicated with neuronal mechanisms and neurotransmission. With one or multiple combinations of the above metabolic markers, we find suggestive causal association with general cognition. The results from this study uncover genetic architecture of complex traits (metabolic and cognitive) in Indians, and forms basis for further studies aiming towards understanding cognitive decline in ageing Indian population.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1616 Investigating Immune Functions of neuronal genes burdening Autism Spectrum Disorder: An integrated gene expression and mutation analysis

Authors:

A. Siddappa Niranjana Murthy[1], S. V.P.[2], M. K.R.[3], R. Nallur B[3]; [1]Natl. Inst. of Mental Hlth.and NeuroSci.s, Bengaluru, India, [2]St Johns Res. Inst., Bengaluru, India, [3]Univ. of Mysore, Mysore, India

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by social-communication deficits, restricted-repetitive behaviours and interests. Neuroinflammation is often implicated in ASD pathogenesis. Recent studies in rats indicate immune activation deregulates the expression of genes associated with synaptogenesis, axonal guidance, synaptic contact and neurogenesis. Thereby, we explored the overlapping immune functions of neuronal genes through systematic in-silico functional analysis of ASD-associated genes from databases (db) like SFARI-db, Denovo-db and Genes4denovo-db. Enrichment analysis was performed with EnrichR to identify genes with prominent neuro-immune functions that were further subjected to protein-protein interaction (PPI) and tissue-specific functional network analysis on STRING and HumanBase, respectively. Prioritised neuro-immune genes were investigated for ASD brain-tissue specific gene expression, biological functional similarity with high-risk ASD genes using tool GOSemSim and were checked for mutations within 15 in-house WES data from Indian ASD children obtained on Illumina HiSeq 2500. From three databases ten thousand ASD-associated genes were collated; 1518 genes had neuroimmune functions, including 950 genes with statistically significant PPIs. Of these, 618 and 590 genes displayed neuronal and immune cell specific functional networks, respectively with 193 common genes holding prominent neuro-immune functions. Their involvement in ASD pathogenesis were validated using ASD brain post-mortem tissues and 15 in-house ASD WES data. Genes BDNF, ANK3, PLCB1, SET, SYT1, LAMB1, PRKAR1, BRCA2, NTRK1 were found differentially expressed in brain tissues and carried deleterious variation in our WES data. Thus, our study provides the first genetic evidence for neuroinflammation commonly observed in ASD subjects.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1617 Investigating the additive and interactive interactions between ADHD polygenic risk and environmental features on ADHD

Authors:

M. Shoaib[1], C. Burton[1], N. Rosalin[1], P. Arnold[1], P. Peters[2], R. Schachar[1], J. Crosbie[1]; [1]Hosp. for Sick Children, Toronto, ON, Canada, [2]Carleton Univ., Ottawa, ON, Canada

Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder with a polygenic component. According to recent evidence, air pollutants, NO2 and fine particulate matter (PM2.5) may increase risk for ADHD while residential greenspace may decrease risk for ADHD among children. The aim of this study is to test the associations between ADHD polygenic risk (PRS) and environmental exposures (NO2, PM2.5 and greenspace) on ADHD trait scores using additive and interactive models.

The study utilizes participants from the Spit for Science population-based study (age 6 to 17 years) where ADHD traits were measured using Strengths and Weaknesses of ADHD Symptoms and Normal Behavior Rating Scale (SWAN). We estimated PRS using a principal component extension to PRSice-2 in genotyped European ancestry individuals (n= 3197) using SNP effect sizes from the largest available ADHD genome wide association study. Environmental exposures (NO2, PM2.5, greenness) were obtained from linking geospatial coordinates from Canadian Postal Codes to Canadian Urban Environmental Health Research Consortium (CANUE) databases. We implemented regression models to test both additive (PRS + E) and interactive (PRS x E) effects on SWAN scores. Each analysis included age, sex and four population principal components as covariates by considering three environmental variables in separate models.

Preliminary analysis revealed a significant association between ADHD PRS and ADHD traits in all additive models (p-values < 0.001). We found a negative association between greenness and SWAN scores trending towards significance (p-value = 0.09) implying exposure to more green space might be associated with lower ADHD traits. Other environmental features NO2 and PM2.5 were not significantly associated with ADHD traits in additive regression models. There were no significant interactions between ADHD PRS and any of the environmental measures on ADHD traits (PRS x NO2 or PM2.5 or greenness).

In this study, we have tested the additive and interactive interactions between ADHD genetics and environment based on the polygenic risk of ADHD individuals. In additive models, we found PRS as a significant predictor of ADHD traits in population-based samples. We observed higher green spaces potentially be associated with low ADHD traits with a marginal significance. No significant interactions emerged between ADHD genetic risk and environmental features. The initial findings motivate us to extend our analysis in a larger sample size to improve power, the next phase of this study will be conducted using a larger cohort (N= 15000) and we will apply PRS methods suitable for diverse ancestry groups

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1618 Investigating the genetic and phenotypic landscape of Ectodermal Dysplasia.

Authors:

C. Munderloh, R. Belanger Deloge, E. A. Rivera-Munoz, H. Du, R. A. Lewis, J. E. Posey; Baylor Coll. of Med., Houston, TX

Ectodermal Dysplasias (EDs) encompass a diverse group of inherited disorders of the embryonic ectoderm that demonstrate substantial genetic and phenotypic heterogeneity. Currently, 49 ED subtypes have a known molecular etiology involving genes encoding critical components of the *TP63*, *WNT*, and *EDA* developmental pathways (~36%), genes in other varied pathways (~8%), and genes encoding structural framework proteins (~11%). The molecular etiologies of the remaining 40 clinically defined EDs are unknown presently. We recognize that many ED subtypes and syndromes meet the criteria for an ED clinical diagnosis via involvement of two or more affected ectodermal derivatives. Comprehensive characterization of ED's genetic and phenotypic spectrum is required to better understand ED and enhance diagnostic evaluation and molecular testing. In this study, we recruited a cohort of 196 individuals from 48 ED families with no firm molecular diagnosis but with observed and suspected modes of inheritance consistent with previously described autosomal dominant, autosomal recessive, and X-linked forms of ED. We collected blood samples from 196 individuals, consisting of 68 affected individuals and 128 unaffected individuals. Generation and analysis of exome and genome sequencing data to identify potentially deleterious variants in both established and/or novel candidate ED genes are ongoing. To date, an analysis of eight cases has revealed three notable findings. These include the identification of a pathogenic variant in the known disease gene *TP63* (NM_003722.5:c.953G>A (p.R318H)) and variants of unknown significance in two novel candidate genes involved in epidermis formation, *KDF1* and *KRT5* (NM_152365.3:c.795C>A (p.D265E); NM_000424.4:c.1682T>G (p.L561R)). We are presently performing further investigations to determine whether *KDF1* and *KRT5* indeed represent novel ED disease genes, and also performing phenotypic clustering analysis of studied cases. This work will inform the phenotypic and molecular contributors that drive ED subtypes, yield potential phenotypic expansions, and reveal genotype-phenotype correlations.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1619 Investigating the Interplay of Sex and the Genetic Risk Factor, APOE, Across Ages in Alzheimer's Disease at a Single Cell Resolution

Authors:

Y. Li[1], Y. Hao[2], C. Pereda Serras[1], S. Yoon[2], B. Grone[2], L. Ding[2], J. Blumenfeld[2], T. Oskotsky[1], Y. Huang[2], M. Sirota[1]; [1]Univ. of California, San Francisco, San Francisco, CA, [2]Gladstone Inst.s, San Francisco, CA

Background: Old age, apolipoprotein E4 (APOE4) genotype, and the female sex are well-established risk factors for Alzheimer's Disease (AD). Almost two-thirds of AD patients are women and most are APOE4 carriers. We aim to study the interplay between these risk factors by analyzing single-nucleus RNA-sequencing (snRNA-seq) data from the hippocampus of human APOE4 and APOE3 knock-in (KI) female and male mice across ages.
Methods: A sex-balanced cohort of APOE3-KI and APOE4-KI homozygous mice were sacrificed at 6 (young), 12 (adult), and 18 (old) months of age. Single nuclei were prepared from the hippocampus of each mouse for snRNA-seq. Demultiplexed fastq files were aligned to a custom reference genome mm10-1.2.0, using the Cellranger v2.0.1. Quality assurance, count normalization, clustering, cell type identification, and differentially expressed gene (DEG) analysis were performed using the Seurat.
Results: Our dataset consists of a total of 527,395 cells covering 27,153 genes. A total of 36 cell clusters were identified, with six major brain cell types (astrocytes, microglia, oligodendrocytes, oligodendrocyte precursor cells, and excitatory and inhibitory neurons). Analysis of the abundance of each cell type showed no differences in cellular composition across ages, APOE genotypes, and sexes in all cell types except astrocytes. Astrocyte abundance was significantly higher in old females versus old males (padj=0.025, Tukey's multiple comparison test) and in young APOE4 versus young APOE3 males (padj=0.042).
Sex and age-stratified DEG analysis comparing APOE4 versus APOE3 astrocytes revealed many shared DEGs between young and adult males but not with old males, while females had few consistent DEGs across the three age groups. We also identified several DEGs associated with plasma membrane assembling and post-synaptic transmission/signaling that are upregulated in old APOE4 versus old APOE3 females while downregulated in young APOE4 females and young and adult APOE4 males versus their APOE3 counterparts. Analysis of interactions among cell types using CellChat revealed sex-biased communication from glial cells to inhibitory neurons.
Conclusion: We identified a clear interplay between age, APOE genotype, and sex in mouse models of AD and revealed the interaction and convergence of these risk factors at a single-cell resolution.

PB1620 Investigating the pleiotropic genetic architecture of impulsivity across biological scales

Authors:

T. Mallard[1,2], M. Jennings[3], Y. Zhang[4], J. Tubbs[1], D. Gustavson[5], A. Grotzinger[5], M. Westwater[6], 23andMe Research Team, S. Elson[7], P. Fontanillas[7], T. Ge[1], K. Choi[1], J. Smoller[1], A. Palmer[3], S. Sanchez-Roige[3]; [1]Massachusetts Gen. Hosp., Boston, MA, [2]Harvard Med. Sch., Boston, MA, [3]Univ. of California San Diego, La Jolla, CA, [4]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [5]Univ. of Colorado Boulder, Boulder, CO, [6]Univ. of Oxford, Oxfordshire, United Kingdom, [7]23andMe, Inc., Sunnyvale, CA

Background: Impulsivity is an important mental construct implicated in various psychiatric conditions, but consensus on its measurement and corresponding biology is lacking. Neuroscientific insights support 'splitting' impulsivity into distinct facets; however, psychological research shows that many mental constructs can be 'lumped' together at multiple levels of analysis. Here, we use multivariate genetic methods to advance genomic discovery for impulsivity by (i) testing the splitting vs lumping hypotheses as they relate to common variant architecture and (ii) characterizing pleiotropy across biological scales.
Methods: We used the Genomic SEM framework to conduct a multivariate analysis of eight impulsivity facets measured in 23andMe (*N*s ~130k), employing two statistical models: (1) an "omnibus" model that provides an unstructured meta-analytic test of association, and (2) a common factor of impulsivity, where genetic associations operate via a latent genetic factor. To gain a comprehensive understanding of the etiology of impulsivity, we examined these models across molecular genetic, transcriptomic, and neurogenomic levels. We then conducted polygenic score (PGS) analyses in two independent cohorts to characterize links with human health and wellbeing.
Results: Results revealed widespread pleiotropy among impulsivity facets, with most trait pairs having moderate-to-large genetic correlations (mean r_g = 0.43, range = -0.09-0.79). Genomic factor analysis indicated that the observed patterns of covariance could be approximated with a common factor model (CFI = 0.94, SRMR = 0.08). However, GWAS analyses revealed that SNP-level effects were largely inconsistent with this model of general liability. This pattern was also seen in multivariate TWAS and neurogenomic analyses, where impulsivity facets had many trait-specific patterns of association, including heterogeneous signals in the inferior frontal gyrus, a region strongly implicated in self-control (all Q_{Trait} P < 2.43e-7 for the pars orbitalis, pars triangularis, and pars opercularis). Finally, PGS results underscored the consequences of lumping impulsivity facets, as 67 links to health outcomes were lost when a common factor PGS was used, including novel links between urgency and neurodevelopmental disorders.
Discussion: By formally comparing splitting versus lumping models, these findings generate new insights into the genetic architecture of impulsivity, implicating novel risk genes and links to human neurobiology and health. Our results support multidimensional approaches as a more informative avenue for studying the heterogeneous biology of impulsivity.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1621 Investigating the underlying genetic architecture of personality traits and overlap with psychopathology in 240,000 US military veterans.

Authors:

P. Gupta[1,2], M. Stein[3,4], S. Beck[1,2], K. Adhikari[1,2], J. Gelernter[1,2], D. Levey[1,2]; [1]Yale Sch. of Med., New Haven, CT, [2]VA Connecticut Hlth.care System, West Haven, CT, [3]Univ. of California San Diego, San Diego, CA, [4]VA San Diego Hlth.care System, San Diego, CA

Background: Personality is influenced by both genetic and environmental factors and is associated with to other complex traits such as anxiety and depression. Of the five commonly classified personality traits - neuroticism, agreeableness, extraversion, conscientiousness and openness, neuroticism has most often been the focus of genetic studies.
Methods: The Million Veteran Program (MVP) cohort has around 900,000 enrollees, with more than 650,000 so far with available genetic data and also has survey response data from the Big Five Inventory-Short. The Big Five assesses five personality traits: neuroticism, agreeableness, extraversion, conscientiousness and openness. We conducted GWAS in the MVP of each trait in approx. 240,000 individuals with available survey personality data. We conducted linkage disequilibrium score regression to calculate heritability and genetic correlation among personality traits and each with psychopathologies.
Results: We identified genome-wide significant loci associated with the 5 personality traits (7 with neuroticism and openness, 11 with extraversion, 2 with conscientiousness and 3 with agreeableness). Gene expression associations were found in TWAS analysis for each of the trait with highest number of associations observed for neuroticism and extraversion. Further, neuroticism showed highest positive correlation with anxiety (rG=0.69) while agreeableness showed lowest negative correlation (rG= -0.31) with anxiety suggesting a differing overlap in their respective genetic architecture.
Conclusions: We provide evidence for a substantial differential genomic architecture underlying the personality traits. Our work yields novel insights and opens new questions about the influence of genetic factors on personality and how this intersects with psychopathology.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1622 Investigation of familial hypercholesterolemia prevalence and association with cardiovascular disease in an African ancestry cohort.

Authors:

A. Winters, M. Kelly, N. Mohammed, A. Berry, L. Jones, S. Gidding, M. Oetjens; Geisinger, Danville, PA

Familial hypercholesterolemia (FH) is an inherited condition consisting of lifelong elevated LDL cholesterol levels and increased risk of cardiovascular disease. Variants in three genes involved in LDL receptor function, *LDLR*, *APOB*, and *PCSK9*, account for most cases. Among Western populations, the prevalence of FH has been reported to be between 1:212 to 1:331. African ancestry individuals are underrepresented in submissions to genetic resources used to determine variant pathogenicity and there are no known reports on the prevalence of FH in those populations. To create an African ancestry cohort, we examined genetic data from Geisinger's MyCode (N = 175,500) and the NIH's All of Us (N = 98,590) cohorts with principal component analyses to identify individuals who cluster with 1000 Genomes African superpopulation (1KG AFR). We assessed sequence variants in FH genes from our African ancestry cohort for pathogenicity using American College of Medical Genetics criteria. Lipid levels and use of lipid lowering medications were compared among those with and without a variant. We identified 29,931 individuals who clustered with the 1KG AFR group. Among these, we identified 31 unique pathogenic or likely pathogenic FH variants among 108 individuals. Most of the pathogenic variants identified (94%) were missense variants in the *LDLR* gene. This gave a prevalence of FH of 1:277 among African ancestry individuals. Mean age for individuals with a pathogenic FH variant was 40.5 years in MyCode and 50.4 years in All of Us. Of those with a pathogenic FH variant and at least one LDL-C measurement, we found that 52.5% had an LDL-C &gt190mg/dl and 37.5% had an LDL-C &gt250 mg/dl, compared to 5.7% and 0.6% of African ancestry individuals without an FH variant. The effect size of an FH variant on maximum LDL-C levels adjusted for age, sex, and the first four principal components of ancestry was 90.4 mg/dL (95% CI [69.8, 111.0], p=1.1x10-17) in MyCode and 126.5 mg/dL (95% CI [110.5, 142.6], p=4.0x10-53) in All of Us. In the combined cohort, 29.6% of individuals with a pathogenic FH variant had been prescribed an LDL-lowering medication, compared to 20.9% of individuals without a variant. We identified a prevalence in an African Ancestry cohort of FH consistent with that observed in studies of European ancestry cohorts. The effect size of an FH variant in this cohort was large. These data suggest that African ancestry individuals with pathogenic FH variants have a high likelihood of increased LDL and concomitant cardiovascular disease risk and that there is an opportunity for additional identification and treatment of FH in this population.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1623 Investigation of the genetic basis of pediatric psoriasis reveals contributions from both common risk alleles and rare *de novo* mutations.

Authors:

J. Frost[1], S. Kumar[2], M. Fang[3], T. Erickson[3], A. Hajek[3], A. Kwon[3], J. Liu[2], A. Zhu[1], R. Pandya[1], S. Rangel[3], M. Lebwohl[1], J. Oksenberg[4], M. Seyger[5], W. Liao[2], A. Paller[3], A. Bowcock[6]; [1]Icahn Sch. of Med. at Mount Sinai, New York City, NY, [2]Univ. of California, San Francisco, San Francisco, CA, [3]Northwestern Univ., Feinberg Sch. of Med., Chicago, IL, [4]Univ California San Francisco, San Francisco, CA, [5]Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands, [6]Icahn Sch. of Med. at Mount Sinai, New York, NY

An understanding of the genetic basis of psoriasis can help in its management, including treatment choice. The need is particularly high for children with psoriasis, which is often a life-altering, chronic disorder associated with extracutaneous comorbidities. Our previous studies revealed that some pediatric psoriasis patients harbor highly penetrant mutations in *CARD14*, but these are rare or *de novo*. The goal of the current study was to examine the genetic underpinnings of pediatric psoriasis via the identification of *de novo* mutations, the presence of HLA class I risk alleles, and weighted genetic risk score (wGRS). Following exome-sequencing of 41 trio families (pediatric patients with no first-degree family history of psoriasis) we first imputed HLA class I alleles with "Optitype". We observed that 60% of pediatric psoriasis cases, including the six guttate psoriasis cases, harbored at least one copy of the major known psoriasis risk allele HLA-C*06:02. None of the probands harbored *CARD14* mutations so we then searched for *de novo* mutations to identify novel highly penetrant coding variants predisposing to psoriasis. In 23 probands we identified 37 *de novo* mutations in multiple genes. A number of these genes encoded proteins with a role in pathogen responsiveness such as *LCAT, SPNS1, CORO1A, SNX6*, and *AMPD3*. Pathogens have long been considered a trigger for psoriasis. One case harbored a p.Arg90Cys alteration in *SNAP29,* a gene mutated in the rare autosomal recessive disorder CEDNIK (Cerebral dysgenesis, neuropathy, ichthyosis, and keratoderma syndrome). This is intriguing given the fact that ichthyosis, like psoriasis, is associated with an altered skin barrier and skewing towards Th17 immune activation. We also computed the wGRS of the trios to understand the genetic influence of common psoriasis risk alleles in pediatric patients. The wGRS were derived from a GWAS meta-analysis (N >39,000), which had revealed 88 independent SNPs associated with psoriasis. These data suggested that both pediatric psoriasis cases and their unaffected parents have a greater wGRS than population healthy controls, indicating an important role for common variants in the pathogenesis of pediatric psoriasis and inheritance of these alleles from silent carrier parents. Overall, these studies suggest that both common and rare variants contribute to psoriasis in the pediatric population.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1624 Investigation of the sex chromosomes in Autism Spectrum Disorder.

Authors:

M. Mendes de Aquino[1,2], W. Engchuan[1,2], B. Thiruvahindrapuram[1,2], E. McKee[1,2], B. Trost[1,2], R. Alexandrova[1,2], T. Peixoto Leal[3], W. Li[1,2], S. Scherer[1,2,4]; [1]The Ctr. for Applied Genomics, The Hosp. for Sick Children, Toronto, ON, Canada, [2]Genetics and Genome Biology Program, The Hosp. for Sick Children, Toronto, ON, Canada, [3]Cleveland Clinic, Cleveland, OH, [4]McLaughlin Ctr. and Dept. of Molecular Genetics, Univ. of Toronto, Toronto, ON, Canada

Autism Spectrum Disorder (ASD) is a neurodevelopmental condition characterized by varying degrees of social communication deficits, restricted interests, and repetitive sensory-motor behaviours, which affects approximately 1% of the global population. However, the prevalence of ASD differs between males and females, with a commonly reported ratio of 4:1; this ratio may increase to 11:1 if Asperger's syndrome is included as a form of ASD. There have been many X-linked genes identified to carry rare ASD-associated variants in males, having even a hypothesis of a potential protective effect of having two X chromosomes and the risk effect associated with the Y chromosome. With many new resources, there is now the opportunity to investigate all aspects of genetic variations on the sex chromosomes in ASD. Here, we explored ASD genetic associations in both sex chromosomes, taking into account their differential recombination patterns and the inactivation of the X chromosome in females. We performed an X-chromosome Wide Association Study (XWAS) and a Y-haplogroup inference, followed by logistic regression for testing statistical association. These methodologies were applied to ASD whole genome sequence resources, including the MSSNG, Simons Simplex Collection and SPARK, with a total of 6,873 cases for the XWAS and 5,835 ASD-affected males for the Y chromosome analyses. To conduct the XWAS, we utilized as controls samples from HostSeq (Host Genome Sequencing Initiative; 6,456 samples) and MGRB (Medical Genome Reference Bank; 2,525 samples). Additionally, for the Y-haplogroups analysis, we included WGS data from two pediatric control cohorts; Canadian Healthy Infant and Longitudinal Development (CHILD) and Inova Health System Cohort (INOVA). We conducted both association tests using European samples and controlling for population structure. From XWAS, we identified a specific region of linkage disequilibrium (LD) in the Xp22.2 that showed significant association with ASD when examining only males (top variant with p-value of $3.57x10^{-7}$, odds ratio (OR) [95%CI]: 0.8 [0.73 - 0.87], global frequency=0.35). For the Y chromosome analysis, we did not find any major Y-haplogroups associated with ASD. However, we discovered one final haplogroup branch, belonging to the I major haplogroup, that exhibited significant association results, with a p-value of $7.27x10^{-7}$ and an OR of 3.03. The identified signals were cross-referenced with phenotype data, family information, gene expression, and gene-set differentiation. Our findings open new avenues of investigation into the genomic architecture in ASD.

PB1625 IPMI: Precision Medicine Genomics Project Advancing Integrated Polygenic Risk Score Development and Drug Target Discovery

Authors:

S-G. Park[1], J. Choi[2], J. Ko[3], E-K. Kwon[4], S. Lee[1], Y. Lee[3], H. Kim[4], B. Choi[1], J. Kim[4], S-S. Byun[5]; [1]Invites BioCore, Yongin, Korea, Republic of, [2]Jeju Natl. Univ. Hosp., Jeju Natl. Univ. Sch. of Med., Jeju, Korea, Republic of, [3]Invites Genomics, Jeju, Korea, Republic of, [4]Procagen, Seongnam, Korea, Republic of, [5]Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of

In this project, called IPMI (Invites Precision Medicine Initiative), the primary objective is to develop an assessment method called iPRS (Integrated Polygenic Risk Score) and identify new drug targets for various diseases. The study will involve the collection of comprehensive data from over 50,000 individuals of South Korean ancestry. IPMI initiated the project in December 2022, and has collected data from around 10,000 individuals to date. The project is expected to be completed by the end of 2025. This data includes genetic information obtained through whole genome sequencing (WGS) and a customized SNP array, clinical data obtained from medical records and surveys, and lifelog information collected from wearable devices and smartphone apps. The iPRS assessment method combines genetic and clinical information to predict an individual's risk of developing diseases like cancer or cardiovascular disease. By identifying high-risk individuals before they display symptoms, early detection and prevention can be facilitated. The IPMI project aims to develop iPRS for different diseases, including cancer, cardiovascular disease, type 2 diabetes, and neurovascular disease. Additionally, the IPMI project aims to discover new drug targets for these diseases. Drug targets are specific molecules or pathways that medications can target to treat diseases effectively. By identifying novel drug targets, the IPMI project intends to accelerate the development of new and improved treatments. Overall, the IPMI project represents a significant endeavor in the field of medicine. Through the development of iPRS and the discovery of new drug targets, it has the potential to enhance prevention, early detection, and treatment of diseases, thereby improving health outcomes worldwide. Furthermore, the IPMI project is expected to contribute to the growth of the digital healthcare market and the precision medicine industry.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1626 Japanese biobank whole genome sequencing analysis identifies hearing loss risk genes for drug discovery.

