Obesity is a complex disorder where a multitude of genes and environmental factors interact to express the disease phenotype. Efforts till now have primarily concentrated on searching for GWAS implied common variants or monogenic rare variants that increase the disease risk. In this study, we used RareComb, a computational framework that uses apriori algorithm along with binomial tests, to identify oligogenic combinations of two or more genes with rare variants and lifestyle factors that contribute to obesity in a cohort consisting of ~200,000 individuals from UK Biobank. Our results demonstrate that oligogenic combinations of rare variants play a significant role as obesity risk factors, similar to monogenic or polygenic variants. In fact, mean effect sizes of the discovered combinations were ~2.3 times higher than that of previously identified obesity-associated genes with low-frequency mutations (t-test, p=4.36E-10). Additionally, we illustrate how obesogenic lifestyle factors in conjunction with rare variants further exacerbate the disease risk. Individuals carrying combinations of obesogenic lifestyle factors and risk genes had significantly higher mean BMI compared to those without such combinations (t-test, p< 3.04E-53). Our results indicate that musculoskeletal genes, such as *SCN10A* and *TTN*, primarily contribute to obesity risk regardless of lifestyle factors, whereas nervous system genes, such as *APC* and *PRPH*, interact with lifestyle factors to increase the risk. We further identify a novel class of variably expressive genes that either increase the risk of or protect from obesity and its related disorders depending on their interaction with distinct partner genes. Our findings challenge the existing landscape of genetic screening for complex disorders which primarily focuses on monogenic variants or polygenic risk scores and emphasize the importance of considering oligogenic risk when assessing predisposition to complex disorders like obesity.

PB4302 Non-additive polygenic scores.

Authors:

R. Ohta[1], Y. Tanigawa[2], Y. Suzuki[1], M. Kellis[2], S. Morishita[1]; [1]The Univ. of Tokyo, Kashiwa, Chiba, Japan, [2]MIT, Cambridge, MA

Polygenic scores (PGSs), which combine multiple SNVs to explain a phenotype, have recently received attention due to their potential for contributing to predicting disease risk. Most existing PGS methods exploit the additive model to construct a best-possible linear model of the effect sizes. However, Palmer *et al.* showed that non-additive heritability was estimated to exist in some phenotypes and to be especially significant in autoimmune diseases such as rheumatoid arthritis and psoriasis.

Considering this background, it is promising to build PGSs under additive and non-additive models; however, the traditional PGS methods are designed to rely heavily on additive effects, and it is non-trivial to revise them with non-additive effects. More precisely, the technical difficulty in devising non-additive models is how to assign optimal independent SNV scores to three allelic dosages (0, 1, and 2), which allows us to handle any genetic inheritance models, including the additive, recessive, dominant, and overdominant models. Here, we propose a method that can build PGSs under additive and non-additive models and is also efficient because it computes analytic exact solutions for optimal SNV scores.

Applied to twelve representative phenotypes in UK Biobank, our software program named **GenoBoost** was competitive across all traits, achieved the highest accuracy for five phenotypes, and ranked second for three phenotypes among seven PGS methods. GenoBoost improved Nagelkerke's R^2 by 4.9% on average compared to LASSO. Non-additive GenoBoost had higher accuracy than additive GenoBoost for rheumatoid arthritis and psoriasis, which is consistent with Palmer *et al.*

Among variants in non-additive GenoBoost PGS models, approximately 40-67% of variants were classified as non-additive, which was consistent with GWAS classification. When prioritizing the associated variants under general non-additive models, GenoBoost exploits one metric, SNV utility, as an association indicator to handle general genetic models, unlike GWAS using *p*-values for each model. Focusing on non-additive variants with the eight largest SNV utilities in the PGS models, four out of eight were in the experimentally validated non-additive genes but not reported in GWAS catalog.

In conclusion, we propose the first PGS algorithm that can incorporate general genetic models to the best of our knowledge and outperformed other PGS methods for five out of twelve phenotypes. Non-additive GenoBoost has the ability to classify genetic inheritance models and prioritize the non-additive variants. Our results demonstrate that the non-additive model is essential in predicting risk for polygenic diseases.

PB4303 Non-APOE genetic risk scores for late-onset Alzheimer disease in a diverse clinical population

Authors:

C. Rose, S. Liu, W. S. Bush, D. C. Crawford; Case Western Reserve Univ., Cleveland, OH

Alzheimer disease (AD), a leading cause of death in the US, is the most common cause of dementia. Most known risk factors such as age, sex, and genetics are not modifiable. Large genome-wide association studies (GWAS) in mostly European-descent populations have identified >75 genetic variants associated with late-onset AD (LOAD). Few GWAS and risk scores derived from them include diverse populations. In the present study, we accessed the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) BioVU, a resource of de-identified electronic health records (EHRs) linked to Illumina Metabochip genotypes assayed on DNA samples extracted from clinical blood draws at a major medical center in Davidson County, Tennessee. From the approximately 11,000, 1,000, and 1,500 African American (AA), Asian American (A), and Hispanic (H) patients in EAGLE BioVU, respectively, we identified a total of 77 cases of LOAD using International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) code 331.0. Controls were defined as absence of the case-defining ICD-9-CM code for patients ≥65 years of age at last clinic visit (n=3,752). We queried the Polygenic Score (PGS) catalog and the largest GWAS for European-descent and African-descent populations in the literature for LOAD-associated ($p<5x10-8$) single nucleotide variants (SNVs), effect alleles, and genetic effects (beta coefficients). Of the 126 SNVs considered, seven were assayed directly by the Metabochip. Tests for Hardy-Weinberg Equilibrium ($p<0.00005$) removed a rare SNV (rs6656401in AA) and rs889555 (in A). Unweighted and weighted risk scores were calculated for each patient stratified by population and case-control status. The unweighted risk scores ranged from [0,8], [0,6], and [0,7] with means (±standard deviations or SD) 2.44 (±1.12), 2.07 (±1.32), and 2.11 (±1.32) for AA, A, and H, respectively. The mean (±SD) weighted risk scores were 0.165 (±0.105), 0.142 (±0.107), and 0.178 (±0.149) for AA, A, and H, respectively. When stratified by case-control status, the unweighted risk scores ranged from [0,5] and [0,8] for cases and controls, respectively. A test of association between case status and genetic risk score was performed using logistic regression across all populations. Genetic risk scores were not associated with LOAD in this diverse patient population (OR=0.468; 95% CI: 0.046-3.688; p=0.498). Work is ongoing to develop risk scores for non-LOAD dementia (vascular dementia, dementia with Lewy body, frontotemporal dementia) as well as to develop additional computable phenotypes for LOAD and related dementias leveraging ontologies in this diverse clinical population.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4304 Novel methods for estimating risk parameters associated with polygenic scores using case-parent trio designs

Authors:

Z. Wang, D. Ray, L. Grosvenor, T. Beaty, H. Volk, C. Ladd-Acosta, N. Chatterjee; Johns Hopkins Univ., Baltimore, MD

Background Hidden population stratification in GWAS of unrelated individuals can lead to overestimation of genetic effects, complicating the applications and interpretations for polygenic scores (PGS) in many settings, including risk prediction and Mendelian randomization. Family-based studies, where genetic effects are estimated through within-family comparisons, provide an opportunity to test for PGS-trait associations while correcting for potential population stratification bias.
Methods We develop a likelihood-based method for estimating genetic effects, parental nurturing effects, and gene-environment interactions using case-parent trios. We assume the disease risk follows a log-linear model and PGS follows a normal distribution, allowing for family-specific terms in both components to account for arbitrary population structures. We show that the likelihood calculations can be simplified into a parental PGS component and a transmission-based likelihood, from which genetic effect estimates can be derived in closed forms. We apply the proposed method to multi-ancestry case-parent-trio studies of non-syndromic orofacial clefts (OFCs) (GENEVA study, European ancestry (EUR) N_{trio} = 778, East Asian ancestry (EAS) N_{trio} = 1126) and autism (SPARK study, multi-ancestry N_{trio} = 1517) to characterize the risk of these childhood disorders associated with established PGS (OFCs: 24 SNPs, autism: 35087 SNPs) and their interactions with several maternally mediated risk factors.
Results Simulation studies demonstrate this proposed method can produce unbiased effect estimates and correct coverage probabilities under complex population structures. In contrast, the polygenic transmission disequilibrium test (Weiner et al., Nat Genet 2017), while producing a valid test for genetic effects, yields attenuated estimates of effect-size due to the use of an incorrect scaling factor. Data analyses using our proposed method indicate transmission-based estimates of PGS effects on the risk of autism (RR_{EUR} = 1.33 per SD change, 95% CI = [1.22,1.44]) and OFCs (RR_{EUR} = 1.73 per SD change, 95% CI = [1.58,1.89]; RR_{EAS} = 1.59 per SD change, 95% CI = [1.46,1.73]) are similar to those reported from population-based studies. Further for OFCs, we observe evidence of maternally mediated nurturing effect (p = 0.03) and gene-environment interaction with maternal primary and environmental smoking status (p = 0.0025 and p = 0.024) in EUR.
Conclusion We provide a novel and comprehensive framework for estimating a collective of risk parameters associated with PGS using case-parent trios. An R package is publicly available on Github.

PB4305 Novel multi-omics analysis methods for the prioritization of therapeutic targets: a versatile platform

Authors:

N. Raghavan[1], A. Musolf[1], J. Miller[1], Y. Yan[1], K. Shkura[2], B. Guo[1], J-H. Sul[1], S. Longerich[1], D. Fagegaltier[1], M. Kennedy[1], A. Tamburino[1], R. Mathew[1]; [1]Merck & Co., Inc., Cambridge, MA, [2]MSD, London, United Kingdom

For many diseases, disparate multi-omics datasets that provide evidence for potential disease-associated genes and proteins are publicly available. However, deriving insights on genes/proteins to prioritize for therapeutics is difficult due to a general lack of integration of these data. We created a framework for therapeutic target prioritization with an integrated -'omics forward approach.

Multiple lines of evidence including statistical genetics approaches followed by functional genomics have highlighted the crucial role specific cell types play in disease and pathology. We leveraged high quality, disease-relevant, public multi-omics data and created a ranking scheme of genes expressed in cell types of interest. Genetics, epigenetics, transcriptomics, and proteomics data were used to score each gene. Genetic and epigenetic data were used to infer the evidence for causality of the gene to disease and of disease relevant chromatin accessibility in these cells. Differences in protein and RNA levels may be indicative of the cause or effect of the disease process. Thus, gene expression, protein level changes in disease-affected regions and/or cell type specific evidence that may be very relevant to the disease were scored highly. Scores were generated within each datatype, scaled, and hypothesis-driven score integration methods were applied.

Final scores prioritized known genes implicated in the disorder, suggesting proper calibration of the score. We also identify novel genes that have roles in disease-implicated processes but with limited research available in published literature, demonstrating the high value of the method to discover novel targets. This framework can integrate proprietary proteomic and disease-specific assay data, along with metrics that reflect the ability to target the protein through known therapeutic modalities. This scoring schema is flexible: with appropriate modifications relevant to the disease pathophysiology and data availability this framework is applicable across a range of human diseases to prioritize genes for drug discovery.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4306 omicsIMC: A Comprehensive Benchmarking Platform for Robust Comparison of Imputation Methods in Mass Spectrometry-based Omics Data

Authors:

W. Lin[1], K-j. Su[1], C. Qiu[1], Q. Tian[2], Z. Luo[1], H. Shen[3], H. Deng[1]; [1]Tulane Univ., New Orleans, LA, [2]Tulane Univ., Mandeville, LA, [3]Tulane Univ, New Orleans, LA

The analysis of mass spectrometry-based omics data such as lipidomics, is pivotal for elucidating biological processes and identifying biomarkers. However, missing information presented in spectrometry-based omics data is a critical challenge, potentially undermining downstream analyses which will hamper the comprehension of biological processes and the identification of biomarkers. To solve this issue, much effort has been done and several imputation methods have been developed with three categories: conventional, model-based and machine learning-based, however comprehensively and systematically comparing existing methods is still lacking, especially for lipidomics data. In this work, we compared 21 distinct imputation methods tailored for handling missing values in simulated spectrometry-based omics data and real lipidomics data from three aspects: (i) differential analysis, (ii) clustering, and (iii) functional enrichment analysis. Based on our simulation results, the machine learning-based methods generally show better performance than others with higher prediction accuracy. Notably, we built omicsIMC (mass spectrometry-based omics Imputation Methods Comparison platform), the first platform that provides researchers with a versatile framework for simulating and evaluating a diverse range of imputation strategies, encompassing machine learning, model-based, and conventional approaches. The strength of omicsIMC lies in its ability to address missing data challenges across diverse mass spectrometry-based omics datasets. By facilitating informed decision-making in imputation method selection, omicsIMC can empower researchers to conduct reliable and accurate downstream analyses using their mass spectrometry-based omics data. The comprehensive benchmarking and versatility of omicsIMC will make it a valuable tool for the scientific community engaged in mass spectrometry-based omics research.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4307 One third of genetic loci associated with coronary artery disease, including *CDKN2B-AS1*, are independent of known heritable clinical risk factors.

Authors:

C. P. Barnhill[1], B. W. Dulken[1,2], M. M. Soliai[1], J. B. Chang[1], S-G. Ji[1]; [1]BridgeBio Pharma, Inc., Palo Alto, CA, [2]Dept. of Pathology, Stanford Sch. of Med., Stanford, CA

Despite advances in the standard of care, atherosclerotic cardiovascular disease is the leading cause of morbidity and mortality in the United States and worldwide. One population with unmet need is those with advanced atherosclerosis and myocardial infarction (MI), but no standard modifiable risk factors (SMuRF-less, 14-27% of individuals with ST-elevated MI). Previous genome-wide association studies (GWAS) have identified over 150 loci associated with coronary artery disease (CAD) risk. Additionally, Mendelian randomization studies have revealed causal associations for risk factors such as hypertension, diabetes, and blood lipids. We sought to determine which of these loci confer risk independent of known heritable clinical risk factors in order to prioritize loci for SMuRF-less CAD. However, two challenges emerged: first, limiting to a sample without any of the risk factors would drastically reduce our power to detect a signal; second, directly conditioning on heritable risk factors as covariates in a GWAS could potentially introduce collider bias. To circumvent these issues, we conducted a multitrait-based conditional and joint association analysis (mtCOJO). GWAS summary statistics from the UK Biobank contain 92 genome-wide significant loci associated with CAD. We applied mtCOJO to remove the effects of 14 known heritable risk factors and found that only a third of loci remained genome-wide significant (n = 32). Among the loci that no longer held significance were genes known or suspected to be associated with circulating lipoprotein levels, such as *LPA* and *PSRC1*. *CDKN2B-AS1* was the most significant locus for CAD risk, maintaining its significance after conditioning without a significant heterogeneity of effect ($p_{initial} = 1.01 \times 10^{-73}$, $p_{conditional} = 6.59 \times 10^{-76}$, $p_{heterogeneity} = 0.26$). We applied two statistical fine-mapping tools, FINEMAP and SuSiE, to variants in the *CDKN2B-AS1* locus, which yielded two independent credible sets of variants. The lead variant in the first set, rs1333042, is associated with an elevated risk of CAD (OR = 1.26, $p = 6.30 \times 10^{-116}$) and increased splicing of exon 1 to exon 5 ($p = 1.70 \times 10^{-6}$) in *CDKN2B-AS1* transcripts in GTEX. The lead variant in the second set, rs3731239, is associated with protection from CAD (OR = 0.87, $p = 8.90 \times 10^{-38}$), reduced expression of *CDKN2B-AS1* ($p = 1.40 \times 10^{-5}$) in GTEX, and increased expression of *CDKN2B* ($p = 3.60 \times 10^{-25}$) in eQTLgen. In summary, we propose a novel approach to prioritize loci for SMuRF-less CAD and suggest that splicing of *CDKN2B-AS1* and its impact on *CDKN2B* expression constitute a significant genetic factor contributing to residual CAD risk, independent of known heritable risk factors.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4308 Optimizing variant impact prediction in autoinflammatory disease

Authors:

B. Matthiasardottir[1,2], S. Blackstone[1], S. Mount[2], D. Kastner[1]; [1]NIH, Bethesda, MD, [2]Univ. of Maryland, College Park, MD

Background: Autoinflammatory diseases are immunological disorders caused by dysregulation of the innate immune system, characterized by seemingly unprovoked attacks of inflammation without evidence of infection, high-titer autoantibodies, or antigen-specific T cells. The identification of genes underlying these diseases has revolutionized our understanding of innate immunity and provided the basis for life-saving therapies. We have sequenced the exomes of approximately 2000 patients and their unaffected family members. Exomes have been analyzed for protein coding variants by family-based and genotype-first approaches. The diagnostic yield of our cohort remains low, and many variants of uncertain significance (VUS) occur in known inflammatory genes.
Methods/Results: We have found that validated pathogenic variants in genes associated with the immune system often score below standard thresholds for variant impact prediction. This indicates that we might be missing variants, or a diagnosis, due to a high false negative rate in the genes underlying these illnesses. Methods for variant impact prediction have relied on training models of known variants found in ClinVar. Variants associated with autoinflammatory diseases are underrepresented in ClinVar, so it is possible that existing mutation pathogenicity prediction tools are not well-suited to these genes. By statistically comparing experimentally validated variants found in ClinVar to validated variants found in the Infevers database, we've shown that the optimal accuracy thresholds for binary classification of variants associated with autoinflammation are lower than those for other genes. The optimal accuracy thresholds of predictors such as REVEL and CADD in autoinflammatory genes are 0.324 and 17.24 vs. 0.65 and 20.0, respectively. This same trend is seen for ten other predictors included in the analysis. The area under the curve is the same, indicating that we do not introduce more noise. We speculate that this difference is due to the nature of selection on these genes, with episodes of strong selection for increased inflammation due to pathogen exposure balanced by selection for reduced inflammation otherwise, which may change the relationship between conservation and functional importance. In support of this, we are exploring the relationship between measures of selection and optimal accuracy thresholds further. Preliminary studies strongly support the hypothesis that autoinflammatory genes are under strong but variable selection.
Conclusion: Our data support the establishment of new variant curation guidelines for autoinflammatory disease.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4309 Outsmarting data limitations: probabilistic data augmentation via simulation of low-coverage whole-genome sequencing

Authors:

K-Y. Chen[1], S-F. Chen[2], R. Dias[3], A. Torkamani[4]; [1]Scripps Res. California, La Jolla, CA, [2]Scripps Res., La Jolla, CA, [3]Univ. of Florida, Gainesville, FL, [4]Scripps Translational Sci. Inst., La Jolla, CA

Low-coverage whole-genome sequencing (lcWGS) has emerged as a cost-effective technique with significant applications in population genomics, enhancing the reliability of statistical analyses, refining bioinformatics workflows, and advancing model construction including genotype imputation and machine learning methodologies. Despite these advantages, the scarcity of publicly available lcWGS data, relative to high-coverage whole-genome sequencing (hcWGS), and the computational burden and time required to generate large-scale lcWGS data, have posed significant challenges. Moreover, there's a notable lack of resources specifically designed to simulate lcWGS data directly into Variant Call Format (VCF) files. This paucity is particularly evident when we seek to carry out downstream analyses and apply probabilistic data augmentation approaches for the advancement of artificial intelligence models, especially for downstream applications in genome-wide association studies (GWAS). To address these challenges, we introduce a cost-effective strategy to simulate lcWGS VCF files from existing hcWGS datasets. To simulate lcWGS data from hcWGS genotype information, we use an admixed population dataset derived from1000 Genome Project (1KGP) from different read depths to develop a multivariate Gaussian mixture model for each genotype. The multivariate Gaussian mixture models were trained on allele presence probability that derived from phred-scaled likelihood scores (PL) in lcWGS, which were aligned to their corresponding hcWGS genotype data. Our findings suggest that the probability distributions of allele presence in simulated low-coverage conditions correspond significantly with the actual probability distributions of allele presence in real low-coverage conditions across different levels of sequencing depth. Furthermore, we demonstrate that applying the lcWGS simulation tools has potential in preserving the power and predictive accuracy of polygenic risk scores. Our work offers a novel and cost-effective method for lcWGS simulation, providing a powerful tool to potentially catalyze the development of new downstream bioinformatics tools for sequencing data analysis. This approach could also benefit probabilistic data augmentation strategies for artificial intelligence.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4310 Partitioning genetic nurture: Investigating the specific parental traits driving the signal of indirect genetic effects on educational attainment

Authors:

A. Perry[1], A. Akbari[1], A. Durvasula[2], N. Patterson[3], D. Reich[1]; [1]Harvard Univ., Cambridge, MA, [2]Harvard Med. Sch., Cambridge, MA, [3]Broad Inst MIT & Harvard, Cambridge, MA

In industrial societies, education is increasingly predictive of a number of life outcomes, including an individual's health, housing prospects, and job opportunities. Thus, it is important to understand the variables, societal and biological, impacting an individual's educational opportunities. Genome-Wide Association Studies (GWAS) have identified genetic variants correlated with educational attainment, implying that an individual's predisposition to higher education is impacted in part by their genotype. Not all of the variants correlated with educational attainment, however, directly modulate the factors that lead an individual to attain more schooling. Previous research has found that some of these variants affect educational attainment by means of "indirect" genetic effects, whereby variants expressed in one individual impact the educational attainment of a different individual. One example of indirect genetic effects that is likely to be particularly relevant to educational attainment is parental effects, where a parent's value of some non-education-related phenotype affects the educational attainment of their children. Because of these parental effects, genetic variants correlated with a parent's non-education-related traits may be correlated with educational attainment in population-level GWAS. Prior research has postulated that parental effects are particularly important in explaining the genetic variants correlated with educational attainment, but a key unanswered question is which parental traits are driving this signal of indirect genetic effects. This study seeks to address this question by correlating parental polygenic risk scores (PRS; a measure of an individual's genetic predisposition toward a phenotype) for many traits to their children's educational outcomes. The study identifies parental traits which, at the phenotypic level, are correlated to children's educational attainment, and differ qualitatively from the PRS score that shapes educational attainment in the children. To control for direct genetic effects, this approach involves computing PRS on the parental genetic information not transmitted to children, and then studies the correlation between parental PRS and child educational attainment phenotypes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4311 Pathway-Specific Polygenic Scores for Atrial Fibrillation Reveal Heterogeneous Genetic Risk Profiles

Authors:

S. Gunn[1], C. Roselli[2], K. Lunetta[1], S. Choi[1]; [1]Boston Univ. SPH, Boston, MA, [2]Broad Inst., Cambridge, MA

Background

Here we derive pathway-specific PGS (PPGS) for pathways associated with atrial fibrillation (AF) and use these PPGS to demonstrate the heterogeneity of genetic risk in individuals with AF.

Methods

Deriving Pathway-PGS

To determine pathways of interest, we used the cardiovascular knowledge portal MAGMA results for GO biological processes annotations for AF, with a Bonferroni threshold to determine a set of 76 pathways. We grouped the pathways in functional categories: conduction, contractile, cardiac development, or other. To produce each PPGS we subset the recent AFGen GWAS (in press) to SNPs within the pathway-specific set of gene bodies, and estimated weights using the PRS-CS approach. We also built a genome-wide PGS (GWPGS) with PRS-CS.

Evaluating Pathway-PGS

We computed and standardized the scores in a white British sample of the UKBB (N = 408884). First, we evaluated the prediction performance of the PPGS in the sample. Next, we considered AF cases with high overall genetic risk, defined by top 10% of GWPGS, (N = 6624) and applied k-means clustering to infer profiles of genetic risk. To summarize the clusters, we computed the overall and functional category-specific means of the standardized PPGS.

Results and Discussion

As expected, we found all PPGS were associated with AF in the UKBB (p-values < 10-20). When we consider 5 clusters we see a significant difference in overall mean PPGS and functional category-specific mean PPGS by cluster using ANOVA (p-values < 2e-16). Three clusters show relatively uniform risk across the PPGS: low, medium-high and high groups with overall mean PPGS of -0.364, 0.699, 1.15, respectively. However two clusters show varying levels of PPGS across the functional categories: one cluster has relatively low PPGS in the conduction and contractile categories (group-specific mean PPGS of -0.166 and -0.039 respectively), with higher PPGS in cardiac development (mean cardiac-development PPGS 0.551), and another cluster has the opposite pattern, relatively higher PPGS for conduction and contractile categories (0.475, 0.555) and lower PPGS in cardiac development (-0.195).