Authors:

T. Monjo[1], P. Yang[1], Y. Ling[1], T. Saito[2], S. Mugikura[2], S. Ogishima[2], F. Nagami[2], K. Kinoshita[2], S. Kuriyama[2], M. Yamamoto[2], T. Ando[1]; [1]Takeda Pharmaceutical Company Limited, Fujisawa, Kanagawa, Japan, [2]Tohoku Med. Megabank Organization, Tohoku Univ., Sendai, Miyagi, Japan

Identification of genetically validated novel drug targets is absolutely required to treat hearing loss (HL) because retrospective studies suggested that genetically supported targets were more likely to be successful in drug development. Tohoku medical megabank organization (ToMMo) is a Japanese biobank that consists of over 150,000 participants' biospecimens and deep phenotyping information (e.g. physiological measurements, questionnaire, and imaging). The partnership between ToMMo and Japanese pharmaceutical companies are proceeding a huge project that sequences whole genome of 100,000 ToMMo participants. In this presentation, we show our drug discovery strategy using genetic data and a case study that used currently available approximately 50,000 WGS data and hearing test phenotypes. Whole genome sequencing (WGS) enables us to detect rare deleterious variants related to various diseases. To identify potential risk genes to HL, we conducted association tests using 40,449 individuals' WGS data in ToMMo. To be specific, we firstly defined hearing ability phenotypes from hearing tests of left and right ears and performed gene-based association tests of rare protein-truncating variants (e.g. frameshift variant, stop gained variants; minor allele frequency < 1%) using scalable linear-mixed model (i.e. Regenie) to increase statistical power. As a result, we found significant genes that were associated to hearing test phenotypes after Bonferroni correction. Some genes were previously reported as a causal gene of hereditary HL. In conclusion, we identified the potential genetic associations with HL including known causal genes using currently available half of WGS data. Further replication with the full dataset and wet validation study would investigate the gene for potential drug development programs by generating and supporting therapeutic hypothesis of HL.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1627 Joint analysis of de novo mutations in autism spectrum disorders, schizophrenia, congenital heart disease, and other developmental disorders improves detection power and implicates shared molecular pathways and CNS processes

Authors:

M. Kealhofer, B. Riley, T-H. Nguyen; Virginia Commonwealth Univ., Richmond, VA

Background: Exome studies have previously implicated shared risk genes and pathways for autism spectrum disorders (ASD), congenital heart disease (CHD), schizophrenia (SCZ), and other developmental disorders (DD). However, an in-depth analysis for this shared information has not been conducted on current large-scale datasets of these disorders. Here, we aim to use a two-trait Bayesian integrative analysis approach to increase statistical power for gene discovery, and to better understand the biological information of genes shared between these disorders.
Methods: We used mTADA to perform joint pair-wise analysis of exome variants identified from 6,430 ASD trios, 3,154 SCZ trios, 2,645 CHD trios, and 31,058 trios with severe DD to identify shared risk genes. We used ClusterProfiler to assess if those risk genes cluster in GO and KEGG genesets. Expression weighted cell type enrichment was performed using EWCE.
Results: All 6 pairwise analyses showed evidence of overlapping DNV signal to varying degrees, with shared risk genes identified using a cut of >80% on their respective posterior probabilities. From the 6 shared risk gene sets, 5 were taken forward for post-hoc systems biology analysis (20 SCZ-ASD genes, 41 SCZ-DD genes, 9 ASD-CHD genes, 153 ASD-DD genes, and 42 CHD-DD genes) due to only 2 shared risk genes being identified in the SCZ-CHD analysis. KEGG and GO gene set analysis revealed that the identified risk gene sets clustered in processes relating to synaptic organization and signaling, histone binding and modification, and learning and cognition. Risk gene sets from pairwise analyses including CHD additionally implicated gene sets relating to response to fibroblast growth factor and adherens junction assembly. Expression weighted cell type enrichment analysis using a reference set of mouse brain single cell expression showed the genes in the SCZ-ASD, SCZ-DD and ASD-DD risk gene sets had significantly elevated expression in pyramidal cells and interneurons, with the SCZ-DD risk gene set showing additional enrichment in vascular smooth muscle cells. Signals for the DD-CHD risk gene set were less clear, with some implication of pyramidal cells but also a trend towards involvement across more cell types in the brain. Enrichment in the ASD-CHD risk gene set did not reach significance, but had similar trends to the SCZ-ASD, SCZ-DD and ASD-DD risk gene sets.
Discussion: The integrative analytic approach increased the power to detect trait-associated risk genes, as well as shared risk genes in pair-wise analyses. Post-hoc systems biology analyses identified important CNS and epigenomic processes that may be implicated in the etiologies of ASD, CHD, SCZ and DD.

Background : Type 2 diabetes (T2D) is a prevalent metabolic disorder and multifactorial disease with several genetic factors associated. MicroRNAs (miRNAs), small noncoding RNA molecules approximately 21 nucleotides in length, have emerged as crucial regulators in numerous biological processes, including diabetes pathogenesis. Single nucleotide polymorphisms (SNPs) are potential contributors to miRNA dysregulation, as they can impair miRNA function and influence disease outcomes. Notably, miRNA 146a rs2910164 and miRNA 27a rs895819 have garnered interest due to their potential association with diabetes susceptibility. Objectives: The aim of the present study was to investigate the association of the single nucleotide polymorphisms *Mir146a* rs2910164, *Mir27a* rs895819 and their target genes respectively *TRAF6* rs540386, *PPARG* rs1801282 with Diabetes type2. Material and methods: *TRAF6* rs540386, *Mir146a* rs2910164, *Mir27a* rs895819 and *PPARG* rs1801282 genotyping were performed by mutagenically separated polymerase chain reaction (MS-PCR with newly designed primers) in 235 type2 diabetes patients and 225 age- and gender-matched controls. Results: The association analysis between these single nucleotide polymorphisms (SNPs) and type 2 diabetes in Tunisian Population revealed that *Mir146a* is not significantly associated with the disease (p=0.99, odds ratio [OR]=0.97 (0.53-1.7)), and similarly, *TRAF6* is also not significantly associated (p=0.72, OR=1.31 (0.56_3.1)). Also, there was no association between *Mir27a* rs895819 (*p*=0.33, OR=1.09 (0.55-2.16)) and *PPARG* rs1801282 (p= =0.27, OR=0.67 (0.11-4.05)) and type2 diabetes in our cohort. Conclusion: Our study revealed that *Mir146a*, *Mir27a*, *TRAF6* and *PPARG* polymorphisms are probably not susceptibility factors to type2 Diabetes in the Tunisian population. Further investigations are needed to elucidate the role of these gene polymorphisms.

PB1629 Lack of association between Native American genetic ancestry and the development of severe/critical COVID-19 in a Peruvian population sample.

Authors:

J. Mesia[1,2], S. Gonzales-Magallanes[1,3], E. Mamani-Pariona[1,4], R. Juscamaita[1,3], E. Tarazona-Santos[5], M. Santolalla-Robles[1]; [1]Univ. Peruana Cayetano Heredia, Lima, Peru, [2]Univ. Ricardo Palma, Lima, Peru, [3]Univ. Natl. Mayor de San Marcos, Lima, Peru, [4]Univ. Natl. Federico Villareal, Lima, Peru, [5]Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil

Background: The COVID-19 pandemic has highlighted the need of studying potential risk factors that may contribute to susceptibility to infectious diseases. Genetic ancestry can influence the development of several diseases, unfortunately, most of reports does not Latino populations. Native American genetic heritage represents about 80% of the Peruvian population. This research aimed to investigate the association between global genetic ancestry and the onset of severe/critical COVID-19 disease in a sample of a Peruvian population. **Methods:** A case-control study was conducted with 239 participants where 130 subjects were clinically diagnosed with severe/critical COVID-19 (cases) and 109 subjects with asymptomatic, mild or moderate disease (controls). The genotyping was performed using the Infinium Exome-24 chip and the ADMIXTURE algorithm was used to examine the markers and estimate genetic ancestry ratios. The statistical analysis was performed in R Studio v4.1.2. **Results:** Our results did not demonstrate a statistical association between genetic ancestry and COVID-19 severity, however, we were able to establish a correlation between Native American ancestry and the presence of metabolic comorbidities, which could indirectly contribute to the development of severe/critical COVID-19. It was observed that a higher Native American ancestry, higher odd of having a metabolic diseases (OR= 1.21-53.82). The confidence interval is very wide since the number of samples is limited. These findings imply that genetic ancestry may have an effect on COVID-19 outcome through its relationship to comorbidities, however is needed a deep analysis of other socio-economical factors.**Conclusions:** Our study did not find a direct correlation between Native American ancestry and COVID-19 severity in a Peruvian population. However, the observed relationship between Native American ancestry and metabolic comorbidities provides insight into the existence of potential pathways linking them to COVID-19 severity, so additional studies would be required to elucidate possible underlying mechanisms.

PB1630 Large-scale analysis of patient-derived induced neurons discover early developmental changes in schizophrenia.

Authors:

B. Rowan[1], C. Seah[1], X. Wang[1], M. Breen[1], J. Friedman[1], E. Drapeau[1], K. Brennand[2], L. Huckins[2], T. Rusielewicz[3], D. Paull[3], The NYSCF Global Stem Cell Array Team, J. Buxbaum[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Yale, New Haven, CT, [3]New York Stem Cell Fndn., New York, NY

Background: Schizophrenia is one of the most costly and debilitating psychiatric disorders with an incidence of 1% worldwide along with limited advances in therapeutic development in decades. Schizophrenia shows high heritability from both common and rare variants. These genetic variants and their mechanisms are poorly understood. Potential differences in ancestry have also not been explored, largely due to lack of collecting enough samples from non-European ancestral populations. Differences by sex also warrant further attention, since multiple studies point to differences in prevalence and potential treatments for schizophrenia by sex. We propose to address these issues by looking at gene expression in over 120 donors, some of admixed ancestry, with either idiopathic or 22q11-associated schizophrenia. We will look at differential expression and differential networks in cases and controls and stratify by ancestry and sex effects. **Methods**: Donor induced pluripotent stem cells (iPSCs) were induced into glutamatergic and GABAergic neurons, followed by RNAseq. In idiopathic cases, we performed differential gene expression (DEG) via limma voom, with a weighted least square linear regression model for GABAergic neurons and a linear mixed model was used for glutamatergic neurons due to cloning. We performed enrichment analysis, and then compared results to Common Mind results in bulk and single cell datasets. We performed weighted gene coexpression analysis (WGCNA) in cases and controls separately and then compared differential expression of modules detected in each one. We also performed WGCNA in a combined case-control dataset. **Results**: DEG analyses were negative for both derived cell types. However, we found statistically significant by multiple correction enrichment for similar genes differentially expressed in Common Mind bulk data and Molecular Signature Database (MSigDB) known schizophrenia risk genes. WGCNA detected some sets of genes more expressed in cases than controls and vice versa. In the combined case-control results, WGCNA detected 2 modules of statistically significant (> 0.05) without multiple testing corrections. One of these modules was also statistically significant for sex differences after multiple test corrections. **Discussion**: We found network module DEGs between cases and controls via WGCNA as well as enrichment for DEGs in Common Mind bulk tissue. We will repeat these analyses in stratified groups of sex, ancestry, and ancestry by sex. Then, we will perform eQTL, local ancestry eQTL, secondary RNA analyses, and compare 22q11 to idiopathic schizophrenia cell lines, resulting in potentially novel therapeutics.

Introduction: Metabolic syndrome (MetS) is a condition where an individual possesses a combination of multiple metabolic traits such as diabetes, dyslipidemia, hypertension, insulin resistance, and obesity. It is known to be associated with an increased risk of cardiovascular diseases. The genetic component of individual MetS risk factors was widely studied, but their unitary effect on MetS was less focused. We utilized a structural equation modeling (SEM)-based multivariate analysis (i.e., Genomic SEM) to elucidate the complex genetic architecture of MetS.
Methods: We collated publicly available large-scale genome-wide association studies conducted in European ancestry for seven MetS risk factors (i.e., body mass index, waist circumference, type 2 diabetes, hypertension, fasting glucose, triglycerides, and high-density lipoprotein) with sample sizes ranging from 151,188-1,253,277. By combining MetS risk factors through exploratory and confirmatory factor analysis, we constructed a hierarchical factor model that represents the genetic architecture of MetS. The association between single-nucleotide polymorphism (SNP) and MetS was computed by leveraging the genetic covariances between the MetS risk factors.
Results: We identified 1,650 lead SNPs that span across 939 genomic risk loci associated with MetS with an effective sample size of 1,384,348. The estimated SNP-based heritability was 11%. These genetic signals were significantly enriched in neurons and brain tissues. The genome-wide significant MetS SNPs were mapped to the genes through three gene mapping strategies available on FUMA (positional, eQTL, chromatin interaction), and combined with MAGMA gene-based analysis results, we pinpointed 886 genes relevant to MetS. To further prioritize the genes, we conducted Summary-based Mendelian Randomization in brain tissue using the BrainMeta database (n=2,865) and identified 43 significantly associated genes after Bonferroni's correction, where two genes, *FEZ2* and *STRA13*, were further replicated in GTEx (n=205).
Conclusion: Our findings provide new insights into the genetic architecture of MetS. We suggest two genes where their expression level is causally associated with MetS. These genes may contribute to multiple MetS risk factors and may serve as potential therapeutic targets.

PB1632 Leveraging >8 million patient records across University of California to understand common variable immunodeficiencies.

Authors:

R. Mester, A. Stephens, A. Chin, R. Johnson, S. Knyazev, B. Pasaniuc, M. Butte; Univ. of California, Los Angeles, Los Angeles, CA

Common variable immunodeficiency (CVID) is a rare primary immunodeficiency disorder characterized by defective antibody production and increased susceptibility to recurrent infections. It affects individuals of diverse genetic backgrounds and typically manifests during adolescence or early adulthood. Although the precise etiology remains elusive, recent studies have highlighted the involvement of multiple genes associated with immune system regulation and B-cell function. CVID is a heterogeneous disorder with various genetic and environmental factors contributing to its development. Diagnosing CVID proves to be a formidable task due to its complex nature and heterogeneous presentation. In 2022, Johnson et al introduced PheNet, an algorithm that utilizes a curated list of 197 confirmed CVID cases at UCLA to identify additional patients with CVID from electronic health record (EHR) data. In this work, we introduce a cohort of 323 clinician-identified CVID patients from 5 health systems across the University of California. This case cohort is 68% female and made up of patients with an average age of 56. Of these patients, 73% self-identified as European, 8% identified as Hispanic or Latino, 3% identify as Asian, and 0.6% identify as Black or African American. We use this large, gold-standard case cohort, to demonstrate the heterogeneity of CVID presentation both between and across health systems. We find that across the health systems, these CVID patients have an average of 2.6 immune-related, 4.5 infection-related, and 0.8 other PheCodes that PheNet demonstrated are useful in identifying CVID. Additionally, we assess the generalizability of PheNet to identify potential new CVID cases across the 8.6 million patients in the University of California health system. This population is 54% female with an average age of 46. In this population, 3.6 million patients self-identify as European, 1.4 million patients identify as Hispanic or Latino, 400,000 patients identify as Black or African American, and over 700,000 patients identify as Asian. Finally, we introduce extensions to the PheNet algorithm with the goal of increasing its sensitivity for identifying CVID patients across health systems.

Cancer Inst., Bethesda, MD, [10]Dept. of Population Hlth.Sci., Geisinger Hlth.System, Danville, PA, [11]Dept. of Genetic Epidemiology, Univ. of Regensburg, Regensburg, Germany, [12]Wellcome Trust Ctr. for Human Genetics, Univ. of Oxford, Oxford, United Kingdom, [13]Oxford Big Data Inst., Li Ka Shing Ctr. for Hlth.Information and Discovery, Univ. of Oxford, Oxford, United Kingdom

GWAS for central obesity have identified many risk loci, but the underlying mechanisms largely remain to be determined. The GIANT Consortium performed GWAS meta-analyses for waist-to-hip ratio adjusted for body mass index (WHR) in 1.18 million individuals. We identified conditionally distinct signals (p<5e-9) in 18 meta-analyses performed separately and together by sex and population group; we then combined signals across analyses based on linkage disequilibrium. We identified 1,009 signals, 49% of which showed significant sex effect heterogeneity (FDR 5%) and 63% of which have been previously reported in GWAS for a non-anthropometric trait. We replicated an enrichment for signals near genes highly expressed in adipose and adipocytes, and also identified 30 additional enriched tissues (e.g. heart, skeletal, endocrine, and digestive systems). We used three approaches to link the signals to target genes: Polygenic Priority Score (PoPS), Data-driven Expression Prioritized Integration for Complex Traits (DEPICT), and colocalization with blood and adipose eQTL. The colocalization analyses included a subset of 659 WHR signals and were performed using two approaches: first, using only raw WHR summary statistics (marginal data), and second, after isolating conditionally distinct WHR signals. Analysis with PoPS identified 353 genes and with DEPICT identified 501 genes. Colocalization (coloc PPH4 >= 0.8) with GTEx subcutaneous adipose eQTL (n=491 samples) identified 79 and 121 genes that colocalized with marginal and distinct WHR signals, respectively, and with eQTLGen blood eQTL (n=31,684) identified 80 and 105 genes with marginal and distinct WHR signals, respectively. Colocalization with distinct GWAS signals identified up to 50% more genes than with marginal data, highlighting the value of analyzing signals separately. The larger number of genes identified using eQTL from adipose vs. blood despite a 64-fold smaller sample size may reflect the relevance of adipose to WHR. Together, these methods identified 901 unique genes. Fewer than 2% were prioritized by all three methods; while some of these 13 genes are known to impact central obesity (e.g. *TBX15* and *RSPO3*), others are at newly identified WHR loci but are associated with related traits. For example, *IGF2* is a well-known type 2 diabetes (T2D) locus that also plays a role in metabolic regulation and obesity, while *TMEM132C* may play a role in insulin secretion and T2D. In conclusion, the 1,009 WHR signals identified by our ongoing GWAS are enriched in a wide range of tissues, and the use of three gene prioritization methods identified 901 candidate genes that may influence the development of central obesity.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1634 Leveraging machine learning derived liver fat predictions from multiple data modalities in the UK Biobank for genetic discovery in NAFLD

Authors:

H. Somineni, S. Mukherjee, J. Pei, K. Guo, D. Light, S. Satapati, D. Lloyd, P. Philip, D. Koller, C. O'Dushlaine, T. Soare; Insitro, South San Francisco, CA

Proxy phenotypes, phenotypes that are associated with a disease of interest, where the association is suspected to be due to shared biology, allow for the utilization of genetic data from large population cohorts to gain a better understanding of the genetic architecture of complex diseases. Nonalcoholic fatty liver disease (NAFLD), liver with more than 5.5% fat content, is a leading risk factor for end-stage liver disease and is associated with a range of cardio-metabolic conditions. To better understand the genetic architecture of NAFLD, we used machine learning (ML) to predict liver fat content using three different data modalities measured in the UK Biobank: magnetic resonance imaging (MRI; n=25,474 participants), blood-based clinical and anthropometric markers (biomarkers; n=262,927), and plasma metabolites (n=82,138). Genome-wide association analyses identified over 800 independent signals, significantly expanding the catalog of likely genetic contributions to liver fat accumulation. Among these signals were well-known associations, including PNPLA3, TM6SF2 and GCKR, with consistent effect estimates confirming established biology. By comparing our results to publicly available summary statistics from clinically-defined NAFLD case-control status (clinical NAFLD, 49 signals) or MRI-derived proton density fat fraction (PDFF; 92 signals), we observed that the MRI modality was most informative (57% precision and 41% recall when compared to clinical NAFLD; 93% precision and 28% recall with PDFF). Plasma metabolites were least informative (8% precision and 20% recall with clinical NAFLD; 8% precision and 14% recall with PDFF). Lastly, liver fat content from biomarkers yielded a 76% recall value, but only had a 5% precision when compared to clinical NAFLD, and 58% recall and 7% precision when compared to PDFF. Genetic correlation analysis indicated a strong correlation between liver fat content from across modalities (ranging from 0.79 to 0.97) and with clinical NAFLD (ranging from 0.73 for metabolite-derived liver fat to 0.87 for MRI-derived liver fat). Overall, these findings demonstrate the value of leveraging ML-based trait predictions across orthogonal data sources to identify potentially novel genetic associations.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1635 Lipidomics profiling and plasma triglyceride concentration in African populations.

Authors:

A. Bentley, A. Doumatey, J. Zhou, K. Meeks, E. Heuston, C. Rotimi, A. Adeyemo; NIH, Bethesda, MD

Studies using metabolomic approaches may help elucidate the biochemical mechanisms underlying associations between serum triglyceride concentration (TG) and cardiometabolic traits (CMT), but such studies in diverse populations are lacking. To characterize the lipidomics profile associated with TG concentration, we conducted an untargeted metabolomics study of 308 Nigerian adults. Samples were assayed on the Metabolon© platform and the 480 metabolites of the Lipids Super Pathway were analyzed. Regression models were used to assess the association of metabolites with TG and high TG (TG>150 mg/dl [highTG]). Models were adjusted for age, sex, and type 2 diabetes status (T2D) and with and without adjustment for BMI or waist circumference. Statistical significance was set at FDR q<0.01. There were 99 metabolites associated with TG, with the strongest associations for diacylglycerols, such as palmitoyl-oleoyl-glycerol (β 0.67, q=5.4E-40). There were 56 significant associations with highTG, also led by diacylglycerols, including oleoyl-oleoyl-glycerol (β 0.66, q=1.4E-38). Overrepresentation analysis identified significant enrichment of diacylglycerols, monoacylglycerols, glycerophospholipids, and sphingophospholipids among the TG-associated metabolites. Most of the significant associations (91%) replicated in a cohort of 199 Kenyan adults. Next, we conducted analyses stratified by T2D, given known perturbations in TG with T2D. While most associations were similar across strata, there were 4 significant associations for fatty acyl carnitines among those without T2D that were not observed among those with T2D or in unstratified analyses. We subsequently assessed the association of lead TG metabolites with CMT with which TG is known to be associated. These metabolites were most strongly associated with LDL, total cholesterol, and measures of adiposity, but patterns of association differed across the metabolites, suggesting the TG-related pathways underlying these traits differ. We conducted mediation analyses for metabolites that were associated with CMT and found that 81% of the TG-CMT associations were partially or completely mediated by these metabolites. For example, after controlling for the mediating effect of N-stearoyl-sphinganine (a dihydroceramide), TG was no longer significantly associated with BMI or waist circumference. In summary, in this lipidomics profile study, variation in TG concentration is associated with both TG and non-TG lipids classes. Differing patterns of association between lead TG metabolites and CMT suggest different TG-related pathways may underlie known relationships between TG and CMT.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1636 Localization of polygenic signal in Alzheimer's disease through the integration of cell-type functional annotations and deep learning models.

Authors:

C. Lakhani[1], J-S. Lin[1], A. Das[2,1], T. Raj[3], D. Knowles[1,2]; [1]New York Genome Ctr., New York, NY, [2]Columbia Univ., New York, NY, [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

The advent of increasingly well-powered Alzheimer's disease (AD) GWAS has made it clear that AD is a polygenic disease. Tools such as stratified LD score regression (*Finucane et al. 2015*) have enabled researchers to study the polygenic signal of disease by quantifying the contribution of functional annotations such as cell-type specific enhancers and promoter annotations to the heritability of AD. In another direction, deep learning methods have been increasingly used in genomics to train models which can predict functional genomics profiles as a function of genomic DNA sequence. We utilized a recent deep learning model, Enformer (*Avsec et al. 2021*), to predict variant transcription factor binding disruption (TF-VEP) scores for hundreds of TFs. However, a key challenge in AD genetics is that most models do not have TF-VEP scores for AD-relevant cell types (e.g. myeloid cells such as microglia and peripheral monocytes). In our study, we constructed functional annotations intersecting TF-VEP scores from ENCODE cell lines with active enhancer and promoter regions (*van de Geijn et al. 2020*) for 4 putatively relevant AD cell types (astrocytes, oligodendrocytes, microglia, and neurons) (*Nott et al. 2019*) and then quantified the extent to which these annotations contributed to AD polygenicity for four recent AD GWAS (*Kunkle (2019)*, *Jansen (2019)*, *Wightman (2021)*, and *Bellenguez (2022)*). Among these 4 cell types, we found microglia enhancers and promoters in open chromatin regions consistently captured the largest proportion of heritability (p_h^2) ($p\_h^2_{Kun}$ = 0.44, $p\_h^2_{Jan}$ = 0.77, $p\_h^2_{Wigh}$ = 0.18, $p\_h^2_{Bell}$ = 0.40). We also found further localizing these regions by integrating TF-VEP scores reduced the proportion of heritability only slightly but did significantly increase the percentage change in the enrichment of heritability (e_h^2) ($p\_h^2_{Kun}$ = 0.30, $e\_h^2_{Kun}$ = 39%, $p\_h^2_{Jan}$ = 0.67, $e\_h^2_{Jan}$ = 73%, $p\_h^2_{Wigh}$ = 0.15, $enrich\_h^2_{Wigh}$ = 64%, $prop\_h^2_{Bell}$ = 0.29, $enrich\_h^2_{Bell}$ = 94%). We also trained a novel transformer-based deep learning model on microglia chromatin accessibility data in order to capture variants with the potential to create new regulatory regions outside of those currently measured. We found the model had good performance on held-out validation data (Pearson correlation 0.45). Our analysis demonstrated how predictions from deep learning models not trained on AD-relevant cell types can be combined with relevant AD data to better localize the polygenic signal in AD GWAS. Such annotations can also be used as strong biological priors to better guide functionally-informed fine-mapping and rare variant analysis.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1637 Loci for Urinary Microbiota Abundance in a Multi-Ethnic Cohort of Children with Urinary Tract Infections and Vesicoureteral Reflux.

Authors:

M. Verbitsky, D. L. Bivona, P. Khosla, Y. Gupta, A. Khan, H. Park, K. Kiryluk, S. Sanna-Cherchi, J. Barasch, C. L. Mendelsohn, A-C. Uhlemann, A. G. Gharavi; Columbia Univ., New York, NY

Background: Gut microbiota and microbiome GWAS have been previously reported. However, host genetic factors associated with the human urinary microbiome composition, of special interest in recurrent urinary tract infections (UTIs) and genitourinary malformations, remain unknown.
Methods: We performed a microbiota GWAS (mGWAS) in a cohort of 278 children with urinary tract infections with or without vesicoureteral reflux (VUR), from the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) and Careful Urinary Tract Infection Evaluation (CUTIE) studies, based on 16S rRNA gene sequencing from urine samples and whole-genome blood DNA genotyping. Given the limitation of our cohort sample size (N = 278), performing global ancestry-specific analyses is not feasible for the less represented and admixed groups and can eliminate the power to detect associations in the largest group (European ancestry, EUR), while analyzing the whole cohort can lead to spurious results, even when correcting for global ancestry. We, therefore, used a local ancestry-aware regression model implemented with Rfmix and Tractor software.
Results: Our initial mGWAS had identified a genome-wide significant association with the zero-truncated relative abundances of Pseudomonas on chr10 ($P = 2x10^{-9}$) and a suggestive association with Clostridia on Chr3 ($P = 5x10^{-8}$), in the whole cohort, correcting for global ancestry with 10 principal components, among other covariates. The top SNPs in these loci were on or near genes associated with immune surveillance, inflammation, and genitourinary tract development and disease (*CXCL12* and *ROBO1*). We further confirmed both these signals with local ancestry-aware mGWAS on the EUR background haplotype tracts extracted from the whole cohort ($P = 2.76x10^{-8}$ and $P = 2.06x10^{-7}$, respectively). In addition, phenome-wide association studies on the UK Biobank and eMERGE cohorts of the top SNPs showed suggestive associations with functional disorders of the bladder ($P = 4x10^{-3}$), urinary obstruction ($P = 2x10^{-3}$), and UTI ($P = 8x10^{-3}$).
Conclusion: We report the first combined urine microbiota analysis and mGWAS in children with UTI and VUR. We used a local ancestry-aware regression model to augment power and identified associations of bacterial taxa's relative abundances with human host genetic factors on the European ancestral background.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1638 Long-chain polyunsaturated fatty acids aberrations in bipolar disorder: Whole genome sequencing analysis

Authors:

E. Czeisler, S. P. Smieszek, R. Torres, P. Sweeney, C. Xiao, C. M. Polymeropoulos, G. Birznieks, M. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC

Long-chain polyunsaturated fatty acids (PUFAs) affect immune responses and inflammation and can be converted to potent inflammatory mediators. The omega (n)-3 and omega (n)-6 PUFA metabolic pathways participate in inflammatory processes and are linked to bipolar disorder (BD) pathophysiology. The omega (n)-3 PUFA helps treat inflammatory conditions, while arachidonic acid, an omega (n)-6 PUFA, causes inflammation. Prior GWAS analyses identified fatty acid desaturase polymorphisms conferring susceptibility to BD across several studied cohorts. In this study, we examined PUFA levels in BD patients in relation to whole genome sequencing (WGS) data. **S**equencing samples were obtained from a multicenter, randomized, double-blind, placebo-controlled, parallel-group study of iloperidone in patients with acute manic or mixed episodes associated with bipolar I disorder. WGS analysis consisted of 456 samples. Linear models on PUFA levels were adjusted for principal components (PCs), sex and age. PUFA panel was analyzed on a subset of 313 samples. We report mean elevated levels of (n)-6 PUFAs, arachidonic acid (mean value = 1487 nmol/mL) and linoleic acid (mean value = 925 nmol/mL). The total polyunsaturated and w6 were higher than the normal range. Vaccenic acid (mean value = 236 nmol/mL) and arachidic acid (mean value = 37 nmol/mL) were lower than the normal range. (n)-6 and (n)-3 PUFAs had a low correlation with BMI. The baseline PUFA levels led to further genetic analysis. We tested the association between variants in FADS genes and levels of (n)-6 PUFAs. We report rs174576 (intron variant; effect allele A, MAF 0.34) located on *FADS2*, which was also a previously reported top hit in the meta-analysis of the GWAS ($P = 1.34 \times 10^{-10}$, OR = 1.13), and rs174548. These variants were statistically and significantly associated with reduced D5D in a linear manner. A whole genome association analysis (linear model) was conducted on (n)-6 PUFAs correcting for age, sex, and PCs. Variants within CABLES2, rs11698818, MAF 0.09, ($P = 1.13 \times 10^{-8}$), exonic variant CABLES2: NM_031215: exon9: c.C1227G:p.G409G ($P = 1.13 \times 10^{-8}$), and variants within *KCNMA1* gene, which encode α-subunit of the large conductance calcium-sensitive potassium channel amongst multiple other loci, were reported. *FADS1/2* genes are expressed in the liver and catalyze the desaturation steps in synthesis of n-3 and n-6 PUFAs. Variants within are associated strongly with variation in blood PUFA levels, likely affecting the expression activities. We confirmed several existing loci and delineated potentially novel associations modifying the blood PUFA levels. These may inform of aberrant pathways driving the BD phenotype.

PB1639 Longitudinal analysis of 4,187 participants in the Atherosclerosis Risk in Communities Study reveals new insights into the determinants of incident clonal hematopoiesis

Authors:

M. Uddin[1], S. Saadatagah[2], A. Niroula[1], B. Yu[3], W. Hornsby[1], S. Ganesh[1], K. Lannery[1], A. Shuermans[1], M. Honigberg[4], A. Bick[5], B. L. Ebert[6], C. M. Ballantyne[2], P. Natarajan[4]; [1]Broad Inst., Cambridge, MA, [2]Baylor Coll. of Med., Houston, TX, [3]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [4]Massachusetts Gen. Hosp., Boston, MA, [5]Vanderbilt, Nashville, TN, [6]Dana-Farber Cancer Inst., Boston, MA

Clonal hematopoiesis (CH), a phenomenon in which blood cells are predominantly derived from a single mutated hematopoietic stem cell, is associated with diverse aging-related diseases, including hematologic malignancy and atherosclerotic cardiovascular disease (ASCVD). Clonal hematopoiesis is common with advancing age, but the factors contributing to the development of CH among older adults are largely unknown. To identify environmental and genetic determinants of incident CH, we analyzed 8,374 whole-exome sequences from 4,187 participants without hematologic malignancy from the Atherosclerosis Risk in Communities Study with a median (range) follow-up of 21 (5-27) years between two sequencing time points. Around 59% of participants were female, 23% were African American, and the mean (range) age was 55.5 (45-83) years at baseline and 75.8 (67-90) years at follow-up visits. We identified 576 and 1,302 clones at variant allele fraction ≥2% in 457 and 1,047 participants at baseline and follow-up visits, respectively. During the follow-up, 735 (~20%) out of 3,730 participants without prevalent CH developed incident CH. Clonal diversity reduced with advancing age, with increased incident CH in *TET2*, *ASXL1*, *TP53*, and splicing factor genes (*SF3B1*, *U2AF1*, *SRSF2*, *ZRSR2*). Age at baseline was associated with a higher incidence of CH. However, ASCVD and other traditional risk factors for ASCVD, including smoking, body mass index, hypertension, type 2 diabetes, high-density lipoprotein cholesterol (HDL-C), and non-HDL-C, were not significantly associated with the incidence of CH. We showed that germline variants associated with prevalent CH, such as *SMC4*, *TERT*, *TCL1A*, and *SETBP1*, are also associated with the incidence of CH. Our comprehensive longitudinal assessment yields new insights into the factors promoting incident CH among older adults.

PB1640 Longitudinal gene expression changes associated with liver measures in Hispanic/Latino population at risk for metabolic-associated fatty liver disease

Authors:

R. Roshani[1], H-H. Chen[1], E. Frankel[1], H. Highland[2], E. Gamazon[3], W. Zhu[1], L. Petty[1], J. Below[4], K. North[2], J. McCormick[5], S. Fisher-Hoch[6], M. Graff[7]; [1]Vanderbilt Univ., Nashville, TN, [2]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [3]VUMC Clare Hall, Univ. of Cambridge, Nashville, TN, [4]Vanderbilt Univ Med Ctr., Nashville, TN, [5]UTH SPH Brownsville, Brownsville, TX, [6]Univ. of Texas Sch. of Publ. Hlth., Brownsville, TX, [7]Univ North Carolina, Chapel Hill, NC

Metabolic-associated fatty liver disease (MAFLD) is a heterogeneous condition with variable severity and progression. Globally, MAFLD affects approximately 25% of adults, with the highest prevalence in Hispanic/Latino populations. Poorly controlled cardiometabolic risk factors (CMRF), genetic factors, lifestyle, and social determinants of health can influence MAFLD progression. However, longitudinal omics studies of MAFLD to understand mechanisms are limited. To interpret genome-wide association studies (GWAS) signals and identify biomarkers, it is crucial to investigate transcriptomics associated with liver disease progression, particularly in populations disproportionately affected by liver disease and underrepresented in biomedical research. This project aims to examine longitudinal gene expression changes related to liver measures in the Cameron County Hispanic Cohort (CCHC), an extensively phenotyped, randomly recruited cohort of Mexican Americans residing at the US-Mexico border with high rates of MAFLD. This study focused on a group of 927 CCHC participants with longitudinal transient elastography phenotyping (FibroScan) to measure liver stiffness, and controlled attenuation parameter (CAP) to measure hepatic fat. Clinical chemistries were used to derive biomarkers: fibrosis-4 index (FIB-4), aspartate aminotransferase/platelet index (APRI). We employed linear mixed-effect regression models to estimate the effects of liver measures on gene expression using up to 1294 measures, adjusting for covariates such as age, sex, and 10 Probabilistic Estimation of Expression Residuals (PEER) factors. We used a false discovery rate corrected p-value (FDR) to account for multiple testing. We identified 800 differentially expressed genes, including several genes within loci that have previously been implicated in GWAS of MAFLD and related traits. These genes include *DDX60L* ($FDR_{FIB\text{-}4}$ = 0.038), which has been implicated for alanine aminotransferase levels, *PARVB* ($FDR_{FIB\text{-}4}$ = 0.043), which has been implicated for measures of hepatic fat, alanine aminotransferase, and both adult and pediatric MAFLD, and *NDRG2* ($FDR_{FIB\text{-}4}$ = 0.028), which has been implicated for pediatric nonalcoholic steatohepatitis. Our results provide evidence of the functional effect driving those GWAS signals, including mapping the effector gene. We also performed sensitivity analyses stratified by the number of visits, to distinguish expression effects driven by cross-sectional and longitudinal effects, while controlling for BMI allowed identification of liver-associated expression effects independent of obesity measures.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1641 Long-read RNA-sequencing identifies novel protein coding transcripts of genes with implications for inherited and complex cardiac disease

Authors:

R. Dore[1], S. Garcia-Ruiz[1], E. Gustavsson[1,2], M. Ryten[1,2]; [1]Dept. of Genetics and Genomic Med. Res. & Teaching, UCL GOS Inst. of Child Hlth., London, United Kingdom, [2]NIHR Great Ormond Street Hosp. BioMed. Res. Ctr., Univ. Coll. London, London, United Kingdom

There has been considerable progress in the identification of genes causing inherited cardiac diseases, yet many individuals remain undiagnosed. In part, this could be explained by incomplete annotation of genes causally linked to these disorders leading to inaccurate variant interpretation. To test this hypothesis, we analysed long-read RNA-sequencing data originating from 16 individuals and nine cardiac regions (ENCODE4). We focused on 105 genes implicated in monogenic disease, as defined by Genomics England PanelApp. Among these genes, 67 met our inclusion criteria, requiring a minimum expression level of RPM≥20 in at least 80% of samples. Subsequent filtering for transcripts mapping to these 67 genes (≥ 2 full-length reads per sample) identified 245 unique transcripts of which 140 (57.1%) were putatively novel (Ensembl v105). Of these, 12 transcripts from six genes were predicted to be protein coding (*BAG3* = 1, *CASQ2* = 1, *DES* = 7, *MYH7* = 1, *TNNC1* = 1 and *SLC40A1 = 1*). These were generated through novel combinations of known splice junctions (n = 3), and through novel splice sites (n = 9). Notably, the novel *CASQ2* transcripts contain a novel coding exon detected in human mass spectrometry data from cardiac tissue. A common variant previously associated with left ventricular strain, left ventricular thickness and atrial fibrillation falls within this novel exon. Upon re-interpretation, this variant is now predicted to cause an amino acid substitution and an increased inclusion of this exon. Expression of the novel exon was also enriched in atrial fibrillation samples. Colocalisation analysis between *CASQ2* expression and atrial fibrillation implicated a lead intronic variant with the closest coding region being the novel exon. In fact, *CASQ2* is already a candidate target for arrhythmia treatments. Additionally, a novel exon in *DES*, also detected in human mass spectrometry data, was demonstrative of an Alu-exonisation event. Whilst this resulted in the loss of a key binding domain, the novel exon was found to be depleted in dilated cardiomyopathy samples. Despite the small sample set, this project demonstrates, through the examples of *CASQ2* and *DES*, that long-read transcriptomics improves the interpretation of pathogenic variants and provides key insights into complex human disease.

PB1642 Long-read sequencing show Japanese myotonic dystrophy type 2 patients carry a haplotype different from the European founder haplotype

Authors:

T. Matsuura[1], K. Tachikawa[2], T. Kimura[3], R. Kitao[4], S. Ura[5], Y. Sanpei[6], H. Funasaka[6], Y. Yamano[2], Y. Kochi[7], L. Ranum[8], K. Ohno[9], S. Mitsuhashi[2]; [1]Jichi Med. Univ., Shimotsuke, Japan, [2]St. Marianna Univ. Sch. of Med., Kawasaki, Japan, [3]Asahikawa Med. Ctr., Natl. Hosp. Organization, Asahikawa, Japan, [4]Natl. Hakone Hosp., Natl. Hosp. Organization, Odawara, Japan, [5]Japanese Red Cross Asahikawa Hosp., Asahikawa, Japan, [6]Akita Univ. Graduate Sch. of Med., Akita, Japan, [7]Med. Res. Inst., Tokyo Med. and Dental Univ., Tokyo, Japan, [8]Univ Florida, Gainesville, FL, [9]Nagoya Univ Grad Sch Med, Nagoya, Japan

Objective: Myotonic dystrophy type 2 (DM2) is a subtype of myotonic dystrophy caused by the expansion of a tetranucleotide CCTG repeat in intron 1 of the cellular nucleic acid-binding protein (*CNBP*) gene1. The aim of this study is to characterize the origin and features of expanded repeats in Japanese DM2 patients. **Methods:** Over the last 15 years, we have identified 7 DM2 patients from 5 unrelated families in Japan. We used Nanopore long-read sequencing (LRS) to investigate the following measures: (1) Repeat length of the expanded repeat, (2) sequence of the repeat tract, (3) adjacent DNA modifications, and (4) the phase of SNPs flanking the repeat. **Results:** LRS revealed that Japanese DM2 patients share a common haplotype, which differs from European DM2 patients. Simultaneous detection of the *CNBP* repeat region revealed that each read has different number of repeats, suggesting somatic mosaicism of the expanded repeat allele. The sequence within the repeat showed interruptions of the CAGA repeat, as recently reported in European DM2 patients. We also detected the CpG methylation in the native DNA molecules, which were not substantially altered in normal and expanded alleles, as previously reported. **Conclusions:** Japanese DM2 patients have a unique founder haplotype. Regardless of origin, the similar clinical features found in DM2 patients from Japan and other parts of the world are likely attributed to the pathogenic effects of the repeat expansion. The study demonstrates the usefulness of LRS for analyzing expanded repeats in a single sequencing experiment.

PB1643 Long-term cardiovascular risk according to genetic risk for hypertensive disease during pregnancy, lifestyle, and metabolic health

Authors:

S-H. JUNG[1], H. Kim[2], J-S. Yun[3], M. Shivakumar[1], Y. Jung[4], S. Kim[5], C-W. Park[2], J. Park[2], J. Jun[2], D. Kim[1,6], S. Lee[2,7]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of, [3]St. Vincent's Hosp., Coll. of Med., The Catholic Univ. of Korea, Seoul, Korea, Republic of, [4]Guro Hosp., Coll. of Med., Korea Univ., Seoul, Korea, Republic of, [5]Univ. of Ulsan Coll. of Med., Asan Med. Ctr., Seoul, Korea, Republic of, [6]Inst. for BioMed. Informatics, Univ. of Pennsylvania, Philadelphia, Philadelphia, PA, [7]Innovative Med. Technology Res. Inst., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Recent studies have reported that genetic risk for hypertensive disorder during pregnancy (HDP) is associated with atherosclerotic cardiovascular disease (ASCVD) later in life. However, the impact of lifestyle and metabolic syndrome on the risk of ASCVD on genetic risk for HDP has not been evaluated despite these factors being modifiable risk factors. The aim of this study was to assess the long-term association between HDP, genetic risk, metabolic syndrome (MetS), lifestyle, and ASCVD. A total of 164,406 women of European descent from the UK Biobank were included. The genetic risk for HDP was determined using a genome-wide polygenic risk score (PRS) derived from a large-scale genome-wide association study (FinnGen Biobank; 13,071 HDP cases and 177,808 controls) using PRS-CS. The study population was divided into two generic risk groups according to PRS (Low risk, <20th percentile; High risk, >80th percentile). The incident ASCVD risk was evaluated according to genetic risk, lifestyle, and MetS. Lifestyle was categorized according to the presence of four modifiable lifestyle components (Favorable, ≥3 factors; Intermediate, two factors; Unfavorable, ≤1 factor) and MetS was categorized into two groups according to the number of metabolic components (Ideal [0-3 components] and poor [>=4 components]). Among the study subjects, 2,423 (1.5%) had a history of HDP, and 8,936 (5.4%) was diagnosed with incident ASCVD during follow-up. Individuals at high genetic risk for HDP had a 25.0% higher risk of ASCVD than those with low genetic risk (HR 1.250; 95% CI, 1.161-1.345; $P=2.89\times10^{-9}$). In both groups with low and high genetic risks for HDP, the risk of ASCVD was reduced by up to 48.2% (HR 0.518; 95% CI, 0.694-0.387; $P=1.07\times10^{-5}$) through ideal MetS and favorable lifestyle. Although a higher the genetic risk for HDP increases the overall risk of ASCVD, maintaining healthy lifestyles and MetS can reduce ASCVD risks regardless of genetic risk.

PB1644 † Looking Back on GWAS Using Hybrid Artificial Intelligence

Authors:

S. D. Crosby, C. E. Storer, R. A. Barve, R. Head; McDonnell Genome Inst., Washington Univ., St. Louis, MO

Multifactorial disorders (e.g. T2 diabetes, cardiovascular disease, etc) also known as complex traits or polygenic disorders, arise from a combination of genetic and environmental factors. A genome wide association study (GWAS) is employed to compare the genomes of individuals with a disorder to those without, to identify genetic variants that are more prevalent in affected individuals. These variants may be located in genes, or as is more often the case, in non-coding regions of the genome. GWAS have been limited not only by design and population size but also by analytical methods. Statistical cut-offs incompletely address the problems of false positives and negatives. Here we present a meta-analysis of 47 **autism** *GWASs (1321 gene associations) using* **CompBio***, a platform we created to facilitate parallel multi-omic analysis. CompBio is novel hybrid AI platform, which combines natural language processing, conditional probability analysis, and machine learning CompBio employs the entirety of PubMed abstracts and millions of full-text papers to create "knowledge maps" out of ALL unique terms found in the biomedical corpus. CompBio simultaneously evaluates all variant-associated genes in a given* input *list. This "holistic" analysis, as opposed to independent observations, allows CompBio to identify both signal and noise components of the input list with great accuracy. The* output *consists of closely related clusters of genes and concepts; these clusters are called* **Themes***. Themes transcend traditional pathways in that they represent not only molecular pathways, but also physiologic processes, cell types, diseases, etc. based on concept relationships. In the present example, we employed the NHGRI-EBI Catalog of Human Genome-wide Association Studies (https://www.ebi.ac.uk/gwas/) to identify "mapped genes" which either include or are nearby variants associated with autism. Of the 1165 mapped genes, 479 clustered within CompBio Knowledge Maps. 44% of the 50 most significant Themes identified were related to neurodevelopment, neurophysiology, or neuropathology. We were reassured to see CompBio validated, in that most previously identified physiologic processes appeared in our results. Interestingly, we also observed the emergence of novel themes in the output, suggesting undetected facets which may be related to better-understood aspects of this disease.*

PB1645 Loss-of CFHR5 conveys protection from Age-related macular degeneration

Authors:

M. Reeve[1,2], S. Loomis[3], Y. Okunuki[3], J. Yang[3], C. Palmer[3], A. Khalifa[3], D. Ben-Isvy[1,2,4,5], J. Fu[1], C. Liao[1], X. Zhao[4], F. Finngen[2], M. Talkowski[4,1], J. Makela[6], M. Kurki[7,2], Z. Zheng[7], K. Connor[3], M. Daly[4,1,2], H. Runz[8]; [1]Broad Inst., Cambridge, MA, [2]Finnish Inst. of Molecular Med., Helsinki, Finland, [3]Biogen, Cambridge, MA, [4]Massachusetts Gen. Hosp., Boston, MA, [5]Harvard Med. Sch., Boston, MA, [6]Finnish Biobank Cooperative (FinBB), Turku, Finland, [7]Broad Inst. of MIT and Harvard, Boston, MA, [8]Biogen Inc., Cambridge, MA

Introduction: Age-related macular degeneration (AMD) is the leading cause of blindness in the elderly. Efficient treatments exist for wet AMD, but therapeutic options for the more common dry form remain limited. Genetic variants in the complement factor H (CFH) locus explain ~25% of dry and wet AMD risk, which has led to clinical trials testing whether increasing CFH might be therapeutic. In a recent meta-analysis of FinnGen and UKBiobank we identified a FIN-enriched frameshift variant within CFHR5 (1:196994128:C:CAA, rs565457964, CFHR5fs) associated with protection from AMD in a presumably CFH-independent manner. Here, we further explored the potential of CFHR5 as a drug target for AMD.
Methods: We performed detailed fine-mapping of the CFH/CFHR5 region and initiated a sample recall study from FinnGen on 200 dry AMD cases and 200 controls, enriched for carriers of CFHR5fs. Serum levels of CFH, CFHR1-5 and ~7000 other proteins were measured using the Somascan assay.
Results: Fine-mapping of the CFH/CFHR5 locus in FinnGen R10 identified two significant AMD associations that were conditionally independent from the two established CFH signals. Both associations could be traced to low-frequency variants that lead to a protein-coding change in CFHR5 and were associated with protection from AMD. Common structural variant maps were explored to test the impact of these variants on disease and proteomic signatures. Carriers of the previously described CFHR5fs had reduced levels of CFHR5 with each additional protective allele ($p<3x10-54$) consistent with complete loss-of-function in CFHR5fs homozygotes. CFHR5fs carriers also showed lower levels of CFHR2 ($p=7.0x10-33$) and CFHR4 (6.5x10-11), but not CFH, CFHR1 or CFHR3 ($p>0.05$).
Discussion: Through fine-mapping and functional analysis we identify two independent protective coding variants that reveal previously unknown complexities at the CFH/CFHR5 locus and establish reduction of CFHR5 as a promising therapeutic strategy for AMD. **Note:** M. P. Reeve and S. Loomis are shared first authors and M. Daly and H. Runz jointly supervising last authors.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1646 Low carnitine palmitoyltransferase 1 activity is associated with narcolepsy type 1 and other hypersomnia

Authors:

T. Miyagawa[1,2], Y. Shigematsu[3], M. Shimada[1,4,2], Y. Honda[1], K. Tokunaga[4,2], M. Honda[1,5]; [1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan, [2]The Univ. of Tokyo, Tokyo, Japan, [3]Univ. of Fukui, Fukui, Japan, [4]Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, [5]Japan Somnology Ctr. and Seiwa Hosp., Tokyo, Japan

Narcolepsy type 1 (NT1), a rare hypersomnia of central origin characterized by excessive daytime sleepiness and cataplexy, is associated with metabolic abnormalities, but their etiology remains largely unknown. Palmitoyltransferase 1B (*CPT1B*) gene and abnormally low serum acylcarnitine levels have been linked to NT1. We measured levels of individual acylcarnitines and evaluated CPT1 activity in patients with NT1 and other hypersomnia to clarify the details of altered fatty acid metabolism. Blood samples from 57 NT1 patients, 51 other hypersomnia patients, and 61 healthy controls were analyzed. The levels of 25 major individual acylcarnitines were determined and the C0/(t[C16] + t[C18]) ratio was used as a CPT1 activity marker. We further performed a transcriptome analysis (RNA sequencing (RNA-seq) using independent blood samples from 73 NT1 patients and 63 healthy controls to examine the relevance of fatty acid metabolism. NT1-specific changes in CPT1 activity and in expression of related genes were investigated. CPT1 activity was lower in patients with NT1 ($p = 0.00064$) and other hypersomnia ($p = 0.0014$) than in controls. Regression analysis revealed that CPT1 activity was an independent risk factor for NT1 (OR = 1.68; $p = 0.0031$) and for other hypersomnia (OR = 1.64; $p = 0.0042$). There was a significant interaction between obesity (BMI <25, ≥ 25) and the genotypes of NT1 associated SNP rs5770917 in *CPT1B* such that nonobese NT1 patients without risk allele had better CPT1 activity ($p = 0.0089$). The RNA-seq showed that expression levels of carnitine-acylcarnitine translocase (*CACT*) and *CPT2* in carnitine shuttle were lower in NT1 ($p = 0.0000073$ and $p = 0.0046$, respectively). Gene set enrichment analysis (GSEA) and pathway analysis using the RNA-seq data also revealed that several pathways related to carnitine shuttle and fatty acid metabolism were significantly associated with NT1. These results indicated that abnormal fatty acid metabolism is involved in the pathophysiology of NT1 and other hypersomnia.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1647 Machine learning-based penetrance of clinical variants

Authors:

I. Forrest, G. Rocheleau, D. Jordan, B. Petrazzini, H. Vy, G. Nadkarni, J. Cho, R. Do; Icahn Sch. of Med. at Mount Sinai, New York, NY

Accurate assessment of disease risk of genetic variants, known as penetrance, is a significant challenge in clinical genetics. Integration of large-scale phenotype data, genetic sequence data, and artificial intelligence holds promise in quantifying variant penetrance. Here, we constructed machine learning models for 10 genetic conditions using 1,347,298 participants with electronic health records (EHRs) from a large health system, then applied the models to an independent set of 28,953 individuals with linked EHR and exome data. Resulting disease probability scores were used to evaluate machine learning-based penetrance (ML penetrance) for 1,648 rare variants across 31 disease-predisposition genes that were pathogenic (P), benign (B), uncertain (VUS), or novel loss-of-function (LoF). The models achieved mean area under the receiver-operating-characteristic curves of 0.85 and 0.84 in validation and holdout sets, respectively. ML penetrance was variable within each variant class but greatest for P variants (median [IQR], 0.52 [0.38]) and novel LoF variants (0.48 [0.36]), then VUS (0.46 [0.31]), and smallest for B variants (0.21 [0.081]). Rare variants (allele frequency<0.001) had a higher ML penetrance than more common variants (median [IQR], 0.46 [0.32] versus 0.29 [0.073]; $P=8.3\times10^{-48}$). Notably, ML penetrance was associated with disease-relevant clinical outcomes such as chronic kidney disease in individuals with polycystic kidney disease variants (OR=1.11 per 0.1 increase in ML penetrance, 95% CI 1.08-1.14; $P=2.9\times10^{-13}$) and myocardial infarction in individuals with familial hypercholesterolemia variants (OR=1.02 per 0.1 increase in ML penetrance, 95% CI 1.01-1.03; $P=2.4\times10^{-3}$). Compared to conventional case-versus-control phenotypes and penetrance estimates, ML penetrance provided more refined quantitative estimates of disease risk. Furthermore, ML penetrance aided VUS and novel LoF variant interpretation by delineating those with high versus low penetrance; individuals with highly penetrant variants exhibited worse clinical trajectories over time. For example, carriers of highly penetrant *KCNQ1* VUS had prolonged QTc and bradycardic heart rates on electrocardiogram versus carriers of B variant or weakly penetrant *KCNQ1* VUS. By leveraging ML and deep clinical phenotyping, we systematically evaluated variant penetrance for a wide range of genetic diseases, thereby streamlining variant prioritization, enhancing risk assessment, and augmenting genetic discovery. This study presents a blueprint for precision medicine approaches that employ ML to accurately quantify disease risk of clinical variants at scale.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1648 Maternal genetic nurture and risk of childhood neuropsychiatric disorders.

Authors:

B. Mahjani[1], A. Kepinska[1], M. Caballero[1], A. Batuure[1], L. Cohen[1], B. Devlin[2], A. Buxbaum Grice[1], C. Hultman[3], M. Janecka[1], L. Klei[4], H. Larsson[5], C. Mahjani[1], A. Reichenberg[1], S. Sandin[1], J. Buxbaum[1], D. Grice[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Univ. of Pittsburgh, Pittsburgh, PA, [3]Karolinska Inst.t, Stockholm, Sweden, [4]WPIC/UPMC, Pittsburgh, PA, [5]Karolinska, institutet, Sweden

Studies have shown that maternal factors are associated with an elevated risk of neurodevelopmental disorders in children. Understanding the causes of these associations is complex; however, the association can arise from factors such as the direct impact of maternally transmitted genotypes on the offspring's phenotype and through maternal effect. In quantitative genetics, maternal effect encompasses the influences on the offspring phenotype that stem from the indirect effect of maternal genotypes, referred to as maternal genetic nurture (dynastic effect) and/or the maternal environment.