Conclusions

Using a novel method for deriving pathway-specific PGS, we show that even in individuals with high overall GWPGS for AF, there are multiple profiles of genetic risk. In future work, we plan to investigate additional sources of genetic risk for AF to identify the missing genetic risk factors for the high GWPGS but low PPGS group. We hope that these pathway-specific PGS can improve our treatment of AF by better understanding the sources of genetic risk at play in this complex trait.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4312 PENGUIN: Progressively Establish Novel Genetics Underlying Interrelation

Authors:

J. Huang[1,2], R. Sun[3], E. Hu[4], G. Deiana[5], J. M. Ranson[6], V. Napolioni[5]; [1]Southern Univ. of Sci. and Technology, Shenzhen, China, [2]Inst. for Global Hlth.and Dev., Peking Univ., Beijing, China, [3]Dept. of Publ. and Ecosystem Hlth., Cornell Univ. Coll. of Vet. Med., Ithaca, NY, [4]Southern Med. Univ. of China, Guangzhou, China, [5]Sch. of BioSci.s and Vet. Med., Univ. of Camerino, Camerino, Italy, [6]Coll. of Med. and Hlth., Univ. of Exeter, Exeter, United Kingdom

Background: The abundance of publicly available genome-wide association study (GWAS) summary statistics is providing golden opportunities for studying the interrelation of complex traits. Well-established methods include the calculation of genetic **correlation** (by LDSC etc.), the assessment of genetic **causation** (through Mendelian Randomization), and the evaluation of genetic **colocalization**. The 1st (correlation) and 2nd C (causation) mainly utilize data at the **DNA** level, while the 3rd C (colocalization) involves data at the **RNA** level. **Methods**: We now propose a heuristic 5-C approach that further includes **coevolution** and **corroboration**. The 4th C (coevolution) utilizes data at the **protein** level and enables the study of protein interaction and genetic evolution among populations of different ancestry. The 5th C (corroboration) represents a broad suite of big data mining approaches that independently support the putative interrelation. These 5-C modules are progressive, meaning that each new module is more zoomed-in and reliable that its precedent module. We nickname this 5-C approach "**PENGUIN**", for "***Progressively Establish Novel Genetics Underlying Interrelation***". **Results**: We developed a pilot version of PENGUIN and made available at github.com/jielab/penguin. The input data for PENGUIN is summary statistics of GWAS. We chose five widely studied **exposures** (adult height, body mass index [BMI], smoking behavior, low-density cholesterol [LDL], C-reactive protein [CRP]) and five **outcomes** of global public health concern (coronary artery disease [CAD], type 2 diabetes [T2D], lung cancer, dementia, COVID-19 severity) for a pilot test. We confirmed well-established interrelation (e.g. BMI and height on CAD), and also discovered novel interrelation (height on COVID-19 severity). We demonstrate that PENGUIN is a powerful and yet user-friendly platform that incorporates established software in a progressive and logic manner. **Conclusion**: Similar to the 5-C situation analysis widely adopted in business marketing (Company, Collaborators, Customers, Competitors, Climate), we designed and developed a 5-C protocol (**Correlation, Causation, Colocalization, Coevolution, Corroboration**) to scientifically generate and conveniently replicate genetic interrelation reported on daily basis.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4313 Personalized transcription factor binding from deep learning sheds light into the cis and trans regulation of gene expression.

Authors:

T. Adeluwa[1], S. Gona[1], S. Baca[2], M. Freedman[2], A. Gusev[2], B. Liu[3], R. Madduri[4], T. Amariuta[5], H. Im[6]; [1]The Univ. of Chicago, Chicago, IL, [2]Dana-Farber Cancer Inst., Boston, MA, [3]Natl. Univ. of Singapore, Singapore, Singapore, [4]Argonne Natl. Lab., Naperville, IL, [5]Univ. of California San Diego, Brookline, MA, [6]Univ. of Chicago, Chicago, IL

Transcription factors (TFs) play a pivotal role in gene regulation and phenotype expression, and their altered binding could potentially result in various human diseases (Reshef et al., 2018). Therefore, the development of reliable genetic predictors for TF activity would significantly advance our understanding of gene regulation and phenotypic implications. Previous research focused on the genetic determinants of Androgen Receptor (AR) binding by measuring AR in prostate tumor samples from 120 subjects (Baca et al., 2022). However, the cost of ChIP-Seq experiments poses significant challenges to extend this approach across a diverse range of TFs and tissue or cell types. To overcome these hurdles, we utilized cutting-edge methods such as ENFORMER, which predicts epigenetic features directly from DNA sequences, to construct a model for individualized TF binding prediction. While currently available ENFORMER models generates a limited selection of TFs and cell types, our study extends this framework by hypothesizing that TF binding can be precisely profiled as a function of genome-wide patterns of numerous epigenetic key features, as shown by the IMPACT method (Amariuta et al., 2019). We used ENFORMER to predict the 5,313 features utilized in the IMPACT framework based on DNA sequences. Subsequently, through logistic regression, we developed predictors of genome-wide TF binding per individual, based on personalized epigenetic features. A key advantage of our approach is that it relies on the same set of 5,313 ENFORMER-predicted features for the training of each new TF binding dataset. We validated our model by comparing predicted and observed AR binding in prostate cancer samples, resulting in 597 Bonferroni significant sites out of 12,812 tested. Additionally, by contrasting our predictions with those from Baca et al., who used linear predictors trained with in vivo measured TF binding across 120 individuals, we achieved correlations up to 75%, with a median of 45% (36.6% of which had BF significant p-values). Lastly, we explored the potential influence of AR binding on gene regulation by correlating the mRNA levels of a gene with the predicted AR binding at the gene's promoter. 167 out of 15,021 demonstrated significant association after Bonferroni correction. Our predictors create a promising platform for linking transcription factors in different cell types and tissues to diseases, enhancing our understanding of the genetic underpinnings of complex, polygenic diseases.

PB4314 Pervasive biases in GWAS using family history of Alzheimer's disease as proxy phenotypes

Authors:

Y. Wu[1], **Z. Sun**[1], J. Fletcher[2], Q. Lu[1]; [1]Univ. of Wisconsin-Madison, Madison, WI, [2]Univ. of Wisconsin, Madison, WI

Genome-wide association studies (GWAS) of Alzheimer's disease (AD) often rely on family health history as a proxy phenotype to boost sample size and statistical power. Recent AD GWASs have combined case-control associations with GWAS-by-proxy (GWAX) associations through meta-analysis. Despite its increasing popularity, there is a lack of careful investigation into the methodological issues and the quality of GWAX association results. In this study, we performed GWAX on parental AD history in the UK Biobank (47,993 proxy cases and 315,096 controls). While GWAX and GWAS exhibited a high genetic correlation (rg=0.887, p=4.1e-7), we observed substantial divergences between the two approaches, particularly in analyses involving genome-wide single nucleotide polymorphisms (SNPs) such as genetic correlation estimation, Mendelian randomization, and polygenic risk score applications. Surprisingly, the genetic correlation with education was positive in GWAX (rg=0.167, p=1.7e-11), contrary to the negative correlation observed in GWAS (rg= -0.133, p=2.4e-5). Such discrepancies were not limited to AD but were also observed in for other reported parental illnesses such as Parkinson's disease, breast cancer, severe depression, and stroke. Furthermore, we found similar issues in AD GWAX using the All of Us data (3,899 proxy cases and 23,218 controls). To identify the bias in AD GWAX, we developed a theoretical framework to decompose GWAX into AD and non-AD components. The positive genetic correlation with cognition was explained by the non-AD component (rg=0.260 with education, p=5.2e-11). Moreover, the non-AD component in GWAX exhibited correlations with lower risks of health outcomes such as coronary artery disease (rg= -0.136, p=2.8e-3) and diabetes (rg= -0.206, p=2.8e-3), indicating the presence of substantial survival bias in samples reporting parental AD history. Although adjusting for parental age in GWAX reduced the genetic correlation with education, additional unaccounted factors in the current GWAX were suggested. We also provide evidence that the genetic correlation between family health history awareness and education (rg=0.285, p=1.4e-10) contributes to these biases in GWAX associations. Our findings highlight that GWAX based on the reported parental health history introduces substantial and systematic biases in AD genetic associations due to the non-representativeness of the biobank's health history survey. Naively combining GWAX with regular case-control GWAS can lead to misleading and erroneous results in genome-wide analyses.

PB4315 Phenome-Wide Admixture Mapping in Hispanic/Latino(a) populations in a Large Hospital-Based Biobank

Authors:

S. Cullina[1,2], R. Shemirani[1,2], B. Rowan[1,2], N. Abul-Husn[3,2,4], S. Asgari[1,4,5], E. Kenny[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Inst. for Genomic Hlth., Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]23andMe, Sunnyvale, CA, [4]Dept. of Med., Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Dept. of Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Biobank-scale association studies in Hispanic/Latino(a) populations (HLs), who share genetic ancestry from Europe, Africa and the Americas, are lacking due to underrepresentation of HLs in genomic research and the insufficiency of genomic discovery pipelines designed for large-scale analysis of admixed populations. We developed a pipeline for admixture mapping, which tests for associations based on differences in disease prevalence and allele frequency between ancestral populations of admixed individuals, within the diverse Bio*Me* biobank in New York City.**Methods:** Global admixture proportions were inferred in ~53,000 Bio*Me* participants and 15,149 HLs were identified based on both self-reported race/ethnicity and genetically inferred admixture patterns. TOPMed imputed genotype data was phased and GNOMIX was used to infer three-way (African, European, and Native American (NA) ancestry) Local Ancestry (LA) haplotypes using a global reference panel constructed for maximal NA representation. A generalized linear mixed model (SAIGE) was used for admixture mapping, testing the association between LA haplotypes and 1,018 phecodes derived from electronic health records, as well as a curated set of over 200 biomarkers and quantitative traits. STEAM, a method that accounts for population structure, was used to derive a genome-wide significance (gws) threshold.Results: We achieve high quality local ancestry calls with correlation between global and local ancestry proportions reaching R^2 0.99. We identify 54 phecode-haplotype associations reaching gws (P&lt4.87x10^{-6}). We replicate known admixture association, such as African haplotypes overlapping the HBB gene associated with “Sickle cell anemia” (P&lt2.74x10^{-9} , Odds Ratio (OR) (95% Confidence Interval (CI)) = 4.72 (2.8-7.95)) as well as identify putatively novel associations, for example, a NA haplotype on chr7q35 associated with “Alzheimer's disease” (P&lt6.57x10^{-7}, OR= 2.33 (1.65-3.28)) and a European haplotype on chr10q26.2 associated with “Cerebrovascular disease” (P&lt9.6x10^{-7}, OR (95% CI) = 1.31 (1.17-1.45)). Current work includes fine-mapping and functional characterization of significant associations and selection scans of these regions using iSAFE.**Conclusion:** Efforts to diversify genomic research will recruit more admixed individuals to biobanks, driving the need for calibrated pipelines for genomic discovery in admixed populations. This approach enhances association testing power compared to GWAS, specifically for population-specific risk loci, and provides valuable insights into population differences in the clinical manifestation of disease risk loci.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4316 Phenome-wide association study of asthma genetic loci reveals potential subtypes of disease.

Authors:

M. J. Saward[1], R. J. Packer[1,2], L. G. Heaney[3], I. Sayers[4], K. A. Fawcett[1]; [1]Dept. of Population Hlth.Sci., Univ. of Leicester, Leicester, United Kingdom, [2]Leicester NIHR BioMed. Res. Ctr., Glenfield Hosp., Leicester, United Kingdom, [3]Wellcome-Wolfson Ctr. for Experimental Med., Sch. of Med., Dentistry and BioMed. Sci., Queen's Univ. Belfast, Belfast, United Kingdom, [4]Ctr. for Respiratory Res., NIHR Nottingham BioMed. Res. Ctr., Sch. of Med., Biodiscovery Inst., Univ. of Nottingham, Nottingham, United Kingdom

Asthma is a chronic, heterogeneous lung condition, affecting over 300 million people worldwide and susceptibility is thought to be due to a combination of genetic and environmental factors. The clinical heterogeneity is thought to be the result of different pathobiological mechanisms, and therefore phenome-wide genetic studies of identified asthma associated variants may help to reveal the genes and pathways underlying different clinical features and subtypes of asthma.

A literature search for GWAS of asthma found 43 studies identifying 478 associated variants. We tested these variants in European UK Biobank participants using Regenie, and confirmed association for 440 of the variants ($P<0.05$), which represented 210 independent signals. We applied the DeepPheWAS package in R to the 210 signals, to test for associations with 1,900 traits using data from 213,402 European participants in UK Biobank. Nine traits showed significant association with at least 10% of the signals, which were: eosinophil count (95 signals), eosinophilia (65), lymphocyte count (31), FEV1/FVC ratio (27), white blood cell count (27), neutrophil count (25), standing height (23), monocyte count (22) and platelet count (21). Eosinophilia and white blood cell count were removed for non-independence with eosinophil and neutrophil counts, respectively. Four signals were associated with six out of seven traits, two with five traits, nine with four traits, 16 with three traits and 29 with two traits. Thirteen signals were associated with both eosinophil and neutrophil counts. Some further, not often reported traits of interest were found to be associated with at least 5% of the independent signals, including IGF-1 (17), gamma-glutamyl transferase (12), nasal polyps (12), coeliac disease (12), type 1 diabetes (12) and hypothyroidism (11).

Our findings show that asthma genetic signals cluster into distinct and overlapping traits providing a potential framework to understand the contribution of these signals to disease mechanisms and identify endotypes. The numbers of signals for each trait also highlights the polygenicity of the potential subtypes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4317 Phenome-wide association study of immune genes with known eQTL and pQTL effects using the All of Us research project

Authors:

S. Boris, B. Bates, K. Bates, M. Bailey; Brigham Young Univ., Provo, UT

Investigating genetic variants associated with disease susceptibility is crucial for understanding complex diseases. Complex diseases develop through a combination of genetic and environmental factors, and it is difficult to identify the specific genetic variants responsible for them. However, by conducting large-scale studies that look at the genomic data of many individuals, it is possible to identify genetic variants that are associated with an increased risk of developing certain diseases. Here we conducted a Phenome-Wide Association Study (PheWAS) to identify genetic variants within three genes - *ERAP2*, *HLA-DQB1*, and *PPIL3* - associated with disease susceptibility. These three genes were recently reported to have strong eQTL and pQTL SNPs found in the National Cancer Institute's Clinical Proteomic Tumor Analysis Consortium (CPTAC) in both tumor and normal adjacent samples. We used the large-scale genomic dataset from the All of Us research program, which includes the whole genome sequencing data of over 245,000 individuals. We also used the electronic health records (EHR) of these individuals to determine which of them had been diagnosed with particular diseases. Using their genomic data as well as the phenotypic information present in their EHRs, we used the PheWAS R-library written by Robert Carroll et al. 2014 to identify which disease phenotypes were linked to the identified variants within *ERAP2*, *HLA-DQB1*, and *PPIL3*. Preliminary results suggest that the previously identified eQTL and pQTL hits from the CPTAC cancer-specific dataset also display potential genetic predispositions in other diseases and are dependent on genetic ancestry. By conducting this PheWAS, we demonstrate the utility of the All of Us research program in exploring the genetic basis of diseases. Furthermore, our findings highlight the importance of investigating multiple genes simultaneously to obtain an immune-specific understanding of disease risk. In conclusion, these findings contribute to the growing knowledge base regarding the genetic underpinnings of complex diseases, paving the way for further research and personalized medicine approaches, and warrant further investigation to experimentally validate our conclusions.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4318 Phenome-wide, metabolomic and proteomic association scan of *SHROOM3* haplotypes based on imputed exonic variants.

Authors:

D. Ghasemi[1], N. Dordevic[1], L. Foco[1], E. König[1], D. Emmert[1], M. Lang[1], E. Hantikainen[1], M. Gögele[1], J. Rainer[1], F. S. Domingues[1], M. Ralser[2], C. Fuchsberger[1], D. J. M. Peters[3], P. P. Pramstaller[1], C. Pattaro[1]; [1]Eurac Res., Bolzano, Italy, [2]Inst. of Biochemistry, Charité - Univ.smedizin Berlin, Berlin, Germany, [3]Leiden Univ. Med. Ctr., Leiden, Netherlands

Introduction: SHROOM3 encodes an actin-binding protein involved in cell shaping, neural tube formation, and epithelial morphogenesis. Genome-wide association studies (GWAS) identified common variants at SHROOM3 associated with chronic kidney disease, creatinine-based estimated glomerular filtration rate (eGFRcrea), and serum magnesium (Mg). While a comprehensive haplotype analysis of this locus is missing, integration of metabolomics and proteomics data may elucidate underlying physiological mechanisms. We conducted a phenome-wide, metabolomic and proteomic analysis of SHROOM3 haplotype diversity in the Cooperative Health Research in South Tyrol (CHRIS) general population study.Methods: We performed genotype imputation of the whole cohort of 13,389 participants based on whole-exome sequencing data from 3,840 of the sample. We reconstructed haplotypes tagged by 146 polymorphic functional variants in FAM47E, STBD1, CCDC158 and SHROOM3, in the ~500kb locus bounded by the recombination hotspots identified by large GWAS. The analysis encompassed 394 traits, including 74 serum, urine and anthropometric traits, 172 targeted serum metabolites, and 148 targeted plasma protein concentrations on 3,423 individuals. We fitted linear models on the inverse normal transformation of each trait, adjusted for age, sex and the first 10 genetic principal components, embedded in an expectation-maximization algorithm for haplotype estimation.Results: We identified 11 haplotypes (H1 to H11; frequency from 24.36% to 2.03%). H8 (frequency 2.67%) was most strongly associated with eGFRcrea (P=2.7e-4), the urinary albumin-to-creatinine ratio (P=3.3e-3) and multiple phosphatidylcholines. H6 (11.61%) was chiefly associated with serum creatinine, several carnitines and coagulation traits. H4 (2.81%) was associated with Mg (P=6.7e-4), eGFRcrea and basophils. H10 (2.32%) was associated with Mg, glutamine, putrescine and afamin protein. H1 (7.65%) and H7 (2.40%) were associated with multiple phosphatidylcholines. H3 (2.32%) and H9 (3.99%) were associated with thyroid-related traits, carnitines and immunoglobulins. Cluster analysis showed that different haplotypes were associated with distinct groups of traits, more specifically eGFRcrea and Mg. Conclusion: Our multiomic, haplotype association analysis highlighted strong pleiotropy at SHROOM3, associated with kidney function but also with other sets of traits. Mechanisms regulating eGFRcrea and Mg are likely distinct. Identification of haplotypes jointly associated with complex traits, metabolites and proteins highlights molecular pathways warranting further investigations.

PB4319 Phenotype projections enable ultra-fast biobank-scale GWAS

Authors:

M. Zietz[1], N. Tatonetti[2]; [1]Columbia Univ., New York, NY, [2]Cedars-Sinai Med. Ctr., Los Angeles, CA

Complex diseases are responsible for significant morbidity and mortality worldwide. Genome-wide association studies (GWAS) are a useful summarization of complex disease genetics. Pan-biobank GWAS have generated shareable summary statistics on thousands of phenotypes and emerged as a powerful tool in genetics. Biobank-scale GWAS, however, have two notable limitations: they are highly resource intensive, and they do not allow for hand-crafted phenotype definitions, which are often more relevant to study. Here we present Indirect GWAS (indGWAS) as a solution to these two challenges. indGWAS is a summary-statistic-based method that computes GWAS for a phenotype defined as linear combination of other phenotypes. Our method is applicable to GWAS using both linear and linear mixed models (e.g. SAIGE). To compute pan-biobank GWAS more quickly, we decompose a large set of phenotypes down to a lower-dimensional latent space, perform GWAS on the latent space, then reconstruct GWAS summary statistics in the original phenotype space. This procedure substantially reduces computation time, and this speedup gets better with more phenotypes. We found a roughly 5x reduction in time to compute GWAS across all ICD codes in the UK Biobank, but, as a large fraction of the computations can be pre-computed, GWAS on all pairs of ICD codes would afford a 2000x speedup. For custom phenotype definitions, our method approximates a map from the phenotypic latent space to the custom phenotype, estimates GWAS for the custom phenotype, and provides estimates of the errors in summary statistics due to the approximate map. GWAS on any arbitrary linear combination phenotype can be computed almost instantaneously. Overall, indGWAS enables two major improvements. First, indGWAS can greatly increase the speed of pan-biobank GWAS studies. This makes it possible, for the first time, to systematically study complex phenotypes definitions. Second, indGWAS can allow researchers to obtain approximate GWAS summary statistics for any phenotype definition of interest, without needing access to individual-level data. This will make GWAS more widely accessible and enables more rapid iteration on phenotype definitions. In summary, indGWAS enables faster pan-biobank GWAS and the ability to estimate GWAS summary statistics for custom phenotype definitions that weren't included in pan-biobank GWAS data releases. Overall, this method will push forward our understanding of complex disease by facilitating more cost-effective, accessible, and representative genetic studies using large observational data.

PB4320 Pitfalls in estimating SNP-based heritability for singleton genetic variants.

Authors:

H. Wang[1], P. Wainschtein[2,1], J. Sidorenko[1], M. Fikere[1,3], Y. Zhang[1], K. Kemper[1], Z. Zheng[1,4], V. Hivert[1], J. Zeng[1], M. Goddard[5], P. Visscher[1], L. Yengo[1]; [1]Inst. for Molecular BioSci., Univ. of Queensland, Brisbane, Australia, [2]Artificial Intelligence Lab., Illumina, Inc., San Diego, CA, [3]Purdue Univ., West Lafayette, IN, [4]Broad Inst. of MIT and Harvard, Boston, MA, [5]Faculty of Vet. and Agricultural Sci., Univ. of Melbourne, Parkville, Australia

The contribution of rare genetic variants to the heritability of human complex traits remains elusive. One major obstacle to addressing this question is a lack of understanding of the sources of bias affecting heritability estimation from rare variants. In this study, we investigate different factors biasing estimates of the SNP-based heritability attributable to singleton genetic variants (i.e., observed only once in the sample). Through simulations, we illustrate that singleton-based heritability estimates can be biased by factors affecting the mean of a trait only if their variance is also correlated with singleton count (SC). Moreover, we found that scale transformations inducing a correlation between the mean and the variance of a trait can yield positive or negative biases, some of which can be corrected by fitting confounders (if measured) both as fixed and random effects in a linear mixed model. Finally, we show that phenotype distribution has a stronger effect on standard errors (S.E.) of SC-based heritability estimates than previously quantified for common SNP-based heritability. We showcased these biases using 22 real phenotypes of 305,813 unrelated European-ancestry individuals in the UK Biobank with whole-exome sequence data. When adjusting for fixed and random confounding effects, we found significant SC-based heritability estimates for 3 traits, including the number of children, which estimate (5.3%, standard error = 0.5%) amounts to the cumulative proportion of variance explained by all common SNPs. Our proposed approaches to detect and correct biases in singleton-based heritability estimates are generalizable for other classes of rare variants.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4321 Pleiotropy-robust methods for high-dimensional multivariable Mendelian randomization

Authors:

N. LaPierre, M. Stephens, X. He; Univ. of Chicago, Chicago, IL

Mendelian Randomization (MR) is a popular class of methods that use genetic variants (e.g. SNPs) to estimate the causal effect of one phenotype (the "exposure") on another phenotype (the "outcome"). The assumptions of MR are violated when SNPs that affect the exposure also affect the outcome directly, or affect a third trait (a "confounder") that is a common cause of the exposure and outcome. These "pleiotropic" effects are common and represent a central challenge in MR method development. More recently, "Multivariable" MR (MVMR) methods have extended this concept to simultaneous estimation of the causal effects of multiple exposures on a single outcome. This allows users to include potential confounders as covariates in the analysis, eliminating their confounding effect. However, in many cases, potentially confounding phenotypes are unknown or unmeasured, so pleiotropy remains an issue for MVMR methods.

We consider MVMR in the high-dimensional setting where many exposures are measured. While traditional MVMR typically involves a few exposures, our work is motivated by the emergence of large datasets that associate genetic variations with dozens to thousands of molecular phenotypes, such as metabolites.

We demonstrate that we can adjust for pleiotropy, including hidden confounding factors, by leveraging some unique properties of the data that arise in such settings. A key idea is that confounding factors will induce genetic correlations among exposures, and therefore can be inferred via factor analysis (FA) methods. Additionally, this setting naturally involves *sparsity*: not all selected SNPs will affect all exposures, and not all exposures will affect the outcome.

We develop a two-stage procedure where we estimate the hidden factors in the first stage via FA and use sparse regression to estimate the effects of exposures in the second stage. This framework enables the identification of a small portion of truly causal exposures while accounting for pleiotropic effects. Furthermore, this framework is (a) *flexible*, accommodating a number of existing methods for FA and regression; (b) *modular*, in that any approach for the first stage can be combined with any approach for the second stage; and (c) work with either summary statistics or individual-level data. We highlight the value of *variational empirical Bayes* methods, which can automatically infer the degree of sparsity from the data itself. We demonstrate that several variations of our framework greatly reduce the number of false discoveries compared to existing approaches in a simulation study, while maintaining similar or even greater power, and apply these methods to blood cell traits in the UK Biobank.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4322 Polygenic etiology underlying atopic dermatitis and asthma in individuals with inborn errors of immunity and immune dysregulation

Authors:

J. Yan[1], M. Similuk[2], M. Kamen[3], C. Jodarski[4], R. Gore[1], N. Reynolds-Lallement[1], K. Lewis[1], B. Beers[1], E. Damskey[5], H. Orellana[1], S. Byers[1], R. Ghosh[2], B. A. Seifert[6], J. Lack[7], W. Cao[1], J. Bergerson[1], A. Freeman[8], S. M. Holland[7], M. A. Walkiewicz[3]; [1]NIH, Bethesda, MD, [2]NIH, Bethesda, MD, [3]NIAID, Bethesda, MD, [4]NIH, Washington, DC, [5]NIH/NIAID, Bethesda, MD, [6]NIH, Fairfax, VA, [7]Natl. Inst. of Allergy and Infectious Diseases, Bethesda, MD, [8]Natl. Inst. of Allergy and Infectious Disease, Bethesda, MD

Background Atopic dermatitis (AD) and asthma represent inflammatory disorders characterized by multifactorial etiology. They are common in the general population; however, individuals with inborn errors of immunity (IEI) such as *STAT3* hyper IgE syndrome, DOCK8 deficiency, and CARD11 deficiency can be particularly susceptible. Prior genome wide association studies suggest shared genetic etiology between AD and asthma in population-based samples. The role of common genetic variation in the relationship between the two phenotypes in the setting of IEI and immune dysregulation remains to be explored. Here, we investigate whether common polygenic risk is associated with AD and asthma among individuals with IEI and immune dysregulation disorders.
Methods Genome sequencing was completed via a centralized sequencing program in a cohort of 1,290 unrelated probands with a spectrum of immune disorders, including IEI and immune dysregulation. Common variants with minor allele frequency>0.01 were extracted, pruned using an r^2 threshold>0.2, and used to calculate polygenic scores (PGS) for AD and asthma using variant effect sizes estimated in large previously published outside studies in FinnGen and the Global Biobank Meta-analysis Initiative respectively. Scores comprised of 1,021,400 variants for AD and 834,809 variants for asthma. Association tests were completed using logistic regression controlling for sex, age, and the first 10 genomic ancestry principal components.
Results The cohort consisted of 220 (17.1%) cases with asthma, 137 (10.6%) with AD, and 56 (4.3%) with both. Participants were 52.8% female (n=681), predominantly of European ancestry (77.9%, n=1,005), and had a mean age of 39 years (range 0-85). Of the individuals with asthma and/or AD, 134 (44.5%) had a molecular diagnosis of IEI, the most common of which included *STAT3, CYBB, PIK3CD, STAT1, TNFRSF13B, DOCK8, LRBA,* and *NOD2*. The PGS for AD was associated with asthma (OR=1.96; 95% CI[1.09, 3.52]; p=0.024) but not with AD (p=0.18). The PGS for asthma was associated with AD (OR=1.24; 95% CI[1.02, 1.51]; p=0.030) and with asthma (OR=1.77; 95% CI[1.51, 2.0]; p=4.9e-12).
Discussion This study supports correlation in polygenic risk between AD and asthma among individuals with immune disorders. Notably, AD PGS was not associated with AD itself but instead with asthma, indicating possible limited power in this cohort. This cohort was enriched for IEI diagnoses; thus, results may be specific to atopic disease related to eosinophilia and elevated IgE. Additional studies are warranted to parse causal relationships underlying these results to better understand the genetic architecture of AD and asthma.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4323 Polygenic risk and early diagnosis of diabetes.