Using data from the Swedish national registries, we estimated direct additive genetic and maternal effect contributions to the liability of obsessive-compulsive disorder (OCD), Tourette syndrome (TS), and attention-deficit/hyperactivity disorder (ADHD). We also examined the role of assortative mating and specific maternal factors, including maternal age, maternal smoking during pregnancy, maternal psychiatric history, and gestational age.

For OCD, our findings revealed that direct additive genetics accounted for 35% of the total variance in risk, and maternal genetic nurture accounted for another 7%. Moreover, our results indicated an association between maternal age, maternal smoking during pregnancy, and the risk of OCD in children. We observed evidence for substantial assortative mating among individuals with OCD, meaning that individuals with OCD chose a partner with OCD more frequently than expected under a random mating pattern. We show that failing to account for maternal effect or assortative mating, if present, leads to overestimates of the impact of direct additive genetic effect. Regarding TS, we estimated 60.7% direct additive genetic effect, 4.8% maternal genetic nurture, and 0.5% environmental maternal effect. For ADHD, our preliminary results suggest 66.1% direct additive genetic effect and 14.3% maternal genetic nurture. We also observed evidence for substantial assortative mating among individuals with ADHD.

The risk of developing OCD, TS, and ADHD arises from a complex interplay of genetic factors (nature) and environmental influences (nurture). Our findings indicate that maternal genotypes play an important role in determining the risk of neurodevelopmental disorders in their children, not only through direct genetic transmission but also through environmental pathways.

Primary open angle glaucoma (POAG) is a heterogeneous disease whose underlying molecular mechanisms and pathophysiology are not well understood. While elevated intraocular pressure (IOP) is a major risk factor, 40% of glaucoma patients have normal IOP levels. Over 130 genomic loci have been associated with POAG from large European and cross-ancestry genome-wide association study (GWAS) meta-analyses. We hypothesize that subsets of POAG-associated variants will affect genes in different or overlapping biological processes associated with various sets of human traits involved in glaucoma pathogenicity. Thus, we applied Bayesian nonnegative matrix factorization (bNMF), a soft clustering method that emulates physiological relevance by allowing variants to belong to more than one pathway, to 133 independent POAG variants and their associations with traits relevant to POAG development. Endophenotypes were selected based on known or putative pathogenic mechanisms of POAG, e.g. vascular, neurodegenerative, metabolic, and mitochondrial, and having available GWAS summary statistics. A standardized association matrix of 133 POAG variants by 28 endophenotypes, accounting for trait direction of effect on POAG risk and normalized to GWAS sample size, was prepared. bNMF identified 4 clusters with 5 to 39 POAG variants each (converging to N=4, 83.8% of 1000 iterations). Each cluster was represented by unique trait and direction of effect combinations. The strongest effects on POAG risk resulted from increased IOP and decreased corneal hysteresis (cluster 3), and decreased platelet crit (PCT, platelet volume-%) and diastolic blood pressure (cluster 2). These results were replicated in an independent study (Mass General Brigham biobank) of up to 54,000 individuals, associating cluster partitioned polygenic risk scores with cluster-defining traits, correcting for age, sex, and top 10 genotype PCs (P<1E-3). PheWAS using the UK biobank and FinnGen study identified additional cluster-related traits (P<1E-08), such as reduced white blood cell counts for cluster 2. To gain cellular insight, genes mapped to POAG loci in each cluster via e/sQTL colocalization analysis were tested for enrichment in specific ocular cell types, highlighting ciliary and iris fibroblasts in the anterior segment for cluster 3 (IOP), and fibroblasts and vascular cells in the optic nerve head and retinal astrocytes for cluster 2 (PCT) (FDR<0.1). This work proposes new disease mechanisms associated with POAG risk, such as reduced PCT and blood pressure potentially affecting optic nerve blood flow, that may inform therapy development and personalized diagnosis and treatment.

PB1650 Medical and surgical complications in paediatric patients with achondroplasia followed in a specialty skeletal dysplasia centre.

Authors:

E. Martin, Y. Wang, L. Dupuis, M. Bouchard, A. Howard, **R. Mendoza-Londono**; The Hosp. for Sick Children, Toronto, ON, Canada

Achondroplasia is the most prevalent skeletal dysplasia. It is typically caused by a single gain of function missense variant in the fibroblast growth factor receptor 3 (*FGFR3*) gene. Increased signalling via FGFR3 leads to abnormal bone, joint, and cartilage development, causing short stature, skeletal dysplasia, and distinctive craniofacial features. In addition, patients with achondroplasia can experience medical and surgical complications requiring a multidisciplinary management approach. Novel treatments are being developed aimed at mitigating the effect of the activating variant; however, primary endpoints have focused primarily on stature and have not documented an impact on other complications. **Objective**: To determine the prevalence and management of the medical and surgical complications associated with achondroplasia in patients referred to The Hospital for Sick Children, Canada's largest children's hospital. **Methods**: We conducted a retrospective chart review and collected longitudinal data on complications, referrals for evaluation, and medical and surgical interventions in a cohort of 60 patients. **Results**: Breathing and airway issues were the most frequent complications. Sleep apnea affected 87% of patients. Fifty-three percent required tonsillectomy/adenoidectomy surgery, and 18% required continuous positive airway pressure (CPAP) treatment. Middle ear effusions requiring myringotomy tubes were documented in 48% of patients. Neurosurgical complications, including foramen magnum stenosis and cervicomedullary compression requiring surgery, were seen in 37% of patients. Orthopaedic concerns included genu varum treated by guided growth in 23% of patients. This study documents the frequency of complications in patients with achondroplasia and provides a benchmark to compare the efficacy of management strategies. Gaining a better understanding of the clinical presentation and prevalence of non-stature related complications in achondroplasia will allow for better monitoring of outcomes as new therapies are introduced. It will also guide counselling of new families regarding the prevalence of these complications and the most effective treatment strategies, ultimately leading to a better quality of life for individuals with achondroplasia.

PB1651 Mendelian randomization analyses identify causal associations between human gut microbiome composition and intelligence.

Authors:

S. Yao[1], J-Z. Han[2], Y. Guo[2], T-L. Yang[1,2]; [1]Natl. and Local Joint Engineering Res. Ctr. of Biodiagnosis and Biotherapy, The Second Affiliated Hosp., Xi'an Jiaotong Univ., Xi'an, China, [2]Key Lab. of BioMed. Information Engineering of Ministry of Ed., BioMed. Informatics & Genomics Ctr., Sch. of Life Sci. and Technology, Xi'an Jiaotong Univ., Xi'an, China

Intelligence is a robust predictor of educational and socioeconomic achievement and broadly implies lifestyle behaviors and health resource advantages across the lifespan. Growing evidence indicates that dynamic changes in the gut microbiome can affect intelligence; however, whether the relationships are causal is unknown. Randomized controlled trials (RCTs) have the potential to establish causal relationships. Nevertheless, most RCTs are expensive and time-consuming, and more importantly, gut microbiome composition cannot be randomly allocated in practice. To disentangle the poorly understood causal relationship, we performed a bidirectional two-sample Mendelian randomization analysis using genetic variants from the largest available genome-wide association studies of gut microbiota composition (N = 18,340) and intelligence (N = 269,867). We observed causal evidence indicating a risk effect of the *Oxalobacter* on intelligence (β = -0.032; 95% CI, -0.049 to -0.015; $P = 1.88\times10^{-4}$) and a protective effect of the *Fusicatenibacter* on intelligence (β = 0.051; 95% CI, 0.023 to 0.079; $P = 3.03\times10^{-4}$) after multiple testing corrections. Considering the close relationship between brain volume and human intelligence, we performed a two-step MR analysis and found that the effect of *Fusicatenibacter* on intelligence was partly mediated by regulating the brain volume, with a mediated proportion of 26.7%. In the other direction, with genetic liability for intelligence as exposure, we performed reverse MR analyses to explore the causal effect of intelligence on the gut microbiome abundance and did not find significant evidence. Our findings may help reshape our understanding of the microbiota-gut-brain axis and development of novel intervention approaches for preventing cognitive impairment.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1652 Mendelian randomization analyses suggest a causal role for circulating GIP levels in homeostatic model assessment (HOMA)-derived measures of beta-cell function and insulin sensitivity.

Authors:

K. Meeks[1], A. Bentley[1], T. Assimes[2], N. Franceschini[3], A. Adeyemo[1], C. Rotimi[1], A. Doumatey[1]; [1]NIH, Bethesda, MD, [2]Stanford Univ Sch Med., Palo Alto, CA, [3]Univ North Carolina at Chapel Hill, Chapel Hill, NC

Certain cytokines have been implicated in the development and progression of type 2 diabetes (T2D). However, studies on their role in T2D in humans are scarce. In a sub-Saharan African cohort, we evaluated associations between 11 circulating cytokines and T2D and tested for causal relationships using Mendelian randomization (MR) analyses. The participants were from Ghana, Nigeria, and Kenya, and included 2,276 individuals with T2D and 2,790 non-T2D individuals from the Africa America Diabetes Mellitus study. We fitted logistic regression models adjusted for age, sex, body mass index (BMI), and country of origin to regress levels of 11 cytokines (adipsin, leptin, visfatin, PAI-1, GIP, GLP-1, ghrelin, resistin, IL-6, IL-10, IL-1RA) on T2D. Linear regression models using the same covariates were fitted with homeostatic modelling assessments of insulin sensitivity (HOMA-S) and β-cell function (HOMA-B) as dependent variables among non-T2D individuals. Circulating GIP and IL-1RA levels were associated with T2D. Nine of the 11 cytokines (all except GLP-1 and IL-6) were associated with HOMA-S, HOMA-B, or both among non-T2D individuals. We subsequently used 35 genetic variants previously associated with at least one of these 11 cytokines among non-T2D individuals as instrumental variables in univariable and multivariable MR analyses. Statistical significance was set at 0.0045 (0.05/11 cytokines). Two-stage least squares MR analysis provided evidence for a causal effect of GIP on HOMA-S and HOMA-B both in univariable (HOMA-S β =-0.78; P-value=1.11×10^{-11} and HOMA-B β=0.67; P-value=1.47×10^{-9}) and multivariable analyses (HOMA-S β=-0.67; P-value=1.88×10^{-6} and HOMA-B β=0.59; P-value=1.88×10^{-5}). Inverse variance weighted MR analysis provided evidence for a causal effect of adipsin on T2D (multivariable OR=1.83, P-value=9.79×10^{-6}), though these associations were not robust in the MR-Egger and weighted median sensitivity analyses. Subsequent mediation analyses revealed that the effect of GIP on HOMA-S and HOMA-B was not mediated through BMI. Our findings indicate that circulating GIP levels are independently causal for reduced insulin sensitivity and increased β-cell function in non-T2D individuals, but not for T2D status. This is concordant with studies reporting impairment of GIP's glucose-dependent insulinotropic effect among T2D individuals. These observations suggest that circulating levels of GIP could be a promising early biomarker for T2D risk or a therapeutic target. Indeed, emerging clinical studies are exploring the therapeutic potential of GIP in combination with other gastrointestinal peptides such as GLP-1.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1653 Mendelian Randomization Analysis of the Effects of Alcohol Use on Cancer Risk

Authors:

H. Zhou[1], B-Z. Yang[2], H. Kranzler[3], J. Gelernter[4]; [1]Yale Univ., Orange, CT, [2]Yale Univ Sch Med, West Haven, CT, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Yale Univ Sch. of Med., West Haven, CT

Background/significance/hypothesis: Cumulative epidemiological evidence shows that an estimated 5.5% of all cancers are attributable to alcohol use, totaling 770,000 cases annually. Alcohol consumption is associated with the development of cancer of the oral, breast, liver, and colon. GWASs have identified risk genes for alcohol-related traits and cancers. However, the relationship between alcohol use and different kinds of cancer remains unclear. **Methods**: To provide adequate power to investigate the causal relations between two alcohol-related phenotypes and different cancers, we used the GWAS summary statistics for problematic alcohol use (PAU, Zhou et al., PMID: 36747741, N=903,147) and drinks per week (DPW, Liu et al., N=941,280). We used Mendelian Randomization (MR) and summary statistics from GWAS of several cancers, including breast, colorectal, esophageal and oral/pharyngeal cancers. Inverse-variance weighting (IVW), weighted median, MR-Egger, and MR-PRESSO were implemented for MR inference. **Results**: We observed nominally significant causal effects of PAU on esophageal cancer (IVW p=0.01) and significant effects (correcting for 8 tests) on breast (IVW $p=2.6\times10^{-3}$) and oral cancer risks (IVW $p=4.4\times10^{-6}$). We found no causal effects of DPW on cancers. **Conclusions**: There are few MR studies on this topic in the literature, mainly due to underpowered GWAS of alcohol-related traits and cancers. This study finds evidence of the causal effects of PAU on the risk of specific cancer types. These results are limited to European ancestry; further studies in underrepresented, understudied, and underreported populations are needed.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1654 Mendelian randomization in approximately 1 million stuttering cases and controls show significant causal effects of genes and illuminate causal relationships between hormonal, behavioral, and psychiatric traits and stuttering liability

Authors:

A. Scartozzi[1], D. Pruett[2], H. Polikowsky[1], D. Shaw[1], H-H. Chen[3], L. Petty[1], A. Petty[2], E. Lowther[4], Y. Yu[5], 2. Research Team[6], H. Highland[7], C. L. Avery[8], K. Mullan Harris[8], R. Gordon[2], J. Beilby[9], K. Z. Viljoen[4], R. Jones[1], C. Huff[10], S. Kraft[11], J. Below[12]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN, [3]Academia Sinica, Taipei, Taiwan, [4]Curtin Univ., Perth, Australia, [5]UT MD Anderson Cancer Ctr., Houston, TX, [6]23andMe, Inc., Sunnyville, CA, [7]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [8]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [9]Curtin Univ., Perth, Austria, [10]U.T. MD Anderson Cancer Ctr, Pearland, TX, [11]Wanye State Univ., Detroit, MI, [12]Vanderbilt Univ Med Ctr., Nashville, TN

Developmental stuttering is a common speech disorder characterized by prolongations, blocks, and repetitions of speech sounds. Stuttering genetic risk factors are complex and involve both familial and population-level variation. Furthermore, stuttering is associated with a variety of comorbid traits. Despite progress in the field, the genetic factors affecting stuttering risk and comorbidity are unknown.

The current study uses 23andMe, Inc. genome-wide association study (GWAS) summary statistics of self-reported stuttering to better understand the causal pathways between stuttering and previously reported comorbid traits, and identify potential causal genes.

To determine if comorbid traits associated with stuttering harbor a causal or horizontal pleiotropic relationship, we performed sex-specific Mendelian randomization with 18 traits and stuttering. We found that the genetic risk of BMI, chronotype, walking pace, suicide ideation, and testosterone levels showed causal effects on stuttering liability, and the genetic risk of stuttering showed causal effects on depression ($p < .05$). These results are consistent with several studies suggesting that males and females who stutter report elevated symptoms of depression compared to their fluent counterparts.

To identify potential causal genes associated with stuttering, we performed sex-specific joint-tissue expression imputation followed by Mendelian randomization. For female stuttering, after multiple test correction, we identified 92 unique causal genes across all tissues. Only three of these genes, *NMUR2*, *MMAB*, *DCC*, were reported at genome-wide significant loci in the original 23andMe GWAS of stuttering (Polikowsky et al., 2023) and are involved in GPCR signaling, metabolic processes, and axon guidance. For male stuttering, we identified 24 causal genes across all tissues. Only *MMAB* was identified in Polikowsky et al. 2023, and ZMAT4 was a top hit in an independent analysis, Shaw et al. 2021, and is involved in nucleic acid binding.

Future studies will examine neuroendophenotypes associated with these potentially causal stuttering genes. Understanding the genetic relationships between stuttering and associated traits, as well as potential causal genes may inform clinical manifestations of stuttering that differ between sexes.

PB1655 Mendelian randomization study of body mass index and all-cause and vascular-metabolic mortality in 125,000 Mexican adults

Authors:

L. Gnatiuc Friedrichs[1], J. Alegre-Díaz[2], E. Trichia[1], R. Ramirez-Reyes[2], D. Aguilar-Ramirez[3], R. Clarke[1], N. Staplin[1], J. Torres[3], R. Wade[1], F. Rivas[2], M. Hill[4], R. Collins[5], J. Emberson[1], J. Berumen[6], P. Kuri-Morales[7], R. Tapia-Conyer[2]; [1]NDPH and MRC PHRU, Univ. of Oxford, Oxford, United Kingdom, [2]Natl. Autonomous Univ. of Mexico, Mexico City, Mexico, [3]NDPH, Univ. of Oxford, Oxford, United Kingdom, [4]CTSU and MRC PHRU, Univ. of Oxford, Oxford, United Kingdom, [5]Univ. of Oxford, Oxford, United Kingdom, [6]Univ. Natl. Autónoma de México, México, Mexico, [7]Inst. Tecnológico y de Estudios Superiores de Monterrey, Monterrey, Mexico

Background: Mendelian randomization (MR) studies are widely used to estimate the causal relevance of adiposity for vascular-metabolic diseases but most previous studies have been conducted in European ancestry populations. Using data from the Mexico City Prospective Study (MCPS), we used MR to estimate the causal relevance of body mass index (BMI) for all-cause and vascular-metabolic mortality in an admixed Mexican population.
Methods: 124,880 MCPS participants with genetic data and aged 35-74 years at recruitment were included. 767 single nucleotide polymorphisms associated with BMI were selected from the GIANT Consortia and, together with their weights, used to create an instrumental variable for BMI. The one-sample ratio method was used to estimate the causal effect of BMI on all-cause and vascular-metabolic mortality at ages 35-74 years, with Cox regression used to estimate sex-specific hazard ratios (HR) per 5 kg/m^2 higher BMI after adjustment for age-at-risk and genetic ancestry. Other MR approaches were used in sensitivity analyses including use of non-linear MR to examine linearity.
Results: The genetic instrument explained 3% of the variation in baseline BMI in men (F-statistic 130) and 5% of the variation in women (F-statistic 420). Over a median of 19 years follow-up there were 11,837 deaths at ages 35-74 years including 6634 vascular-metabolic deaths (3221 vascular, 1908 renal, 1006 hepatobiliary and 499 acute diabetic crises). Each 5 kg/m^2 higher genetically-predicted BMI was associated with a doubling in all-cause mortality (HR 2.05, 95% CI 1.84-2.29) and more than a doubling in vascular-metabolic mortality (HR 2.40, 2.07-2.78). For the vascular-metabolic deaths, each 5 kg/m^2 higher genetically-predicted BMI was associated with a doubling in vascular death (HR 1.94, 1.58-2.39) but more than a quadrupling in renal death (HR 4.04, 3.08-5.31) and death from an acute diabetic crisis (HR 5.69, 3.37-9.61). For deaths from hepatobiliary disease the HR was 1.42 (0.96-2.08). Hazard ratio estimates were generally larger in younger than in older people and among those with a higher proportion of Indigenous ancestry, but were similar in men and women. Much of the effect of BMI on mortality was explained by its effect on diabetes and the remaining (ie, residual) effects of BMI on mortality were comparable in individuals with and without diabetes. Non-linear MR analyses showed no departure from linearity and the results were consistent using alternative MR approaches.
Conclusion: These findings indicate that the causal relevance of higher levels of adiposity for death from cardiometabolic and other causes is particularly strong in Mexican adults.

PB1656 Metabolome-wide association study of obesity in a high-risk pediatric cohort

Authors:

A. Apsley, K. Passero, J. Noll, I. Shalev, M. Hall; The Pennsylvania State Univ., University Park, PA

Childhood obesity is a nationwide problem and is a risk factor for many later-life cardiometabolic disorders such as type-2 diabetes, hypertension and dyslipidemia. While it is well-established that the experience of child maltreatment (CM) is a risk factor for obesity, it is unclear whether the biological mechanisms underlying risk for obesity are unique for individuals who have experienced CM. The human urine metabolome, the complete collection of small molecules found in human urine, contains a plethora of information about an individual's physiological state and is a prime biological domain for investigating the molecular mechanisms of childhood obesity in this high-risk population. Using data from a pediatric cohort from the Pennsylvania State University's Child Health Study (CHS; N=408; N_{CM}=347; $N_{Comparison}$=61; 51.5% Female; Age=11.4±1.4; BMI=21.6±5.8), we sought to determine the metabolomic signatures of childhood obesity and to uncover whether these signatures are different for obese children having experienced CM vs. comparison youth. We used liquid chromatography coupled with mass spectrometry (LC-MS) to identify and quantify an average of 165±8.2 metabolites per sample. Samples were spiked with appropriate internal standards (e.g., stable isotope-labeled amino acids/nucleosides) that were later used for correcting for batch effects and for normalizing instrument responses. We used a metabolome-wide approach to detect individual metabolites associated with BMI and found nine metabolites were associated with BMI with $p < 0.05$. Three of these metabolites also had nominally significant CM and BMI interaction terms (Vanillylmandelic acid, 5-Hydroxylysine and L-Carnitine), indicating potential modifying mechanisms of CM on these metabolome-BMI associations. Further analysis using weighted gene co-expression network analysis (WGCNA) framework identified two groups of metabolites that were significantly correlated with BMI. Using a metabolite pathway analysis on the WGCNA identified groups, we found an overrepresentation of metabolites in the "Aminoacyl-tRNA biosynthesis pathway" (adjusted p-value=5.05E-08), which was enriched in individuals with higher BMI. These results demonstrate the value of evaluating the urine metabolome to uncover the biological mechanisms of obesity in a high-risk population.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1657 Metabolomic signatures of cognitive impairment in the Canadian Longitudinal Study on Aging

Authors:

S. Selber-Hnatiw[1,2,3], K. Trajanoska[1,2,3], V. Mooser[1,2,3], S. Zhou[1,2,3]; [1]McGill Univ., Montreal, QC, Canada, [2]McGill Genome Ctr., Montreal, QC, Canada, [3]McGill Canada Excellence Res. Chair in Genomic Med., Montreal, QC, Canada

Background and Objectives:
Dementia and Alzheimer's disease (AD) are cognitive disorders that represent major disparities in healthcare as there are no effective interventions nor robustly established biomarkers for disease detection. As such, it is important to focus on the earliest stages of disease onset, such as identifying modifiable circulating molecules (e.g., metabolites) that can be probed for controlling AD development, maintaining cognitive function, and mitigating early symptoms of dementia.
Methods:
We used data from 10,000 Canadian Longitudinal Study on Aging participants with 1,458 serum metabolite measurements with scores from in-depth cognitive tests to identify metabolites with large effects on cognitive function. We constructed three cognitive composite scores using cognitive tests related to general cognitive function, memory (i.e., verbal episodic memory and delayed recall), and executive function (i.e., executive and set switching, and verbal fluency). Log transformed, normalized metabolite data was assembled, and values with SD > 5 and > 50% missingness were removed, totalling 1,093 metabolites. Linear regression analyses were conducted to examine the association of the post-QC metabolites with each composite score, accounting for sex, age, and hours since consuming food or drink.
Results:
We identified 200 metabolites associated with at least one of the three composite scores following Bonferroni correction ($p < 1.52 \times 10^{-5}$). Several findings were supported in the literature as protection from cognitive decline and AD or biomarkers of early AD pathology, including carotene diol (beta = 0.34, $p = 3.56 \times 10^{-37}$, CI = 0.283-0.399), beta-cryptoxanthin (beta = 0.316, $p = 7.74 \times 10^{-27}$, CI = 0.259-0.374), and long, branched-chain dicarboxylic acids (beta = 0.248, $p = 3.88 \times 10^{-17}$, CI = 0.190-0.306). Other metabolites of interest included sphingomyelins (beta = 0.143, $p = 2.863 \times 10^{-06}$, CI = 0.083-0.203), which are critical in myelination and cognitive development, and 4-hydroxyphenylacetate and lactosyl-N-palmitoyl-sphingosine (d18:1/16:0), which appeared to be solely associated with executive function, suggesting the importance of focusing on a specific biological pathway of cognitive function.
Conclusions:
In this study, we have identified several metabolites associated with cognitive function and AD biology. The findings of this work may contribute to early AD and dementia management and understanding new pathophysiological mechanisms. Future work will focus on validating these metabolites by estimating their causal effects on cognitive decline and combining them with proteomic signatures.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1658 Meta-Prediction Reveals Polygenic Scores are the Principal Features Distinguishing Prospective Risk Reduction Profiles in Coronary Artery Disease

Authors:

S-F. Chen[1], A. Torkamani[2], H. Javedani Sadaei[1], S. Lee[1]; [1]Scripps Res., La Jolla, CA, [2]Scripps Translational Sci. Inst., La Jolla, CA

Coronary artery disease (CAD) remains the leading cause of mortality and morbidity worldwide. Recent advancements in large-scale genome-wide association studies have sparked renewed interest in polygenic risk scores (PRSs), highlighting the potential of genetic risk in clinical prevention and therapeutic selection. However, the current clinical utility of PRS models is limited to simply identifying high-risk populations based solely on the top percentiles of genetic likelihood. While some studies have attempted integrative prediction using genetic and non-genetic factors, many of these studies have been cross-sectional and lacked actionable recommendations. Our primary objective in this study was to address the limitations of current approaches by integrating genetic risk factors in a prospective prediction framework. We achieved this through a machine learning (ML) model capable of identifying interactions between risk factors and interventions, facilitating the identification of personalized risk reduction strategies.Thus, we present an omnigenic meta-prediction framework, employing an explainable ML approach, which effectively captures CAD risk subgroups, primarily distinguished by degree of genetic risk, with differing benefits from standard interventions. Our initial model development considered over 4000 predictive features, including demographic data, lifestyle factors, physical measurements, laboratory tests, medication usage, diagnoses, and PRSs. To drive our meta-prediction approach, we stratified the UK Biobank into two primary cohorts: 1) a prevalent CAD cohort which was employed to develop baseline predictive models for contributing risk factors and diagnoses, and 2) an incident CAD cohort used to train the final CAD incident risk prediction model. The final model included 200 predictive features, including meta-features derived from models trained on the prevalent risk cohort, that significantly enhanced 10-year incident CAD risk prediction. The final model achieved an AUC of 0.81 or F1-score of 0.67, outperforming prior models and able to identify interventions that provided the most benefit at an individual level.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1659 Microbic Risk Score to mapping metabolic networks in childhood obesity.