Authors:

C. German, W. Wang, 23andMe Research Team, J. Granka, S. Aslibekyan, J. Tung, S. Shringarpure, M. Holmes; 23andMe, Sunnyvale, CA

It is estimated that of the 37.3M adults in the USA with diabetes, 23% are undiagnosed. Undiagnosed disease can lead to avoidable disease-related sequelae and morbidity that affect various parts of the body, including the heart, nerves, kidneys, eyes, and immune system. Here we explore the utility of a polygenic risk score (PRS) for identifying individuals with undiagnosed diabetes and prediabetes in the UK Biobank (UKB). We include individuals self-reporting an absence of doctor-diagnosed diabetes at study baseline in the UKB with values on HbA1c to identify individuals with undiagnosed diabetes. We used a T2D PRS comprising ~1.3 million SNPs derived from a GWAS of over 250,000 cases in the 23andMe research database. We conduct a comparison of the PRS to body mass index (BMI). In this exploratory analysis, participants were restricted to white individuals to enable use of an ancestry-appropriate PRS. Undiagnosed diabetes was defined as HbA1c ≥6.5% and prediabetes as HbA1c ≥5.7% and <6.5%. Of 414,959 individuals self-reporting an absence of doctor-diagnosed diabetes and who had an HbA1c measurement at baseline, 3061 (0.7%) had undiagnosed diabetes, representing 12.2% of all (diagnosed and undiagnosed) diabetes. Over half (1,717, 56%) of undiagnosed diabetes cases were in the top 25% of the T2D PRS. Individuals with a BMI <25kg/m^2 who were in the top 12.5% of the T2D PRS had a similar risk of undiagnosed diabetes (0.3-0.6% probability) as individuals with a BMI ≥30kg/m^2 in the lowest 12.5% of the T2D PRS (0.1%-0.6% probability). Among individuals with the highest BMI (≥35kg/m^2) in the cohort, those in the lowest 12.5% of the T2D PRS had the risk of undiagnosed diabetes equivalent to the population average with a BMI of 27.2 kg/m^2. When the number of individuals evaluated by the T2D PRS was made equivalent to those with overweight and obesity (66% of the study population), the T2D PRS was similar to BMI in identifying undiagnosed diabetes: 91.4% (2782 of 3045 with data on HbA1c and BMI) for T2D PRS vs 93.2% (2839 of 3045) for overweight/obese. Prediabetes was common (14% prevalence), with measured BMI and T2D PRS providing additive risk. 1 in 10 individuals that were in the top 12.5% T2D PRS and with BMI ≥35kg/m^2 developed incident diabetes over 4 years of follow-up, as compared to the population average of 1.6%. We find that a T2D PRS is informative in identifying undiagnosed diabetes. PRS may have utility in detecting individuals at risk of asymptomatic disease that may not be caught by routine checkups.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4324 Polygenic risk score prediction accuracy convergence

Authors:

H. Aschard[1], J. Kim[2], Z. Yang[3], S. Rubinacci[4], G. Pires[1], C. Albiñana[5], C. Boetto[1], H. Julienne[1], A. Frouin[1], A. Auvergne[1], Y. Suzuki[1], S. Djebali[6], O. Delaneau[7], A. Ganna[8], B. Vilhjálmsson[5], F. Privé[5], L. Henches[1]; [1]Inst. Pasteur, Paris, France, [2]Harvard T. H. Chan Sch. of Publ. Hlth., Boston, MA, [3]Univ. of Helsinki, Helsinki, Finland, [4]Brigham and Women's Hosp., Boston, MA, [5]Aarhus Univ., Aarhus, Denmark, [6]INSERM, Toulouse, France, [7]Univ. of Lausanne, Lausanne-Dorigny, Switzerland, [8]Inst. for Molecular Med. Finland, Helsinki, Finland

Polygenic risk scores (PRS) trained from genome-wide association study (GWAS) results are set to play a pivotal role in biomedical research addressing multifactorial human diseases. The prospect of using these risk scores in clinical care and public health is generating both enthusiasm and controversy, with varying opinions about strengths and limitations across experts. The performances of existing polygenic scores are still limited, and although it is expected to improve with increasing sample size of GWAS and the development of new powerful methods, it remains unclear how much prediction can be ultimately achieved. Here, we conducted a retrospective analysis to assess the progress in PRS prediction accuracy since the publication of the first large-scale GWASs using six common human diseases with sufficient GWAS data (type 2 diabetes, coronary artery disease, breast cancer, Alzheimer disease, asthma, and obesity). We show that while PRS accuracy has grown rapidly for years, the improvement pace from recent GWAS has decreased substantially, suggesting that further increasing GWAS sample size may translate into very modest risk discrimination improvement. We next investigated the factors influencing the maximum achievable prediction using recently released whole genome-sequencing data from 125K UK Biobank participants, and state-of-the-art modelling of polygenic outcomes. Our analyses point toward increasing the variant coverage of PRS, using either more imputed variants or sequencing data, as a key component for future improvement in prediction accuracy.

Thousands of mutations have been associated with human phenotypes, enabling greater understanding of the genetics of complex traits and disease risk prediction through polygenic scores (PGSs). Because genes, and so genetic factors, operate within biological networks, interactions between mutations are expected to exist. Their modeling could aid biological understanding and improve predictive performance by PGS. However, detecting such interactions to link phenotypes to biological networks has so far been complicated by the vast search space of variant combinations, and multiplicatively small expected effect sizes of interactions between individual variant pairs.

To increase power, we created a test for interactions between a SNP and *groups* of other variants, e.g. within a PGS. Our method is enabled by a new computational algorithm for PGS construction which iteratively adjusts for detectable additive signal for a trait. In realistic simulations, this approach avoids false positives and is well-powered to find interacting networks.

We identified 144 interactions involving 52/97 quantitative traits examined in the UK Biobank. A subset of previous GWAS hits show interaction signals, implying they also modify effects at distant loci. These include important variants modifying human disease risk, e.g. at the *FTO*, *HFE*, *HLA-C*, *LDLR* and *TCF7L2* genes. Conversely, some interaction signals are *not* identified in the original GWAS: these impact the trait by altering the predictive power of its PGS, but show no significant direct effect.

We developed a test to identify, for each interaction signal, SNPs driving that interaction. This correctly identified a known interaction between *ABO* and *FUT2* affecting alkaline phosphatase, and revealed these operate within a larger network including *FUT6*, *PIGC*, *ASGR2* and *ZNF678*. A second interaction affecting eosinophil count links a noncoding *IL33* variant and an *ALOX15* missense mutation. Interestingly, a recent functional study in mice identified *ALOX15* as reducing *IL33*-induced airway eosinophilic inflammation, implicated in asthma. Additional interactions involve distinct Alzheimer's-associated *APOE* coding mutations, for distinct traits (lipoprotein(a) and the liver-function marker alanine aminotransferase), supportive of connections among Alzheimer's disease, lipids and liver function.

Our results demonstrate the power of widely-available GWAS data to uncover key "core" genes able to modulate the impacts from some, or even all, other regions of the genome. They offer the potential for functional deconstruction of observed signals to identify subgroups of variants whose impacts reinforce one another.

PB4326 Population Scale Analysis of Copy Number Variation in 23andMe Research Cohort

Authors:

S. Saini[1], J. Shi[1], 23andMe Research Team, A. Auton[2], S. Shringarpure[3]; [1]23andMe, Inc., Sunnyvale, CA, [2]23andMe, South San Francisco, CA, [3]23andMe, Sunnyvale, CA

The human genome contains hundreds of thousands of regions harboring structural variants, including copy number variants (CNVs), that are known to affect around 20 million bases. CNVs contribute to numerous genomic disorders including neuropsychiatric diseases and account for a high fraction of all rare loss-of-function events. Phenotypic effects of these CNVs are largely understudied because many of these are very rare in general populations, and only larger CNVs (tens of kilobases or longer) are ascertainable from SNP-array data generated by large biobanks. Traditional methods used for CNV detection from SNP-array data tend to suffer from poor resolution and inability to accurately detect breakpoints.

We used a recently developed CNV detection method, Hi-CNV, to detect CNVs in 1 million European ancestry research participants from the 23andMe, Inc cohort. Hi-CNV leverages haplotype sharing to substantially increase CNV detection power and accuracy, and is therefore well-suited for large datasets like 23andMe.

We performed extensive QC and validation of the CNV calls using multiple orthogonal approaches. The median CNV length was 8.0 kilobases (median 5.3 kilobases for deletions, median 15.4 kilobases for duplications). Compared to an older CNV detection method PennCNV, Hi-CNV is more sensitive to detecting rarer and smaller CN events, and more accurate at harmonizing CNV breakpoints. After applying standard QC, we observed 23.6 CNVs on average per sample (>4x increase than PennCNV caller). We observed the Mendelian error rate of <1%, estimated using CNV calls from 5,000 trio samples. We also validated the calls using whole genome sequencing (WGS) data from 10,000 samples. We compared the CNV type (deletion/duplication) with the WGS read-depth direction, and observed that most of the CNVs had read-depth direction below the mean for deletions (60% of the mean read-depth on average) and above the mean for duplications (139% of the mean depth on average).

We analyzed the total genomic deletion burden and duplication burden, and observed associations of deletion and duplication burden with decreased height, with deletions appearing to be significantly more deleterious than duplications. Finally, we ran genome-wide association study analysis of several traits and successfully replicated known CNV associations with Height, BMI and Triglyceride levels. Expanding our analysis to the entire 23andMe cohort will increase our power to detect CNV associations, as well as allow us to perform trans-ethnic comparisons of CNVs distribution.

PB4327 Power of Inclusion: enhancing polygenic prediction with admixed individuals

Authors:

Y. Tanigawa[1,2], M. Kellis[1,2]; [1]Massachusetts Inst. of Technology, Cambridge, MA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA

Admixed individuals offer unique opportunities to address limited transferability in polygenic scores (PGS), given the substantial trans-ancestry genetic correlation in many complex traits. However, they are rarely considered in PGS training: most modern PGS methods operate on association summary statistics and ancestry-matched linkage-disequilibrium (LD) reference panels and face challenges in representing LD for admixed individuals.

Here, we overcome the technical limitations and present inclusive PGS (**iPGS**). Our iPGS model captures ancestry-shared genetic effects by finding the exact solution for L_1 and L_2- penalized regression on individual-level data, thus naturally applicable to admixed individuals. To jointly model the ancestry-shared and -dependent genetic effects, we develop **iPGS+refit**, which further considers population-specific effects of genetic variants, genotype PCs, and their interactions.

We first test our approach using 336,000 synthetic individuals across 33 simulation configurations with varying heritability, polygenicity, and ancestry composition in the training set. We find that the direct inclusion of the minority population, even at 5%, in iPGS training improves transferability.

We then apply iPGS to 60 quantitative traits in UK Biobank and show the benefits of inclusive training. When trained on the same number of N=237,055 individuals, we find the greatest improvements in Africans by 31.0% on average and up to 50-fold for some traits (neutrophil count, R^2=0.058) over the baseline model trained only on European individuals. When allowing iPGS to use all individuals (N=284,661) across the continuum of genetic ancestry in training, we observe an average improvement of 39.1% for African, 9.9% for South Asian, 5.8% for non-British white, 4.1% for white British, and 12.9% for the other individuals.

Moreover, we show that joint modeling of ancestry-shared and -dependent effects with iPGS+refit further increases predictive performance when heterogeneous genetic associations are present. For neutrophil count, for example, iPGS+refit shows the highest predictive performance in the African (R^2=0.115), which exceeds the best predictive performance for white British (R^2=0.090 in the iPGS model), even though only 1.49% of individuals used in the iPGS training are of African ancestry.

Lastly, we found that our iPGS and iPGS+refit outperformed PRS-CSx, a commonly-used multi-ancestry-aware PGS method, in all 60 tested traits in UK Biobank, even though our models were trained on fewer individuals.

Overall, our results highlight the benefits and importance of inclusive PGS training for developing more equitable PGS models.

PB4328 Powerful detection of *trans*-eQTL partially explains missing heritability of gene expression

Authors:

K. Brunton, T. Amariuta; Univ. of California, San Diego, La Jolla, CA

While most disease-associated variants from GWAS are uncharacterized yet thought to impact disease via gene expression regulation, comprehensive maps of eQTLs (genetic variants that are associated with changes in gene expression) are critical to their mechanistic interpretation. Most previous studies exclusively detect *cis*-eQTLs, e.g. variants within +/- 1Mb of the gene. However, it has been estimated that more than 70% of genetic regulation of gene expression occurs beyond the *cis* region (Liu et al. 2019 *Cell*). Identification of *trans*-eQTLs remains challenging due to large multiple testing burdens from associating gene expression with genotypes across billions of variant-gene pairs. Despite advances in reducing this burden (transPCO: Wang et al. 2022 *bioRxiv*) and increasing sample size (eQTLGen: Vosa et al. 2021 *Nat Genet*), there is negligible gene expression heritability explained by associated *trans*-eQTLs. Here, we propose two complementary approaches to powerfully detect *trans*-eQTLs and partially recover the missing heritability of gene expression. While *trans*-eQTLs are widely believed to act through genome-wide transcription factor (TF) programs, our first approach identifies upstream regulators of gene expression marked by TF binding sites. For a target gene, we identify TF sequence motifs in the gene promoter and consider *cis* regulatory variants of the TF gene as candidate *trans*-eQTLs. Our second approach ranks variants by their best linear unbiased prediction (BLUP) effect size and finds the smallest set of candidate *trans*-eQTLs that maximizes the accuracy (cross-validation R^2) of the L1-regularized linear regression. We applied these approaches to data for 574 European individuals from GTEx across 19,587 genes expressed in whole blood. Our first approach increased the average per-gene heritability estimate by 47% compared to models of only *cis*-variants (genome-wide $h^2_g = 0.12$ vs $h^2_{cis} = 0.085$), which is significantly greater than adding a random, equally sized set of variants. Our second approach increased the average per-gene heritability (in a held-out sample) by 88% compared to models of only *cis*-variants (genome-wide $h^2_g = 0.16$). *Trans*-eQTLs of competing methods explained less heritability (transPCO: $h^2_g = 0.089$, eQTLGen: $h^2_g = 0.099$). We then fit L1-regularized gene models with our candidate *trans*-eQTLs and identified 66 *trans*-eQTLs per-gene (e.g. those with non-zero coefficients), more than transPCO (3.3) and eQTLGen (3.6). We expect that these improved models of gene expression will enhance our interpretation of GWAS variants, for example via transcriptome-wide association studies.

PB4329 Precise genetic instruments in Mendelian randomization improve causal estimates of complex traits: Exemplified by fresh fruit intake and diastolic blood pressure reduction

Authors:

K. James, J. B. Cole; Univ. of Colorado Anschutz Med. Campus, Denver, CO

Background: MR has strict underlying statistical assumptions that are often violated by pleiotropic genetic instruments (GI), leading to inaccurate causal associations and over-simplified interpretations. This is especially common with variants from genome-wide association study (GWAS) of complex traits with large environmental influences and substantial correlation with other health/lifestyle components, such as those relating to dietary intake. To better utilize environmental MR, we need more objective methods for selecting GI that directly proxy the exposure of interest, and not their correlated traits.
Method: We evaluated three methods for selecting GI variants for two-sample MR by testing their ability to validate a known randomized controlled trial (RCT) association between fruit intake and blood pressure. The standard method, which often violates pleiotropic assumptions, included all genome-wide significant variants associated with the exposure (GWS-GI) while our unique filtering methods included a phenome-wide association study (PheWAS) strategy to identify variants with direct effects on fruit intake (direct-GI), and a biological plausibility strategy to identify variants with mechanistic ties to fruit intake (bio-GI). GI variants for fruit were obtained from a GWAS in the UK Biobank (UKB) and from a GWAS meta-analysis of the UKB and the International Consortium of Blood Pressure for diastolic blood pressure (DBP).
Results: The GWS-GI method included 43 variants and demonstrated causality between fresh fruit and decreased DBP only when relying on 50% of the GI weight to come from valid variants (weighted median: beta=-0.69, P=0.04) and not the traditional inverse variance method (IVW: beta=-0.11, P=0.81) suggesting many variants violated the assumptions. Thus, the 43 variants were subjected to a PheWAS against >2,000 health/lifestyle traits and retained if they explained more phenotypic variance in fruit intake than any other trait (direct-GI method). This method strengthened the association for both the weighted median (beta=-0.96, P=0.01) and IVW (beta=-1.04, P=0.035) methods. Two variants mapped to olfactory receptor genes providing biological evidence for influencing fruit intake (bio-GI method). The bio-GI had limited heterogeneity (Cochran's Q=0.019, P=0.9) and similar effect estimates to the other methods (IVW: beta=-0.67, P=0.1) despite being non-significant due to less GI power.
Conclusion: Objective methods that filter GI variants using complementary information can improve causal estimates as we demonstrated by strengthening the validation of a known RCT association between fruit intake and reduced DBP.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4330 Predictive imputation of gene expression from genotype data in the Louisiana osteoporosis study

Authors:

M. Song[1], K-J. Su[2], X. Zhang[2], A. Liu[2], J. Greenbaum[2], J. Luttrell[1], L. Huang[1], W. Zhou[3], C. Wu[4], Z. Luo[2], C. Qiu[2], L. Zhao[2], Q. Tian[2], H. Shen[2], P. Gong[5], C. Zhang[1], H-W. Deng[2]; [1]Univ. of Southern Mississippi, Hattiesburg, MS, [2]Tulane Univ., New Orleans, LA, [3]Michigan Technological Univ., Houghton, MI, [4]UT MD Anderson Cancer Ctr., Houston, TX, [5]U.S. Army Engineer Res. and Dev. Ctr., Vicksburg, MS

Background: Multi-omics datasets, including genomic, transcriptomic, and methylomic data, have the potential to provide refined insights into a better understanding of the biological system and the functional mechanisms of human diseases such as Alzheimer's disease, osteoporosis, and diabetes. However, missing values within omics or across different omics for large cohort studies are a common critical issue for multi-omics data analysis, with impacts that include reducing sample size and statistical power, obstructing downstream analysis, and leading to inappropriate health policy decisions. To address this issue, predictive molecular traits, such as using genomics to predict gene expression, have been proposed. In this study, our objective is to leverage the current PrediXcan method to perform gene expression data imputation from genotype data in the Louisiana Osteoporosis Study (LOS) cohort. **Methods**: We built a customer-defined gene expression prediction model following the PredictDB pipeline, using 5-fold cross-validation on 504 subjects in LOS data. This dataset includes 315 Caucasian (CA) subjects and 189 African American (AA) subjects, all of whom have both whole genome sequencing (~22X) and transcriptome data. To mitigate the effects of distinct genetic structures among different racial groups, we performed data preprocessing for these two race groups including CA and AA populations separately. Then we trained the PrediXcan model and compared the imputation performance between LOS CA and AA populations with metrics such as Pearson correlation coefficient (PCC), p-value, and $R2$. **Results:** After training the PrediXcan model with our preprocessed LOS data, we evaluated the performance with PCC and $R2$ for LOS CA and AA populations separately. For the metrics of PCC and p-values, the number of well-predicted genes, defined as PCC>0.1 and p-value<0.05, is 2,307 (2,307/13,930 =16.56%) and 1,289 (1,289/14,065=9.16%) for LOS CA and AA populations, respectively. As for the metric of $R2$, the number of well-predicted genes, defined as $R2$ >=0.01, is 1,651 (1,651/13,930 =11.85%) and 961 (961/14,065=6.83%) for LOS CA and AA populations, respectively. For the number of overlapped genes between these two race groups, there are 557 and 389 genes with metrics of PCC and $R2$, respectively. Our results showed that the imputation performance of LOS CA subjects is better than AA subjects and the reason for it is that AA subjects has a more admixed population structure than CA subjects. **Conclusions**: We developed the data preprocessing pipeline for LOS cohort and built a customer-defined prediction model following the PredictDB pipeline from the PrediXcan method.

PB4331 Pre-processing and quality control of whole genome sequencing data: a case study using 9000 samples from the GENESIS-HD study.

Authors:

R. Betschart[1], D. Garcia-Aguilera[2], H. Babel[1], S. Blankenberg[3], L. Guo[3], H. Moch[2], D. Seidl[2], F. Thalén[1], A. Thiéry[1], R. Twerenbold[3], T. Zeller[3], M. Zoche[2], A. Ziegler[1]; [1]Cardio-CARE, Medizincampus Davos, Davos Wolfgang, Switzerland, [2]Inst. of Pathology and Molecular Pathology, Univ. Hosp. Zurich, Zurich, Switzerland, [3]Univ. Ctr. of Cardiovascular Sci. and Dept. of Cardiology, Univ. Heart and Vascular Ctr., Univ. Med. Ctr. Eppendorf, Hamburg, Germany

Rapid advances in high-throughput DNA sequencing technologies have enabled the conduct of large-scale whole genome sequencing (WGS) studies. Before association analysis between phenotypes and genotyped can be conducted, extensive pre-processing and quality control (QC) of the raw sequence data need to be performed. This case study describes the pre-processing pipeline and QC framework we have selected for the GENEtic SequencIng Study Hamburg-Davos (GENESIS-HD), a study involving more than 9000 human whole genomes. All samples were sequenced on a single Illumina NovaSeq 6000 with an average coverage of 35x, using a PCR-free protocol and unique dual indices (UDI). For quality control (QC), one genome in a bottle (GIAB) trio was sequenced in tetraplicate, and one GIAB sample was successfully sequenced 70 times in different runs. First, we describe the sequencing technology as well as important QC metrics on the data at various stages of the processing (raw, mapping and alignment, variant calling, multi-sample calling). Finally, we provide empirical data for the compression of raw data using the novel original read archive (ORA). Our results show that the most important quality metrics for sample filtering were ancestry, sample cross-contamination, deviations from the expected Het/Hom ratio, relatedness, and too low coverage. The compression ratio of the raw files using ORA was 5:1, and the compression time was linear with respect to genome coverage. In summary, the pre-processing, joint calling, and QC of large WGS studies is feasible in reasonable time, and efficient QC procedures are readily available.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4332 Probabilistic identification of loci of interest from GWAS summary statistics with a Bayesian mixture model

Authors:

R. Kumar, M. Ritchie; Univ. of Pennsylvania, Philadelphia, PA

Genome-wide association studies (GWAS) are a popular method for analyzing the association of genetic mutations or alterations with disease or other phenotypes. Many genetic mutations are inherited with each other, in an observed mechanism called linkage disequilibrium that results from recombination (leading to a shuffling of variants between parental chromosomes) not occurring uniformly across the genome.
This means that a variant that is linked to a causal variant may be mistakenly identified as causing disease, when in reality it is merely likely to be inherited alongside the true causal variant. Generally, variants that are close to each other are likely to be inherited together (though there are exceptions to this rule), which leads to an abundance of signals that may or may not truly be actionable or useful. These often occur in regions ("loci") called "recombination hotspots", within which multiple variants may be shown to have a significant association if any one does.
As such, people have developed downstream analysis methods that make use of GWAS results to try to identify specific causal variants or identify the functional underpinnings of their effect on disease within these loci. These include methods such as genomic colocalization analyses, Mendelian randomization, and meta-analyses, among many others. However, many of these analyses require users to define the bounds of specific regions of the genome that they would like to assess, and these bounds can have quite significant impacts on the results of these analyses. There is therefore a need for a method that identifies these boundaries in a rigorous and reproducible way.
We present a method that uses Bayesian mixture models to perform statistical inference on GWAS summary statistics to identify whether individual genomic positions represent “breakpoints” between regions containing insignificant variants and regions containing significant variants, allowing one to identify probabilistically which regions represent possible regions where variants are in linkage that may be valuable for downstream studies. We will show the results of this analysis on a synthetic set of GWAS summary statistics to show its ability to provide a probabilistic estimate of loci boundaries and then reproduce its performance on various existing GWAS summary statistics that are publicly available over a variety of hyperparameters to identify putative loci of interest.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4333 Proteogenomics often fails to identify clinically valuable targets: a Mendelian randomization study.

Authors:

J. Willett; McGill Univ., Montreal, QC, Canada

Genetically supported findings are more likely to yield a successful clinical trial. Promising targets can be identified using proteogenomics Mendelian randomization (MR), which can estimate the effect of a circulating protein's level on disease and provide a biomarker to assist in drug development. Few have investigated inconsistencies between proteogenomic MR and clinical trial results. Using MR with sensitivity tests, including pairwise colocalization (PWCoCo), we determined if the MR results of *cis*-protein quantitative trait loci (cis-pQTLs), determined using Somalogic assays in the Fenland cohort, matched pre-clinically or clinically supported targets for circulating proteins. This is because the level of circulating hormones, a subset of proteins, often determines function. Of the proteins in our initial cis-pQTL MR analysis, circulating PTHrP conferred no protection against fracture, while renin and ACE did not affect hypertension. In clinical trial data, however, abaloparatide, a PTHrP analog, decreases osteoporotic fracture risk, and renin and ACE inhibitors effectively treat hypertension. These drugs are either truncated protein isoforms (such as abaloparatide) or target specific protein domains. Further, the frequency of administration of medicines can change their effect, as has been seen for PTH, which is not reflected well in cis-pQTL studies. Somalogic assays are specific for more complete and physiological isoforms. These results demonstrate the care required when interpreting proteogenomic results, given that most assays evaluate full isoforms versus specific domains and assume constant levels of the circulating proteins—which may not reflect physiological conditions. Proteomics studies could benefit from greater resolution by targeting specific domains versus whole proteins and measuring throughout the diurnal cycle.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4334 PRS methods for equitable application across ancestrally diverse biobanks

Authors:

C. Hoggart[1], Y. Ruan[2], P. O'Reilly[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Broad Inst., Cambridge, MA

For polygenic risk scores (PRS) to be universally applicable and equitable they need to have the same clinical interpretation across all individuals, regardless of ancestry and admixture. Recent methods, such as PRS-CSx and BridgePRS, have improved PRS for individuals in populations of non-European ancestry by combining information across ancestrally diverse genome-wide association studies. However, these methods focus on computing PRS in individuals from a single "homogenous" ancestral population, yet many individuals are admixed with ancestry from two or more populations from different continents. Moreover, PRS trained in one ancestral population can have a markedly different mean when applied to another ancestral population, independent of phenotypic differences between populations. For PRS to be applied clinically they need to make direct prediction of the phenotype, incorporate other predictors, and be unbiased across all strata of the population to which they are applied. Here we develop, apply and compare three methods to achieve this goal: weighting ancestry specific PRS by (1) individuals' distance in PC space to each of the discovery GWAS (2) individuals' admixture proportion, and (3) normalization of a single PRS model via PCs such that the mean and variance is similar across the diverse ancestries in the cohort. The methods are applied by estimating prediction models with predictors including both PRS and other relevant covariates in both the UK Biobank cohort and the diverse BioMe cohort recruited at Mount Sinai in New York City. Validation is performed in both unseen individuals in the same cohort and out-of-cohort. Results are reported across all ancestry strata of the target cohort, for different scenarios of available training data, considering metrics such as mean square error, bias, false positive and negative rates and variance explained.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4335 PRS training and performance evaluation in two large Han Chinese cohorts

Authors:

D. Wells[1], F-J. Hsieh[2], E-C. Yeh[2], C-H. Chen[2], S. Landon[1], R. M. Sivley[1], V. Plagnol[1], P-Y. Kwok[2,3]; [1]Genomics plc, Oxford, United Kingdom, [2]Inst. of BioMed. Sci., Academia Sinica, Taipei, Taiwan, [3]Cardiovascular Res. Inst., Inst. for Human Genetics, and Dept. of Dermatology, Univ. of California, San Francisco, CA

Polygenic risk scores (PRS) have gained interest as tools for population stratification and to improve disease prevention and screening. Yet, it is well established that PRS perform best in the population they were trained in, and their portability is a major obstacle on the path toward broad adoption. In addition to evaluation of PRS performance, sufficiently large cohorts also provide an opportunity to optimise PRS for the populations of interest. We created PRS using a range of cohorts, including several Biobanks with East-Asian ancestry participants (Biobank Japan, Tohoku Medical Biobank Project, UK Biobank, Korean Genome and Epidemiology Study). We combined these data with two additional large Han-Chinese cohorts with electronic health records or health questionnaire data (Taiwan Biobank [TWB, n=85K] and Taiwan Precision Medicine Initiative [TPMI, n=120K]) to evaluate and optimise PRS trained outside of TPMI and TWB for 12 diseases: prostate/breast/colorectal cancer, type 2 diabetes (T2D), myocardial infarction, cardiovascular disease, ischemic stroke (ISS), primary open angle glaucoma (POAG), asthma, hypertension, atrial fibrillation, and osteoporosis. We then used 140K samples from TPMI and TWB to retrain these PRS and evaluated them in a held out set, using a cross-ancestry methodology. Analyses based on additional TPMI genotyping (n=250K) are ongoing and will be reported at the meeting. Measured using odds ratio per standard deviation of the PRS, controlling for age and sex, performance varied between 1.23 (ISS) and 2.37 (T2D). A small number of these estimates differed between TPMI and TWB, most likely reflecting differences in demographics, phenotype definition and data collection methodologies. On average, the retraining of the PRS using the Han-Chinese training set generated a modest but consistent improvement, with an average benefit of 3% in the OR per SD. Compared to European ancestry performances in UK Biobank, the retrained Han-Chinese performance was better for prostate cancer (OR per SD:2.32), T2D (OR per SD:2.37) and atrial fibrillation (OR per SD:1.97). In contrast, POAG (OR per SD:1.46) and ISS (OR per SD:1.23) performed substantially worse. For the remaining seven traits, we observed a moderate attenuation of performance in Han-Chinese compared to European data (average reduction 8.3%).
Overall, and after retraining using Han-Chinese data, PRS performance for this set of common traits shows limited performance reduction compared to European ancestry data. Traits with substantially lowered performances (ISS and POAG) suggest meaningful differences in disease aetiology that may warrant dedicated case control collection.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4336 PURE: Protein-trait association Using *cis*- and *tRans*-regulation Estimation.

Authors:

Z. Zhang[1], H. Melton[1], S. Liu[2], L. Wu[2], C. Wu[3]; [1]Florida State Univ., Tallahassee, FL, [2]Univ. of Hawaii Cancer Ctr., Honolulu, HI, [3]UT MD Anderson Cancer Ctr., Houston, TX

An enhanced comprehension of genetic regulation of the proteome can accelerate the elucidation of causal mechanisms for complex traits. Proteome-wide association studies (PWAS), which leverage protein quantitative trait loci (pQTL) datasets integrated with genome-wide association studies (GWAS), are frequently used to identify probable causal proteins. Analogous to transcriptome-wide association studies (TWAS), current PWAS methods predominantly focus on *cis*-acting elements, constructing protein levels prediction models using individual-level pQTL datasets, often limited by sample size. However, *trans*-acting elements can account for a significant proportion of variation in many protein markers and often play essential regulatory roles. To maximize the potential of *trans*-acting elements and summary-level pQTL data for improving the robustness and power of PWAS, we introduce a novel PWAS method, referred to as Protein-trait association Using *cis*- and *tRans*-regulation Estimation (PURE). Our method involves two steps. First, we develop prediction models using each *cis*- and *trans*-acting element leveraging summary-level data with large sample size, thereby addressing the relatively weak effects of *trans*-acting elements. Next, we estimate the associations between phenotype and genetically predicted protein levels for each *cis*- and *trans*-acting element. These associations, estimated from each locus, are then combined using an iterative algorithm to account for certain outliers and randomness in outlier detection. Applying our novel method to deCODE summary-level data, encompassing plasma protein levels of 4,907 proteins derived from 35,559 Icelanders, we constructed 2,127 protein prediction models demonstrating satisfactory performance (R^2>0.01), achieving a 58% improvement over the existing model constructed using the ARIC dataset. Further external validation of our models using the INTERVAL data yielded a high validation rate. Finally, in a case study for Alzheimer's disease using recent GWAS data of 111,326 clinically diagnosed/proxy cases and 677,663 controls, our model identified 207 likely causal proteins under Bonferroni correction. In contrast, competing methods identified 19 likely causal proteins. We will release a companion software on GitHub to enable wider use of our method.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4337 pyGEMMA: A User-Friendly Python Implementation of Linear Mixed Models for Genome-Wide Association Studies

Authors:

R. Langefeld, B. Gao, X. Zhou; Univ. of Michigan, Ann Arbor, MI

Linear mixed models (LMMs) are widely used association analysis tools for genome-wide association studies (GWAS) to account for population stratification and relatedness among individuals. While multiple efficient LMM software packages like GEMMA, Bolt-LMM, and REGENIE exist, they often lack an accessible user interface and require specific data formatting. Here, we introduce pyGEMMA, a Python/Cython-based implementation of GEMMA that provides a user-friendly framework for conducting LMM-based analyses in genetic studies. With pyGEMMA, researchers can perform end-to-end experiments with LMMs using high-level functions and scripts. pyGEMMA provides functions for both Python and R (through reticulate) for model-fitting and visualization without requiring the specific data formats required by other standard software. It includes functions for standard GWAS visualization (e.g., Manhattan plot, Q-Q plot). We also include computational efficiency improvements by leveraging tensor-based storage in NumPy to take advantage of additional BLAS operations and a variation of Brent's root finding algorithm using hyperbolic extrapolation. The package includes functionality to run numerous SNPs in parallel in order to scale to the hardware availible. We demonstrate the effectiveness of pyGEMMA through GWAS and *cis*-eQTL analyses on two datasets. Our results show that pyGEMMA produces identical results to GEMMA with at least comparable runtime, while being more convenient and user-friendly. Additional computational improvements are currently underway. By integrating GEMMA into Python, researchers can leverage its extensive functionality for LMM analysis while enjoying the ease and flexibility of Python programming. pyGEMMA is freely available on GitHub from the authors.

PB4338 Quantitative and qualitative contextualization of polygenic scores in genetically diverse and admixed populations.

Authors:

S. Laskey[1], P. Wilton[1], J. Zhan[1], J. Ashenhurst[2], B. Koelsch[1]; [1]23andMe, Sunnyvale, CA, [2]23andMe Inc., Sunnyvale, CA

Motivation: One of the most prominent challenges limiting the adoption of polygenic scores (PGSes) is a failure to contextualize these raw scores into meaningful interpretations, both quantitative (i.e., the absolute chance of developing a disease) and qualitative (i.e., whether risk is "increased" with respect to some baseline). PGSes often vary systematically with genetic structure and other factors, so that an individual's raw PGS — even in units of lifetime risk — may be a poor estimate of their true disease risk, particularly for admixed individuals. Many otherwise state-of-the-art PGS algorithms separate individuals into discrete, genetically homogeneous categories, which means these algorithms are poorly suited to supporting PGS contextualization for admixed people.
Methods: To contextualize PGSes quantitatively, we recalibrated estimated probabilities against condition prevalence in a cohort at the age of peak prevalence, adjusting for sex and genetic principal components. To contextualize PGSes qualitatively, we developed a baseline model trained on admixed and unadmixed individuals to estimate a person's expected PGS given their sex and genetic principal components. We compared an individual's actual PGS to this expected value and assigned them a qualitative "increased risk" interpretation if their actual PGS exceeded their expected PGS by a clinically meaningful margin.
Results: Recalibrated PGSes were far better calibrated to true condition prevalence than raw PGSes (in deciles of 11 self-reported race/ethnicity cohorts across 12 phenotypes, error between average PRS and prevalence of 24.2% and 52.7%, respectively), particularly for PGSes that vary greatly with population structure (e.g., errors of 35.6% and 89.1% for a type 2 diabetes model). A recalibration strategy representing genetic structure as continuous was also more effective than a strategy relying on discrete categories. Without adjustment for genetic structure, qualitative interpretation of PGSes was highly confounded (e.g., 100% of people with East Asian-like ancestry in this cohort were classified as having increased risk for nearsightedness), and genetic similarity categories were inadequate to support interpretations for admixed individuals. In contrast, the baseline model produced mean PGS estimates with high accuracy for admixed and unadmixed cohorts, enabling meaningful qualitative interpretations for all individuals regardless of their admixture profile.
Conclusion: For PGSes to be practically useful in the clinic and elsewhere, they must be contextualized in a way that accounts for the impact of continuous genetic population structure.

PB4339 Rare variant and gene-based analysis in Early-Onset Alzheimer Disease.

Authors:

M. Jean-Francois[1], J. Bradley[2], N. Gomez[1], D. Western[3], C. Wang[4], E. Lucio Da Fonseca[5], J. Thulaseedhara Kurup[6], V. Fernandez[3], C. Cruchaga[7], C. Reitz[6], G. Beecham[1], R. Sims[8], J. Williams[8], M. Pericak-Vance[9], M. Jean-Francois[1], Alzheimer's Disease Genetics Consortium (ADGC); [1]Univ. of Miami, Miami, FL, [2]Washington Univ. in St. Louis, St. Louis, MO, [3]Washington Univ. St. Louis, St. Louis, MO, [4]Washington Univ. in St Louis, St Louis, MO, [5]Univ. of Miami, Miller Sch. of Med., Miami, FL, [6]Columbia Univ., New York, NY, [7]Washington Univ., Saint Louis, MO, [8]Cardiff Univ., Cardiff, United Kingdom, [9]Univ. of Miami Miller Sch. of Med., Miami, FL

Background: Early-onset Alzheimer (EOAD) disease is a progressive dementia characterized by memory impairment and cognitive decline by 65 years of age or younger. It is estimated that 5-6% of individuals with Alzheimer disease (AD) have EOAD. In this study, we aimed to identify genetic variants and genes associated with EOAD, a less studied form of AD. To achieve this, we conducted a comprehensive analysis using a two-pronged approach that combined single variant analysis and gene-based analysis.
Methods: Whole-genome sequence data of 3,281 unrelated individuals were analyzed to identify rare variants and genes associated with EOAD. The cohort consisted of 2,545 EOAD (AA0 ≤ 65 years) affected individuals and 736 controls (Age >65). Samples were provided by the University of Miami, Columbia University, Washington University, and the Alzheimer Disease Research Centers. Single variant association analysis was performed using logistic regression on two models: model1 (SNP and PCs) and model2 (SNP, PCS, Sex, and APOE-4 dosage). Preliminary gene based optimal sequence kernel association test was performed to investigate the cumulative effects of the rare variants within the genes. Samples were also analyzed to identify carriers of any of the known EOAD genes.
Results: The preliminary gene-based analysis of model 1 showed nominal association at KLRF2 (P=2.39×10^(-5)) and DCAF1 (P=8.13×10^(-5)). A recent study has demonstrated that depletion of natural killer cells improves cognitive functions in AD mouse models, highlighting the role that KLRF2, a gene associated with natural killer cell regulation, may have with the disease. DCAF1 has been linked to T-cell regulation senescence which can lead to uncontrolled inflammation. The single variant analysis identified five novel variants that met initial association to EOAD. Several genes within 1Mb of the significant variants have been identified across all five variants that may play a role in the progression of symptoms in EOAD. Mutations in known EOAD genes (PSEN1, PSEN2, APP) were relatively rare in our cohort, with less than 2% of cases being carriers. These findings emphasize that there could be additional factors contributing to the development of the disease.
Conclusion: Several genes have been identified that show potential association with EOAD. While many of these genes have not been specifically linked to Alzheimer's Disease (AD), they are associated with various symptoms commonly experienced by individuals affected by AD. Further research is necessary to gain a deeper understanding of these genes and their implications.

PB4340 Rare Variant Genetic Evidence and Drug Approval Success Rates: Insights from the UK Biobank

Authors:

G. Mcinnes, M. Luth, Y. Han, D. Jakubosky, B. Cajes, S. Bruse, O. Gottesman; Empirico Inc., San Diego, CA

Despite significant technological and methodological advances to the drug discovery and development process over the past two decades, approximately 90% of investigational therapies that enter clinical development fail, most commonly for lack of efficacy. Previous studies have shown that drug targets with some level of human genetics support are more likely to be approved. However, these studies have largely considered common variants in the target gene locus, potentially overlooking the more valuable inference that can be derived from rare nonsynonymous variants, particularly loss-of-function (LoF) variants, which tend to have larger effect sizes and may better approximate the effects of a drug intervention. Additionally, whereas it is often difficult to confidently assign a causal gene for common variant phenotypic associations, both because these variants are more likely to be non-coding and because of linkage disequilibrium with nearby variants; rare nonsynonymous variants offer a more tractable path towards establishing both a causal gene and the mechanism through which the variant impacts gene or protein function. With the emergence of large-scale biobanks comprising genotyping and/or next generation sequencing data linked to rich phenotypic information, such as the UK Biobank, rare variant analyses, either individually or in aggregate via burden testing, are a potentially powerful tool for drug discovery and development. In this study, we sought to characterize rare variant genetic evidence for the targets of approved drugs, as compared to common variants. Using exome sequencing and imputed genotype data from up to 452,401 individuals in the UK Biobank, we generated associations between rare nonsynonymous variants, either individually or in aggregate, with thousands of traits, focusing on drug-target indication pairs derived from inhibitors in the OpenTargets database. Our findings revealed a notable increase in the likelihood of drug approval for target-indication pairs backed by supportive genetic evidence from rare nonsynonymous variants, particularly LoF variants. This study underscores the value of rare variant analyses for drug discovery and development and the potential for this approach to augment success rates in clinical development. This research has been conducted using the UK Biobank Resource under Application Number 34229.

PB4341 Rare-variant region-based tests in whole-genome sequencing of ~490,000 UK Biobank participants

Authors:

J. Liu[1], Y. Lo[1], J. Sandhuria[1], J. Davitte[1], Y. Aulchenko[2], T. Johnson[2], R. Scott[2], A. Cortes[2]; [1]GSK, Collegeville, PA, [2]GSK, Stevenage, United Kingdom

The availability of sequencing data in biobank-scale cohorts has enabled powerful rare-variant gene-based methods for identifying gene-phenotype associations. There is seldom a most powerful mask or region-based method for identifying associations, and any such analyses will likely include a range of masks, allele frequency cutoffs and methods. Due to greater and more uniform coverage, whole-genome sequencing (WGS) can identify more than 10% of coding variants when compared to whole-exome sequencing (WES), potentially enabling identification of associations that have previously been overlooked. Here, we use WGS of ~490K UK Biobank participants to perform a comprehensive set of rare-variant gene-based association analyses across ~1500 manually derived binary and quantitative phenotypes.

We defined a series of overlapping and non-overlapping loss of function, deleterious missense, missense and synonymous annotations across a range of allele frequency cutoffs to use as masks for burden, SKAT, ACAT and omnibus association methods as implemented in Regenie. We will use permutation approaches to derive gene-based genome-wide significance cutoffs and compare our results to those derived from WES. We will perform conditional analysis on region-based signals to assess the extent to which results may be driven by LD with strong nearby common-variant associations. Finally, we will assess the consistency of gene-phenotype association signals across masks, allele frequencies and association methods, and how differences can be interpreted. Our results will inform the design and interpretation of rare-variant region-based tests using WGS data, as well as provide opportunity for discovery of novel gene-phenotype associations.

PB4342 Real-time polygenic prediction for streaming data.

Authors:

J. Tubbs[1,2,3], H. Huang[3,4,5], T. Ge[1,2,3]; [1]Psychiatric and Neurodevelopmental Genetics Unit, Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [2]Dept. of Psychiatry, Massachusetts Gen. Hosp., Harvard Med. Sch., Boston, MA, [3]Stanley Ctr. for Psychiatric Res., Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [5]Dept. of Med., Harvard Med. Sch., Boston, MA

Human genetic and phenotypic data is rapidly and continuously being generated through the efforts of large consortia, biobank repositories, and consumer genetic companies. However, GWAS are conducted only at periodic intervals, meaning that **subsequently collected samples do not contribute to polygenic prediction** until the next GWAS is conducted, often after accumulating tens of thousands of additional samples. As efforts to integrate polygenic risk scores (PRS) into routine clinical care continue to expand, a method for **dynamically integrating streaming data** into PRS construction and optimization is needed to **maximize prediction accuracy** for incoming patient samples.

Built on the PRS-CS framework, we introduce a new method, **real-time PRS-CS** (rtPRS-CS), to perform online update of SNP weights for PRS construction as each new sample is collected, maximizing available power for polygenic prediction without the need to perform intermediate GWAS. Given an initial set of SNP weights estimated from a baseline training GWAS, rtPRS-CS uses **stochastic gradient descent** to iteratively update the weights by incorporating information from each subsequent sample. We performed **extensive simulation studies** and showed that **rtPRS-CS continuously improves prediction accuracy** as the number of contributing samples increases and is robust to varying baseline GWAS sample sizes, trait heritability (h2 = 0.2, 0.5, 0.8) and polygenicity (0.1%, 1% and 10% causal variants). In addition, rtPRS-CS is highly **computationally efficient**, taking &lt 1 sec to update SNP weights from a single sample using a single processing thread.

We next applied rtPRS-CS to a range of **quantitative traits measured in the UK Biobank** (UKBB; N~300,000) and observed **steadily improving prediction accuracy** for all traits as SNP weights were updated with additional samples. For example, when applying rtPRS-CS to body mass index (BMI) with initial SNP weights trained on a GWAS from ~322,000 individuals, the variance explained in BMI increased from a baseline of 8% by an average of 0.11% for each additional 10,000 samples, and the 95% confidence interval for the variance explained in the final decile of the test sample (10.5%, 11.8%) overlapped with that of the theoretical maximum (11.6%, 12.7%), as estimated in an independent sample by meta-analyzing the baseline GWAS with GWAS from the full UKBB sample. Lastly, we validated rtPRS-CS in a dataset of **schizophrenia patients and controls** collected by the Psychiatric Genomics Consortium and Stanley Global Asia Initiatives, and demonstrated that rtPRS-CS can dynamically incorporate samples to **refine PRS calculation and maximize the power of disease risk prediction**.

PB4343 Recurrent CNVs and psychiatric disorders: iPSYCH2015 case-cohort study provides evidence of significant associated risk increases for ASD, ADHD, and SSD but not MDD, while highlighting locus contents as the significant predictor of CNV pathogenicity, not locus type

Authors:

s. vaez[1,2,3], M. Simone[1,2,3], X. Calle Sanchez[1,2], i. Collaboraters[2], A. Raznahan[4], W. K. Thompson[2,5], T. werge[1,2,6], D. Helenius[1,2], A. Ingason[1,2,6]; [1]Inst. of biological psychiatry, Roskilde, Denmark, [2]The Lundbeck Fndn. Initiative for Integrative Psychiatric Res. (iPSYCH), Copenhagen, Denmark, [3]The Univ. of Copenhagen, Faculty of Hlth.and Med. Sci., Copenhagen, Denmark, [4]Section on Dev.al Neurogenomics, Human Genetics Branch, Natl. Inst. of Mental Hlth.Intramural Res. Program,, Bethesda, MD, [5]Herbert Wertheim Sch. of Publ. Hlth.and Human Longevity, Univ. of California, San diego, CA, [6]Lundbeck Fndn. Ctr. for GeoGenetics, GLOBE Inst., Univ. of copenhagen, Copenhagen, Denmark

Background:

Recurrent copy number variants (CNVs) have been found to confer an increased risk of neuropsychiatric disorders in clinical case-control studies. Yet, little is known about their pathogenic impact at the level of an individual or an entire population. We sought to estimate the true population prevalence of recurrent CNVs and their associated risk of psychiatric disorders.

Methods:

We used the iPSYCH2015 case-cohort study, including all individuals born in Denmark in 1981-2008 diagnosed with a major psychiatric disorder (autism, ADHD, major depressive disorder, schizophrenia spectrum disorder, or bipolar disorder)(n= 82,626) by 2015, and a random comparison sample from the same birth cohort (n=41,346). Samples were genotyped and recurrent CNVs at 18 loci were called by PennCNV and population-representative hazard ratios (HR) were derived using a Cox proportional hazard model with inverse probability of sampling (IPS) weights. Furthermore, cross-diagnosis comparisons across the CNVs, and analyses of the effect of locus features on CNV penetrance, were performed utilizing generalized estimating equation (GEE) models.

Results:

The overall population-based prevalence of duplications was higher than that of deletions. The population prevalence of overall deletion was higher compared to the UK Biobank (0.98% vs 0.70%; $P=7.7\times 10^{-12}$), whereas overall duplication prevalence did not differ between the two studies. HR estimates varied widely across the loci, with significantly increased HR most often seen to be associated with ASD and ADHD (13 CNVs each) and less often with SSD (9 CNVs), while no CNV was associated with increased HR for MDD. Pairwise comparisons of HRs (between ASD, ADHD, and SSD) revealed high correlations between diagnoses across CNVs, with the most notable exception being higher PWAS duplication and 16p11.2 deletion associated risks of ASD than of ADHD or SSD, and higher 15q11.2 deletion and 22q11.2 duplication associated risks of ASD and ADHD, than of SSD. Increased locus size and LOEUF score associated with increased HRs across all three disorders (ADHD, ASD, and SSD) and increased iPSYCH/UKBB CNV prevalence ratio.