Authors:

N. Vergara Lope Gracia, M. Pedone; Univ. of Florence, Florence, Italy

Childhood obesity is a major global public health problem. In 2023, WHO estimated that one in three primary school-aged children is living with obesity or overweight**.** Obesity is a chronic metabolic disease influenced by the interaction of genetic and modifiable factors such as gut microbiota (GM). In a healthy status, the GM participates in the regulation of multiple physiological functions of the host. Herein, gut dysbiosis is unfavourable for the host and putatively participates in the pathogenesis of obesity. In this study, we propose a mathematical method to compute the individual's genome content based on the information theory to quantify the risk of a complex disease and offer a trail to predicting future metabolic paths associated with childhood obesity. Our analysis yields 48 Mexican children aged 6-10 years categorised as normal-weight, overweight and obese. The children's information includes biochemical measurements and bacterial DNA from human stool samples. We compute (1) the Microbic Risk Score (MRS) by summing the trait-associated alleles across genetic loci nurturing the genetic information content of bacterial signatures between individuals. Subsequently, we employ (2) a Bayesian Gaussian graphical model with covariates (GGMx) to estimate a metabolic network among established biochemical risk factors. The GGMx formulation allows both the strength and sparsity pattern of the precision matrix (controlling the network pattern) to change with the MRS, resulting in population-level and subject-specific graphs. The findings will indicate that the bacterial genomic information may help to evaluate potential variations in global genomic architecture between overweight/obese and normal-weight children. According to the estimated network, our goal is to provide that the genetic profile from MRS will elucidate a major implication to be associated with metabolic pathways in child populations. These results may suggest that the genetic and non-genetic factors are involved to disrupt energy homeostasis, increasing lipid synthesis/storage or dietary behaviour. Overall, our study will enhance our understanding of the role of GM in the pathogenesis of obesity and highlights the necessity for nuanced study designs in the association between biochemical patterns and genetic information.

PB1660 Microglial genes show significant difference in transcriptional burst kinetics between minor cognitive impairment and Alzheimer's disease cases

Authors:

B. Jin[1], W. Bush[2]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Case Western Reserve Univ, Cleveland, OH

Microglial function is highly associated with neurodegenerative diseases. As innate immune cells in the central nervous system, microglia play critical roles in maintaining brain homeostasis. However, overactive microglia potentially cause synaptic loss, which is one of the pathologies of Alzheimer's disease (AD). Single-cell RNA-seq in microglia from AD mice has uncovered AD-associated microglia subtypes; however, the gene expression patterns associated with these subtypes are not replicated in human microglia.A reason is that human microglia have highly variable gene expression profiles. Such variability is not necessarily from differences in microglia sub-cell types. Instead, human genes are highly bursting in nature and exhibit large heterogeneity between alleles and within a population of cells. Moreover, increased transcriptional heterogeneity in humans is associated with aging, which is one of the biggest risk factors for AD.We hypothesize that transcriptional bursts are different for critical genes in AD cases compared to mild cognitive impairment individuals (MCI). We use a statistical model to quantify the heterogeneity of human microglia due to bursting gene expression. In detail, we used single-cell RNA-seq on microglia with 8 AD cases and 4 MCI cases from the ROSMAP project to estimate single chromosome transcriptional burst kinetics (burst size, and burst frequency) transcriptome-wide. We identified two genes, C1QC and ACTB, with significant differences in burst size between AD and MCI. Both C1QC and ACTB show larger burst sizes in MCI than in AD cases (p-value for C1QC: 0.00504; p-value for ACTB: 0.00511; p-value for candidate gene SPP1: 0.0359). Consequently, C1QC and ACTB show a higher expression level variability among microglia cells in MCI cases than AD. We found that even at the bulk level, such cell-cell variability can contribute to inter-sample gene expression variability. With an independent pseudo bulk RNA-seq data from single nucleus RNA-seq on 25 samples (16 AD, 9 Controls), the inter-sample variability in AD is significantly different for ACTB (AD:1.513; Control: 26.38) and SPP1 (AD:0.341, Control: 6.553). C1Q is associated with synaptic and neuron loss by microglial phagocytosis, whose expression increases with aging, especially in the hippocampus. Both highly variable expressions of C1QC and ACTB in MCI than AD indicate a globally elevated microglia state, increased mobility of microglia in MCI, and promoted microglial phagocytosis. The active microglia physiological states undergo potential functional change with AD progression and are prime targets for further experimental validation.

Tokyo / RIKEN, Osaka, Japan, [10]Coll. of Med. and Hlth., Exeter Univ., Exeter, United Kingdom

Adult height is the classic model polygenic trait. It is highly heritable, with an estimated broad-sense heritability of 80%. Recently, a GWAS by the GIANT consortium of height in 5.4 million individuals identified 12,111 independent SNPs, which explain >90% of the SNP-based heritability for height due to common variants. Similar to other polygenic traits, height exhibits a difference between the broad and narrow-sense heritability. There are several potential explanations for this discrepancy, one of which is non-additive interactions between SNPs, a form of epistasis. Few examples of epistasis have been discovered and verified for human traits. The paucity of detected epistasis signals has largely been attributed to the statistical power required to detect these interactions, which is limited in human studies, and the possibility of more complex epistasis (beyond simple pairwise interactions).
We leveraged the results from the largest GWAS of height to date to quantify the contribution of certain types of genetic interactions to the genetic architecture of height. We first tested for interaction effects between all pairwise combinations of the recently identified 12,111 height-associated SNPs. There was no evidence of interaction between any of the variants. Additionally, we observed 3 interactions between sex and the height-associated SNPs at variants near *NKX2-1*, *KIAA0319*, and *CYP19A1*.
To look for more global evidence of interactions, we constructed a PRS of height and compared PRS-predicted height versus inverse-normalized height in the UK Biobank. We found significant deviations for individuals in the upper tail of the PRS (p-value = 2.21e-04), where individuals were taller than expected, suggesting the possibility of non-additive interactions at the taller extremes.
Lastly, we created gene-set-specific height PRS to search for evidence of interactions within and between gene sets (gene sets defined using DEPICT; SNPs assigned to genes based on proximity). To mitigate inflation due to cis-acting effects, we generated an odd and even PRS for each gene set based on chromosomes. Overall, no significant within or between pathway interactions were found. There was suggestive enrichment of between and within gene set interactions based on individuals with extreme height PRS. In summary, we found no statistical evidence of SNP-by-SNP interactions between height-associated SNPs. Guided by the recent GIANT GWAS results, we found 3 examples of height-associated interactions between genetic variants and sex. There was no overall evidence of genetic interactions between or within gene sets.

PB1662 Minor genetic overlap between rheumatoid arthritis and myocardial infarction.

Authors:

A. Öberg Sysojev[1], L. Alfredsson[1], L. Klareskog[1], The SRQ Biobank Group, G. N. Silberberg[1], S. Saevarsdottir[1,2], L. Padyukov[1], P. Magnusson[1], J. Askling[1], H. Westerlind[1]; [1]Karolinska Inst.t, Stockholm, Sweden, [2]deCODE Genetics Inc, Reykjavik, Iceland

Background: Patients with rheumatoid arthritis (RA), a chronic inflammatory disease affecting 0.5-1% of the Western population, are at increased risk of cardiovascular disease (CVD), including myocardial infarction (MI). This increased risk can be partly attributed to an increased prevalence of traditional cardiovascular risk factors, partly to the chronic and systemic inflammation of the disease and partly to interplay with various treatments. However, we and others have recently implicated familial factors as potentially contributory, indicating that also underlying genetic effects may predispose individuals to both RA and CVD. Nevertheless, targeted attempts at quantifying such shared genetic predisposition has yet to be undertaken.
Objectives: We attempted to quantify the genetic overlap between RA and MI by estimating the genetic correlation between the two traits.
Methods: We conducted a genome-wide association study (GWAS) in 26,637 Swedish RA cases and controls taken from the Epidemiological Investigation of RA study (EIRA), the Swedish Rheumatology Quality register biobank (SRQb) and the Swedish Twin Register (STR). The resulting RA GWAS data was paired against publicly available GWAS data on MI. Estimation of genome-wide genetic correlation was done through linkage disequilibrium score regression (LDSC) while estimates of local genetic correlation was obtained via local analysis of variant associations (LAVA). Furthermore, to assess the genetic overlap between RA and various traditional CVD risk factor traits, we estimated the genome-wide genetic correlation between RA and body adiposity, LDL-cholesterol, blood pressure, CRP-levels as well as smoking traits, using publicly available GWAS data.
Results: After quality control, our RA GWAS contained 25,826 individuals and ~5 million SNPs of which ~4.1 million overlapped the reference panel and the two GWASs. Genome-wide genetic correlation was estimated to rg = 0.13 (95%CI -0.03 - 0.29). Of 2495 distinct genomic regions tested for a genetic overlap, six showed significant local genetic correlation after correction for multiple testing, of which none were within the major genetic risk loci for RA, the MHC region on chromosome six. In analyses contrasting RA with CVD risk factor traits, no significant correlations were observed in any pairing, with the highest absolute genetic correlation being between RA and CRP (rg = 0.13, 95%CI -0.04 - 0.29).
Conclusions: Our findings indicate that any genetic overlap between RA and MI is minor. Furthermore, genetic overlap between RA and CVD risk factor traits seems unlikely to provide a major contribution to the increased risk of CVD observed in RA.

PB1663 miRNA & mRNA gene networks in Major Depression in a large postmortem brain sample

Authors:

Z. Taylor[1], J. Drake[1], A. Denham[1], S-A. Bacanu[2], J. Shin[3], J. Kleinman[2], T. Hyde[3], V. I. Vladimirov[1]; [1]Univ. of Arizona, Phoenix, AZ, [2]Virginia Inst. for Psychiatric and Behavioral Sci., Virginia Commonwealth Univ., Richmond, VA, [3]Lieber Inst. for Brain Dev., Johns Hopkins Univ., Baltimore, MD

Major Depression (MDD) is a disorder characterized by low mood and anhedonia that affects roughly one out of every six adults worldwide. While GWAS studies have identified genome-wide significant variants associated with MD much work remains in elucidating the functional impact of such variants. Complimentary research into MDD's underlying neuropathology involves identifying transcriptome changes associated with major depression in postmortem brain tissues. MicroRNA (miRNA), a class of small non-coding RNA with gene regulatory functions and high expression in the brain, has been studied in relation to neuropsychiatric phenotypes. Here, we used miRNA-Seq to compare the expression of over 1000 miRNAs between 150 MDD patients and 150 matched controls in the subgenual anterior cingulate cortex (sACC) and Amygdala. We performed differential expression analysis (DEA) of individual miRNAs, weighted gene co-expression analysis (WGCNA) of miRNA and mRNA expression, and miRNA/mRNA correlation-based analyses to identify miRNAs with a converging role in the etiology of MDD. We identified differentially expressed miRNAs (at FDR of 5%) including several previously associated with MDD and/or associated with neurodevelopment or other psychiatric illness. Our network analyses detected both significant miRNA and mRNA modules associated with MDD at the Bonferroni corrected $p \leq 0.05$. Using miRNA target site and gene enrichment analyses further identified gene ontologies that may constitute regulatory targets of the differentially expressed miRNAs. Ours is the largest to date postmortem brain miRNA expression study of major depression, and our ongoing analyses provides solid evidence of the importance of miRNA as a contributing factor to the development of MDD.

PB1664 Mitochondrial DNA heteroplasmy and incident cardiovascular disease

Authors:

Y. Hong[1], W. Shi[1], D. Puiu[2], N. Pankratz[3], N. Lake[4], M. Lek[4], E. Guallar[5], D. Arking[1]; [1]Johns Hopkins Univ Sch. of Med., Baltimore, MD, [2]Johns Hopkins Univ. Dept. of BioMed. Engineering, Baltimore, MD, [3]Univ. of Minnesota, Minneapolis, MN, [4]Yale Univ. Sch. of Med., New Haven, CT, [5]Johns Hopkins Univ Sch. of Publ. Hlth., Baltimore, MD

Background: Variants of mitochondrial DNA (mtDNA) may exist in heteroplasmy and have been associated with increased risk of mortality and cancer. Previous studies suggest an increased risk of cardiovascular disease (CVD) with mitochondrial dysfunction, represented as low mtDNA copy number (mtDNA-CN). Better understanding of the mtDNA heteroplasmy on CVD will provide insight into the molecular physiology of disease development and progression.**Methods:** We used the MitoHPC pipeline to quantify mtDNA heteroplasmy and mtDNA-CN from whole genome sequencing data in 194,871 participants in the UK Biobank. We defined a heteroplasmy allele frequency of 5% as heteroplasmic. We functionally characterized mtDNA single nucleotide variants using a novel constraint-based score, mitochondrial local constraint score sum (MSS). We evaluated the associations of MSS, mtDNA-CN, and incident CVD, defined as fatal or non-fatal myocardial infarction (MI) or ischemic stroke, using Cox proportional hazards models stratified by center and adjusted for age, sex, smoking, body mass index, blood pressure, blood lipid and glucose levels, and history of hypertension and diabetes in 191,204 participants without prevalent CVD. For mtDNA-CN, we further adjusted for neutrophil and platelet counts. We performed additional analysis stratified by MSS for each complex/region in the mtDNA. Lastly, we performed analysis separately for MI and ischemic stroke. **Results:** During a median (1^{st} and 3^{rd} quartiles) follow-up of 12.6 (11.8, 13.8) years, there were 8340 incident CVD events (5665 MI and 3206 ischemic stroke cases). 30.4% of the study population had 1 or more heteroplasmies. We found that higher MSS was associated with CVD (adjusted hazard ratio [aHR] for a 1-unit increase in MSS 1.16; 1.04, 1.28). On the other hand, mtDNA-CN was not associated with CVD (aHR for 10-copy increase in mtDNA-CN 1.00; 0.98, 1.02) after adjusting for neutrophil and platelet counts. Additionally, there was no interaction between MSS and mtDNA-CN on the risk of CVD (p for interaction 0.11). When stratified by complex / region, higher MSS in Complex I increased the risk of CVD by 31% (aHR 1.31; 1.09, 1.57) but not in other complexes / regions. In addition, higher MSS was associated with incident MI (aHR for a 1-unit increase in MSS 1.24; 1.09, 1.40), whereas it was not associated with incident ischemic stroke (aHR for a 1-unit increase in MSS 0.96; 0.81, 1.15). For MI, higher MSS in Complex I and rRNA regions was associated with higher incidence. **Conclusion:** These results indicate that mitochondria may have a functional role in the development of CVD, particularly MI, and MSS may serve as a biomarker for CVD risk.

PB1666 † Multi-ancestry genetic analysis of long COVID in 23andMe Research Participants

Authors:

N. Chaudhary, C. Weldon, P. Nandakumar, J. Shelton, 23andMe Research Team, M. Holmes, S. Aslibekyan; 23andMe, Sunnyvale, CA

Background: Long COVID (LC), a post-acute sequelae of SARS-CoV2 infection, is a heterogeneous condition with poorly understood etiology and limited insights into its genetic architecture. We identified genetic risk factors predisposing individuals with a history of acute SARS-CoV2 infection to LC in a large-scale study of 23andMe, Inc research participants . Methods: Consented and genotyped 23andMe adult research participants who had previously reported SARS-CoV2 infection completed web-based surveys on LC diagnosis, LC-related symptoms and impact on daily activities, initial disease severity, and vaccination status. Cases were defined via self-report of LC experience or diagnosis; controls had a history of acute SARS-CoV2 infection but did not self-identify as having LC. We conducted GWAS adjusting for age, sex, and ancestry-specific principal components among European, African American and Latinx populations. We then conducted multi-ancestry meta-analysis. Variants that met a genome-wide statistical threshold (P<5*10-08) were functionally characterized. We estimated genetic correlations of LC with phenotypes with similar symptomatology using LD score regression. Results: Among the 171,025 participants that responded to the LC survey, 50,393 cases had self-reported LC and 120,632 were identified as controls. The mean age of participants was 45 (SD=15) years. Compared to controls, LC was more common among females (77% vs 64% in controls), and individuals with LC had more co-morbidities. Twenty-six percent of individuals with LC reported a moderate to severe impact on daily activities. Our GWAS in the European population yielded four independent loci: hits on chromosome 3 were related to depression and anxiety disorder, and hits on chromosome 6 were related to COPD as well as to immune function. The immune-related loci remained genome-wide significant (P-value for the index variant=8.8x10-10) in the multi-ancestry analysis. LC showed strong genetic correlations with chronic fatigue (rg=0.71), fibromyalgia (rg=0.70), chronic pain (rg=0.69), and dysautonomia (rg=0.54). Conclusion: We conducted the largest GWAS of LC to date and identified multiple genetic associations. We also report evidence of a shared genetic architecture between LC and several chronic disease phenotypes.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1667 Multi-ancestry genetic architecture of heart failure subtypes.

Authors:

C. Liu[1], Q. Hui[1,2], Q. Wells[3], J. M. Gaziano[4,5], P. Wilson[1,6], the Million Veteran Program, L. Phillips[1,6], J. Joseph[7,8], Y. Sun[1,2]; [1]Emory Univ. Rollins Sch. of Publ. Hlth., Atlanta, GA, [2]Atlanta VA Hlth.care System, Decatur, GA, [3]Vanderbilt Univ. Sch. of Med., Nashville, TN, [4]VA Boston Hlth.care System, Boston, MA, [5]Harvard Med. Sch., Boston, MA, [6]Emory Univ. Sch. of Med., Atlanta, GA, [7]VA Providence Hlth.care System, Providence, RI, [8]The Warren Alpert Med. Sch. of Brown Univ., Providence, RI

Heart failure (HF) affects an estimated 6.2 million patients in the US, and is associated with high morbidity, mortality, and healthcare cost. Clinical subtypes are currently defined by the left ventricular ejection fraction (LVEF), including two major subtypes - HF with reduced ejection fraction (HFrEF) with LVEF ≤ 40%, and HF with preserved ejection fraction (HFpEF) with LVEF ≥ 50%. Genetic factors contribute to HF risk, supported by an estimated heritability of 26%. The genetic architecture of HFrEF and HFpEF can be different given their distinct pathophysiology and risk profile. Previous large genome-wide association studies (GWAS) mainly focused on all-cause HF. The genetic architecture of HF subtypes was studied only among European ancestry. Therefore, we performed a multi-ancestry GWAS meta-analysis to identify HF-associated loci, focusing on clinical subtypes of HFrEF and HFpEF. Ancestry-specific GWAS of all-cause HF, HFrEF and HFpEF were conducted among European, African, Hispanic and Asian American participants from the Million Veteran Program (MVP), and European and African American participants from the BioVU study. Under the assumption of additive genetic model, logistic regression models were used, with adjustment of age, sex, and top 10 principal components derived from each ancestry group. Meta-analysis was then performed using the Genome-Wide Association Meta-Analysis (GWAMA) software, which implements random-effects model that allows heterogeneity in effect sizes. Using a total of 200,070 all-cause HF cases and 2,076,466 controls of European, African, Hispanic, Asian ancestries from the MVP, BioVU, and a recent multi-ancestry GWAS, we identified 136 genome-wide significant all-cause HF loci, including 93 novel loci. Using 38,781 HFrEF cases, 38,163 HFpEF cases and 526,135 controls of European, African, Hispanic, Asian ancestries from the MVP and BioVU, we identified 34 novel loci for HFrEF including *MAP3K7CL* and *SPI1*, and 2 novel loci for HFpEF (*ARSG, LOC107985511*). Two loci (*FTO, ARSG*) were shared between the two subtypes. Using Genotype-Tissue Expression (GTEx) data, the gene expression analysis suggested that the HFrEF loci are enriched in heart tissues such as coronary artery and aorta, while HFpEF loci are enriched in tissues related to the endocrine system, including the pituitary and adrenal gland. These findings from this diverse population shed light on the differences in the underlying molecular pathways of HFrEF and HFpEF. Future studies are warranted to further characterize the less-understood HFpEF phenotypes and expand the genetic discoveries among diverse populations.

Hlth.Sci., Fred Hutchinson Cancer Ctr., Seattle, WA, [8]Dept. of Epidemiology, Univ. of Washington, Seattle, WA, [9]Kaiser Permanente Washington Hlth.Res. Inst., Kaiser Permanente Washington, Seattle, WA, [10]Seattle Epidemiologic Res. and Information Ctr., Dept. of VA Office of Res. and Dev., Seattle, WA

D-dimer is a peptide product of fibrinolysis and clinical biomarker of diseases involving activated coagulation, including venous thromboembolism and ischemic cardiovascular disease. Circulating D-dimer levels are heritable and heterogeneous across populations, with, for example, higher levels observed in African (AFR) ancestry relative to European (EUR) ancestry populations. To date, our understanding of genetic contributors to D-dimer variation has been limited to the European ancestry population. Here, we performed the largest, most diverse genome-wide analysis of circulating D-dimer [total n=46,031: including 36,688 EUR, 7,397 AFR, 1,321 Hispanic, and 654 East Asian participants]. We performed both single variant and gene-based aggregate rare variant tests in whole genome sequences (WGS) from 14,334 participants within the Trans-Omics for Precision Medicine (TOPMed) program. For single variant tests, we then meta-analyzed TOPMed-imputed genotype results from 31,697 participants within the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium using a fixed-effects, p-value based method. Single-variant analysis results revealed 5 known genetic loci associated (P<5E-9) with D-dimer, including the AFR-driven *HBB* sickle-cell locus, and 2 new signals, at *F2* and *PROCR*, respectively. The lead variant at *PROCR* is a common (EAF=10%) intergenic variant in near-perfect correlation (r^2>0.99) with rs867186, a missense variant in *PROCR.* Variants at this locus have previously been associated with circulating measures of Protein C, Factor VII, and Factor XI, as well as thrombotic disease risk. Conditional analyses in TOPMed identified multiple variants distinctly associated with D-dimer at the *F5* locus and the fibrinogen gene locus**.** Sex-differentiated effects were observed at the *F3* locus, where effect-size heterogeneity tests in TOPMed revealed the lead variant (rs2022309) had a significantly higher effect-size for D-dimer association in females compared to males (P=1.57E-04). Gene-based aggregate tests further implicate *FGL1* missense variants (P=7.46E-06) in D-dimer regulation. Together, these loci provide new targets for functional work to disentangle mechanisms regulating fibrin production and fibrinolysis.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1669 Multi-ancestry genome-wide association study of broad psychiatric symptom domains in the Adolescent Brain Cognitive Development Study.

Authors:

M. E. Kumagai[1], L. M. Hernandez[1], M. J. Gandal[2]; [1]Univ. of California, Los Angeles, Los Angeles, CA, [2]Univ. of Pennsylvania, Philadelphia, PA

Psychiatric symptoms and disorders in adolescence are often highly heritable, yet few genome-wide association studies (GWAS) have been conducted in this population. To address this critical gap, here we ran GWAS on a broad range of quantitative psychiatric traits using the Child Behavior Checklist (CBCL)—a widely used parent-report questionnaire indexing child behavior across a number of psychiatric domains. Data were acquired for 10,612 multi-ancestry youth between the ages of 9-11 who participated in the Adolescent Brain Cognitive Development Study (European: EUR, N=6,654; African American: AFR N=2,168; Admixture American: AMR N=1,790). Within ancestry heritability and GWAS analyses were conducted using GCTA and FastGWA-mlm with covariates including age, sex, genotyping array batch, and the first 10 ancestry principal components. Multi-ancestry fixed effect meta-analyses were then performed using METAL. We identified a genome-wide significant association between the CBCL Thought Problems Scale (i.e. psychosis symptoms) at chromosome 8p21.2 (index SNP rs113595871, $p=3.4x10^{-8}$). Concordantly, Thought Problems Scale exhibited significantly heritability across ancestries—38.5%, 66.4%, and 54.6% for AFR, AMR, EUR groups, respectively ($p<0.001$)—indicating substantial genetic contribution to this childhood behavioral trait. Genetic correlations showed significant positive genetic correlations between the Thought Problems Scale and all other CBCL subscales ($p<0.001$), except for the Anxiety/Depression Scale ($p=0.38$). Finally, functional genomic follow up analyses identified specific enrichment of Thought Problems Scale GWAS results with gene expression in the pituitary ($p<0.001$), suggesting potential involvement of the endocrine system in the biological processes underlying adolescent thought problems. Together, these findings enhance our understanding of the genetic underpinnings of adolescent psychiatric symptoms and underscore the significance of considering diverse ancestry groups in investigating genetic associations with behavioral traits.

Cancer Inst, Rockville, MD, [22]Univ of Southern California, Los Angeles, CA, [23]USC, Santa Cruz, CA, [24]Veterans Admin. Connecticut Hlth.care system, West Haven, CT, [25]Stanford Univ., San Francisco, CA, [26]Stanford Univ., Stanford, CA

Prostate-specific antigen (PSA) is encoded by KLK3 and abundantly secreted by the prostate gland with a miniscule fraction (10-6) normally circulating in blood, but levels increase with prostate cancer. Most countries recommend against universal population screening for prostate cancer with prostate-specific antigen (PSA) testing due to potential for overdiagnosis and overtreatment of non-aggressive disease. Heritability of PSA in blood ranges between 30% and 40%, suggesting that polygenic variation is an important modulator of basal PSA levels in blood. Adjusting measured PSA levels for an individual's genetically determined baseline PSA could remove variation unrelated to cancer risk and improve overall test accuracy. Previous work investigating genetic determinants of PSA has focused largely on European ancestry individuals and has identified 128 independent variants, but many more PSA-associated loci remain to be discovered. Thus, we conducted the largest ever multi-ancestry genome-wide association study (GWAS) of PSA levels in 296,754 men without prostate cancer (211,342 European ancestry; 58,236 African ancestry; 23,546 Hispanic/Latino; and 3,630 Asian ancestry) across 9 cohorts (Million Veteran Program, 96.5%).

We identified 319 independent variants ($p<5x10^{-8}$), 185 of which were novel. Most of the novel variants had evidence of replication in an independent sample of 95,768 men. Of the novel variants, 47 reached genome-wide significance only in the multi-ancestry analysis (compared to individual ancestry-specific analysis), including rs372203682 in LMTK2, a gene implicated in spermatogenesis. A signal in the androgen receptor (AR) gene that was detected in the multi-ancestry analysis (rs184476359, $P_{Meta}=3.4x10^{-10}$) was primarily driven by the African ancestry population ($P_{AFR}=5.8x10^{-9}$). Combining GWAS results from the discovery and replication meta-analyses (N=392,522) identified an additional 112 novel variants. A total of 21% of discovery identified variants and 17% of meta-analysis identified variants met a Bonferroni significance level in the PRACTICAL consortium prostate cancer GWAS (107,247 cases; 127,006 controls).

The variance in PSA levels explained by a multi-ancestry genome-wide polygenic risk score (PRS-CSx) derived from our discovery GWAS in multiple independent cohorts was up to 16.9% (95% CI=16.1%-17.8%) in European ancestry, 9.5% (95% CI=7.0%-12.2%) in African ancestry, 18.6% (95% CI=15.8%-21.4%) in Hispanic/Latino, and 15.3% (95% CI=12.7%-18.1%) in Asian ancestry. Altogether, these results further our efforts towards more personalized and equitable prostate cancer screening.