Discussion:

We provide population-based prevalence and risk estimates, which reveal an overall higher CNV prevalence, and no evidence of increased risk association for MDD compared to case-control studies. Therefore, our findings lay the foundation for implementing genetic predictions into clinical practice.

PB4344 Redefining control selection: Resolving population label issues in genetic studies reliant on genetic data with a low breadth of coverage.

Authors:

J. Russ-Silsby, T. W. Laver, M. N. Wakeling, M. B. Johnson, S. E. Flanagan, E. De Franco; Univ. of Exeter, Exeter, United Kingdom

The National Academies have issued new guidelines that stress the need for a radical shift in the use of ethnic population descriptors, urging a departure from reliance on arbitrary labels. The report highlights the issue of using self-declared ethnicity as a surrogate for ancestry, a practice deemed problematic, particularly in the context of selecting controls for genetic studies. The capacity to pinpoint suitable genetic controls is instrumental in conducting valid and reproducible genetic studies, reinforcing the importance of these new guidelines. However, conventional methods for establishing genetically similar control populations are often unsuitable for sequencing techniques with lower breadth of coverage, such as targeted next-generation sequencing (tNGS). This study's objective was to establish a robust empirical strategy for determining the optimal gnomAD control population applicable to individuals sequenced using tNGS. We performed population similarity analysis on 389 unrelated, globally diverse individuals with monogenic insulin secretion disorders who had been sequenced using both tNGS and whole genome sequencing (WGS). We employed the LASER ancestry tool on the tNGS data and Principal Component Analysis (PCA) projection on the WGS data to place individuals into a reference PCA space built using the combined 1000 Genomes and Human Genome Diversity Project (HGDP) datasets. The most genetically similar gnomAD population was then determined from the PCA scores using a bespoke neural network classifier trained on the subset of the 1000 Genomes and HGDP datasets that has been population classified by gnomAD. There was high correlation between the PCA scores generated from tNGS data by this method and those from WGS data (median r^2=0.965). When using an “argmax” classification which outputs the most probable population determined by the model, 92% of individuals were identically classified using data derived from either tNGS or WGS. When a probability threshold was imposed, whereby any individual without a determined population probability greater than 0.8 is categorized as “other”, the concordance increased to 98%. Employing this approach ensures that genetics will stay at the forefront of this ethical dilemma, substituting arbitrary labels for scientifically derived, reproducible measurements of genetic ancestry. Furthermore, while we currently rely on the population labels used by gnomAD, the ability to place individuals into a multidimensional PCA space establishes a foundation to examine genetic ancestry as a spectrum and dynamically select the most appropriate controls without fixed labels.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4346 Refining the genetic architecture of protein quantitative trait loci

Authors:

C. Benner, R. Pendergrass, M. McCarthy, A. Mahajan; Genentech, South San Francisco, CA

Understanding the genetic architecture of protein quantitative trait loci (pQTLs) is instrumental to identify novel biomarkers and drug targets for complex diseases. Given the moderate to large effect sizes at causal variants, a large part of the regional heritability of proteins is expected to be captured by fine-mapping. In cases where the fine-mapping explains a large proportion of the total regional heritability, we attain a much more informative picture of the regional architecture compared to that obtained by the existing heritability estimation methods that do not identify individual causal variants.

Here, we compared regional heritability estimation across the statistical fine-mapping model FINEMAP and both the variance component model BOLT and fixed-effect model HESS in 14,189 pQTLs from 2,940 plasma proteins in 32,867 randomized European individuals from the UK Biobank study. We observed that on an average FINEMAP identified 2.5 causal variants at an association signal and captured 36% more regional heritability than the variant with the lowest P-value. At the cis-pQTL of Peptidoglycan recognition protein 2, which has been implicated in systemic lupus erythematosus, we identified seven causal variants that together explained 20% more regional heritability than the variant with the lowest P-value, 44% more than BOLT and 14% more than HESS. In pQTLs with considerable contribution to the total heritability, FINEMAP captured on average 13% and 40% more regional heritability than BOLT and HESS. We leveraged this information about the genetic architecture of pQTLs to predict the genetic component of protein levels in the rest of the UK Biobank individuals without measured protein levels. Using genetically predicted *cis*-protein levels and 1,570 disease endpoints, we identified 189 protein-disease associations after accounting for multiple-testing correction, replicating previously reported findings of Kallikrein Related Peptidase 3 prostate cancer biomarker and recapitulating the idea of repurposing Janus kinase inhibitors for treating asthma.

Comparisons between the regional heritability estimates originating from different modeling assumptions, including a fine-mapping model, illustrated how violations of model assumptions on polygenicity or unspecified genetic architecture induce inaccuracy to the existing heritability estimates. Our analysis provides insights to understand how FINEMAP, BOLT and HESS relate to each other in cases where inference of a variant-level picture of the regional genetic architecture is indeed possible.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4347 Regional burden analysis of functional variants reveals genomic hotspots enriched for regulatory elements and overlapping with recurrent pathogenic CNVs.

Authors:

N. Safarian[1], B. Trost[1], W. Engchuan[1], M. Mendes de Aquino[1], B. Thiruvahindrapuram[1], M-C. Lai[1], R. Yuen[1], L. Gallagher[1], P. Szatmari[2], S. Scherer[1], J. Vorstman[1], E. Breetvelt[1]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]Ctr. for Addiction & Mental Hlth., Toronto, ON, Canada

Background:We recently developed the regional burden (RB) approach, a novel analytic method that examines the regional burden of low-frequency functional genetic variants. Using this approach, we showed that a regional excess of these genetic variants is associated with increased schizophrenia (SCZ) risk as well as decreased educational attainment. In this study, we implemented the RB analysis in autism spectrum disorder (ASD). We subsequently compared the identified RB hotspots in ASD to those found in SCZ and examined overlap with recurrent pathogenic CNVs. Lastly, we explored the biological function of genomic regions most vulnerable to excess regional burden.
Methods:We combined the two largest ASD datasets (SSC and SPARK-WES-1) comparing probands (8,842) with unaffected siblings (3,968) with available sequence data. We used 22q11.21 as template and applied our sliding-window approach across the genome, using logistic regression with ASD as outcome, regional SNV excess as predictor, while accounting for sex and 20 population stratification components. We determined RB hotspots indicated by consecutive associated windows. We subsequently compared the top 20% of ASD-related RB hotspots with those for SCZ, and with regions where recurrent pathogenic CNVs occur, using permutation to test for significance. We used enrichment analyses to explore the function of the overlapping hotspots for ASD and SCZ (10% of the genome).
Results:We found similar results for ASD as for SCZ reported in our initial study for 22q11.21 (OR=2, p=0.005). The RB-hotspots for ASD overlapped with hotspots for SCZ ($p<1e-19$) and pathogenic CNVs ($p<1e-09$). The overlapping hotspots for ASD and SCZ were highly enriched for evolutionary constrained transcriptional factors ($p<1e-99$), suggesting implication of these regions in genome regulation.
Conclusion:Our findings show that genomic regions most vulnerable for the cumulative regional impact of sequence level variants strongly overlap with regions of recurrent pathogenic CNVs, as well as RB-hotspots for SCZ. The genomic regions where the RB has the strongest impact on ASD and SCZ risk are strongly enriched for transcription factors suggestion a role in genome regulation. The question raised by these results is how evolutionary strongly constrained non-coding DNA sequences are implicated in the risk for two uniquely human conditions, ASD and SCZ. Our findings suggest that RB analysis is a novel tool that may contribute to the elucidation of genomic regions influencing vulnerability for ASD and SCZ.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4348 Regional European genetic ancestry predicts type I interferon level and risk of severe viral infection.

Authors:

I. Nln[1], J. Shum[2], Y. Ghodke-Puranik[1], R. Tipon[3], D. Vsetecka[4], S. Amin[4], A. Makol[4], T. Osborn[4], K. Moder[4], V. Chowdhary[5], U. Thanarajasingam[4], E. Svenungsson[6], G. N. Goulielmos[7], T. Niewold[1]; [1]Hosp. for Special Surgery, New York, NY, [2]MarinHlth.Med. Ctr., Kentfield, CA, [3]The New York Stem Cell Fndn., New York, NY, [4]Mayo Clinic, Rochester, MN, [5]Yale Sch. of Med., New Haven, CT, [6]Karolinska Inst., Stockholm, Sweden, [7]Univ. of Crete, Heraklion, Greece

Background. Viral infections cause significant morbidity and mortality around the world, despite progress in preventative and therapeutic development. The severity of a viral infection varies widely between individuals, ranging from mild symptoms to severe organ failure and death, and it is clear that host genetic factors play a role in this variability. Type I interferon (IFN) is a critical anti-viral cytokine, and we have previously noted differences in type I IFN levels between world populations. In this study, we investigate the interrelationship between regional European genetic ancestry, type I IFN levels, and risk of severe viral infection outcomes. **Methods & Results.** We measured type I IFN in serum samples using a WISH cell reporter assay. Regional ancestry within Europe was determined using a validated set of European-American ancestry informative markers (AIMs). Principal component analysis was performed on the AIMs data to infer each subject's proportional regional European ancestry. In cohorts of European ancestry lupus patients from Europe, we noted a Northwest vs. Southeast gradient in type I IFN levels. We then studied an independent cohort of lupus patients from the Midwestern United States with varying proportional regional European genetic admixture. Here we again observed a significant gradient in IFN level, with a greater percentage of Northwestern European ancestry corresponding to higher IFN levels. Using these data, we developed a model to predict type I IFN level based on regional European ancestry (AUC=0.73, p=6.1e-6). We next examined large databases containing serious viral infection outcomes data for European countries. Lower predicted IFN level in the corresponding European country was significantly correlated with increased fatality rate due to viral infections, including COVID-19, viral hepatitis, and HIV, with correlation coefficient ranging from -0.79 (p=4e-2), -0.94 (p=6e-3) to -0.96 (p=8e-2) respectively. This association between predicted type I IFN level and outcome severity is consistent with the expectation that greater intrinsic type I IFN response is beneficial in host defense against viral infection. **Conclusion.** We observed significant gradient in circulating type I IFN level in Northwestern vs. Southeastern European genetic ancestry. Predicted type I IFN level based upon regional European ancestry was associated with population-level fatality rates in viral infection, including COVID-19, viral hepatitis, and HIV. These findings suggest that genetic testing could provide insight into an individual's fatality risk due to viruses prior to infection, across a wide range of viral pathogens.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4349 Reimagining gene-environment interaction analysis for human complex traits

Authors:

J. Miao[1], G. Song[1], Y. Wu[1], J. Hu[1], Y. Wu[1], S. Basu[1], J. Andrews[2], K. Schaumberg[1], J. Fletcher[1], L. Schmitz[1], Q. Lu[1]; [1]Univ. of Wisconsin–Madison, Madison, WI, [2]Univ. of Washington, Seattle, WA

Most human complex traits result from multiple genetic and environmental factors and their interactions. Understanding the mechanisms by which genetic and environmental factors interact (GxE) offers valuable insights into the genetic architecture of complex traits and holds great potential for advancing precision medicine. While this concept seems intuitive, GxE has not been consistently defined in the literature, especially for complex traits due to their polygenic nature. It is often unclear how to compare different GxE approaches, or even whether they can be compared, since they may be estimating entirely different parameters. Existing approaches are also plagued by technical challenges including statistical biases, computational burden, and constraints in the data. Here, we present a unified theory and method, called PIGEON, for modeling polygenic GxE effects for complex traits. We proposed two major objectives for GxE inference, one is to quantify the overall contribution of GxE to the trait and the other is to provide mechanistic insights into the interaction mechanisms, respectively. We showed that all existing methods can be linked to these two objectives but yield flawed results. Motivated by our theory, we have developed a novel approach to estimate GxE which only requires summary statistics as input. It is unbiased, computationally efficient, robust to sample overlap, heteroscedasticity, and gene-environment correlation. We illustrated the versatility of PIGEON through applications that leverage genome-wide data and exogenous environmental exposures. We deployed PIGEON to create an atlas of polygenic gene-by-sex interactions for 530 complex traits in UK Biobank. We found that the sex difference in BMI genetics is partly explained by the genetics of anorexia - anorexia polygenic score (PGS) is significantly more associated with lower BMI in females than in males (P = 5e-14). We further applied PIGEON to a randomized clinical trial, the Lung Health Study to quantify the heterogeneous treatment effect on lung function among smokers, due to individual genetic differences. We found that bronchodilator significantly reduced FEV1 decline in individuals in the high smoking initiation PGS group (BETA = 32, P = 7e-03), whereas no such effect was observed in all samples (BETA = 14, P = 0.1) or the low PGS group (BETA = -2.8, P = 0.8). In conclusion, PIGEON is a clear demonstration that modern statistical genetics that embrace the polygenicity of human traits and rely on summary data alone can also apply to GxE research. Our analyses across different exposures and outcomes showcase the broad questions that can be addressed using this analytical framework.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4350 REMETA: Efficient meta-analysis of gene-based tests in large-scale genetic studies.

Authors:

T. Joseph, J. Mbatchou, A. Ghosh, K. Watanabe, A. Marcketta, Regeneron Genetics Center, DiscovEHR Collaboration, Mayo Clinic Project Generation, M. Ferreira, G. Abecasis, **J. Marchini**; Regeneron Genetics Ctr., Tarrytown, NY

Identifying genes and variants associated with complex traits is essential for understanding the genetic architecture of disease. Meta-analysis, which combines information across studies, has proved a powerful approach for boosting association power in genetic studies without requiring access to individual level data. Meta-analysis can be performed using summary statistics from a genome-wide scan of individual variants, or from gene-based tests that aggregate variants within a gene. The former approach is effective at identifying common variants with modest effects, while the latter boosts power for detecting rare variant associations.

Here we introduce REMETA: a software tool for meta-analysis of exome-wide association studies. In contrast with many current tools, REMETA performs meta-analysis of both single variants and gene-based tests, including burden tests, the sequence kernel association test (SKAT), and the aggregated Cauchy association test (ACAT), providing a comprehensive tool for meta-analysis. REMETA is fully integrated with REGENIE and requires no additional post-processing of REGENIE's output files.

REMETA provides several novel contributions to meta-analysis of gene-based tests. First, we show that reference LD files derived from all individuals in a cohort can be accurately substituted for the exact LD files for a given study, even if it includes just a subset of individuals. Such reference LD matrices can be pre-calculated once for a cohort and used for subsequent analyses which can substantially reduce the compute and storage requirements of gene-based tests. Second, we develop a compact per-chromosome file format for efficiently storing and sharing per study LD matrices that are required for gene-based tests. Third, we develop a method for meta-analysis of gene-based tests with high case-control imbalance that is well calibrated. Finally, we implement an omnibus strategy to aggregate results across tests and correct for multiple testing.

Using data from 740,000 individuals in UK Biobank, the Geisinger Health System DiscovEHR Collaboration, and Mayo Clinic Project Generation we demonstrate the computational efficiency and ease of use of REMETA compared to other approaches, the accuracy of using reference LD files, and the calibration when applied to binary traits with high case-control imbalance. REMETA will made available at https://rgcgithub.github.io/remeta.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4351 Reproducible causal genetic variants discovery of Alzheimer's disease via knockoffs.

Authors:

J. Gu, Z. He; Stanford Univ., Palo Alto, CA

The significance of genetic factors in the development of Alzheimer's Disease (AD) is widely acknowledged, yet the causal mechanisms remain poorly explained by existing large-scale sequencing association studies of whole-exome or whole-genome. To shed light on biological insights of different AD-associated traits, we develop a novel statistical approach based on knockoffs to discover causal genetic variants with reproducibility. By constructing knockoffs that mimic the dependency structure of variant groups, feature importance scores of both original and knockoff variants are obtained through statistical inference or machine learning. Based on a new filter that accounts for group structure, we discover causal variants by sorting importance scores of those reported positive with control on false discovery rate (FDR). Experiments of simulated data and real data demonstrate its advantage over the existing methods in both power and FDR control.

PB4352 Revealing associations between gut microbiome and host bone mineral density via SHAP values

Authors:

L. Jiang[1], Z. Wang[2], L. Zhang[2], B. Tian[3], X. Lin[4], X. Zhang[1], A. Liu[5], Y. Gong[5], C. Qiu[5], K-J. Su[5], Z. Luo[5], Q. Tian[5], L. Wu[5], H. Shen[5], H-W. Deng[5]; [1]Tulane Univ. Sch. of Med., New Orleans, LA, [2]Beijing Jiaotong Univ. Sch. of Sci., Beijing, China, [3]Central South Univ. Sch. of Basic Med. Sci., Changsha, China, [4]Shunde Hosp. of Southern Med. Univ., Foshan, China, [5]Tulane Univ., New Orleans, LA

Previous studies have associated alterations in gut microbiota with conditions such as inflammatory bowel disease (IBD) and obesity, and these conditions may cause bone loss or increased fracture risk. Therefore, changes in gut microbiota can potentially affect bone status. In addition, some studies have examined the associations between gut microbiome and host bone mass/microstructure and have suggested that gut microbiota can possibly regulate bone tissue mechanical properties. In this project, we aim to further elucidate this association by inspecting the relationship between gut microbiome relative abundance variations and changes in bone mineral density (BMD). We collected BMD records, demographic information, and gut microbiome relative abundance at different levels (e.g., species, genus) for over 2,000 subjects in Louisiana. Instead of using statistical modeling/testing, a random regression forest was fitted, and we calculated the Shapley Additive Explanations (SHAP) value matrix that characterizes the contribution of each microbe in predicting the BMD score of each subject. Machine learning approaches like random forest normally have less prerequisites than the conventional statistical models, and recent studies have demonstrated their strong predictive power and high capability in capturing complex data structures. SHAP values were calculated based on the Shapley values from game theory, which indicates how to fairly distribute payout among players working in coalition. The SHAP value matrix allows the revealing of local associations, which could be masked by global associations (i.e., normally the focus of conventional statistical modeling/inference), between microbiome relative abundance and BMD for subgroups of individuals (with similar demographics and/or lifestyle). In our results, we found that SHAP values can help clearly visualize the global associations regarding specific microbes. Furthermore, by clustering the subjects according to the SHAP value-derived Principal Components, we obtained subgroups with distinct BMD distributions, and observed that the microbe with highest contribution in predicting BMD differs across subgroups. Overall, our results support the idea of applying SHAP in association analysis, and the microbes highlighted in different subgroups can help us develop a better understanding of the local gut microbiome-host BMD associations in different sub-populations.

Inst., Univ. of California Los Angeles, Los Angeles, CA, [10]Dept. of Computational Med., David Geffen Sch. of Med., Univ. of California Los Angeles, Los Angeles, CA

BACKGROUND:
A critical step towards realizing the promise of precision medicine is the identification of clinically-relevant disease subtypes. Existing phenotype subtyping methods primarily rely on data clustering or dimensionality reduction. However, they are tuned to capture dominant sources of variation in the data, which often originate from variation that is not descriptive of the mechanistic heterogeneity of the phenotype of interest.
OBJECTIVE:
We aimed to develop a method to identify de novo clinically-relevant subtypes from patient data that can robustly isolate subphenotypic variation even when the signal strength tends to be weak.
METHODS:
We introduce Phenotype Aware Component Analysis (PACA), a novel model-based contrastive learning algorithm. Given case/control status of any data modality that may harbor meaningful sub-phenotypic signals, PACA learns gradients of variation unique to cases (hence subphenotypic signal), while accounting for variation and imbalances of biological/technical confounders between cases and controls. We applied PACA to three clinical case/control datasets to learn new subtypes.
RESULTS:
When compared to several dimensionality reduction and contrastive learning algorithms in simulations, we show that PACA is better powered and the only well calibrated method, reporting no heterogeneity under the null. Using the PsychENCODE clinical data (N=1,321), we grouped transcriptomes from participants with either bipolar disorder (BD) or schizophrenia (SZ) diagnosis. PACA, blind to the BD/SZ labels, isolated a gradient that differentiates BD from SZ (p=2.7e-14; Pearson correlation) and reflects heterogeneity in the genetic architecture (p=1.4e-6; Subtest). Next, applying PACA to voice recordings of female Han Chinese major depressive disorder (MDD) patients and controls from the CONVERGE study (N=1,206) allowed us to leverage the voice data to define two MDD subtypes driven by previous treatment type and educational attainment (p=4.5e-3, p=3.0e-4; linear regression). These subtypes replicated (p=8.7e-3; N=6,142) in an independent sample of voice recordings collected 10 years earlier. Finally, applying PACA to DNA methylation data from Mexican and Puerto Rican pediatric asthma cases and controls (N=1,017) revealed subphenotypic variation associated with disease control level and the intensity of the treatment received (p=4.6e-3, p=3.3e-3; linear regression).
CONCLUSIONS:
Our results render PACA as a calibrated and well-powered new state-of-the-art tool for learning de novo subtypes that are more likely to reflect clinically significant heterogeneity.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4354 Revealing disease genetics: unveiling genetic architecture through differential copy number variation in admixed populations

Authors:

B. Carvalho[1,2], B. Henning[3], T. de Araujo[1,2], H. Tadiello[1,2], V. Almeida[1,2], A. Coan[1,2], M. Montenegro[1,2], M. Alvim[1,2], C. Yasuda[1,2], F. Cendes[1,2], I. Lopes-Cendes[1,2]; [1]Univ.e Estadual de Campinas (UNICAMP), Campinas, Brazil, [2]Brazilian Inst. of NeuroSci. and Neurotechnology (BRAINN), Campinas, Brazil, [3]Univ. of Washington, Seattle, WA

Changes in the DNA may lead to changes at the protein level, which may ultimately be transferred to organisms and diagnosed as a disease. Understanding the genetic landscape of epilepsy will significantly improve patient lives and healthcare delivery. We have seen that copy number variants (CNVs) have contributed to elucidating the etiology in several epilepsy patients. CNVs are genomic intervals (ranging from 1 kilobase to an entire chromosome) that deviate from the normal diploid state of a reference genome. Recent technological and analytical advances revealed the abundance of CNVs in human genomes, showing thatCNVs account for a large amount of human genetic variation and contribute to interindividual variation in complex phenotypes such as disease susceptibility. We propose a statistical learning-based method for CNV detection from whole exome sequencing (WES) data, with extensions to whole genome sequencing(WGS) data. Our focus is on Brazilians, an admixed population often underrepresented in genomic studies, and this approach allows us to investigate population-specific associations between CNVs and phenotypes. In the algorithm's training phase, we use CNV calls from SNP arrays (109 epilepsy cases and 237 controls) as gold-standard to improve the method's sensitivity. When predicting CNV calls on new samples, the method uses only allele dosage and overall abundance derived from site-specific depths. Investigating the inheritance patterns and the genes affected by the CNVs we found in high frequency in case samples should shed light on their influence on the disease phenotype. Complex traits are associated with large and de novo CNVs, while small CNVs that disrupt haploinsufficient genes also implicate the development of diseases. The CNV calls we detected will be combined with statistical learning approaches to provide the community with a well-calibrated CNV calling strategy for NGS data. We expect this approach to play an essential role in untangling the complexity of traits in samples of the Brazilian population, withan easy way of generalizing it to other underrepresented populations.

PB4355 Revealing variable genetic association patterns in COVID-19 patient subgroups: A machine learning approach in genome wide association studies

Authors:

N. Avramidis[1], S. Sohan[2], N. Pirastu[3], E-P. Castineira[1], K. Rawlik[1], K. Baillie[1,4,5]; [1]Pandemic Sci. Hub, Ctr. for Inflammation Res. and Roslin Inst., The Univ. of Edinburgh, Edinburgh, United Kingdom, [2]4Inst. for Adaptive and Neural Computation, Sch. of Informatics, The Univ. of Edinburgh, Edinburgh, United Kingdom, [3]Human Technopole, Milan, Italy, [4]MRC Human Genetics Unit, Inst. of Genetics, Edinburgh, United Kingdom, [5]Intensive Care Unit, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom

There is evidence that critically ill COVID-19 patients exhibit a range of clinical phenotypes which can affect the patient's response to treatment. Understanding the underlying biological reasons for this variation can facilitate the development of advanced therapeutic interventions. Using combined linked electronic health care record data and genotypes for individuals who were recruited to both the Genetics of Mortality in Critical Care (GenOMICC) and the ISARIC Coronavirus Clinical Characterisation Consortium, (ISARIC4C) studies, we aimed to identify and genetically characterize subgroups of critical illness in COVID-19. We stratified 6,996 critically ill COVID-19 patients into distinct subgroups, by applying latent class analysis on the presence of 25 symptoms at hospitalization. Furthermore, we conducted a Genome-Wide Association Study (GWAS) in a one-vs-rest design, where each cluster in turn is treated as a case group with the rest of the clusters acting as control group. The resulting clusters are stable for a number of subgroups from 2 to 9. As the model progresses to higher level solutions, new clusters are formed by partitioning of one of the existing clusters, with minimal sample movement amongst already existing clusters. Most subgroups exhibit at least two of three core symptoms: fever, cough, and shortness of breath. The subgroup's distinction is based on the presence of less common symptoms, such as myalgia, loss of taste and smell, and gastrointestinal symptoms. A model with more than 6 clusters results in an underpowered study design for a one-vs-rest GWAS. Accounting also for cluster stability and phenotypic differentiation, an efficient study design for one-vs-rest GWAS lies between 4 and 6 clusters.The results from the cluster specific GWAS are indicative for genetic heterogeneity amongst the identified subgroups. Examining 49 previously identified genetic susceptibility loci, we found that cluster specific effect sizes exhibit variability in the association patterns. We are currently exploring these differences with the aim of identifying cluster-specific genetic informed drug targets.