Previous Alzheimer's disease (AD) genetic studies lack ancestral diversity, limiting the ability to detect risk variants more prevalent in non-European ancestry groups. Here we constructed and analyzed the largest multi-ancestry collection to date of directly genotyped genome-wide association study (GWAS) datasets from the Alzheimer's Disease Genetics Consortium (ADGC) to identify novel shared and ancestry-specific AD susceptibility loci, evaluate genetic architecture in different ancestries, and explore potential functional effects. These data included TOPMed R5-imputed genotypes from 37,382 non-Hispanic White (NHW), 6,728 African American (AFA), 8,899 Hispanic (HIS), and 3,232 East Asian (EAS) individuals. We performed a two-stage analysis: (1) single-variant association using score-based logistic regression for population-based datasets and GLMM for family-based studies, adjusting for onset/exam age, sex, population substructure principal components, and *APOE* ε4 genotype, followed by within-ancestry fixed-effects meta-analysis using METAL; and (2) cross-ancestry meta-analysis using the Han-Eskin random-effects (RE_{HE}) model in METASOFT. Secondary analyses included functional annotation, differential expression follow-up, and pathway analysis using EnrichR. We identified 13 loci with genome-wide significant (GWS; $P \leq 5\times10^{-8}$) cross-ancestry associations. These include known AD loci at/near *CR1*, *BIN1*, *TREM2*, *CD2AP*, *PTK2B*, *CLU*, *SHARPIN*, *MS4A6A*, *PICALM*, *ABCA7*, *APOE* and two novel loci at 11p12 (*LRRC4C*) and 12q24.13 (*LHX5-AS1*). We identified three GWS ancestry-specific loci, *PTPRK* ($P=2.4\times10^{-8}$) and *GRB14* ($P=1.7\times10^{-8}$) in HIS and *KIAA0825* ($P=2.9\times10^{-8}$ in NHW). Functional follow-up revealed the lead *LRRC4C* SNP, rs12576934, is a significant splicing quantitative trait locus (sQTL) for *LRRC4C* in brain frontal cortex ($P=5.89\times10^{-4}$) in GTEx expression data. Pathway analysis implicated multiple amyloid regulation pathways (strongest: negative regulation of APP catabolism, $P_{adjusted}=1.6\times10^{-4}$) and the classical complement pathway ($P_{adjusted}=1.3\times10^{-3}$). In summary, cross-ancestry analyses identified novel AD susceptibility loci in/near *LRRC4C* and *LHX5-AS1*, both genes with known roles in neuronal development, and several novel ancestry-unique loci found in biologically plausible pathways, including *PTPRK*, which encodes a protein tyrosine phosphatase involved in neuronal development and outgrowth, and *GRB14*, which encodes a negative modulator of insulin receptor activity. These highlight the value of data from traditionally underrepresented populations for gene discovery in AD, even with smaller sample sizes.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1672 Multi-ancestry phenome-wide association analyses of genetic liability for problematic alcohol use

Authors:

R. Kember[1], J. Johnson[2], K. Johnston[3], H. Lee[4], J. Xu[3], L. Davis[5], J. Smoller[4], T. Mallard[4], L. Huckins[3], S. Sanchez-Roige[6], H. Kranzler[1], J. Gelernter[3], H. Zhou[3]; [1]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Yale Sch. of Med., New Haven, CT, [4]Massachusetts Gen. Hosp., Harvard Med. Sch., Boston, MA, [5]Vanderbilt Univ. Med. Ctr., Nashville, TN, [6]Univ. of California San Diego, La Jolla, CA

Problematic alcohol use (PAU) and alcohol use disorder (AUD) are major causes of death and disability worldwide, in part because they increase risk for other mental and medical illnesses. While PAU may potentiate the course of comorbid conditions, there is accumulating evidence suggesting common genetic architectures for these disorders. We conducted a phenome-wide association study (PheWAS) to improve our understanding of the relationship between genetic liability for PAU and comorbid conditions. We used a cross-ancestry genome-wide association study (GWAS) of PAU (a phenotype based on a meta-analysis of AUD, alcohol dependence, and AUDIT-P [Alcohol Use Disorders Identification Test-Problem score, a measure of problematic drinking], N=1,079,947) for discovery. We calculated polygenic risk scores (PRS) using PRS-continuous shrinkage (PRS-CS) for PAU (in EUR; N=131,500) and AUD (in AFR; N=27,494) in four independent datasets (Vanderbilt University Medical Center's Biobank [BioVU], Mount Sinai [BioMe], Mass General Brigham Biobank [MGBB] and Penn Medicine Biobank [PMBB]) from the PsycheMERGE Network. We performed a PheWAS in each dataset, followed by a meta-analysis across all sites. In the EUR cross-site meta-analysis, after controlling for multiple comparisons, 58 of the 1,493 tested phenotypes were significantly associated with the PAU PRS, and 78 were significantly associated with the AUD PRS. Patterns of associations were mostly consistent across sites, although there was significant heterogeneity in the strength of associations. The most common associations were with substance use or mental disorders (e.g., tobacco use disorder, mood disorder, posttraumatic stress disorder), respiratory traits (e.g., chronic airway obstruction), and neurological conditions (e.g., chronic pain). Phenotypes potentially arising from alcohol use were also identified, such as alcoholic liver damage, and chronic liver disease and cirrhosis. In the AFR cross-site meta-analysis, 3 of the 793 phenotypes were significantly associated with the AUD PRS, all substance related (alcoholism, alcohol-related disorders, and tobacco use disorder). Covarying for AUD in the target samples reduced the significance, but not the pattern, of associations, with most phenotypes remaining significantly associated following correction. Genetic liability for PAU and AUD is associated with a range of disorders across the phenotypic spectrum, even in the absence of an AUD diagnosis. This suggests that there are shared pathways of risk for these common comorbid conditions.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1673 Multi-ancestry polygenic risk scores improve prediction of PTSD symptom severity and trajectory

Authors:

M. Sendi[1], Y. Zhao[2], X. An[2], D. A. Pizzagalli[1], K. Ressler[1], AURORA group, N. Daskalakis[1]; [1]Harvard Med. Sch./ McLean Hosp., Boston, MA, [2]The Univ. of North Carolina, Chapel Hill, NC

Post-traumatic stress disorder (PTSD) can affect those who experience trauma, and genetic variants for PTSD have been identified in different ancestry populations. But, the potential of polygenic risk score (PRS) for predicting genetic risk for PTSD and its role and interaction with demographic factors in predicting different PTSD trajectories are still unclear. Here, we aim to understand the role of multi-ancestry PRS in predicting PTSD symptoms and trajectories and their interaction with demographic factors, including age, sex, years of education, body mass index, and socioeconomic conditions. Data of 2637 individuals seeking emergency department care after traumatic stress exposure were analyzed as part of the AURORA study. Participants aged 18 to 75 sought care within 72 hours of a traumatic event at selected sites. Participants were phenotyped at pre-trauma (PRE), two weeks (WK2), eight weeks (WK8), three months (M3), six months (M6), and twelve months (M12) post-trauma using the PCL-5 scale. We calculated PRS using three genome-wide association study datasets: PRS_{EUR} (European), PRS_{AFR} (African), and PRS_{META} (European and African). Next, the null model (covariates only) R^2 values were compared to the full model (PRS and covariates) ones to evaluate PRS as a predictor of PCL-5 at different time points. Also, participants were grouped into resilient PTSD (Res-PTSD), moderate PTSD (Mod-PTSD), recovery PTSD (Rec-PTSD), and continuous PTSD (Con-PTSD) trajectories. Next, a binary classification method was employed to classify trajectory pairs based on demographic variables, genetic-based ancestry, and PRS data, with significant features identified using a feature learning approach. Including PRS_{META} at all time points ($p<0.001$) led to a significant improvement in the model, with the full model consistently exhibiting higher R^2 values compared to the null model. Furthermore, PRE_{AFR} contributed to the model improvement by increasing the R^2 values of the full model compared to the null model at PRE, WK2, WK8, and M6 ($p<0.05$ to $p<0.01$). On the other hand, PRS_{EUR} did not contribute to the improvement of the model. The integration of demographic, ancestry, and PRS information yielded a significantly better prediction of the PTSD trajectory than what would be expected by chance. Notably, certain demographic variables (including age, sex, and education level) and PRS_{META} were the most effective predictors of the PTSD trajectory. In conclusion, multi-ancestry PRS outperformed single-ancestry ones in predicting PTSD symptoms, and a combination of demographic factors and PRS_{META} effectively predicted different PTSD recovery trajectories.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1674 Multi-ethnic meta-analysis GWAS of autism uncovers four novel genes.

Authors:

J. Glessner[1,2], M. Khan[1], X. Chang[1], Y. Liu[1], F. Mentch[1], C. Kao[1], M. March[1], J. Connolly[1], H. Hakonarson[1,2]; [1]Childrens Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

We report the results of a Genome-Wide Association Study (GWAS) meta-analysis of Autism Spectrum Disorder (ASD) that has identified several significant novel genes associated with the disorder. The study was conducted as part of an ongoing autism cohort analysis at the Center for Applied Genomics (CAG) program at Children's Hospital of Philadelphia (CHOP), which uses SNP array genotyping and imputation to identify genetic variants that may contribute to complex diseases. Our analysis included a total of 7,714 individuals with ASD and 19,620 controls of EUR, AFR, AMR, EAS, and SAS ancestry. We used imputation referencing Trans-Omics for Precision Medicine (TOPMed) data to increase the number of genetic variants tested, and then performed a meta-analysis across multiple race and sex stratified cohorts (using tools SAIGE and METAL) to identify genetic variants associated with ASD. Our results revealed several significant genes that have not previously been linked to ASD. Specifically, we identified three genes that showed a strong association with ASD in our meta-analysis: FOXL3-OT (p=1.87E-8), MCPH1-AS1(p=2.69E-8), and DDAH1 (p=2.97E-8). We also identified a fourth gene, DNAH14 (p=3.52E-7), that was borderline significant but still showed a strong trend towards association with ASD. FOXL3-OT is an antisense RNA gene located on chromosome 1p31.3 that has been implicated in various biological processes, including cell differentiation and development. DDAH1 is involved in the regulation of nitric oxide synthesis, which is important for neuronal development and function, including neuronal synaptogenesis and synaptic pruning. MCPH1-AS1 is an antisense RNA gene that has been linked to microcephaly, a condition characterized by a small head circumference that is associated with cognitive impairment. Finally, DNAH14 encodes a protein involved in the movement of cilia, which are essential for the development and function of various organs, including the brain. While the exact mechanisms by which these genes contribute to ASD are still unclear, our findings suggest that they may play a role in the development and function of the brain. Further studies will be needed to fully understand the functional consequences of the genetic variants we have identified. In conclusion, our GWAS meta-analysis has identified several novel genes associated with ASD in ethnically diverse patients, providing new insights into the biological basis of this complex disorder. Our results may ultimately lead to the development of new diagnostic and therapeutic strategies for individuals with ASD.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1676 Multi-modal characterization of type 2 diabetes in Project Baseline beyond clinical diagnosis

Authors:

A. Breschi, Y. Wang, S. Short, W. Luk, P. Kheradpour, P. Cimermancic, G. J. Tong, J-P. Martin, M. Liu, L. Cao, D. Liu, A. Han, K. A. Drake, C. C. Kim; Verily Life Sci., South San Francisco, CA

Around 11% of the US adult population, 28 million people, have been estimated to have type 2 diabetes, with 3% more, 8.5 million people, estimated to be undiagnosed. The main clinical diagnostic tools are measurements of glycated hemoglobin (HbA1c) in blood and blood glucose level, fasting or in response to a glucose oral tolerance test. Understanding the disease at the molecular level is paramount to improve diagnosis and prevention. The Project Baseline Health Study longitudinally performed deep phenotypic, clinical and molecular profiling for 2,502 volunteers.Comprehensive profiling included demographics, medical history, laboratory tests, echocardiograms, physical assessments, lifestyle monitoring through a proprietary smart watch and multi-omics assays. Of these, 957 participants had sufficient clinical and proteomics data from their initial visit. We integrated information from the participants' medical history and laboratory tests to determine their diabetes status, so we could identify biomarker plasma proteins of diabetes. By integrating clinical and molecular data, we trained a logistic regression classifier that better discriminated between diabetic and normoglycemic individuals as compared to clinical and proteomics data alone. We identified 85 high confidence differentially expressed proteins in diabetics. Of these, 71 were upregulated in diabetics; are involved in lipid transport, inflammation, and blood coagulation; and appeared to be transcribed in distinct liver zones. By clustering the participants on their clinical and molecular profiles, we noticed that inflammation-related proteins were also present in overweight normoglycemic participants with diabetic-like proteomics profile, and that this profile was associated with worse physical performance and cardiac health as measured by orthogonal signals. We observed that proteomics data can be used to predict diabetes status with balanced accuracy over 85% when used in combination with clinical data. We showed that molecular data can enhance diabetes phenotyping obtained with clinical data, suggesting that a more holistic approach to diabetes diagnosis, beyond HbA1c and glucose measurements, might help identifying people with diabetes or metabolic alterations, and target them with personalized treatments or interventions.

PB1677 Multiomic association network: Capturing cardiovascular disease complexity with the genomic, metabolomic, drug treatment, and disease features.

Authors:

M. Aguilar[1], M. A. Hall[2]; [1]Penn State Univ., State College, PA, [2]The Pennsylvania State Univ., State College, PA

In the US, the prevalence of cardiovascular disease (CVD) in adults ≥ 20 years of age was 48.6% overall (127.9 million in 2020). CVD encompasses various phenotypes: stroke, heart disease, hypertension, diseases of the veins, peripheral artery disease, and others. Previous genome-wide association studies revealed that CVD has a complex genetic architecture that can be understood by analyzing molecular components underlying the trait. Metabolomics (a collection of small quantified molecules) studies intermediate molecular traits to be used as markers of CVD. Commonly prescribed drugs for CVD have metabolic on- or off-target effects that require mapping; this is crucial in generating new drug efficacy and repurposing hypotheses. Thus, the following domains, metabolomic, drug treatment, and disease phenotypes were evaluated in our study to supplement our understanding of complex diseases beyond their genetic basis. The statistically significant results from association tests between domain features can be organized into a network to generate new hypotheses about the features' roles in disease development. We used data from the LUdwigshafen RIsk and Cardiovascular Health (LURIC) study because it investigated the metabolic and genetic risk factors of CVD, and each sample had data on all four domains of interest (drugs, metabolites, and genomic single nucleotide polymorphisms (SNPs) used to build our association network. We ran nine regression analyses cumulatively yielded 3,254 statistically significant results (total tests: 183,520,500). Each regression analysis had a Bonferroni corrected significance threshold ($\alpha = 0.05$) divided by the number of outcomes (5×10^{-8} divided by the number of outcomes for GWAS). The network was analyzed with clustering coefficient, betweenness centrality, and PageRank algorithms to identify network hubs. Dyslipidemia disease was the top-ranked feature in the network (1054 significant results, i.e., 732 in-degrees and 322 out-degrees) according to betweenness centrality and PageRank measurements; this indicated that dyslipidemia was central to CVD and had associations across the genomic, metabolic, and drug domains. New genome-metabolite associations related to collagen synthesis and cell proliferation may describe CVD's coronary and vascular structural changes. When targeting genes is not feasible as a therapy, an association network offers new hypotheses on targetable molecular traits. Results show how a high-dimensional search space can be narrowed to identify features for future multi-factor risk models of complex diseases.

PB1678 Multi-omic integration uncovers biological pathways underlying HIV viral load

Authors:

K. Sullivan[1], I. Miller[1], B. C. Quach[2], C. Willis[3], M. R. Garvin[1], A. Townsend[4], P. Kruse[4], M. Lane[4], D. Kainer[1], M. Cashman[1], K. Xu[5], B. E. Aouizerat[6], D. B. Hancock[2], D. A. Jacobson[1], E. O. Johnson[7]; [1]Oak Ridge Natl. Lab., Oak Ridge, TN, [2]RTI Intl., Durham, NC, [3]RTI Intl., Carrboro, NC, [4]Univ. of Tennessee-Knoxville, Knoxville, TN, [5]Yale Sch. of Med., New Haven, CT, [6]New York Univ., New York, NY, [7]RTI Intl., Duluth, MN

While antiretroviral therapy (ART) has significantly improved disease prognosis in people living with HIV (PLWH), substance use in these individuals can increase HIV/AIDS viral load and accelerate disease progression. It is critical to understand the biological mechanisms underlying HIV viral load to understand how to prevent substance use from exacerbating HIV disease progression. Here, we integrated multi-omic datasets and used machine learning network biology tools to identify biological mechanisms associated with HIV viral load across 10 cohorts: the Veterans Aging Cohort Study (VACS; n = 2,465), Swiss HIV Cohort (n = 198), and 7 cohorts of whole-genome sequencing data used to obtain an MHC locus fine mapping reference panel (n = 21,546). We integrated three genes from HIV set point viral load GWAS using fine mapping from WGS data (*HLA-A*, *HLA-B*, *HLA-C*), 258 differentially expressed genes in CD4+ T-cells associated with HIV viral load from the Swiss HIV Cohort, 143 genes based on differential DNA methylation status from the VACS cohort, and 8 genes known to affect the pharmacokinetics of anti-HIV drugs (*ABCC2*, *CYP2A6*, *CYP2B6*, *CYP2C9*, *CYP2C19*, *CYP3A4*, *SLCO1B1*, and *UGT1A1*). Using our network biology tool GRIN, we retained 194 genes related to HIV viral load based on their network topological connectivity to one another. Next, we used our recently developed Functional Partitioning tool to identify functional network relationships among our multi-omic viral load genes, based upon hierarchical clustering of multiplex network random walk-based vector comparisons among genes in the gene set. We identified three large clades of highly inter-connected genes based on these network topology-based vector comparisons. Within the first clade, we identified genes known to be involved in cell cycle checkpoints, DNA repair, and epigenetic modifications to histones. In the second clade, we identified genes known to be involved in mitochondrial function and oxidative stress. In the third clade, we identified genes known to be involved in viral replication and host antiviral response. Across all clades we identified several host genes known to physically interact with HIV viral proteins. The empirically derived, densely connected, network is highly enriched for gene sets linked to non-AIDS defining cancers. Together, we demonstrate that multi-omic integration using network biology tools can identify biological pathways and create a conceptual model of the mechanisms underlying HIV viral load that would not have been identified with the use of a single omics data type.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1679 Multi-omics analyses to prioritise genes at migraine risk loci.

Authors:

A. Ghaffar, The International Headache Genetics Consortium, D. Nyholt; Queensland Univ. of Technology, Brisbane, Australia

Migraine—a painful, throbbing headache disorder that can cause nausea, vomiting, and sensitivity to light and sound—is the most common brain disorder, affecting almost 14% of the adult population. Genome-wide association studies (GWAS) have proven successful in identifying migraine risk loci. However, most of the GWAS risk variants are in non-coding regions, hence they act by altering the regulatory mechanism such as gene expression. Epigenetic mechanisms such as methylation have also been reported to be associated with migraine. Utilizing data from the largest known migraine GWAS (Hautakangas et al. 2022), which comprised 102,084 migraine cases and 771,257 controls and identified 171 independent single nucleotide polymorphism (SNP) risk loci significantly associated with migraine, we performed an imputation-based transcriptome-wide association study (TWAS), to identify genetically regulated gene expression (eQTLs) associated with migraine. We used SMultiXcan (a gene-based TWAS approach that leverages the correlation of eQTLs across tissues) and prediction models generated from 49 GTEx tissues to impute differential expression associated with migraine for 21,647 genes. Of the 21,647 genes, 244 were study-wide significant at the Bonferroni adjusted threshold of $P < 2.31 \times 10^{-6}$, of which 212 genes were within ±1 Mb of one of the 171 independent SNP risk loci from Hautakangas et al. (2022). We also performed a methylome-wide association study (MWAS) which integrates GWAS and DNA methylation (mQTL) data to discover the genetically regulated DNA methylation sites (CpGs) associated with migraine. We used EstiMeth and prediction models from blood to impute differential methylation associated with migraine for 86,518 CpGs. Of the 86,518 CpGs, 258 were significant at the Bonferroni adjusted threshold of $P < 5.78 \times 10^{-7}$. The 258 CpGs mapped to 115 genes, of which 227 CpGs mapping to 99 genes were within ± 1 Mb of an independent risk SNP from Hautakangas et al. (2022). Notably, 43 genes at 33 loci were implicated by both the TWAS and MWAS analysis, suggesting genome-epigenome-transcriptome mechanistic relationships. Colocalization analyses of the migraine GWAS risk SNPs with the associated eQTL and mQTL within these genes will be completed by October 2023, to further characterize the likely functional consequence of these migraine risk loci.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1680 Multi-omics approaches reveal key molecular signature of severe obesity

Authors:

Sch. of Med., Boston, MA, [6]Icahn Sch. of Med. at Mount Sinai, New York, NY, [7]Geisinger Hlth., Danville, PA, [8]The Pennsylvania State Univ., University Park, PA, [9]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX, [10]Univ. of London, London, United Kingdom, [11]The Univ. of Texas Hlth.Sci. Ctr. at Houston Sch. of Publ. Hlth., Brownsville Regional Campus, Brownsville, TX, [12]Univ. of Cambridge, Cambridge, United Kingdom, [13]Univ. of Texas Hlth.Sci. Ctr. at Houston Sch. of Publ. Hlth., Brownsville Regional Campus, Brownsville, TX

Background: Severe obesity [body mass index (BMI) $\geq$ 40 kg/m^2] is a driver of many cardiometabolic diseases, and disproportionately impacts marginalized populations, including Hispanic/Latinos, yet we know little about its underlying mechanistic pathways. Multi-omic analyses can link genetic variation and disease, highlighting pathways for targeted therapeutic intervention, but have not been fully leveraged for studying severe obesity.
Methods: We deployed integrative multi-omics approaches in whole blood to enable discovery of new genes involved in severe obesity in Mexican Americans from the Cameron County Hispanic Cohort (CCHC). First, using RNA-sequencing data for 49 severe obesity cases and 81 controls (BMI < 25 kg/m^2) from CCHC, we assessed differential expression using DESeq2 and performed Mendelian randomization to estimate causality. We replicated our top findings in an independent sample of 52 cases and 59 controls from CCHC. We validated our transcriptomic results using proteomic data for 49 cases and 42 controls from the CCHC and explored the specificity of detected effects by leveraging gene expression data from abdominal subcutaneous adipose tissue from 19 community volunteers from New York City, New York. Lastly, we tested for enrichment of associations of genetically regulated expression of our identified genes with obesity-related diseases in a large electronic health record-linked biobank, BioVU, N=70k.
Results: We identified 124 significantly differentially expressed genes after false discovery rate correction (FDR <0.05), of which 33% replicated, and 22% of those measured showed differential protein abundance associated with severe obesity. Top genes included *C1RL*, *IL4R*, *RGS16*, *OSM*, and *SDC2*. Twenty-six of the differentially expressed genes showed correlation with BMI in abdominal subcutaneous adipose tissue in a diverse independent sample. Transcripts with causal effects on severe obesity also showed enrichment for causal impacts on sequelae of obesity, including hyperlipidemia and obstructive sleep apnea, in BioVU.
Conclusion: We provide compelling evidence for genes whose expression is associated with severe obesity in an underrepresented and disproportionately impacted population, observing highly concordant effects in an independent replication, generalization of effects in abdominal subcutaneous adipose with BMI, and translation effects in the proteome. Our findings illuminate new mechanisms of risk and consequences of severe obesity, revealing novel targets for prevention, intervention, and treatment.

PB1681 Multi-omics in nasal epithelium reveals three axes of dysregulation for asthma risk in the African Diaspora populations

Authors:

B. Szczesny[1], M. Boorgula[2], M. Campbell[3], R. Johnson[4], K. Kammers[5], I. Ruczinski[6], S. Chavan[2], C. Figueiredo[7], C. N. Rotimi[8], C. R. Landis[9], H. Watson[10], N. Hansel[1], I. Yang[11], C. Olopade[12], C. Ober[13], A. Liu[11], E. Kenny[14], M. Taub[15], K. Barnes[2], R. Mathias[16]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Univ. of Colorado Denver, Denver, CO, [3]Univ. of Colorado, Aurora, CO, [4]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [5]Johns Hopkins Univ Sch. of Med., Baltimore, MD, [6]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [7]Federal Univ. of Bahia, Salvador, Brazil, [8]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [9]Caribbean Inst. for Hlth.Res., The Univ. of the West Indies, Bridgetown, Barbados, [10]The Univ. of the West Indies, Queen Elizabeth Hosp., Bridgetown, Barbados, [11]Univ. of Colorad Denver, Denver, CO, [12]Univ. of Chicago Med., Chicago, IL, [13]Univ. of Chicago, Chicago, IL, [14]Icahn Sch. of Med. at Mount Sinai, New York, NY, [15]Johns Hopkins, Baltimore, MD, [16]Johns Hopkins Univ, Baltimore, MD

Asthma, a complex chronic lung disease affecting the airways, has striking disparities, but the molecular underpinning of these differences is poorly understood and minimally studied. A major goal of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to use multi-omics to address this gap. RNASeq and DNA methylation data (DNAm) were generated from nasal epithelium (NE) in subjects recruited from 7 sites (US: Baltimore, Washington DC, Chicago, Denver; international: Salvador Brazil, Barbados, and Nigeria). Current asthma cases (N=253) were compared to never-asthma controls (N=283) to identify DEGs. Network analyses were performed with Ingenuity Pathway Analysis (IPA) and weighted gene co-expression network analysis (WGCNA). DNAm data were used to identify eQTMs for DEGs limiting to CpGs ≤5kb from the transcription start site or within enhancer regions identified by promoter-capture HiC in bronchial epithelial cells. CpGs from significant eQTMs were tested for differential methylation by asthma to assess the contributions of expression and methylation in asthma risk. All models were adjusted for ancestry, sampling site, and appropriate latent factors.
We identified 389 DEGs; the top DEG, FN1, was downregulated in asthma cases (q=3.26x10-9) and encodes fibronectin which plays a role in wound healing. Other top 10 DEGs are highly relevant for asthma: SNTG2 (q = 1.12x10-4) is the target of multiple miRNAs related to asthma; PPP1R9A expression (q=7.60x10-5) was previously found to be influenced by IL-13 in mouse lung; and SPTBN1 (q=1.12x10-4) plays a role in mediating TGFβ signaling. IPA revealed upstream regulators relevant for immune response (IL4; p=7.25x10-10 and TGFβ1; p=5.47x10-8) and drug response (dexamethasone; p=4.31x10-10 and fluticasone propionate; p=9.42x10-8). The top three WGCNA modules implicate networks related to immune response (CEACAM5; p=9.62x10-16 and CPA3; p=2.39x10-14) and wound healing (FN1; p=7.63x10-9). Multi-omic analysis identified FKBP5 as a key contributor to asthma risk, whereby the association between nasal epithelium gene expression is mediated through methylation and is associated with increased use of ICS. FKBP5 is a co-chaperone of glucocorticoid receptor signaling and known to be involved in drug response in asthma.
Our analyses reveal genes and networks differentially expressed in NE of asthma cases of African ancestry in CAAPA. Importantly, this work reveals molecular dysregulation on three axes - increased Th2 inflammation, decreased capacity for wound healing, and impaired drug response - that may play a critical role in asthma within the African Diaspora.

PB1682 † Multi-organ genetic causal connections inferred from imaging and clinical data through Mendelian randomization

Authors:

J. Shu[1], R. Zheng[2], C. Copana[1], B. Li[1], Z. Fan[3], X. Yang[4], Y. Yang[3], X. Wang[1], Y. Li[1], B. Xi[1], T. Li[5], H. Zhu[6], B. Zhao[7]; [1]Purdue Univ., West Lafayette, IN, [2]First Hosp. of Shanxi Med. Univ., Taiyuan, China, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]Purdue Univ., Lafayette, IN, [5]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [67]Univ. of Pennsylvania, Dept. of Statistics and Data Sci., Philadelphia, PA

Functional and morphological architectures of major human organs have been well characterized using imaging biomarkers. Nevertheless, deciphering the causal relationships between imaging biomarkers and major clinical outcomes, as well as understanding the causal interplay across multiple organs, remains a formidable challenge. Mendelian randomization (MR) presents a framework for inferring causality by using genetic variants as instrumental variables. Here we report a systematic multi-organ MR analysis between 402 imaging biomarkers and 88 clinical outcomes. We identified 488 genetic causal links for 62 diseases and 130 imaging biomarkers from 9 organs, tissue, or systems, including the brain, heart, liver, kidney, lung, pancreas, spleen, adipose tissue, and skeleton system. We prioritized crucial intra-organ causal connections, such as the bidirectional genetic links between Alzheimer's disease and brain function, as well as inter-organ causal effects, such as the adverse impact of heart diseases on brain health. Our findings uncover the genetic causal links spanning multiple organs, offering a more profound understanding of the intricate relationships between organ imaging biomarkers and clinical outcomes. We have made our database publicly available and developed a browser framework to facilitate the exploration of MR findings of multi-organ images (http://mr4mo.org/).

Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Background: Multiple infectious agents have been identified as risk factors for Alzheimer's disease (AD). Viruses can cause inflammatory damage and potentially increase the formation of the AD hallmark proteins amyloid-β protein and hyperphosphorylated tau. We and others previously reported association between AD and the quantity of whole genome and whole exome sequence reads mapping to herpes simplex type 1 (HSV-1), human herpes virus 6B (HHV-6B) and human papilloma virus 71 (HPV-71). Here, we conducted GWAS using these viruses to identify genetic associations that 1) affect viral load and 2) modify the effect of viral load on AD risk. **Methods:** DNA sequence reads that did not align to the human genome in whole exome and whole genome sequences generated by the Alzheimer Disease Sequencing Project from 57,000 AD cases and controls from multiple populations (European ancestry (EA), Caribbean Hispanic (CH), and African American) were mapped to 318 viral reference sequences and quantified. After quality control, there were 4,298 sequences derived from brain (AD cases= 3,404, controls= 894) and 40,156 sequences derived from blood (AD cases=15,612, controls=24,544). Two GWAS models for each virus were tested: 1) viral load ~ SNP + sex + age + tissue source and 2) AD ~ SNP + viral load + SNP*viral load + sex + age + tissue source. **Results**: We observed genome-wide significant (GWS) associations between HSV-1 presence and *HLA-DQA1* SNP rs28654242 (OR=3.01, P=2.15x10^{-8}) with HPV-71, *POTEE* SNP rs199606922 (OR=2.03,P=1.91x10^{-8}), and *USP49* SNP rs201585090 (OR=0.26, P=1.28x10^{-8}) , and between HHV-6B and *CASS4* SNP rs6014724 (Beta=5.52, P=1.26x10^{-4})and rs16941239 near *FOXF1* (Beta=6.93, P=5.95x10^{-4}), all in CHs. The *CASS4* and *FOXF1* SNPs were previously associated with AD risk. We also observed, in EAs, GWS interactions between HSV-1 presence and rs201217710 in *ABCC2* (OR= 0.15, P=3.28x10^{-8}), rs113432200 in *KMT2C* (OR=0.54, P=2.11x10^{-8}), and rs62345265 in *FRG1* (OR=0.65, P=5.56x10^{-11}) predicting AD risk. **Conclusions:** These findings provide further evidence for the role of herpes viruses in the pathogenesis of AD and highlight the importance of genetic factors in modulating these associations.

PB1684 Multi-trait analysis characterizes the genetics of thyroid function and identifies causal associations with clinical implications

Authors:

A. Teumer[1,2], R. B. T. Sterenborg[3,4], I. Steinbrenner[5], Y. Li[5], M. N. Bujnis[6], T. Naito[7], E. Marouli[8], M. Medici[4], ThyroidOmics Consortium; [1]Univ. Med. Greifswald, Greifswald, Germany, [2]DZHK (German Ctr. for Cardiovascular Res.), partner site Greifswald, Greifswald, Germany, [3]Dept. of Internal Med. Radboud Univ. Med. center, Nijmegen, Netherlands, [4]Academic Ctr. for Thyroid Diseases, Erasmus Med. Ctr., Rotterdam, Netherlands, [5]Faculty of Med. and Med. Ctr., Univ. of Freiburg, Freiburg, Germany, [6]The Univ. of Utah, Salt Lake City, UT, [7]Osaka Univ. Graduate Sch. of Med., Suita, Japan, [8]William Harvey Res. Inst., Barts and The London Sch. of Med. and Dentistry, Queen Mary Univ. of London, London, United Kingdom

Thyroid function tests based on thyrotropin (TSH) are among the most frequently ordered biochemical tests for assessing thyroid dysfunction, a common disorder with a prevalence of ~5% in the general population. Thyroid hormones including thyroxine and triiodothyronine (T3) play a key role in cellular growth, development and metabolism. Genetic factors are responsible for up to 58-71% of the variation in TSH and free thyroxine (FT4). We conducted a genome-wide association study meta-analysis of thyroid function in up to 271,040 individuals of European ancestry, including reference range TSH, FT4, free and total T3, and proxies for metabolism (T3/FT4 ratio). Secondary analyses included colocalization with mRNA levels using GTEx, polygenic risk score analysis on clinical endpoints, and Mendelian randomization on thyroid function-related outcomes including thyroid cancer. We revealed 198 loci associated with TSH (84 novel), 84 loci associated with FT4 (45 novel), and 29 novel loci for the T3 related traits. The loci explained 14.1%, 6.0%, 10.9% and 1.1% of the variation in TSH, FT4, total and free T3 concentrations, respectively. Genetic correlations strongly suggest that TSH associated loci reflect the thyroid function determined by the active thyroid hormone T3, whereas FT4 as well as free and total T3 loci reflect the thyroid hormone metabolism. Colocalization with FT4 revealed genes expressed in various peripheral tissues, where TSH-associated genes were predominantly expressed in the thyroid including multiple genes with a known role in the TSH signaling cascade and thyroid hormone synthesis, such as *PDE8B, PDE10A, TPO* and *GLIS3*. Polygenic risk score and Mendelian randomization analyses showed the effects of genetically determined variation in thyroid function on various clinical outcomes, including cardiovascular risk factors and diseases, autoimmune diseases, and cancer.

Our study increased the number of loci discovered for the most important thyroid function parameters, improved our understanding of the genes altering mRNA expression in different tissues and their contributing effects in various pathways influenced by thyroid function parameters. Furthermore, it provides a comprehensive overview of the effects of genetically determined variation in thyroid function on many known and newly suggested clinical outcomes. This could foster possibilities for using genetics in prevention and diagnosis, and to identify candidates for therapeutic targets to reduce the burden of thyroid diseases.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1685 Multi-trait analysis of GWAS identifies 52 novel genomic loci associated with circulating polyunsaturated fatty acids

Authors:

H. Xu[1], J. Xue[1,2], Y. Sun[3], K. Ye[1,4]; [1]Dept. of Genetics, Univ. of Georgia, Athens, GA, [2]Coll. of Life Sci., Wuhan Univ., Wuhan, China, [3]Dept. of Genetics, Univ. of Goergia, Athens, GA, [4]Inst. of Bioinformatics, Univ. of Georgia, Athens, GA

BACKGROUND: Polyunsaturated fatty acids (PUFAs) play crucial roles in a wide variety of physiological processes and have been implicated in the development and prevention of various diseases, such as cardiovascular diseases and psychiatric disorders. Despite the identification of hundreds of genomic loci for circulating PUFA (cPUFA) levels through single-trait genome-wide association studies (GWAS), these loci account for only a small fraction of cPUFA variance. **METHODS:** To address this limitation, we employed a multi-trait analysis of GWAS (MTAG) by leveraging GWAS summary statistics of 11 cPUFAs (N=114,999) from UK Biobank. The 11 PUFA traits include total PUFAs, omega-3, omega-6, docosahexaenoic acids (DHA), linoleic acid (LA), and their relative percentages in total fatty acids. To prioritize genes related to cPUFAs and gain insights into the biological roles of significant loci, we performed functional annotation and gene set enrichment analysis using FUMA. Additionally, we conducted a colocalization analysis of MTAG summary statistics with HyPrColoc to identify genomic regions and potential causal variants shared among cPUFA traits. **RESULTS:** Our MTAG analyses identified 420 genomic loci that are significantly associated with 11 cPUFAs, including 52 novel discoveries. Functional annotation and gene set enrichment analysis identified 1,947 candidate genes, which are enriched in lipid-related pathways ($P < 3.2\times10^{-6}$) and highly expressed in the liver (FDR adjusted $P < 0.05$). Furthermore, our pairwise colocalization analysis detected 2,054 genomic regions (posterior probability > 0.7) colocalized among multiple cPUFAs. We identified 540 unique SNPs that could potentially serve as shared causal variants, indicating a pleiotropic effect of certain loci on multiple cPUFA traits. The highest number of shared loci was observed between omega-6 and PUFA, totaling 124, whereas the omega-6 to omega-3 ratio and PUFA% exhibited the fewest shared loci, with only 9. Notably, a few pairs, such as DHA% and PUFA, had 5 colocalized regions with the same effect directions and 6 with opposite directions. This finding helps explain the observed low genetic correlation between these traits, as the genetic effects canceled each other out when estimating the overall correlation across the genome. **CONCLUSION:** Our multi-trait GWAS identifies 52 novel genomic loci associated with 11 circulating levels of PUFAs. These findings enhance our understanding of the genetic basis of PUFAs and pave the way for further investigation into their associations with other diseases.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1686 Multi-trait investigation of inflammation-associated DNA methylation among people with HIV

Authors:

J. Chen[1], Q. Hui[2], B. Titanji[1], K. So-Armah[3], M. Freiberg[4], A. Justice[5], K. Xu[6], X. Zhu[7], M. Gwinn[1], V. Marconi[1], Y. Sun[2]; [1]Emory Univ., Decatur, GA, [2]Emory Univ., Atlanta, GA, [3]Boston Univ., Boston, MA, [4]Vanderbilt Univ., Nashville, TN, [5]Yale Univ., New Haven, CT, [6]Yale Sch. Med., New Haven, CT, [7]Case Western Reserve Univ., Shaker Heights, OH

Inflammation is one of the primary causes for the excess morbidity and mortality among people with HIV (PWH). A handful of epigenome-wide association studies (EWAS) have suggested that inflammation is associated with DNA methylation (DNAm) among PWH. Although many inflammatory markers may share a common physiological pathway, current EWAS usually study one trait at a time. Multi-trait EWAS that analyze multiple inflammatory markers can further improve statistical power in detecting DNAm and help provide an interpretation of shared epigenetic architecture between inflammatory markers. We conducted a multi-trait EWAS investigation of three inflammatory markers including soluble CD14, D-dimers, and interleukin 6 in a subset of PWH in the Veteran Aging Cohort Study that collected biomarker data 2005-2007 (n = 920). The study population are all males with an average age of 52 years old, and 85% self-reported as Black. EWAS summary statistics for individual markers were obtained by linear mixed models using DNA methylation as the outcome, inflammatory marker as the exposure, and chip ID as random effect to adjust for batch effect. All models were adjusted for concurrent age, race/ethnicity, viral load, antiretroviral therapy, smoking, BMI, diabetes, hepatitis B/C viral infections, and cell type proportions. We applied both methods CPASSOC and OmniTest to EWAS summary statistics for individual markers. CPASSOC is a meta-analysis method accounting for the correlations induced by correlated traits and overlapping samples. OmniTest is an aggregated Cauchy association test that combine p-values from multiple tests including the minimum of the p-values approach, generalized Berk-Jones test and the generalized higher criticism test. CPASSOC and OmniTest identified 189 and 157 inflammation-associated DNAm sites including 112 overlapping DNAm sites. Among the total 234 DNAm sites identified, 132 had not been reported as significant in any single-marker EWAS. We showed that CPASSOC tends to identify DNAm sites that are associated with all 3 inflammatory markers while OmniTest prioritizes strong signals from single-marker EWAS. Top DNAm sites were mapped to inflammation-related genes such as *IFITM1*, *PARP9*, *NLRC5*, *PSMB8* and *STAT1*. These genes were significantly enriched in pathways such as “type I interferon signaling” and “immune response to virus”. In conclusion, our results show that multi-trait EWAS can increase statistical power to identify inflammation-associated DNAm sites, genes, and pathways. These DNAm sites suggest molecular mechanisms underlying the accelerated aging and the elevated chronic disease burden observed among PWH.

PB1687 Mutations in Cardiomyopathy Genes are Enriched in Pediatric Postural Orthostatic Tachycardia Syndrome

Authors:

H-Q. Qu[1], J. Glessner[1], X. Chang[1], F. Mentch[1], Y. Liu[1], M. Bakay[1], J. Boris[2], H. Hakonarson[1,3]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Jeffrey R. Boris, MD LLC., Philadelphia, PA, [3]The Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Introduction: Postural orthostatic tachycardia syndrome (POTS) is a severe disorder with significant functional impairment and psychological distress to the patients, warranting development of new and effective treatments. However, the etiology of POTS is poorly understood, and has been largely regarded as a form of dysautonomia. **Hypothesis:** POTS is a complex genetic disease requiring integrative sequencing and translational approaches to identify its genetic underpinning and better understand its pathogenesis with the aim at promoting the development of novel precision-based therapies. **Methods:** There are numerous chronic health conditions in adults associated with the risk of POTS. We studied a unique collection of pediatric POTS subjects including 87 unrelated European cases (61 females and 26 males, 6~21 years old). We adopted exome sequencing to identify pathogenic (P) or likely pathogenic (LP) mutations in these POTS patients with POTS patients. **Results:** Whole exome sequencing of the 87 patients resulted in 8 patients identified each with a heterozygous LP mutation (classified by InterVar) involving a cardiomyopathy gene, including 6 titin (*TTN*, related to dilated cardiomyopathy) mutations (exon188 R26587Q, E26494Q; exon154 I19603V, S19023N, S15470Y; and exon46 K4455R), 1 ryanodine receptor 2 (*RYR2*, related to catecholaminergic polymorphic ventricular tachycardia) mutation (exon21 S756N), and 1 myosin heavy chain 7 (*MYH7*, related to hypertrophic cardiomyopathy) mutation (exon21 R787C). Compared to the frequencies in the Non-Finnish European (gnomAD v3.1) dataset, the POTS LP mutations are significantly enriched in the *TTN* gene (Fisher's exact *P*=1.00E-05), as well as in the three cardiomyopathy genes (Fisher's exact *P*=6.98E-08). In addition to the 3 genes with LP mutations, we also identified rare coding variants with predicted deleterious effects in a number of other genes related to cardiomyopathy in the POTS cases, demonstrating significant *P* value by over-representation analysis (ORA) of gene sets, including some drug target genes. The LP variants of interest were functionally characterized in both cell based assays and *in silico*. **Conclusion:** Our results suggest, for the first time, that POTS may be a clinical manifestation of non-penetrant mutations in cardiomyopathy genes. Further study is warranted to clarify how these mutations contribute to atypical structural or functional changes of the heart in these patients. Several of these mutation profiles involve drug-gene targets and may help promote new therapeutic development for this disabling disorder.

PB1688 New Histological Approach in Spatial Transcriptomics Implicates Glandular Cell Involvement in Pathophysiology of Sjögren's Disease

Authors:

C. Lessard[1], P. Czarnota[1], R. Wilbrink[2], B. Khatri[1], A. M. Stolarczyk[1], C. Pritchett Frazee[1], C. Li[1], M. C. Marlin[1], K. Wright[3], K. L. Tessneer[1], L. Radfar[4], J. A. James[1], R. H. Scofield[1], I. Adrianto[5], A. Rasmussen[1], J. M. Guthridge[1], A. D. Farris[1]; [1]Oklahoma Med. Res. Fndn., Oklahoma City, OK, [2]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [3]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, [4]Univ. of Oklahoma Coll. of Dentistry, Oklahoma City, OK, [5]Henry Ford Hlth., Detroit, MI

Background: 10X Visium spatial transcriptomics evaluates gene expression in a 50um tile coordinate of a sectioned tissue, yielding heterogeneous cell sampling. Spatial PCA algorithm used homogenous tissue types with distinct boundaries to identify like tissue regions and determine the cellular context of spatial coordinates [1]. It is less effective at differentiating like tiles from heterogenous tissue types such as the Sjögren's disease (SjD) target tissue, minor salivary gland (MSG). This study introduces a novel algorithm, HistoPCA, that connects pathologically annotated and segmented images with spatial coordinates to group like tiles based on similar cellularity.
Methods: Histopathological images of minor salivary gland biopsies were annotated by tissue type (fibrosis, glandular, inflammatory, fat). Annotations were combined with spatial coordinates using HistoPCA. Image segmentation was used to obtain cell numbers in tiles. Segmentation data was combined with pseudo-color percentages associated with certain tissue types to perform unsupervised KMeans clustering. SjD case-control differential expression (DE) was analyzed using pseudo-bulk gene expression, then DE transcripts were analyzed by Ingenuity Pathway Analysis.
Results: HistoPCA and UMAP with KMeans clustering outperformed Spatial PCA (Adjusted Rand Index (ARI) of 0.52 vs. 0.51), identifying four distinct clusters in MSG. Despite distinct features like inflammation in Cluster 1 (21% inflammatory, 32% fibrosis, 23% glandular tiles) and increased glandular involvement in Cluster 3 (0% inflammatory, 48% fibrosis, 41% glandular tiles), DE and pathway analyses showed similar patterns of dysregulation in SjD cases (n=28) compared to controls (n=16). As a positive control, elevated interferon signatures were observed in all SjD cases and anti-Ro positive SjD cases (n=19). Other immune pathways (T cell receptor, Th1, Th2, and IL-4 signaling, etc.) were also upregulated in SjD cases while CTLA4, IL-10, and IL-12 signaling pathways were downregulated.
Conclusions: HistoPCA successfully grouped like tiles from spatial transcriptomic analysis of heterogeneous MSG. Cluster annotation of HistoPCs, followed by DE and pathway analyses identified four clusters with dysregulated immune pathways in SjD. Dysregulated immune pathways in Cluster 3 (devoid of tiles associated with inflammation) implicate glandular involvement in SjD pathogenesis. Spatially aware technology will provide new insights into the role of different cell/tissue types in SjD pathobiology of the salivary gland.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1689 New Insights into Genetic Factors Associated with Helicobacter pylori Infection: A Large-Scale GWAS in Japan

Authors:

T. KYOSAKA[1], A. Narita[2], G. Tamiya[1,2]; [1]Tohoku Univ. Sch. of Med. AI and Innovative Med., Sendai, Japan, [2]Tohoku Univ. Tohoku Med. Megabank Organization, Sendai, Japan

Background & Aims

Preventing *Helicobacter pylori* (*H. pylori*) infection is crucial for reducing the risk of gastric cancer. Although susceptibility to *H. pylori* is known to be influenced by genetic factors, large-scale genome-wide association studies (GWAS) have yet to be conducted in Asia, where infection rates are relatively high. In this study, we conducted a large-scale GWAS on a Japanese cohort with the aim of elucidating the genetic background associated with *H. pylori* infection.

Methods

We analysed data from 100,362 individuals from the Tohoku Medical Megabank (TMM) Project database, which included both genomic information and serum anti-*H.pylori* IgG antibody titres. The top 25% of individuals with the highest IgG antibody titres were defined as cases, with the remaining 75% serving as controls, for the purposes of conducting GWAS and fine mapping.

Results

Our GWAS identified several new loci associated with *H. pylori* infection. The most strongly associated variant was rs9273002 (P = 3.32e-27), located downstream of the HLA-DQA1 gene on chromosome 6 at position 6p21.32. Fine mapping revealed significant associations with rs13194769 (P = 1.13e-39), located near HLA-DRB9, and rs1130399 (P = 5.07e-12), situated in the exon region of HLA-DQB1. Alongside these novel loci, significant associations were also observed with variants at loci 8q24.3 (P = 4.94e-8), which have previously been implicated in gastric cancer.

Conclusions

Our large-scale GWAS has revealed new genetic loci associated with *H. pylori* infection. Notably, we found a strong association within the HLA region; these genetic variations may partially explain individual variability in risk for *H. pylori* infection. Future work will involve conducting a cross-ancestry meta-analysis with existing studies on populations of European ancestry to explore the genetic factors associated with *H. pylori* infection in different populations.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1690 New phenotyping approaches are essential to advance genetic discovery for psychiatric disorders.

Authors:

J. Thorp, Z. Gerring, E. Derks; QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Genome-wide association studies have revolutionised the study of genetic factors underlying psychiatric disease and led to the identification of hundreds of robustly associated genetic variants for many disorders. There are, however, several characteristics of psychiatric disorders that complicate genetic studies and the complete understanding of the genetic basis of psychopathology. I will discuss two core themes in psychiatric genetics: pleiotropy and heterogeneity.

Pleiotropy between psychiatric disorders is widespread and pervasive. I will present some of our recent work that has found extensive genetic overlap between disorders at genome-wide, regional, and transcriptomic levels. Furthermore, I will discuss work that has investigated whether the extreme clinical heterogeneity observed in patients is recapitulated at a genetic level, and present recent evidence of genetic heterogeneity in patients with major depressive disorder.

The substantial heterogeneity within and pleiotropy between psychiatric disorders challenges the utility of studying psychopathology as categorical and distinct disorders that are conceptualized in currently used classification systems such as the DSM. There is developing interest in alternative phenotyping / classification systems of psychopathology that overcome limitations of current systems. I will discuss such phenotyping approaches and present our recent research showing that implementation of these systems into genetic studies of psychiatric disorders can offer major benefits and provide novel insight into the genetic basis of psychopathology.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1691 NMR-based analyses identify serum metabolites associated with acute stroke using patients from the MISS and UK biobank

Authors:

D. Sanghera[1], M. Rout[2], A. Vaughan[3], A. Blair[3], S. Stavrakis[3], E. Sidorov[3]; [1]Univ. of Oklahoma Hlth.Sci. Ctr., Edmond, OK, [2]OUHSC, Oklahoma City, OK, [3]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma, OK

Stroke is a significant health issue in the United States, and identifying biomarkers for the prevention and functional recovery after an acute stroke remains the highest priority. This study aims to identify circulating metabolite signatures associated with stroke pathophysiology by performing discovery and validation studies. We performed targeted metabolomics profiling of 420 participants of the discovery dataset of Metabolome in an Ischemic Stroke Study (MISS) using high-throughput nuclear magnetic resonance (NMR) spectroscopy. A validation study of significantly altered metabolites was conducted using an independent cohort of 117,988 participants from the UK Biobank, available with metabolomics profiles using the same NMR technology. Our study identified 13 metabolites significantly perturbed during acute stroke. Amino acid phenylalanine was significantly increased, while the circulating levels of glutamine and histidine were significantly decreased in stroke. Serum levels of apolipoprotein A-1, several essential fatty acids, and phosphatidylcholine were reduced, while ketone bodies like 3-hydroxybutyrate and acetoacetate were markedly increased in stroke. Our study demonstrates the potential of high throughput metabolomic technology to unravel metabolic dysregulation in stroke not captured by traditional clinical measurements. Further work will be required to ascertain whether these markers have clinical utility. **Funding:** This work was funded by the College of Medicine Alumni Association (COMAA), the Presbyterian Health Foundation, and the Leinbach Foundation grants, and from Dr. Geoffrey Altshuler Endowment funds from the Children's Health Foundation of the University of Oklahoma Health Sciences Center.

Session Title: Complex Traits and Polygenic Disorders Poster Session III

PB1692 Non-coding regulation of mitochondrial copy number in humans.

Authors:

T. Hall, S. Cannon, G. Hawkes, M. Weedon, K. Patel; Univ. of Exeter, Exeter, United Kingdom

Introduction:
Mitochondrial DNA copy number (mtDNA-CN) alterations are associated with common, complex and rare genetic disorders and can be regulated by nuclear genome variation. Previous studies focused on rare or common nuclear coding variants affecting mtDNA-CN. Using whole-genome-sequence (WGS) data on 199,940 individuals, we aimed to identify rare, non-coding variants' contribution to the nuclear genetic regulation of mtDNA-CN.
Method:
We performed the largest WGS-based analysis for mtDNA-CN to-date using 199,940 individuals from UK Biobank. We used mitoHPC to derive mtDNA-CN and performed association testing, with extensive adjustment for blood cell measurements and technical covariates, on 143,114 individuals passing quality control. We tested 75,311,546 single variants which each had ≥20 carriers in the UK Biobank, and performed 52,749,161 rare variant (MAF <0.1%) genomic aggregate tests split into gene-centric (e.g. proximal-regulatory), non-gene-centric (e.g. intergenic-regulatory), and grouped by measures of conservation, constraint and deleteriousness.
Results:
We identified two aggregated rare coding variants in *JAK2* and *SIRPA* that reduced mtDNA-CN by -0.7 and 0.17 SD at genome wide significance ($p<1x10^{-7}$) respectively. We also identified 19 aggregated proximal rare-noncoding variants units associated with mtDNA-CN (beta 0.08 to -0.6 SD) at genome wide significance. Of these, the proximal variants to *USF2* had the largest effect.
In 12 known genes associated with rare mitochondrial depletion syndrome (lower mtDNA-CN), we identified 9 aggregate non-coding variant units proximal to *TFAM* at Bonferroni corrected significance $p<6x10^{-6}$. The strongest signal was an upstream proximal aggregate unit ($p=3x10^{-6}$) which was driven by a novel, rare, promoter variant associated with an almost 2SD reduction in mtDNA-CN; chr10:58385409C>A ($MAF=3.49x10^{-5}$, beta=-1.9SD [95% CI: -1.3, -2.5], $p<8x10^{-10}$).
Conclusion:
Our WGS based approach identified novel coding and non-coding associations for mitochondrial copy number. Our study highlights the benefit of using WGS to study mitochondrial genetics in humans and opens a next phase of genetic studies to understand the non-coding regulation of mtDNA-CN.