PB4356 Revisiting statistical modeling of sQTLs leads to significant improvement in identification and characterization of RNA splicing associated variants.

Authors:

D. Wang, M. Gazzara, S. Jewell, C. Brown, Y. Barash; Univ. of Pennsylvania, Philadelphia, PA

Identification and characterization of splicing quantitative trait loci (sQTLs) has emerged as a critical component in understanding the function of noncoding genetic variants implicated in disease. However, a significant number of sQTLs remain undiscovered due to limitations in both splicing quantification and statistical methods. Here we present a sQTL mapping framework that identifies thousands of novel variants that have been recurrently omitted in recent studies. Our method combines event and transcript level quantifications to identify variants associated with a more comprehensive set of splicing phenotypes that includes intron retention and alternative transcript start/end which are not considered by existing approaches. Using GTEX as a case study, we show that existing pipelines using Leafcutter (Li et al. 2017) fail to report over 25% of complex slicing variation across multiple tissues compared to our hybrid approach using MAJIQ (Vaquero et al. 2016, 2023).

We also develop robust statistical methods to handle discrete and highly correlated multivariate splicing phenotypes which have more power to detect sQTLs while reducing false discoveries. In brief, our method leverages an optimized beta-binomial regression implementation to account for uncertainty in splicing quantifications computed from sparse junction spanning reads. Through further modeling of overdispersed count data, phenotype correlation, missing values, and heteroscedasticity, our model outperforms current methods which were adapted 'as is' from eQTL studies but are still the standard in the field.

To handle multiple hypothesis testing across highly correlated splicing phenotypes, we introduce a permutation free approach based on a multivariate null resampling model. This is followed by optimization of the cis-window size around splice sites which maximizes sQTL discovery relative to the testing burden incurred by a larger search space. The method is many orders of magnitude faster than permutations while still controlling FWER.

Finally, to facilitate downstream variant interpretation, we also introduce improved visualization tools which are implemented as part of the Voila package in MAJIQ. Some key features of this tool include visualization of coordinate splicing changes and a combined transcript-splice junction view of sQTLs. Our pipeline discovers novel intron retention associated variants in the Alzheimer's CASS4 gene and variants in NAGNAG motifs which provide novel insight into the functional role of genetic variants in splicing regulation.

PB4357 Robust inference with summary statistics knockoffs in genome-wide association studies

Authors:

X. Qi[1], M. E. Belloy[1], X. Liu[1], H. Tang[2], Z. He[1]; [1]Stanford Univ., Palo Alto, CA, [2]Stanford Univ. Sch. of Med., Stanford, CA

Genome-wide association studies (GWASs) are widely used to identify genetic variants that impact diseases by meta-analyzing genotyped deoxyribonucleic acid (DNA) sequences across populations and cohorts. Motivated by the limitations of GWASs to capture weaker associations of susceptibility variants and to construct polygenic architecture for complex diseases, we extensively evaluate the robustness of a summary statistics knockoff inference method, GhostKnockoff, and develop a pipeline for the genome-wide discovery of putative causal variants and downstream function interpretations. With empirical simulation studies, we show that GhostKnockoff based on mixed effect model score test control false discovery rate (FDR) and achieve high power for data with related samples. GhostKnockoff also demonstrates robustness to the source of input Z-scores, e.g. Z-scores from different types of marginal association tests or from a meta-analysis for data with independent samples. We apply GhostKnockoff to the meta summary statistics aggregated over nine European ancestral genome-wide association studies and whole exome/genome sequencing studies to select potentially causal genetic variants of the Alzheimer's disease (AD) and to identify functionally informed genes. The downstream analysis of single-cell transcriptomics data is performed to validate genes' biological signals between AD cases and controls.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4358 Role of Epigenetics in the Oral Health Status of Monozygotic and Dizygotic Twins - A Comparative Study

Authors:

D. Francis; Saveetha Dental Coll. and Hosp., SIMATS, Chennai, India

Background: For years, twin research has been at the center of the nature vs. nurture argument. They have been a great source of knowledge on the genetic basis of complex traits, as well as a means of investigating genetic and environmental influences on behavioral and medical characteristics. Twin studies are an intriguing research tool because of its capacity to accurately isolate a feature and measure its influence. The aim was to assess the oral health status and concordance between monozygotic and dizygotic twin pairs. Materials and Methods: After obtaining prior consent, a cross-sectional descriptive study was conducted among 9 monozygotic and 21 dizygotic twin pairs who were reared together. Perception towards oral health practices was assessed using a pre-tested questionnaire. The WHO oral health assessment form (1997) was employed to assess the oral health status. Zygosity determination was determined using the medical records, dermatoglyphics and details about chorionicity and number of placental cords. Pearson's correlation was calculated to determine the correlation among the monozygotic and dizygotic twin pairs. Results: The monozygotic twin pairs showed a greater correlation compared to the dizygotic twin pairs in dental caries, periodontal disease and malocclusion. Conclusion: In the present study, monozygotic twin pairs showed a higher correlation rate than the dizygotic twin pairs, suggesting considerable evidence that genes play a significant role in the etiology of dental caries, periodontal disease and malocclusion.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4359 Safety evaluation of elevated fetal hemoglobin level: Evidence from human genetics

Authors:

T. Zou, L. Barrera, M. Parker; Beam Therapeutics, Cambridge, MA

Background: Elevation of fetal hemoglobin (HbF) is a promising therapeutic strategy to treat thalassemia and sickle cell disease. However, the side effects of elevated HbF are unclear. We aimed to evaluate the safety of elevated HbF level through large-scale association analysis of HbF-increasing genetic variants in UKBB.
Methods: From previous literature, we identified 4 independent common variants (rs7482144 in *HBG2*, rs1427407 and rs11886868 in *BCL11A*, and rs9399137 in *HBS1L/MYB*) and three rare variants (11:5250055:A:G, 11:5249971:G:A, and 11:5254983:G:C) significantly associated with increased HbF levels. For common variants, we calculated the total score of HbF-increasing variants and conducted phenome-wide association studies (PheWAS) of this score with 297 continuous traits, 916 ICD10 diagnoses, and 3 pregnancy outcomes (offspring birth weight, small for gestational age (y/n), and live birth status (y/n)). Analyses were performed using PLINK in unrelated European ancestry individuals in UKBB (n=337,420) adjusting for age, sex, and 20 genetic principal components. For rare variant carriers identified from the 150k whole genome sequencing data, we characterized their demographic factors, pregnancy outcomes, and disease diagnoses.
Results: A total of 255,773 individuals in UKBB carried at least 1 common HbF-increasing variant and 31,100 carried ≥ 6 HbF-increasing common variants. On average, each common variant increased HbF by 0.5%, thus the total score could elevate HbF ~0-4% assumably. PheWAS revealed significant associations between HbF-increasing alleles and measured blood cell traits in UKBB (most significant association with mean corpuscular hemoglobin, Beta=0.04, $P= 1.7x10^{-184}$). There was no association between common HbF-increasing alleles and any ICD10 diagnoses, pregnancy outcomes, or death in UKBB ($P> 5.4x10^{-5}$). We identified 69 heterozygous carriers of known HbF-increasing rare variants in the *HBG1/HBG2* promoter, which are expected to increase HbF to 2-24%. We did not observe abnormal blood cell traits, disease patterns, or pregnancy outcomes in rare variant carriers. Together, these analyses in UKBB suggest lifelong moderate elevation of HbF levels in the general population is not associated with adverse outcomes. Additional analysis is needed to understand the effect of HbF elevation beyond 24% and the effect in thalassemia and sickle cell patients.
Conclusions: We leveraged large-scale human genetics to evaluate the safety of elevated HbF. HbF-increasing alleles were significantly associated with measured blood cell traits, but not any ICD10 disease diagnoses, pregnancy outcomes, or death in UKBB.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4360 SaseR: a novel tool forfast and Scalable Aberrant Splicing and Expression Retrieval in R

Authors:

A. Segers[1], J. Gilis[1], M. Van Heetvelde[1], E. De Baere[2], L. Clement[1]; [1]UGent, Ghent, Belgium, [2]Ghent Univ. and Ghent Univ. Hosp., Ghent, Belgium

Millions of patients suffer from rare Mendelian diseases, for whom a diagnostic rate of their pathogenic variants of 15-75% is currently achieved with whole exome sequencing (WES) and whole genome sequencing (WGS). There is growing evidence that the diagnostic rate can be further improved by discovering mutations in intronic and in other non-coding regions that contribute to disease by disrupting transcriptional regulation. Therefore, WGS is increasingly complemented with RNA-seq profiling to boost the diagnostic rate by identifying aberrant expression (AE) and aberrant splicing (AS).

The AE and AS discovery, however, is not possible with default bulk RNA-seq workflows. With this respect, Outrider and Fraser have disrupted the field by providing formal count-based outlier tests to pick up AE and AS, respectively, while automatically controlling for latent confounders. But, their approach is slow and Fraser is discarding a lot of information as it only uses junction reads. We argue that juggling with input counts and offsets can effectively unlock conventional bulk RNA-seq workflows for fast and scalable AE and AS analyses.

We introduce a single workflow for differential expression, differential splicing (DS), AE and AS based on conventual bulk RNA-seq workflows. Moreover, our workflow is very flexible and provides a simple and unified workflow that can be extended to many applications, e.g. modelling allele specific expression. Our framework also remains future proof to novel sequencing-based technologies and applications, such as transcript counts with long read sequencing, as long as the quantification can be recasted in specific feature counts in conjunction with proper offsets.

In this study, we show how different input counts and offset combinations can be used to assess many research questions in our framework, with a particular focus on aberrant expression and splicing. We further discuss the performance of our workflow to detect AE and AS analyses in simulation and real case studies. We show how our workflows vastly outperform existing state-of-the-art tools in terms of computational speed and scalability, while also dramatically boost the performance to detect ASwhile maintaining a similar performance for AE detection.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4361 Scalable knockoff-based framework for summary statistics analysis

Authors:

b. chu; Stanford Univ., MENLO PARK, CA

We propose GGhostKnockoff for analyzing GWAS (genome-wide association study) summary statistics data. GGhostKnockoff empirically clusters tightly linked variants into groups, runs a joint Lasso regression on marginal Z-scores, and returns a set of conditionally independent discoveries with guaranteed False Discovery Rate control. The methodology is based on recent advances in statistical knockoff theory. Using GGhostKnockoff, we re-analyzed 400+ GWAS results based on publicly available data. We show that GGhostKnockoff makes 10-30% additional (independent) discoveries compared to conventional GWAS, that the discoveries explain additional heritability of the traits, that they are consistent with known genetic correlation across phenotypes, and that the discoveries overlap with real functional experiments. Each phenotype takes ~1 hour utilizing a personal laptop, making GGhostKnockoff a practical approach to analyze the largest summary statistics datasets today.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4362 Scalable summary statistics-based heritability estimation method with individual genotype level accuracy

Authors:

M. Jeong, A. Pazokitoroudi, S. Sankararaman; UCLA, Los Angeles, CA

Heritability estimation of complex traits on large-scale biobanks has allowed us to better understand the genetic architecture underlying various diseases and traits. While numerous methods have been developed to accommodate the increasing size of data and address privacy concerns, most approaches have inherent limitations. For instance, the widely used LD-score regression (LDSC) allows for easy sharing and fast estimation based on summary statistics but lacks the accuracy of methods utilizing individual genotypes. On the other hand, methods that directly use individual genotypes either fail to scale to modern biobanks with nearly millions of samples or are limited in their applicability due to privacy constraints. Often, analyzing individual genotype data such as the Whole Genome Sequencing (WGS) data in the UK Biobank (UKBB) is restricted to its cloud server, highlighting the need for a scalable summary statistics-based approach with high accuracy to reduce its cost. Here we present SUMmary statistics-based Randomized Haseman-Elston regression (SUM-RHE), an extension of a previously proposed method-of-moments heritability estimator to the setting where only summary statistics are available. Our method estimates heritabilities of complex phenotypes with accuracies comparable to approaches that require individual genotypes, while exclusively relying on summary statistics. SUM-RHE employs the same summary statistics (GWAS and LD scores) as LDSC, and an additional population parameter obtained on a reference population, which can be efficiently estimated and readily shared for public use. To validate our approach, we conduct a comprehensive benchmark using simulated phenotypes from the UKBB genotype data with diverse genetic architectures. Our results demonstrate that SUM-RHE achieved a substantial improvement in the Mean Squared Error (MSE) by nearly four-fold compared to LDSC across various genetic architectures while being calibrated (effectively increasing the sample size by a factor of four). We apply our method to real phenotypes for additional validation.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4363 SCiMS: Sex calling for metagenomic sequences.

Authors:

E. Davenport, K. Kirven, H. Tran; Pennsylvania State Univ., University Park, PA

There is growing interest in the bacteria, archaea, and other microbial species that live in our bodies, otherwise known as the microbiome. To characterize it, metagenomics targets all of the DNA in a sample for sequencing in order to gain a complete picture of what microbial taxa and functions exist in a sample. Host characteristics like age and sex are often associated with microbiome composition and are therefore important metadata variables to consider during analysis. However, these metadata are not always collected during sampling. Additionally, sample swaps can occur during processing prior to sequencing and are often challenging to detect. Metagenomic processing pipelines currently lack the ability to confidently call host sex from sequence data alone, either when that metadata is not available or as a QC check. To address this gap, here we present an easy to implement bioinformatic tool that calls sex from shotgun metagenomic data called Sex Calling in Metagenomic Sequences, or SCiMS. In short, SCiMS takes in an alignment file of reads mapped to the human genome, which is typically generated as one of the first steps during metagenomic data analysis. It uses a statistic based on the ratio of reads mapping to the autosomes and to the X (Rx) and Y (Ry) chromosomes to assign biological sex. First, to assess accuracy and depth requirements of the method, we simulated metagenomic datasets with increasing amounts of host reads, from 100 host reads/sample to 1 million host reads per sample using wgsim (v.0.3.1-r13). SCiMS accurately calls sex with as low as 1000 simulated host reads total, demonstrating its potential utility on metagenomic samples with low host:high microbial read content. Second, we applied SCiMS to 639 metagenomic samples from 15 tissues from the Human Microbiome Project. These samples varied in host read content anywhere from 194 host reads to 3,311,380 host reads per sample. SCiMS correctly called sex from 90% of the samples, even from body sites with low host read sequence content such as stool and left retroauricular crease. Finally, we applied SCiMS to 107 mouse fecal and cecal samples and also demonstrated high accuracy in sex calls (95% called correctly compared to metadata). In conclusion, we present SCiMS as the first tool for calling sex from metagenomic reads. SCiMS can be applied to data collected from any species with a heterogametic sex system and is freely available online.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4364 scTIE: data integration and inference of gene regulation using single-cell temporal multimodal data

Authors:

Y. Lin[1], T-Y. Wu[2], X. Chen[2], S. Wan[3], B. Chao[2], J. Xin[2], J. Yang[4], W. H. Wong[2], R. Wang[4]; [1]Yale Univ., New Haven, CT, [2]Stanford Univ., Stanford, CA, [3]Natl. Yang Ming Chiao Tung Univ., Hsinchu, Taiwan, [4]The Univ. of Sydney, Sydney, Australia

Single-cell technologies offer unprecedented opportunities to dissect gene regulatory mechanisms in context-specific ways. Although there are computational methods for extracting gene regulatory relationships from scRNA-seq and scATAC-seq data, the data integration problem, essential for accurate cell type identification, has been mostly treated as a standalone challenge. Here we present scTIE, a unified method that integrates temporal multimodal data and infers regulatory relationships predictive of cellular state changes. scTIE uses an autoencoder to embed cells from all time points into a common space using iterative optimal transport, followed by extracting interpretable information to predict cell trajectories. Using a variety of synthetic and real temporal multimodal datasets, we demonstrate scTIE achieves effective data integration while preserving more biological signals than existing methods, particularly in the presence of batch effects and noise. Furthermore, on the exemplar multiome dataset we generated from differentiating mouse embryonic stem cells over time, we demonstrate scTIE captures regulatory elements highly predictive of cell transition probabilities, providing new potentials to understand the regulatory landscape driving developmental processes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4365 Selecting Covariates for Genome-Wide Association Studies

Authors:

N. Rappoport[1], E. Dor[2], I. Margaliot[3], N. Brandes[4], O. Zuk[3], M. Linial[5]; [1]Ben-Gurion Univ. of the Negev, Beer-sheva, Israel, [2]Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel, [3]The Hebrew Univ. of Jerusalem, Jerusalem, Israel, [4]UCSF, San Francisco, CA, [5]The Hebrew Univ., Jerusalem, Israel

A central goal in performing Genome-Wide Association Study (GWAS) is to identify statistically significant associations between genetic variations and phenotype, thus pointing to the possible biological mechanisms underlying the studied phenotype. However, GWAS is often prone to multiple uncontrolled confounders and biases (e.g., selection bias and population structure). The standard practice in GWAS is to test each SNP independently for association with the trait, which may lead to a high rate of false positives when confounders that are correlated with both the trait and the variant are not included in the model as covariates. The routine GWAS protocol suggests including covariates whose purpose is to control for the indirect effects unrelated to the phenotype of interest and eliminate the influence of confounders. These covariates include technical components (e.g., the genomic center and SNP-chip technology) but also covariates of biological and medical importance, such as the sex and age of the individual that may directly affect the phenotype and Principal Components used to adjust for population structure.The choice of which covariates to include in a GWAS is important since it affects the ability to detect true association signals of variants, to correct for confounders and avoid false positives, and the running time of the analysis. Despite the importance of this issue, there is no consensus or clear guidelines for the right choice of covariates. Therefore, studies typically employ heuristics for their selection with no clear justification. Here, we explore the dependence of the GWAS analysis results on the choice of covariates for a wide range of quantitative and binary human phenotypes. We propose guidelines for the choice of covariates based on the phenotype's type (quantitative vs. disease), heritability, and disease prevalence, aiming to maximize the statistical power to detect true associations and fit accurate polygenic scores while avoiding spurious associations and minimizing computation time.We analyze 36 traits in the UK-Biobank dataset. We show that the genotype batch and assessment center can be safely removed as covariates, thus significantly reducing the GWAS computational burden for these traits.

PB4366 Sensitivity of MR analyses to pQTL instrumental variable selection contributes to lack of replication in heart failure

Authors:

K. Catalano[1], C. Li[1], A. Hukku[1], E. Kvikstad[2], S. Vasquez-Grinnell[2], J. Szustakowski[2], E. Holzinger[1], J. Maranville[1]; [1]Bristol Myers Squibb, Cambridge, MA, [2]Bristol Myers Squibb, Lawrenceville, NJ

Heart failure (HF) has become increasingly prevalent, and there is a need to identify druggable targets to expand treatment options. Mendelian Randomization (MR) analysis of HF using circulating protein data can identify proteins found to enhance or reduce disease risk that may be targeted with inhibition or agonist therapies. MR is a power tool for causal inference, but the method relies on assumptions that are easily violated by methods of instrumental variable (IV) selection, potentially affecting different MR methods to an heterogenous extent. Recent HF MR work using proteomic data highlights this challenge, because despite common proteomic and GWAS data, there is little overlap in the proteins identified as putatively causal and previous loci implicated in HF GWAS[1,2,3,4]. Here, we use pQTL data from the UK Biobank Pharma Proteomics Project Consortium[5] and publicly available HF GWAS summary data[6] to identify the sensitivity of MR analysis to pQTL IV selection across commonly implemented MR methods. We focused on two methodology decisions that can introduce bias, identifying pQTLs that are 1) independent signals (LD pruning), and 2) not confounded by horizontal pleiotropy (inclusion or exclusion of *trans*-pQTLs). We iteratively filtered pQTL instruments across a range of r^2 thresholds used in the literature to assess the sensitivity of MR to IV independence. We then conducted MR analysis with *cis*-only instruments, defined by a range of distances from a protein encoding gene used in the literature, and tested the sensitivity of the analysis to including *trans*-pQTL instruments in concert with varying definitions of *cis*-acting instruments. We applied three commonly used MR analyses to understand the extent to which the results of each method were affected, IVW[7], MR-Egger[8], and GSMR[9]. We found all MR analysis methods were sensitive to IV selection methods to varying extents. Protein significance increased when multiple non-independent instruments were included for the gene. This effect was amplified when considering only *cis*-pQTLs, especially when the number of IVs used was limited. This sensitivity analysis reveals avenues for consensus-building in methodology that may improve accuracy and replication success, thus enriching the possibility successful drug target identification. PB4367 Serum IgA and Gd-IgA1 levels associate with pulmonary phenotypes. The Multi-Ethnic Study of Atherosclerosis (MESA) Lung Study

Authors:

T. Pottinger[1], Z. Liu[1], L. Liu[2], K. Buschur[1], A. Manichaikul[3], J. L. Curtis[4], S. Rich[5], E. A. Hoffman[6], B. M. Smith[1], K. Kiryluk[7], R. Barr[1]; [1]Columbia Univ., New York, NY, [2]Columbia Univ., New York City, NY, [3]Univ Virginia, Charlottesville, VA, [4]Univ. of Michigan, Ann Arbor, MI, [5]Univ. of Virginia, Scottsville, VA, [6]Univ. of Iowa, Iowa City, IA, [7]COLUMBIA Univ. HEALTH Sci.S, New York, NY

Immunoglobulin A (IgA) protects mucosal surfaces against pathogens. IgA deficiency is associated with impaired lung function, and small airway remodeling; and is highly heritable. Subclinical levels of IgA in plasma could have similar correlations. IgA1, an isotype of IgA, is susceptible to inheritable deficits in O-glycosylation; the resulting galactose-deficient IgA1 (Gd-IgA1) is pathogenic in IgA-related vasculitis and nephropathy. Plasma Gd-IgA1 levels have been less investigated in pulmonary diseases. We hypothesized that there was a causal relationship between serum IgA (all isotypes) and lung function, airway wall thickness, and emphysema. **Methods:** The Multi-Ethnic Study on Atherosclerosis (MESA) recruited participants free of cardiovascular disease in 2000-02. IgA was measured in serum using ELISA assays. The MESA Lung Study performed spirometry and chest CT, upon which percent emphysema (-950 HU) and airway dimensions were measured. Linear regression models were used to analyze percent emphysema controlling for age, sex, genetic ancestry, smoking, pack-years, height, weight, and education. Generalized estimating equations were used to account for multiple airway measures per participant controlling for the covariates previously described. Mendelian randomization analyses were also conducted using MR MiSTERI. Variants associated with serum total IgA and Gd-IgA1 levels were extracted from the Trans-Omics for Precision Medicine (TOPMed) database for analysis. **Results:** Among 1,296 participants of diverse genetic ancestries with serum IgA and serum Gd-IgA1 levels and segmental CT measures, there were significant positive associations between log normalized serum Gd-IgA1 levels and segmental airway average minor inner diameter and average wall thickness (β=0.067; p = 0.034 and β=0.12; p = 0.012, respectively). In addition, there was a statistically significant negative association of percent emphysema with log normalized serum IgA levels (n=5,397; β=-0.08; p = 0.0045) and log normalized serum Gd-IgA1 levels (n=2,811; β=-0.089; p = 0.019). Lastly, MR analyses of emphysema and serum total IgA showed a causal association of the biomarker on the phenotype (n=4,153; β=-0.08; p = 0.01). **Conclusions:** In one of the first cohort studies analyzing serum Gd-IgA1 levels, we identified associations between reduced serum IgA concentration with percent emphysema (both total IgA and Gd-IgA1) and lower airway abnormalities (Gd-IgA1). In addition, MR analyses indicated a causal impact of serum total IgA on emphysema but not serum Gd-IgA1. These findings support the protective role of IgA and Gd-IgA1 in lung host defense and COPD pathogenesis.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4368 Sex, onset-age, and APOE-stratified genetic association studies of dementia reveal novel risk loci in African Americans

Authors:

R. Sherva[1], C. Zhu[2], R. Zhang[3], R. Hauger[4], MVP Cognitive Decline and Dementia During Aging Working Group, G. Schellenberg[5], M. Pericak-Vance[6], R. Mayeux[7], J. Haines[8], L-S. Wang[9], L. Farrer[10], M. Logue[11]; [1]Boston Univ. Sch. of Med., Boston, MA, [2]Boston Univ., Natick, MA, [3]VA Boston, Boston, MA, [4]VA San Diego, San Diego, CA, [5]Univ Pennsylvania Sch Med, Philadelphia, PA, [6]Univ. of Miami Miller Sch. of Med., Miami, FL, [7]Columbia Univ, New York, NY, [8]Case Western Reserve Univ, Cleveland, OH, [9]UPENN, Philadelphia, PA, [10]Boston Univ Sch Med, Boston, MA, [11]Natl. Ctr. for PTSD at VA Boston, Jamaica Plain, MA

Alzheimer's disease (AD) risk variants have been identified in European ancestry cohorts that only manifest in or have stronger effects at certain disease stages or in individuals with a specific sex or Apolipoprotein-E (*APOE*) genotype. Until recently, sample sizes in non-European ancestry cohorts have been underpowered to perform stratified analyses to detect these associations. We generated African ancestry (AA) genome-wide association study datasets stratified by sex, age at onset (<75 vs ≥75), and *APOE*-ε4 carrier status in participants from the Million Veterans Program (MVP) and the Alzheimer's Disease Genetics Consortium (ADGC). Outcomes in MVP were Alzheimer's Disease and related dementias (ADRD; n=4073 cases and 19,648 controls) and proxy dementia (i.e., reported dementia in a parent, n=6216 cases and 21,566 controls) while ADGC analyses examined AD (n=2425 cases and 5069 controls). Results from the proxy dementia GWAS were included the corresponding sex-stratified results based on the sex of the affected parent. Analyses were performed using logistic regression models adjusted for age, sex, and ancestry principal components. MVP and ADGC results were combined via sample size-weighted meta-analysis. Genome-wide significant associations were observed in an intergenic region near ephrin receptor A5 (*EPHA5*) (rs141838133, $p=2.19x10^{-8}$) in individuals with onset < 75 years, in glutamate ionotropic receptor NMDA type subunit 3B (*GRIN3B*) near the known AD risk gene *ABCA7* (rs115882880, $p=3.83x10^{-8}$) in females, and near thrombospondin type laminin G domain and EAR repeats (*TSPEAR*) (rs139130053, $p=4.27x10^{-8}$) in *APOE*-ε4 non-carriers. *EPHA5* has two possible AD-related functions: ephrin receptors modify the strength of existing synapses in the brain an in pancreatic islets EPHA5 affects basal and glucose-stimulated insulin secretion to improve glucose homeostasis. Another ephrin family member, *EPHA1*, is a well-established AD risk gene. It is unclear whether *GRIN3B* represents a locus distinct from *ABCA7*. The peak *GRIN3B* SNP is in weak to moderate LD with previously reported *ABCA7* SNPs. *GRIN3B* acts as an inhibitory subunit of CNS ion channels that decreases the current amplitude and calcium permeability of motor neurons. It has been linked to amyotrophic lateral sclerosis and schizophrenia. *TSPEAR* regulates Notch signaling but has not been linked to neuronal function. In summary, age, sex, and *APOE*-stratified analyses of dementia in AA participants from two cohorts revealed new associations. Stratified analyses may yield critical information about the genetic heterogeneity underlying dementia risk and lead to advances in precision medicine.

PB4369 Sex-specific association between anthropomorphic traits and intraocular pressure in the Canadian Longitudinal Study on Aging: A bidirectional Mendelian randomization study.

Authors:

J. Bastasic[1], E. Freeman[1], J. Little[1], P. G. Hysi[2], K. M. Burkett[3], M-H. Roy-Gagnon[1]; [1]Sch. of Epidemiology and Publ. Hlth., Univ. of Ottawa, Ottawa, ON, Canada, [2]Section of Ophthalmology, Sch. of Life Course Sci., King's Coll. London, London, United Kingdom, [3]Dept. of Mathematics and Statistics, Univ. of Ottawa, Ottawa, ON, Canada

Background: Observational studies have found evidence of association between anthropomorphic traits and intraocular pressure (IOP). It is important to determine whether these associations are causal and/or sex-specific in order to develop prevention and treatment approaches. Using Mendelian randomization (MR), we aimed to determine if anthropomorphic traits are causally related to IOP in the Canadian Longitudinal Study on Aging (CLSA).
Methods: We used the baseline data from the European descent subgroup of the CLSA participants with phenotype and genotype data (n=23,004 individuals after sample quality control exclusion). Anthropomorphic traits were based on measured values and included body mass index (BMI), waist-to-hip ratio, and waist-to-hip ratio adjusted for BMI. The outcome was defined as the treatment-adjusted corneal-compensated IOP. We used an MR two-stage least-squares regression analysis with instrumental variables defined as sex-specific polygenic risk scores for the three anthropomorphic traits. Polygenic risk scores were constructed based on published genome-wide association results.
Results: We observed significant associations ($p<0.05$) between all anthropomorphic traits and IOP after adjustment for age, sex, province of recruitment, education, total household income, marital status, smoking and alcohol consumption status. Using the same adjustment variables in the MR analysis, we did not find evidence of a causal association between the anthropomorphic traits and IOP at the 5% significance level. The estimated causal effect of BMI on IOP in males was close to significant ($p=0.0518$).
Conclusion: MR analyses found borderline significant evidence of a causal male-specific association between BMI and IOP. Further investigation of sex-specific associations with better defined instrumental variables would be important.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4370 Shared genetic associations between asthma and COPD stratified by age of onset of asthma.

Authors:

Y. Li[1], Y. Yang[1], D. Cornejo-Sanchez[2], G. Wang[2], S. M. Leal[2], A. T. Dewan[1]; [1]Yale Sch. of Publ. Hlth., New Haven, CT, [2]Columbia Univ., New York, NY

Asthma is the leading chronic disease for children and is also common among adults. Chronic obstructive pulmonary disease (COPD) is a leading cause of death and disability worldwide, primarily affecting individuals > age 65. Studies have suggested that patients with asthma and COPD experience more symptoms, frequent exacerbations, poorer quality of life, a more rapid decline in lung function, higher mortality, and greater use of healthcare resources, compared to those with either condition alone. Shared genetic risk factors may contribute to both asthma and COPD, and these factors may differ between adult and childhood onset asthma. This research was conducted using the UK Biobank. We included subjects who self-defined as White British and have similar genetic ancestry based on a principal components (PCs) analysis. Asthma was defined by either ICD-10 code or diagnosis by a doctor which was self-reported by the study subject. Childhood asthma was defined as asthma with age of onset ≤10 years (N=8,134) while adolescent/adult asthma (hereafter referred to as adult asthma) had onset >10 years (N=29,369). Controls (N=290,722) for childhood and adult asthma, did not include individuals with autoimmune disease. A proxy COPD status as previously described in PMID 32477647 was determined by the ratio of the best measures for forced expiratory volume in 1-second (FEV1) to forced vital capacity (FVC). Cases had a FEV1/FEV ratio < 0.70 (N=44,323) while controls had an FEV1/FEV ratio >0.70 (N=232,489). Imputed (INFO>0.8) and directly genotyped variants were included in the generalized linear mixed model as implemented in REGENIE. Age at recruitment, genetic sex, and 10 PCs were included in all the models and baseline smoking status was adjusted for in the COPD proxy model. FUMA 1.5.4 was used to annotate SNVs to genes and only SNVs with P < 5?10-8 were used to investigate the genetic overlap between traits. The number of significant SNVs were 3,186 for adult asthma, 5,685 for childhood asthma, and 7,594 for proxy COPD with a subset of these SNVs that mapping to 445, 624, and 990 genes, respectively. There was overlap of significant SNVs/genes between phenotypes: 1,875 SNVs (256 genes) for adult and childhood asthma; 177 SNVs (62 genes) for adult asthma and proxy COPD; 101 SNVs (67 genes) for childhood asthma and proxy COPD, and 89 SNVs (46 genes) were shared between all three phenotypes. For genes shared between all phenotypes, the number is almost double what is expected to be shared by chance (46 vs. 26.1). These data confirm that there is overlap in the genetic architecture of asthma and COPD, and this shared genetic etiology is largely irrespective of the age of onset of asthma.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4371 Shared genetic factors between type 1 diabetes and co-occurring autoimmune diseases.

Authors:

A. Nwagbata[1], A. Iakovliev[1], S. McGurnaghan[2], H. Colhoun[2], A. Spiliopoulou[1,2], P. McKeigue[1]; [1]Usher Inst., Univ. of Edinburgh, Edinburgh, United Kingdom, [2]Inst. of Genetics and Cancer, Univ. of Edinburgh, Edinburgh, United Kingdom

Background: People with type 1 diabetes (T1D) have a higher frequency of other autoimmune diseases (AIDs). Which causal mechanisms underlie this co-occurrence is unclear. Most studies investigating the genetic overlap between T1D and other AIDs have used independent cases for each trait. The aim of this study was to investigate if genetic factors associated with T1D are also associated with co-occurrence of other AIDs among people with T1D.
Methods: Among 4964 people with T1D in the Scottish Diabetes Research Network Type 1 Bioresource, we ascertained who also had hypothyroidism (915), pernicious anaemia (355), celiac disease (189), psoriasis (193), inflammatory bowel disease (187) and rheumatoid arthritis (184). Genetic markers for T1D comprised 23 genotypic scores computed by genome-wide aggregation of *trans*-effects (GATE) of common SNPs on gene expression in whole blood (9) and on circulating protein level (14). We previously showed that the GATE scores for these genes and proteins were strongly associated with T1D and supported an "omnigenic" model for its genetic architecture, where *trans*-effects of many SNPs coalesce on relatively few core genes. Logistic regression was used to test the association of these 23 GATE scores with case-control status for each co-occurring AID and the remaining T1D cohort as controls. Proteins were mapped to their corresponding gene names using Uniprot-ids.
Results: The GATE scores for the expression or protein level of 8 and 4 T1D core genes were associated with the risk of hypothyroidism and of pernicious anaemia, respectively ($P < 5.5 \times 10^{-3}$ for expression scores, $P < 3.5 \times 10^{-3}$ for protein scores). Genes *FOXP3*, *CD5* and *CD247* were associated with both hypothyroidism and pernicious anaemia. Genes *LGALS3BP*, *STAT1*, *CRTAM*, *CCL19* and *CD5L* were associated only with hypothyroidism, and *CCL15* was associated only with pernicious anaemia. These significant associations had the same effect direction on co-occurring AIDs as on T1D. Besides *CD247* and *LGALS3BP*, which play other significant roles in the immune system, these genes are involved in the induction and activity of CD4+ regulatory T cells (Tregs). There were no significant associations for the remaining AIDs, which can be attributed to moderate sample sizes.
Conclusion: We provide evidence of association between GATE scores for the expression or protein level of T1D core genes and the risk of co-occurring hypothyroidism and pernicious anaemia among people with T1D. This suggests shared immune system pathways between these AIDs and highlights possible causal mechanisms underlying this co-occurrence; the detected genes could serve as potential targets for drug development.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4372 Shared mutational burden within human Spina Bifida cohort and genetic similarities with comorbidities

Authors:

M. Strain; Duke Univ., Durham, NC

Neural tube defects (NTDs) are the most common congenital malformation of the brain and spinal column, affecting approximately 1/1000 births in the US annually. Despite strong evidence for a complex genetic architecture, the specific genes and inheritance models underlying NTD risk have not been fully elucidated. Most risk variants identified thus far have been private mutations in individual NTD families. In an effort to further identify genetic factors influencing the most prevalent NTD subtype, the Spina Bifida (SB) Sequencing Consortium has performed whole genome and exome sequencing of 139 patient-parent trios from the Duke NTD cohort. To identify genes that may harbor an excess of rare variants in SB, we compared the aggregate burden of rare variants (MAF ≤ 0.005) within gene bodies from our 139 SB probands against 776 non-Finnish European controls from the gnomAD data base. While controlling for population stratification, we identified three genes with increased mutational burden in the SB cases ($q < 0.05$). The most notable of these three was tubulin beta 3 (*TUBB3*; $p = 0.0003$), for which clinical variants linked to other brain malformations have been identified. We were also interested in whether there was a potential overlap between the genetic basis of hydrocephalus (HC) and SB. HC can occur idiopathically, but is also a common comorbidity of SB (31% of our SB cases; NTD+HC). We used summary statistics from a publicly available idiopathic HC genome-wide association study (GWAS) to generate polygenic risk scores for HC within our SB cohort. Using 18 SNPs surpassing a p-value threshold of 5e-4 from the HC GWAS, the resulting PRS explained nearly 30% of the variability in our SB cohort ($p = 0.003$). These data support the hypothesis that specific genes with a burden of rare variants contribute to NTD, as well as the overlap between the genetic basis of idiopathic HC and comorbid NTD+HC.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4373 Single Nuclei Transcriptome-Wide Association Study Atlas of the Human Brain Uncovers Cell-Type-Specific Contributions to Schizophrenia and Alzheimer's Disease

Authors:

S. Venkatesh[1], G. Hoffman[1], D. Lee[1], D. Mathur[1], P. NM[1], B. Zeng[1], A. Hong[1], C. Casey[1], M. Alvia[1], Z. Shao[1], S. Argyriou[1], K. Therrien[1], P. Auluck[2], D. Bennett[3], S. Marenco[2], V. Haroutunian[1], J. Bendl[1], J. Fullard[1], G. Voloudakis[1], P. Roussos[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Natl. Inst. of Mental Hlth., Bethesda, MD, [3]Rush Univ. Med. Ctr., Chicago, IL

Transcriptome-Wide Association Studies (**TWAS**) complement Genome-Wide Association Studies (**GWAS**) by integrating tissue specific variation, uncovering mechanistic effects of genomic loci (especially in non-coding regions), and by adding power to discover associations between genomic features and phenotypes. However, until now, TWAS efforts have been mostly limited to tissue homogenate specimens, from e.g. dorsolateral prefrontal cortex (**DLPFC**) or heart. To address this, we built cell-type-specific transcriptomic imputation models (**TIMs**) using DLPFC single-nuclei RNA sequencing (**snRNAseq**) from genotyped individuals to perform TWASs with single cell resolution for schizophrenia (**SCZ**) and Alzheimer's Disease (**AD**).

We utilize the psychAD cohort that includes snRNAseq in more than 6 million nuclei from the DLPFC of 1,495 unique donors. We use PrediXcan to build TIMs, S-PrediXcan to perform summary-level TWAS, and custom scripts to perform Phenome-Wide Association Studies (**PheWAS**) in the Million Veteran Program (**MVP**).

Cell-type-specific TIMs predict several thousand genes in 36 cell types. Using the latest Psychiatric Genetics Consortium GWAS for SCZ, we find over 300 significant associations across over 200 unique genes. Of note, the majority of these significant associations came from excitatory neurons and oligodendrocytes. We then compare SCZ TWAS of cell-type-specific TIMs with a previously established TIM for DLPFC. Among genes with a prediction performance R^2 of 0.01 or greater in both TIMs, TWASs of excitatory neurons and oligodendrocytes have the highest correlation with tissue homogenate (0.55 and 0.40 respectively). Using AD summary statistics, we find over 120 significant associations across over 80 significant genes. Moreover microglia TWAS of AD correlates strongly with a fresh sorted microglia TWAS of AD (0.82). Finally, we perform PheWAS analysis on critical genes selected from summary-level TWAS in MVP.

Cell-type-specific TIMs find unique contributions of particular cell types to SCZ and AD. Of particular interest are genes that have opposite effect sizes in different cell types. For example, *ASPHD1* has significant but opposite effects in association with SCZ between astrocytes and oligodendrocytes. This is consistent with the literature, which finds that *ASPHD1* overexpression and knock-out are associated with SCZ. This suggests our approach can identify associations that would otherwise be lost in bulk tissue analyses. Finally, the high correlation between our frozen snRNAseq pseudobulk microglia AD TWAS and fresh bulk RNAseq sorted microglia AD TWAS lends credibility to our TIMs.

PB4374 † Single nucleus multi-omics profiling reveals epigenomic and transcriptional dynamics in Alzheimer's disease

Authors:

Y. Gong[1], X. Zhang[1], C. Qiu[1], K. Su[1], Q. Tian[2], H. Shen[3], H-W. Deng[4]; [1]Tulane Univ., New Orleans, LA, [2]Tulane Univ., Mandeville, LA, [3]Tulane Univ, New Orleans, LA, [4]Tulane Univ, Mandeville, LA

Alzheimer’s disease (AD) is a debilitating neurodegenerative disorder characterized by progressive cognitive decline and memory loss. The intricate molecular mechanisms underlying AD pathology remain poorly understood, necessitating innovative approaches to elucidate key regulatory factors. In this study, we employed single nucleus Assay for Transposase-Accessible Chromatin sequencing (snATAC-seq) and single nucleus RNA sequencing (snRNA-seq) to investigate the epigenomic and transcriptomic landscapes in AD-affected human prefrontal cortex. Our analysis focused on the snATAC and RNA -seq from 18 AD cases (10 female and eight male) ranging from 77 to 90 and 15 age-matched controls. Following the integration analysis of chromatin accessibility and transcriptional profiles, we identified seven distinct cell clusters corresponding to astrocytes, oligodendrocytes, excitatory neurons, inhibitory neurons, oligodendrocyte progenitor cells, endothelial cells, and microglia. Delving deeper through differential expression analysis, we unveiled unique epigenetic and transcriptional signatures tied to AD. These encompassed genes involved in synaptic function, neuroinflammation, and amyloid-beta metabolism. Intriguingly, we noticed substantial dysregulation of transcription factors and CD44 in astrocytes, hinting at an intricate nexus of epigenetic and transcriptional regulatory networks implicated in AD pathogenesis. In summary, our study provides a comprehensive single-nucleus multi-omics perspective on the epigenomic and transcriptomic alterations in brains afflicted by AD. This insight significantly enhances our understanding of the molecular pathways implicated in AD pathogenesis, offering potential targets for future therapeutic intervention

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4375 Sixteen years' experience of *SMA* carrier screening and prenatal diagnosis in Iranian populations.

Authors:

A. Khanbazi[1,2], M. Beheshtian[1,2], M. Azad[1], M. Akbari[1], A. Kariminejad[1], K. Kahrizi[2], H. Najmabadi[1,2]; [1]Kariminejad - Najmabadi Pathology & Genetics Ctr., Tehran, Iran, Islamic Republic of, [2]Univ. of Social Welfare and Rehabilitation Sci., Tehran, Iran, Islamic Republic of

Spinal muscular atrophy (SMA), generally characterized by muscle weakness and degeneration, is caused by the deterioration of motor neurons in the spinal cord due to the deletion or mutation in the *SMN1* gene on chromosome 5. To promote genetic counseling and enable families to make more informed decisions, determining SMA carrier status in multi-ethnic populations with a high rate of consanguineous marriage such as Iran is crucial. Therefore, in this study we aimed to investigate the prevalence of SMA carriers among individuals referred to Kariminejad - Najmabadi Pathology & Genetics Centre for carrier screening, between 2006-2022, by physicians, healthcare centers, and genetic laboratories from across Iran. Additionally, we report the results of prenatal diagnosis (PND) tests conducted in this Centre.We calculated the carrier frequency of SMA among unrelated individuals who did not have a confirmed or probable family history of the disease. Ninety-six percent (n=569) of tests were done by Multiplex ligation-dependent probe amplification (MLPA) (MRC Holland) and the remaining (n=23; 4%) were conducted by quantitative RT-PCR.A total of 592 individuals met our criteria. The mean age (SD) of investigated cases was 30 (±7) years. The carrier frequency of SMA was estimated to be 4.5% (CI=0.95%, 3.1-6.4). Among normal individuals, 87% (n=516) had two copies, 7% (n=43) had three copies, and 1% (n=6) had four copies of *SMN1*. PND was performed on 331 fetuses; of which 21% (n= 70) were affected, 28% (n=91) were normal, and 51% (n=170) were carriers. 188 out of 257 families (73%), had a history of at least one affected offspring, and parents were considered as obligate carriers. However, in 12 families (5%), one of the parents had a normal copy number of *SMN1* that might be suggestive of silent carriers.Considering the historical influx and the subsequent genetic diversity in Middle east countries including Iran, our result showed a higher rate of carrier frequency than that reported from European or East Asian populations (~1.8%) and aligned more closely with nations possessing similar cultural backgrounds including consanguineous marriage, specifically Morocco (4%) and Saudi Arabia (2.6%). Therefore, providing genetic counseling and premarital screening for couples in such countries along with prenatal diagnosis among at-risk couples plays a pivotal role in preventing the births of children affected by SMA. Furthermore, our result emphasizes the necessity for considering the risk of a silent carrier state among individuals with normal results.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4376 Statistical challenges with GWAS on ratio traits obscure the interpretation of many published associations

Authors:

T. Soare[1], Z. McCaw[1], H. Somineni[1], S. Mukherjee[1], K. Sandor[1], Insitro Research Team, P. Tagari[1], D. Koller[1], G. Davey Smith[2], D. MacArthur[3,4], C. O'Dushlaine[1]; [1]Insitro, South San Francisco, CA, [2]Univ. of Bristol, Bristol, United Kingdom, [3]Garvan Inst., Sydney, Australia, [4]Murdoch Children's Res. Inst., Melbourne, Australia

Ratio traits are metrics defined by a numerator trait and a denominator trait, and are widely used clinically to assess health (e.g. BMI, waist-to-hip ratio). Such traits have been a target for many genome-wide association studies (GWAS), generally with the implicit or explicit goal of uncovering the genetic underpinnings of the numerator while controlling for the denominator. In the GWAS catalog, ratio traits represent 3% of traits analyzed and 8% of reported associations.

However, there are conceptual problems with the ratio approach. Using a naive ratio as the outcome does not actually test the direct effect of genotype on the numerator while holding the denominator constant, and the genetic effect estimate in the ratio model is difficult to interpret: as the association may be due to the numerator alone, the denominator alone, or both the numerator and the denominator. Further, the genetic effect estimate is likely to be biased. Such issues could be avoided by simply testing the numerator trait as the outcome and using the denominator trait as an additional covariate ("adjusted model").

To explore the impact of issues with the ratio model on published GWAS results, we use waist circumference, hip circumference, and their ratio (WHR) to assess central adiposity. Permuting waist circumference (the numerator) while leaving hip circumference unchanged, we find the ratio model has a 5-10% false positive rate, identifying 77 spurious genome-wide significant loci in the UKBB (N=350k). In contrast, the adjusted model effectively controls type I error (0 genome-wide significant loci). False positive variants are enriched for denominator associations, suggesting the false positive rate is driven by the heritability of the denominator. A properly adjusted model identifies 20% more loci than the ratio model, and variants identified by both models have stronger associations in the adjusted model, showing the adjusted model is better powered to detect direct effects on the numerator.

We find similar effects in other ratio traits, suggesting that published GWAS findings are substantially affected by this statistical issue. We recommend re-analysis of ratio-based GWAS results using a covariate adjustment model in order to reduce false positive associations, maximize power, and aid in biological interpretation.

PB4377 Statistically robust familial variant analysis

Authors:

A. Janiszewski, I. Protopopov, J. Behr, X. Bonilla, N. Arrigo, Z. Xu; SOPHiA GENETICS, Rolle, Switzerland

Familial variant analysis (FVA) can be a powerful tool for the identification of disease-causing germline variants. FVA investigates variant segregation patterns and excludes variants that do not follow the inheritance patterns of interest, reducing the number of candidate disease-causing variants that need to be further assessed. However, the sequencing noise present in large-panel sequencing may cause errors in variant zygosity estimation, hindering the filtering ability of FVA. This effect is expected to grow with increasing pedigree size, as sequencing errors in one individual can negatively affect the analysis of the entire family. Here, we develop an FVA algorithm that combines sequencing data and affection status of family members in a statistically robust way and guarantees full control over the false negative rate. Our approach is based on characterizing the consistency of sequencing data with the expected variant zygosity, in each family member, for all inheritance modes available, and representing it as a set of p-values with the subsequent combination of the relevant scores using Fishers p-value combination procedure. This approach supports the analysis of pedigrees of any size, and data missingness: it leverages on affection status of a family member even if sequencing data is unavailable, extending the use of FVA in clinical sample analysis. Using in-silico simulations of family data, we demonstrate the controlled false negative rate of our algorithm and estimate its efficiency defined as the fraction of variants that do not follow the tested segregation pattern that are correctly filtered out. The experiments cover autosomal recessive, autosomal dominant, X-linked and compound heterozygous variants propagating in pedigrees with up to 3 generations and siblings. For each case, we simulated 100 families with average read coverage of 30 and 100 and defined noise model. We show that the filtering efficiency increases with increasing availability of affection status and/or sequencing data of individuals. For example, filtering power for autosomal dominant variants increased by 16,2% if grandparents' affection status was added to a trio analysis, and by 45% if grandparents' sequencing data were also added. Altogether, our FVA algorithm provides enhanced variant filtering capabilities for identification of disease-causing variants from large NGS data such as whole-exome or whole-genome sequencing. Combined with the ability to analyse pedigrees of any size and to include individuals for which only affection status is available, our algorithm provides means to improve the efficiency and accuracy of variant analysis and interpretation.

PB4378 Studies of Linkage and Polygenic Risk to Improve Genetic Testing for Cardiovascular Disease Across Populations

Authors:

G. Tietz[1], A. Ellison[1], T. Tan[1], N. Shah[1], S. Behera[1], J. Belyeu[2], R. Gibbs[3], F. Sedlazeck[3], E. Atkinson[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Illumina, Inc., San Diego, CA, [3]Baylor Coll. Med., Houston, TX

Cardiovascular disease (CVD) is the leading cause of death in the United States. Genetics can influence CVD risk through regulating lipids like lipoprotein A (Lp(a)), which can double an individual's risk for heart attack at elevated levels. Given its high heritability of 90%, Lp(a) is especially promising for genetic testing and several variants within the gene *LPA* are integrated into a clinical gene panel to identify those at risk of CVD. However, recent findings have identified poor predictive transferability of these variants to Hispanic individuals, which may be explained by different patterns of genetic variation and linkage across ancestries impacting tagging of a shared causal locus.

To combat this inequity, we aim to refine genetic testing for Lp(a) through ancestry-informed analyses of linkage structure in *LPA*, combined with the development of a novel polygenic scoring model accounting for both a single locus of large effect with polygenic variation. Considering both with an ancestry-aware approach, we observed improved prediction for populations in which genetic testing for CVD currently underperforms.