Session Title: Complex Traits and Polygenic Disorders Poster Session I

PB1693 Novel modifiers of age-at-onset for Alzheimer's disease identified in African American datasets as well as meta-analyses across populations.

Authors:

K. Nuytemans[1], S. Guo[1], J. La[2], A. Naj[3], X. Gao[4], Y-J. Li[2], E. Martin[1], Alzheimer Disease Genetics Consortium (ADGC); [1]Univ. of Miami, Miami, FL, [2]Duke Univ., Durham, NC, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]The Ohio State Univ., Columbus, OH

Background: Several studies have attempted to identify genes for age-at-onset (AAO) of Alzheimer's disease (AD) through genome-wide linkage and genome-wide association studies (GWAS). While these efforts thus far have focused predominantly on non-Hispanic white (NHW) populations, we present analyses identifying genetic contributors to AAO in African Americans (AA) as well as across population groups using genotype and phenotype data from the Alzheimer's Disease Genetics Consortium (ADGC). **Methods:** We combined genotype data from 13 AA prospective and case-control ADGC datasets, excluding family-based datasets, performed QC and imputed to the TOPMed R2 reference panel using the Michigan Imputation Server. Data were merged across cohorts using QCTOOL and GTOOL, filtering out variants with MAF≤0.005. We performed two analyses: case-only linear mixed-model regression with AAO as outcome (LMM); and survival analysis using Cox proportional-hazards frailty modeling (COXPHF) with time-to-AD-onset (AAO in cases and censoring of controls at age-at-last-exam). Both models were adjusted for sex, principal components capturing population substructure, and *APOE*-ε4 dosage with a random cohort effect. Second, we performed meta-analyses across AA and previously reported NHW results using MetaSoft2.0.1's Han and Eskin's random effects model. **Results:** We examined 2,262 AA AD cases (69% female) with mean (SD) AAO of 77.7 (8.1) years. The *APOE*-adjusted COXPHF analyses identified seven genome-wide significant regions ($P<5\times10^{-8}$), of which five were driven by African-specific variants (MAF<0.0002 in gnomAD Non-Finish Europeans) and the most significant one is *ABCA7* ($P=3.57\times10^{-10}$), known to be associated with AD risk in AAs. In the LMM analysis, we observed strong novel associations with variants in *CCDC141* on chr2q31.2 ($P_{min}=2.93\times10^{-9}$). *In silico* analyses of LD structure and functional potential suggest *SESTD1*, a gene involved in synaptic regulation, as driving the *CCDC141* locus signal. Meta-analyses combining results from AA dataset and NHW ADGC cohorts (9,220 AD cases/10,350 controls; Li et al. *Alz Dement* 2023) identified *BIN1*, *CR1*, *ABCA7* and *CLSTN2* in the COXPHF analyses as well as loci on chr2q36.3 and chr11p15.4 in the LMM analyses (p<5x10-8 overall, p<0.001 in each dataset). **Conclusion:** In a large ADGC African American dataset, we confirmed AAO associations in the *APOE* region and *ABCA7* and observed evidence for potential novel AD AAO loci including *SESTD1*; many of which might be African-ancestry specific. Meta-analyses across population groups further identified known AD genes as well as two novel loci to be involved in AAO overall.

Session Title: Complex Traits and Polygenic Disorders Poster Session II

PB1694 Novel variants identified in black South African families with vitiligo

Authors:

T. Ngcungcu, B. Nonyane, M. Ramsay; Univ. of the Witwatersrand, Johannesburg, Gauteng, South Africa

Vitiligo, a skin pigmentation disorder characterized by acquired depigmentation and melanocyte deficiency, affects 0.4-2% of the general population across all ethnic groups. Environmental factors play a role in triggering the development of the disorder, but genetic susceptibility is important as family members have an increased risk for developing vitiligo. The occurrence of vitiligo in multiplex families (more than one affected family member) supports the role of genetic variants in the aetiology of vitiligo and the pattern of inheritance suggests that it is polygenic and multifactorial. Published genetic association studies have been done in European and Asians populations, but none in continental African populations. The aim was to identify genetic variants in families of African descent with at least two individuals affected by vitiligo. Three families (two affected members per family and one unaffected family member; n=7) were recruited. Whole exome sequencing was done from libraries prepared using the Ion AmpliSeq™ Exome RDY library 4x2 kit and sequenced using the Ion S5™ sequencer. Three novel variants in the *FLG*, *TSPYL* and *MANF* genes were identified and were present exclusively in the affected participants. These results require validation and family segregation analyses to understand their contribution as large effect variants to the vitiligo phenotype. None of the identified genes have previously been implicated in vitiligo pathogenesis.

PB1695 Older adults with Alzheimer's disease had a higher burden of infections diagnosed before AD, and it was influenced by sex, race, and *APOE4* status

Authors:

S. Ukraintseva, R. Holmes, H. Duan, D. Wu, A. Yashkin, I. Akushevich, A. Yashin, K. Arbeev; Duke Univ., Durham, NC

Introduction and Method: Infectious diseases may play a role in Alzheimer's Disease (AD) development, though exact mechanism is unclear. Genetic and other risk factors for AD may interact with infections and modulate their relations with AD. Here we compared frequencies of moderate to severe infections in medical history (based on hospitalization ICD10 codes) of UK Biobank participants with and without AD, stratifying these analyses by AD risk factors, such as sex, race, and *APOE4* carrier status. The latter was based on the information about rs429358 and rs7412 polymorphisms. To avoid reverse causation, we only considered infections diagnosed before age 72, and AD diagnosed at ages 73 or later. These age cut-offs were chosen based on the age distributions of AD and infectious diseases in the data, and they allowed us to include majority of cases of both AD and infections in the analysis. We used the following binary variable for infections: *(0) Infection occurred before age 72 vs. (1) no infection before age 72, and both groups survived age 72*. SAS procedure PROC FREQ and Chi-square test were implemented to compare significance between groups. Bonferroni correction (P_{bon}) was also calculated. **Results:** UKB participants who developed AD at ages 73+ had a higher proportion of infectious diseases diagnosed before age 72 compared to those without AD, in the total sample (P_{bon} =1.12E-84, N=42503, AD=64.18%, noAD=42.33%), as well as in females (P_{bon} =1.86E-38, N=20821, AD=60.78%, noAD=40.45%), males (P_{bon} =9.60E-47, N=21682, AD=67.86%, noAD=44.32%), Whites (P_{bon} =3.07E-81, N=41032, AD=64.14%, noAD=42.30%), and Blacks (P_{bon} =0.0121, N=330, AD=74.19%, noAD=39.72%). The difference in the proportion of infections among AD vs noAD was larger and more significant in non-carriers of *APOE4*, compared to carriers: *APOE4* carriers (P_{bon} =7.47E-29, N=8900, AD=61.87%, noAD=41.47%); non-carriers (P_{bon} =3.58E-38, N=24834, AD=68.72%, noAD=42.19%). **Conclusion:** Burden of prior infections was higher in UKB participants who developed AD later in life than in those without AD, in line with the idea that adult infections may contribute to AD development. The higher proportion of infections preceding AD was seen in males, Blacks, and non-carriers of *APOE4*, the latter suggesting that the impact of *APOE4* on AD risk may overweigh that of infections.

PB1696 Ongoing Natural History study in Phosphomannomutase 2 Congenital Disorder of Glycosylation (PMM2-CDG): Clinical and Basic Investigations

Authors:

T. Moors[1], E. Morava[2], M. Patterson[2], A. Cechova[3], T. Honzik[3], A. C. Edmondson[4], C. Ficicioglu[4], M. G. Serrano[5], R. Barone[6], P. Witters[7], D. Ryman[7], C. Lam[8], M. C. H. Janssen[9], E. Martins[10], D. Quelhas[10], J. Sykut-Cegielska[11], M. Schiff[12], P. De Lonlay[12]; [1]Glycomine, Inc., San Mateo, CA, [2]Mayo Clinic, Rochester, MN, [3]Charles Univ. and Gen. Univ. Hosp., Prague, Czech Republic, [4]Children's Hosp. of Philadelphia, Philadelphia, PA, [5]Hosp. Sant Joan de Deu, Barcelona, Spain, [6]Univ. of Catania, Catania, Italy, [7]Univ. Hosp. Leuven, Leuven, Belgium, [8], Univ. of Washington Sch. of Med., Seattle, WA, [9]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [10]Centro Hosp.ar Universitário do Porto, Porto, Portugal, [11]Inst. of Mother and Child, Warsaw, Poland, [12]Necker Hosp., Paris, France

Background: Phosphomannomutase 2 congenital disorder of glycosylation (PMM2-CDG) is the most common CDG, yet there are no prospective studies to provide a cohesive natural history. This is a systematic clinical study to capture data across multiple domains to better understand the course of disease. Clinical presentation can be variable, ranging from infants who die in the first weeks of life to mildly affected adults. Apart from neurologic manifestations patients have variable, sometimes severe, immunologic, hematologic, cardiac, pulmonary, gastrointestinal, renal, endocrine, musculoskeletal, developmental and/or ophthalmologic involvement. This global, collaborative study represents the largest and longest set of natural history longitudinal data collected in PMM2-CDG.**Methods**: PMM2-CDG subjects were enrolled based on enzymatic and/or molecular tests. Medical history, physical examination, laboratory testing and imaging studies were performed at baseline and approximately every 6 months, depending on standard of care at the investigator's institution as well as the clinical status of the individual patient. **Results:** 139 subjects enrolled across 11 sites in 9 countries (US & Europe). Mean age at enrollment was 14.7y (range 0.5 to 68.4y), and almost 70% were under 18y. Enrolled subjects had 60 unique genetic variants, which included 6 novel variants not previously reported. Subjects were 15 times more likely to have weight Z-score below -2, reflecting faltering growth across all ages. Laboratory abnormalities included low coagulation parameters (ATIII, Factor XI, Protein C) in most subjects and elevated liver enzymes (2-10x ULN) in children. Nijmegen Progression CDG Rating Scale (NPCRS) data collected after 1 year on study suggests clinical complications arising from coagulation defects occurring in 10% of subjects in the previous 6 months. As of February 2023, 7 (5%) subjects had completed 4 years on study and 54 (39%) 2 years. **Discussion:** This ongoing natural history study provides an observational data set to understand clinical manifestations, morbidity, and disease progression of PMM2-CDG.

PB1697 Opioid Overdose Death and Gene Dysregulation: A Transcriptome-wide Association Study in Nucleus Accumbens

Authors:

C. Willis[1], B. Quach[1], O. Corradin[2], R. Sallari[3], D. Hancock[1], D. Mash[4], S. Akbarian[5], E. Johnson[1]; [1]RTI Intl., Research Triangle Park, NC, [2]MIT, Cambridge, MA, [3]Axiotl Inc, Cleveland, OH, [4]Nova Southeastern Univ., Fort Lauderdale, FL, [5]Icahn Sch. of Med. at Mount Sinai, New York, NY

The opioid epidemic in the US continues unabated, with 5.6 million people having an opioid use disorder and over 80,000 opioid overdose deaths (OODs) occurring in 2021. Our neurobiological understanding of opioid addiction remains limited. There has been one previous study of differential gene expression associated with opioid overdose death in human nucleus accumbens (NAc), a key brain region for studying addiction. Here, we analyze a new cohort of NAc RNAseq samples, meta-analyze results with the previous study, and compare results with prefrontal cortex, another key brain region for addiction. Bulk RNAseq was performed on NAc tissue collected from 92 decedents (50 OOD cases, 42 controls) of European (64) and African American (28) ancestry. Samples were analyzed separately in two batches then meta-analyzed using the weighted fisher's method. Genes were tested for differential expression by OOD status using negative binomial regression models controlling for plate effects and unsupervised surrogate variables as covariates that accounted for known and unknown covariates. Of 18,867 genes that were meta-analyzed across batches, 125 showed significant differential expression (FDR < 0.05). We replicated 4 genes (*ATG4D*, *SLC10A3*, *SCAMP4*,*SLC19A1*) in a previously published study's results (Seney et al., Biological Psychiatry 2021), after applying Bonferroni correction ($P < 4x10^{-4}$). Meta-analysis of the two independent cohorts resulted in 96 significant genes at FDR < 0.05. These 96 genes were significantly enriched (FDR < 0.05) for gene ontology terms and pathways related to immune function (such as IL2, IL6, and TCR pathways) and calcium ion channel function (such as regulation of calcium ion export across plasma membrane). Only 3 genes' differential expression in NAc overlapped with significant genes in a meta-analysis of bulk RNAseq in prefrontal cortex tissue (*WDFY3, CITED2, ARL4D*). By substantially increasing sample size, this study identifies novel differences in OOD-associated gene expression in human NAc. These results suggest genes that play a role in the immune system and calcium ion channel function which may impact the neurobiology of OOD and indicate that OOD-associated gene dysregulation differs across brain regions.

PB1699 Overweight as a causal factor for survival in late life: A Mendelian randomization study.

Authors:

H. Duan[1], R. Holmes[1], K. Arbeev[1], O. Bagley[1], D. Wu[1], N. Schupf[2], A. Yashin[1], S. Ukraintseva[1]; [1]Duke Univ., Durham, NC, [2]Columbia Univ., New York, NY

Background: The "obesity paradox" refers to an intriguing association of overweight with better survival at the oldest old ages observed in some studies; however, mechanism is not well understood. Mendelian Randomization (MR) is a common approach to uncovering causality in observational data using SNPs as instrumental variables (IVar). In our previous MR study of the Health and Retirement Study (HRS) data, we implemented a new strategy of selecting IVar, and found significant causal relationship between overweight and survival to ages 85+ in both sexes. Here, we use similar strategy to replicate the HRS finding in the Long Life Family Study (LLFS) data.
Method: To select IVar for MR, we used eight candidate obesity genes (*ADIPOQ, FTO, LEP, LEPR, INSIG2, MC4R, PCSK1, PPARG*), and cross-paired all SNPs in these genes to create new "composite SNP"s with genotypes 0,1,2, based on summed dosage of minor alleles (MA) of original SNPs. For each new composite SNP, '0' corresponded to 0-1; '1' corresponded to 2; and '2' corresponded to 3-4 MA (combined dosage) of the two original SNPs. The composite SNPs were tested to satisfy the assumptions for IVar. F-value>10 criteria was used to ensure IVar strength. This approach yielded considerably more IVar candidates that passed all the assumptions, compared to single-SNP approach. The following binary variables were used as "exposure": (1) 'overweight' BMI 25-30 vs. (0) 'normal' BMI 18.5-25, at ages 75-85; and as "outcome": (1) survived 85+ vs. (0) died before age 85. Covariates included field center, education, sex, smoking status, and first two principal components. The relatedness in LLFS data was addressed using SAS mixed models to calculate statistics. Inverse-Variance Weighted (IVW), and maximum likelihood (ML) methods in R-package MendelianRandomization were applied to test causality. Analyses were stratified by sex.
Result: We found that being overweight at ages 75-85 had significant protective effect on survival at ages 85+ in White males (IVar: 135 "SNP"s, IVW causal estimate(CE)=0.19, p-value=1.02E-15; ML CE=0.19, p-value=3.11E-15), and in total sample (IVar: 47 "SNP"s, IVW CE=0.31, p-value=2.52E-9; ML CE=0.31, p-value=7.98E-9). CEs for females didn’t reach statistical significance.
Conclusion: This MR study of LLFS data confirms our findings in HRS that being overweight in late life causally contributes to longevity in White males. Potentially better resilience of the overweight men to late life stresses may play role in this relationship. The observed sex difference may reflect better resilience of the longest-lived overweight men compared to women, as well as smaller LLFS sample compared to HRS.

PB1700 Parkinson's disease is associated with an imbalance in circular RNA expression

Authors:

B. Whittle, M. Santibanez-Koref, G. Hudson; Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Neurodegeneration occurring in Parkinson’s disease (PD) can precede clinical diagnosis by decades. Earlier diagnosis of PD, as well as the ability to recognise individuals who will develop non-motor symptoms such as dementia, would facilitate the delivery of life-altering treatments earlier in the disease course. Many biomarkers of PD have been proposed, although, to date, none have been replicated or validated to the extent that they have been deployed in a clinical setting. Recent reports suggest that the effects of early neurodegeneration may be reflected in RNA levels in easily assessable tissues such as blood. However, despite several RNA studies, there is little concordance or agreement - in part hindered by cohort sizes, the heterogeneous nature of PD and the variability in analysis methodologies. We present the largest quantification of whole blood linear and circular RNAs (circRNA) in early-stage PD patients, using RNA sequencing data from two cohorts (PPMI = 259 PD, 161 Controls; ICICLE-PD = 48 PD, 48 Controls). We identified and replicated an increase in *TMEM252* and *LMNB1* gene expression in PD. We identified novel differences in the expression of circRNAs from *ESYT2*, *BMS1P1*, and *CCDC9*, in addition to replicating trends of some previously reported circRNAs. CircRNA expression showed a specific global reduction in PD patients, complemented by an increase in *RNASEL* expression. Overall, using circular RNA as a diagnostic biomarker in PD did not show any clear improvement over linear RNA. However, integrating the expression of the linear and circular transcriptome identified potential PD-related changes in the global expression of circRNAs. Interestingly, our data suggest that genes involved in mounting an immune response, specifically through the regulation of RNA subtypes, may play an important role in the development and pathoetiology of PD.

PB1701 Pathway-based genetic risk score analyses identify biological pathways linking together hypertension and dementia-related cognitive impairment traits

Authors:

O. Meirelles[1], C. Cabrera[2], H. Warren[3], D. Li[1], P. Munroe[4], L. Launer[1]; [1]Natl. Inst. on Aging, Baltimore, MD, [2]Queen Mary Univ. of London, London, United Kingdom, [3]William Harvey Res. Inst., Barts and The London Sch. of Med., QMUL, London, United Kingdom, [4]Queen Mary Univ. of London, London, United Kingdom

Cerebral small vessel disease is highly prevalent and contributes to cognitive impairment and dementia in the elderly. Elevated blood pressure (BP) increases risk for cerebrovascular damage, but the related mechanisms are uncertain. Published studies show associations between BP polygenic risk scores (PRS) and brain-MRI (magnetic resonance imaging) endophenotypes of dementia. However, analyses of full genome-wide BP-PRS cannot reveal which biological pathways are involved. Using novel methodological approaches, we constructed genetic risk scores (GRS) based on individual BP-associated pathways ("BP-path-GRS"). We selected 59 KEGG pathways most enriched for BP-genes from GWAS-based pathway analysis. Per pathway we listed all *k* genes, then per gene we extracted the variant most significantly associated with BP from BP-GWAS. Following pairwise-LD filtering, these *k* top variants were combined to construct three BP-path-GRS variables per pathway, using BP-trait-specific (systolic-BP, diastolic-BP, Pulse Pressure) weights in the GRS from BP-GWAS. Weights were adjusted according to the number of independent variants per gene, determined by Principal Component Analysis. We tested each of the 177 BP-path-GRS for association with three brain-MRI phenotypes [grey (GM), white (WM) matter, WM hyperintensity (WMH) volume]. Analyses were performed within n=37,599 UK-Biobank individuals with MRI data available. 27 of the 59 BP-pathways were significantly associated with at least one brain-MRI trait. Five pathways were robustly associated with WMH for all three BP-path-GRS. Two of these pathways remain jointly independently associated after multivariate stepwise analyses: "Cytomegalovirus" and "Endocrine/Calcium-regulating" pathways. These results suggest new underlying biological pathways linking hypertension and dementia, which could indicate potential novel drug targets.

PB1702 Personality traits are consistently associated with blood mitochondrial DNA copy number estimated from genome sequences in two genetic cohort studies.

Authors:

R. Oppong[1], A. Terracciano[2], M. Picard[3], Y. Qian[1], T. J. Butler[1], D. Zweibaum[1], T. Tian[1], T. Tanaka[1], A. Z. Moore[1], E. Simonsick[1], M. Gorospe[1], S. M. Resnick[1], F. Cucca[4], S. W. Scholz[5], B. J. Traynor[6], D. Schlessinger[1], L. Ferrucci[1], J. Ding[1]; [1]Natl. Inst. on Aging, BALTIMORE, MD, [2]Dept. of Geriatrics, Florida State Univ., Tallahassee, FL, [3]Dept. of Neurology, Columbia Univ., New York, NY, [4]IRGB CNR, Monserrato, Italy, [5]NIH, Bethesda, MD, [6]Natl. Inst Aging, Bethesda, MD

Levels of mitochondrial DNA copy number (mtDNAcn) in tissues and blood can be altered in conditions like diabetes and major depression and may play a role in aging and longevity. However, little is known about the association between mtDNAcn and personality traits, which are linked to emotional states, metabolic health, and longevity. This study aimed to test the hypothesis that blood mtDNAcn is related to personality traits and mediates the association between personality and mortality risk. We assessed the big five personality domains and facets using the Revised NEO Personality Inventory (NEO-PI-R), assessed depressive symptoms using the Center for Epidemiologic Studies Depression Scale (CES-D), estimated mtDNAcn levels from whole-genome sequencing, and tracked mortality in participants from the Baltimore Longitudinal Study of Aging (722 participants with complete data, mean age 75 (48 - 100) years, 48% women). Results were replicated in the SardiNIA Project (587 participants with complete data, mean age 57 (15 - 96) years, 62% women). We found that mtDNAcn was negatively associated with the Neuroticism domain and its facets and positively associated with facets from the other four domains (Extraversion, Openness, Agreeableness, and Conscientiousness). These associations were consistent across both cohorts and robust to adjustment for potential confounders. Additionally, higher depressive symptoms (CES-D) were associated with lower mtDNAcn levels, consistent with the Neuroticism finding. Finally, our analyses showed that mtDNAcn mediated the association between personality and mortality risk. To our knowledge, this study is the first to demonstrate a replicable association between blood mtDNAcn levels and personality traits, revealing a novel link between mitochondrial biology and emotional traits and states relevant to human health. Furthermore, we found that mtDNAcn mediates the association between personality and mortality risk, suggesting that mtDNAcn may be a biomarker of the biological process that underlies the association between personality and mortality risk. Currently, we are extending our study to the psychosocial traits using UK Biobank data and the preliminary analyses show that negative psychosocial traits are associated with lower mtDNAcn, and positive psychosocial traits are associated with higher mtDNAcn. These initial findings are in line with our results from the BLSA and SardiNIA cohorts.

PB1703 Personalizing body mass index thresholds for obesity using polygenic scores.

Authors:

I. Shim[1], M. Kim[1,2,3], B. Kim[1], P. Natarajan[2,3], R. Do[4], W-Y. Park[5], A. V. Khera[6], P. T. Ellinor[2,3], A. C. Fahed[2,3], H-H. Won[1,5]; [1]Samsung Advanced Inst. for Hlth.Sci. & Technology (SAIHST), Sungkyunkwan Univ., Seoul, Korea, Republic of, [2]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [3]Broad Inst. of Harvard and MIT, Cambridge, MA, [4]Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Samsung Genome Inst., Samsung Med. Ctr., Seoul, Korea, Republic of, [6]Verve Therapeutics, Boston, MA

Background

The global obesity crisis continues to be a key driver of type 2 diabetes (DM-2) and cardiovascular diseases (CVD). Current guidelines use a 30 kg/m^2 body mass index (BMI) threshold to define obesity and decide on behavioral interventions, anti-obesity medications, and sometimes weight reduction surgery. Since BMI is a highly heritable trait, we sought to determine if obesity thresholds for management should be personalized based on genetic predisposition.

Methods

We quantified genetic susceptibility to obesity in 335,835 UK Biobank participants of European ancestry using a polygenic score (PGS) for BMI. We defined two obesity outcomes, DM-2 and a composite CVD outcome consisting of 7 obesity-related cardiovascular morbidities (coronary artery disease, heart failure, atrial fibrillation, pulmonary embolism, venous thromboembolism, hypertension, and aortic valve stenosis). We quantified the risk associated with the two outcomes among a population with obesity (BMI ≥30 kg/m^2) compared to a normal weight reference group (BMI 18.5-24.9 kg/m^2). We then identified BMI thresholds for equivalent risks across different genetic risk categories. Logistic regression models were adjusted for age, sex, education level, socioeconomic status, smoking, genotyping array, principal components of ancestry, and obesity-related lifestyle factors.

Results

Among 335,835 participants (mean age 57.37±7.99 years; 53.6% female; mean BMI 27.45±4.71 kg/m^2), individuals with obesity as defined by BMI ≥30 kg/m^2 had 8-fold (OR 7.99, 95% CI 7.52-8.50) increased risk of DM-2 and 4-fold (OR 3.68, 95% CI 3.58-3.78) increased risk of composite CVD outcome, compared to a group with normal weight. However, genetic risk-adjusted BMI thresholds varied from 28.53 kg/m^2 (top 5% PGS) to 30.27 kg/m^2 (bottom 5% PGS) for DM-2 risk, and from 28.91 kg/m^2 (top 5% PGS) to 31.23 kg/m^2 (bottom 5% PGS) for the composite CVD risk. BMI threshold showed a dose-responsive decrease with PGS increase. With the genetic risk-adjusted BMI threshold, 6.9% of participants with conventionally defined obesity were recalibrated, while the net population with obesity remained stable.

Conclusions

Incorporating genetic risk into BMI thresholds can enrich personalized risk assessment and better inform management strategies. We found that nearly 7% of individuals with obesity were recalibrated after considering genetic risk.

Single Nucleotide Polymorphism (SNP) arrays have been used in the clinical diagnostic context to identify disease-causing copy number variations for decades. SNP data collected in large scale by various research studies and biobanks have empowered Genome Wide Association Studies (GWAS) to identify common variants associated with a particular phenotype of interest, and phenome-wide association studies (PheWAS) have further emerged to relate variants across the phenotypic landscape. However, diagnostic genotyping represents a data source with relatively untapped potential to identify such associations across the phenome, especially given the wealth of clinical information readily accessible in the electronic medical record (EMR). Here, we leverage the unique opportunity afforded by secondary research use of clinical SNP arrays of 11,860 individuals with EMR data from the Children's Hospital of Philadelphia to detect epilepsy-associated variants and perform PheWAS. We identified 2,301 cases with an epilepsy-related ICD10 code (G40, G41, R56 or P90). GWAS analysis revealed 49 genomic loci that achieved genome-wide significance, representing 28 genes. Of these, 4 genes have known epilepsy associations from the GWAS Catalog. Furthermore, 9 genes with genome-wide significant loci also have known rare variant associations with Mendelian epilepsy or neurodevelopmental phenotypes, suggesting possible convergence of common and rare variant mechanisms in these genes. Lastly, PheWAS across 11,312 unique ICD10 diagnoses mapped to 1,547 phecodes identified 335 phenome-wide significant SNP-phenotype associations including atypical development with variants in *PRDM5* and *MAD2L1*. Overall, our analyses indicate the relationship between common variants and phenotypes in individuals with epilepsy phenotype and entail for further evaluation. These associations reflect the potential for discovery from merging already available clinical and diagnostic genotyping datasets with corresponding deep EMR phenotyping.