Here, we start by investigating linkage in Latin American (LAT) and European (EUR) individuals of the 1000 Genomes Project. We identified a recombination event within *LPA* with population-specific patterns where recombination rates decreased with the proportion of EUR ancestry present in LAT individuals. This recombination event differentially disrupts linkage of a clinically used *LPA* variant to KIV-2, a critical locus in *LPA* that is infrequently called given its repetitive nature. In the context of the variants within *LPA* that are clinically tested, this suggests that their decreased predictiveness may be explained by more frequent recombination events decreasing their tagging of KIV-2.

We then evaluated whether considering polygenic burden with a KIV-2 proxy locus would improve predictive performance across populations. First building an Lp(a) PRS on EUR individuals of the UK Biobank, we then added consideration of variants associating well with KIV-2 across populations to generate an extended PRS model. Through testing and benchmarking, we identified improved prediction accuracy of Lp(a) levels across diverse ancestries with our new extended PRS model.

Collectively, our work proposes new approaches to improve transferability of genetic testing for CVD across populations through analyses of structure, and integration of polygenic burden and a locus of large effect into a novel model. Building from this work will help narrow a current gap in genetic testing and ensure that the promise of precision medicine is extended to all populations.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4379 † Subcontinental admixture in Europeans and European Americans can affect GWAS findings and polygenic score performance.

Authors:

M. Gouveia[1], T. Leal[2], K. Meeks[1], E. Tarazona-Santos[3], C. Bustamante[4], A. Adeyemo[1], C. Rotimi[1], D. Shriner[1]; [1]NIH, Bethesda, MD, [2]NIH, Cleveland Clinic, OH, [3]Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil, [4]Stanford Univ. Sch. of Med., Stanford, CA

Failing to account for local ancestry, which is a result of admixture, can introduce residual confounding and thereby affect studies of association, polygenic adaptation, and polygenic risk scores. However, admixed populations are often considered as those resulting from recent interbreeding between continentally separated populations. Thus, European-ancestry populations are recognized as stratified but not as admixed. We recently showed that European-ancestry individuals are three-way admixed at the European subcontinental level. Using the classical *LCT*-height false positive association, we demonstrated that adjusting for both global and local ancestry enables the identification of spurious associations. In the present study, we evaluated the impact of ancestry adjustment in genome-wide association studies (GWAS) findings and polygenic score (PGS) performance. We performed a GWAS of height in 17,684 European Americans (EA) with different levels of ancestry correction, namely unadjusted, global, and global + local (full). Previously reported GWAS associations ($p < 5x10^{-8}$) that were significant in our analysis unadjusted for ancestry but not significant after full adjustment were considered likely false positives. Following this approach, we interrogated 1,147 independent associations for height reported in the GWAS Catalog and identified 75 (6.5%) likely false positives due to uncorrected ancestry stratification. Two associations (at rs2857693 and rs10838798) showed strong residual confounding by local ancestry, i.e., they were replicated in analyses unadjusted and adjusted for global ancestry, but lost significance after full ancestry adjustment. To assess the utility of our approach in identifying spurious associations, we calculated PGS for height in our EA dataset using GWAS summary statistics from the GIANT consortium (> 4 million European ancestry individuals). The PGS estimated from loci in GIANT that we identified as likely false positives had 5-fold lower predictive value than PGS estimated from randomly selected sets of GIANT height associations ($p < 0.001$). Overall, our findings provide evidence that spurious associations in GWAS resulting from failure to fully account for population stratification can have substantial downstream consequences, including poorer PGS performance. Additionally, accounting for subcontinental admixture minimizes the risk of follow-up functional analysis of novel but false positive findings.

PB4380 Synthetic Slope Analysis Empowers GWAS of Physiological Decline

Authors:

Z. McCaw, D. Amar, C. O'Dushlaine, T. Soare; Insitro, South San Francisco, CA

Certain measures of physiological function are known to deteriorate with advancing age. Examples include grip strength, lung function, and cognitive performance. Accelerated decline of these variables is often a hallmark of disease, such as amyotrophic lateral sclerosis (ALS). Understanding the genetic basis of accelerated physiological decline may be key to patient risk stratification and drug target identification.

Performing genome-wide association studies (GWAS) for the rate of physiological decline is hindered by the paucity of genotype-phenotype cohorts with extended longitudinal follow-up. For example, in the UK Biobank, only ~10% of subjects have follow-up measurements. Machine learning (ML) models can be trained to predict a subject's rate of decline from baseline covariates. However, the accuracy of such models is fundamentally limited because predicting a rate of change from a single time point is an ill-posed problem. Limited predictability poses a significant challenge for imputation or proxy GWAS.

Recently, synthetic surrogate analysis (SynSurr) was developed for leveraging an ML-derived surrogate phenotype to improve GWAS on a partially missing target phenotype. Here, we use the predicted rate of decline as a synthetic surrogate for the incompletely observed empirical rate of decline, an application of SynSurr we described as Synthetic Slope Analysis (SSA). SynSurr has several advantages over imputation-based GWAS. Unlike imputation, SynSurr does not assume that the predicted and observed rates of decline come from the same distribution. Rather, SynSurr jointly models the observed and predicted rates within a bivariate regression framework. SynSurr estimates the same effect size as standard GWAS of the observed rate of decline; properly controls the type I error, even when the predicted rate of decline is unreliable; and improves power in proportion to the correlation between the observed and predicted rates of decline.

We apply SSA to empower GWAS on the rates of decline for several traits known to deteriorate in ALS. Compared with standard GWAS on the observed rate of decline, SSA identifies more genome-wide significant associations. We assess the biological relevance of the associations identified by SSA to ALS and neurological disease more broadly.

Sch. of Med. and Boston Univ. Sch. of Med., Boston, MA, [15]Div. of Cardiology, Dept. of Internal Med., Wake Forest Univ. Hlth.Sci., Winston-Salem, NC, [16]Univ. of Southern California, Los Angeles, CA, [17]Univ. of Michigan, Ann Arbor, MI, [18]NHLBI, Bethesda, MD, [19]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [20]Univ Virginia, Charlottesville, VA

Coronary artery disease (CAD) is a leading cause of death and disability worldwide. Prior genome-wide association studies (GWAS) of CAD have identified over 400 independent loci. However, the molecular consequences of the GWAS variants and their relevance to subclinical atherosclerosis have not been explored comprehensively in human cohorts. In this study, we aimed to prioritize the CAD-related molecular targets and investigate their relationship with subclinical atherosclerosis using molecular 'omics data from TOPMed Multi-Ethnic Study of Atherosclerosis (MESA). We performed Bayesian colocalization to identify the genes underlying genetic loci from a multi-ancestry GWAS of CAD (Tcheandjieu et al. 2022) using transcriptomic data from peripheral blood mononuclear cells (PBMCs) in MESA, a multi-ethnic longitudinal genetic epidemiology cohort. To prioritize CAD-related genes, we performed additional follow-up of the colocalized genes using (a) Colocalization with GWAS of subclinical atherosclerosis (CAC and cIMT), (b) regression analysis of subclinical atherosclerosis on measured expression in MESA, (c) examination of protein QTL (pQTL) and methylation QTL (mQTL) evidence for the CAD causal variants and (d) phenotypic consequences of gene knockouts in mice. We also performed weighted gene co-expression network analyses (WGCNA) on the MESA transcriptomics data to identify modules of highly correlated genes and their association with subclinical atherosclerosis in MESA. Based on our Bayesian colocalization, we identified 54 putative causal genes underlying CAD-assocatied loci. Among these, we observed 10 genes showing at least three forms of evidence in follow-up analyses,
including *PLEKHJ1*, *LAYN*, *BICC1*, *SCARB1*, *PAN2*, *CCDC30* and *CARCAL*. For example, *PLEKHJ1* shows association with CAC and cIMT in MESA. *BICC1*, *SCARB1* and *PAN2* show significant association with heart/cardiovascular traits in mice. WGCNA identified four modules associated with subclinical atherosclerosis in MESA. Overlapping our 54 colocalized genes with the modules from WGCNA, we found one module was significantly enriched for colocalized genes. Pathway analysis of genes from this module highlighted common features among the identified genes, including encoding components of the complement system and inflammatory response. Our study identified multiple candidate genes at GWAS loci that are supported by molecular QTL, and additional follow-up analyses predicted effects of these genes on CAD and subclinical atherosclerosis in both humans and mice. Additionally, our study showed the value of network analysis further characterize pathways implicated by GWAS genes.

PB4382 TargPred: a web-based platform to uncover SNP-gene associations within genomic regulatory blocks

Authors:

F. Uljanic, K. Mandic, D. Hrsak, A. Baresic; Ruder Boskovic Inst., Zagreb, Croatia

The quest to pinpoint genetic variants tied to complex diseases and traits has led to an extensive number of genome-wide association studies (GWAS). These studies have uncovered countless genetic variants, but the task of connecting non-coding single nucleotide polymorphisms (SNPs) to their affected protein-coding genes remains challenging. Within the genome, segments known as Genomic Regulatory Blocks (GRBs) are populated with highly conserved non-coding elements. These elements exhibit preserved gene order, or synteny, across a range of vertebrate species, suggesting that the genes situated inside the GRBs are under long-range regulation.
In this research, we introduce TargPred, an online tool that unlocks the potential of linking regulatory SNPs within GRB regions to their putative target genes. This innovative approach leverages previously established associations between enhancer and promoter transcriptional activity within the GRB, and likely target genes for each GRB. TargPred, an open-access tool, provides a comprehensive view of genomic landscapes and highlights enhancer-promoter associations in genes that are under long-range regulation for 2544 traits from the GWAS catalog. An application of TargPred is showcased in a schizophrenia population study where the target gene, initially identified based on its proximity to a GWAS-identified SNP, was reassessed through the lens of our GRB-focused methodology.
TargPred aims to empower researchers to explore patterns of heritability in complex traits and diseases, prioritize drug targets, and uncover genetic features that are primarily governed by long-range regulation. This tool, we hope, will offer new insights into disease and trait patterns, further illuminating the complex nature of genetic regulation. Targpred is available at: targpred.irb.hr.

PB4383 Testing for differences in Hardy-Weinberg Disequilibrium between groups

Authors:

E. Garg[1], J. Romain[2], L. Sun[2], A. Paterson[1]; [1]Hosp. for Sick Children, Toronto, ON, Canada, [2]Univ. of Toronto, Toronto, ON, Canada

Testing for deviation from HWE (Hardy-Weinberg Equilibrium) is a standard quality control approach before conducting genetic analyses. However, deviation from HWE can be caused either by technical biases or violation of numerous assumptions related to population structure. Therefore, assessing HWE differences between groups is important. In our pilot work, we assessed HWE across groups in the Illumina 2.5M array data from the 1000 Genomes Project phase 3 data. Further, we combined group results by using inverse-variance and second-order meta-analysis. Additionally, we compared group results using Cochran's Q to test for variability among the groups. We identified 26 autosomal SNPs with MAF>5% with significant HWE (p<E-8) in one or more population or sex groups, and further with heterogeneity in effect sizes between ancestry- or sex-based groups. The most common basis for heterogeneity was evidence for deviation in males, but not females. BLAST of the sequence around such SNPs typically identified similarity to the recently released T2T chromosome Y sequence, which contains 30Mb of sequence missing from previous references, implying that they are paralogous sequence variations (PSV). We aim to implement similar analysis using the T2T (telomere-to-telomere v2) aligned high-coverage 1000 Genomes Project data. We hypothesize that the T2T data will have less technical biases, and thus allow us to better investigate heterogeneity across groups arising due to population structure.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4384 The association between Copy number variations, Congenital Heart disease, and the risk of Mental Illness.

Authors:

S. Sabtiy[1], s. vaez[2], S. Montalbano[1], T. Werge[1], A. Ingason[3], D. Helenius[1]; [1]Inst. of Biological Psychiatry, Roskilde, Denmark, [2]Inst. of biological psychiatry, Roskilde, Denmark, [3]Inst. for biological psychiatry, Roskilde, Denmark

<Objective: This study aims to elucidate an unbiased, population-based association between recurrent copy number variations (CNVs), congenital heart disease (CHD), and the risk of developing a psychiatric disorder (PD). Furthermore, it seeks to determine whether the presence of CNVs confounds this association, accounting for other relevant birth factors. **Background:** The number of adult survivors with CHD is steadily increasing. Thus, there is a growing awareness of the significant risk of neurodevelopmental issues in children and adults affected by CHD. Recent studies have highlighted the role of CNVs, a well-known genetic risk factor, in CHDs and PDs, including attention-deficit/hyperactivity disorder (ADHD), schizophrenia (SCZ), SCZ spectrum disorder, affective disorder, autism (ASD), and bipolar disorder (BDP). Despite previous studies investigating the association between CNVs and CHD, there remains a significant gap in obtaining unbiased, population-based estimates for the true extent of this association. Also, there is a notable knowledge gap regarding the underlying genetics contributing to the association between CHD and PDs. **Method:** We used a Danish population-based case-cohort study, utilizing the extensive Lundbeck Foundation Initiative for Integrative Psychiatric Research (iPSYCH) 2015 database. The iPSYCH2015 case-cohort study encompassed a study base of N=1,657,449 singleton births between 1981 and 2008, with known maternal residence in Denmark and a follow-up period extending until 2015. A population cohort consisting of N=50,615 individuals was randomly selected, and it overlapped with cases identified with ADHD (N=29 668), schizophrenia (SCZ) (N=8 113), SCZ spectrum disorder (N=16 008), ASD (N=24 975), BDP (N=3 819), and affective disorder (3 819). CNVs had been previously identified from the iPSYCH2015 database, and relevant clinical information was integrated into the analysis. The associations were analyzed through rigorous statistical analysis using Weighted Cox proportional hazards models to estimate the risks of each PD associated with CHD and each CNV associated with CHD while accounting for other relevant birth factors. **Findings:** The findings of this study validate the increased risk of CHD in individuals carrying CNVs at 22q11.2 and 2q13 loci. Additionally, this study demonstrates a statistically significant association between CHD and an increased risk of ADHD and ASD within an unbiased random population cohort. Our initial results indicate that the two risk factors of PDs, CHD and carrier status, act independently.>

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4385 † The expected polygenic risk score (ePRS) framework: an equitable metric to quantifying polygenetic risk via modeling of ancestral makeup.

Ctr., Jackson, MS, [16]Fred Hutchinson Cancer Ctr., Seattle, WA, [17]Univ. of Virginia, Scottsville, VA, [18]Albert Einstein Coll. of Med., Bronx, NY, [19]Univ North Carolina at Chapel Hill, Chapel Hill, NC, [20]NHLBI/NIH, Framingham, MA, [21]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [22]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA

Introduction: Polygenic risk scores (PRS) are useful for predicting and quantifying genetic risk. However, PRS depends on genetic ancestry due to differences in allele frequencies between ancestral populations. This leads to implementation challenges when analyzing diverse populations. First, because race and ethnicity-defined groups sometimes have different mixes of genetic ancestry proportions, distributions of PRS may differ across such groups, potentially leading to wrong interpretations when stratifying individuals into risk groups. Second, while adjustment for principal components (PCs) is an effective way to account for population stratification when estimating PRS effects, PCs do not capture equivalent information when constructed using different datasets. We aim to propose a comprehensive framework that can calibrate PRS based on one's ancestral makeup, protect from population stratification in association analysis, and provide an equitable way to quantify genetic risk across diverse populations.
Methods: We propose an individual-level metric called "expected PRS (ePRS)", defined as the expected value of a PRS based on one's global or local admixture patterns. Further, we define the "residual PRS (rPRS)", as measuring the deviation of the PRS from its expected mean (the ePRS) according to admixture patterns. Because ePRS captures the ancestral composition of individuals, we hypothesize that adjusting for ePRS in PRS-outcome association analysis will account for population stratification.
Results: Simulation studies confirm that it suffices to adjust for ePRS to obtain nearly unbiased estimates of the PRS-outcome associations, without further adjusting for PCs. Using TOPMed dataset, the estimated effect size of the rPRS adjusting for the ePRS is similar to the estimated effect of the PRS adjusting for 11 genetic PCs. For diastolic blood pressure, African American individuals had higher PRS values than individuals self-reported from other race/ethnic groups. By calibrating these PRSs via ePRS, rPRS values have similar distributions across self-report race/ethnic groups.
Conclusions: The ePRS framework provides a strategy to differentiate individual genetic risk from differences in PRS distributions due to ancestral makeup. Unlike PCs, the interpretation of ePRS is intuitive, and the meaning of ePRS is identical across datasets while protecting from population stratification bias in association analysis.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4386 The extent to which augmenting extant reference panels with population-specific sequences improves imputation quality

Authors:

J. Carlson[1], M. Krishnan[1], S. Liu[1], K. Anderson[1], J. Zhang[1], H. Cheng[2], T. Naseri[3], M. Reupena[4], S. Viali[5], R. Deka[2], N. Hawley[6], S. McGarvey[7], D. E. Weeks[8], R. L. Minster[1]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [3]Naseri & Associates Publ. Hlth.Consultancy Firm and Family Hlth.Clinic, Apia, Samoa, [4]Lutia i Puava ae Mapu i Fagalele, Apia, Samoa, [5]Natl. Univ. of Samoa, Apia, Samoa, [6]Yale Sch. of Publ. Hlth., New Haven, CT, [7]Brown Univ., providence, RI, [8]Univ of Pittsburgh, Pittsburgh, PA

Genotype imputation is fundamental to association studies, and even gold standard panels like TOPMed have limitations to the populations and variants for which they yield good imputation.
To quantify the impact that varying the number of population-specific sequences in the reference panel has on imputation quality, we constructed 6 in-house reference panels from 2,504 1000G samples plus varying numbers of Samoan samples (4, 24, 48, 96, 384, and 1,285) from whole-genome sequencing and compared them to the 1000G Phase III and TOPMed imputation panels. Each reference panel was used to impute genotype data for 1,897 Samoan participants who were not part of any reference panel. We examined average imputation quality (r^2) and the number of well-imputed variants ($r^2 \geq 0.8$) on chromosomes 5 and 21 to assess performance and compared them to two gold-standard reference panels: TOPMed and 1000G Phase III. To further characterize variants that might gain the most in imputation accuracy, we also calculated LD scores split into low and high strata at the median value within MAF bins.
The 1000G + 1285 Samoan panel yielded > 200,000 more high-quality variants on chromosome 5 than the TOPMed panel, with 48,374 of these having a MAF $\geq$ 0.01. The largest gains were seen for lower-frequency variants with an up to 125% increase in well-imputed variants with MAF < 0.01 compared to the TOPMed imputation. Imputation quality increased as the number of Samoans represented in the panel increased. Panels with 48 or more Samoans included outperformed the TOPMed panel for all variants with MAF $\geq$ 0.001. The gains in imputation quality for the 1000G + 1285 Samoan reference panel compared to the TOPMed panel were greatest for low LD score variants. For rs200884524, a variant on chromosome 5 associated with dyslipidemia and enriched in Polynesians, the imputation quality was highest (r^2 = 0.89-0.95) for the reference panels that included Samoan haplotypes. Additionally, the imputed MAF from the reference panels with Samoans (0.207-0.222) was much closer to what is expected via targeted genotyping (0.202-0.233).
While not necessarily prescriptive for future studies, in this study we showed that as few as 48 population-specific participants added to 1000G yielded superior imputation quality to TOPMed. Our findings also demonstrated that panels containing Samoan-specific haplotypes improve the imputation of population-specific variants located in small LD blocks the most. These findings provide a framework to help future studies construct reference panels of their own to obtain high-quality imputation for genetic association studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4387 The genetic basis of covariance between blood and urine biomarkers

Authors:

C. Boetto[1], L. Henches[1], A. Auvergne[1], A. Frouin[1], H. Aschard[1,2]; [1]Inst. Pasteur, Paris, France, [2]Harvard TH Chan Sch. of Publ. Hlth., Boston, MA

Our comprehension of the genetic basis of individual human metabolites has improved significantly over the past years, providing critical insights into the biochemical pathways and potential functional implications of disease-associated variants. Conversely, the mechanism driving co-regulation and interaction between metabolites remains poorly understood. Metabolites often display high correlation and an increasing number of studies show that multivariate methods, including simple approaches such as biomarker ratios, can offer a promising path towards better disease prognosis. However, screening methods for predictors of correlation effect are lacking and real data application have therefore been very limited in scope. Here we conducted a genome-wide association screening (GWAS) for covariance effect between 28 urine and blood biomarkers in 150K unrelated participants from the UK Biobank, using MANOCCA (Multivariate Analysis of Conditional CovAriance), a novel, robust and powerful method we recently developed. Briefly, the concept of the MANOCCA approach to capture effects on the covariance consists in applying a multivariate test to the products of original variables. We identified 75 independent loci associated at genome-wide significance level ($P<10^{-8}$) with effects on covariance between the biomarkers. The strongest signal was observed with rs887829 ($P<10^{-300}$), within a region of nine UDP-glucuronosyltransferase genes. The variant, highly associated with the mean of albumin and alkaline phosphatase, displays a strong effect on the covariance between those two biomarkers and several other biomarkers. Although the proposed test is by construction orthogonal to tests based on the mean, most loci identified by the MANOCCA also display mean effect as measured by either univariate (standard linear regression) or multivariate (MANOVA) methods. Nevertheless, across the 75 signals, we observed a range of patterns, including cases where the covariance between a pair of biomarkers was associated with a variant not displaying any marginal mean effect on those biomarkers. Altogether, this study shows there exists a substantial genetic component of biomarker covariance, providing novel working hypotheses that can improve our understanding of the physiological processes and pathways involved in health and diseases.

PB4388 The genetically regulated transcriptome better predicts plasma protein levels than the observed transcriptome and reveals mechanisms underlying autoimmune diseases

Authors:

H. Wittich[1], S. Rich[2], J. Rotter[3], H. Im[4], A. Manichaikul[5], H. Wheeler[6], NHLBI TOPMed Consortium; [1]Loyola Univ. Chicago, Chicago, IL, [2]Univ. of Virginia, Scottsville, VA, [3]Lundquist Inst., Harbor-UCLA Med Ctr, Torrance, CA, [4]Univ. of Chicago, Chicago, IL, [5]Univ Virginia, Charlottesville, VA, [6]Loyola Univ Chicago, Chicago, IL

Genetic regulation of transcription and translation are important mechanisms through which noncoding genetic variants affect complex traits. While many studies have been successful at identifying cis-eQTL (within 1 Mb of the transcription start site), low effect sizes and a high multiple testing burden have made it challenging to detect trans-eQTL. Furthermore, eQTL studies do not consider translation and post-translational modifications that affect the function of proteins. Here, we leverage the TWAS method, PrediXcan, to test the cis component of gene expression for association with observed plasma protein levels to identify cis- and trans-acting genes that regulate protein levels. We performed a TWAS for 3,622 plasma proteins measured in 3,301 individuals with European ancestry from the INTERVAL study and replicated our results for 1,039 proteins measured in 971 individuals from the Trans-omics for Precision Medicine (TOPMed) Multi-Ethnic Study of Atherosclerosis (MESA). We used gene expression prediction models from 49 tissues trained with GTEx Project genotype and RNA-Seq data to predict the cis component of gene expression (GReX) for every gene in each tissue. We then tested the GReX of each gene for association with the observed abundance of each protein measured via SOMAscan assay. We found 1,210 trans-acting associations for 239 target proteins that replicated in TOPMed (FDR<0.05) with a median expected true positive rate (pi1) across tissues of 0.390 and 1,168 cis-acting associations for 218 target proteins that replicated in TOPMed (FDR<0.05) with a median pi1 of 0.806. Gene set enrichment analysis revealed that both the cis- and trans-acting targets were enriched for associations with blood protein levels and autoimmune diseases in the GWAS catalog. We found the highest pi1 for replicated associations between predicted RNA levels and protein levels of the same underlying gene (cis-same), with a median of 0.888 across tissues. This contrasts the findings of many studies that RNA and protein levels do not correlate. Using RNA-Seq data from the TOPMed MESA study, we found that the mean Pearson correlation of expression and protein levels for significant cis-same genes was higher in predicted tissues (R=0.17) than in observed (R=0.10, p=7.50e-11). We found higher correlations between predicted expression and protein levels in tissues closely involved in regulating circulating protein levels like liver and whole blood than in the brain tissues, perhaps due to the blood-brain barrier. These results indicate that predicted expression levels may be a better proxy for plasma protein levels because they exclude variation due to environmental factors.

PB4389 The identification of high-confidence disease-gene associations at the intersection of genetic and genomic evidence.

Authors:

C. Mordaunt, V. Kumar, A. Rupp, E. Laing; Computational Biology, Genomic Sci., GSK, Upper Providence, PA

Identifying high-confidence disease-gene associations from GWAS studies remains a difficult task. The application of orthogonal genomic datasets at scale in an indication-aware manner promises to improve gene prioritization. Here, we present an approach to integrate and score multiple lines of genomic evidence for genes at GWAS loci to identify high-confidence disease genes. We show that these genes are enriched for previous clinical success and apply this method to multiple sclerosis as an example disease.

Genes were evaluated across multiple types of genomic evidence. Expression specificity was calculated by combining disease-tissue and -cell-type associations from text-mining with mRNA expression levels from bulk and single-cell RNA-seq and protein expression from mass spectrometry. Human disease and mouse model phenotype data were compiled and phenotypic similarity was assessed. Gene characteristics such as protein class, mouse orthology, and loss-of-function essentiality were also included. Each piece of evidence was benchmarked to estimate the enrichment of previous clinical success for high scoring genes, and then an overall score was calculated as a weighted sum of the benchmarking ratios relative to the maximum possible score.

An integrated table was prepared compiling genomic scores across 20,226 genes and 6,863 diseases (137 million gene-disease pairs). Through benchmarking, each evidence type was found to identify genes with significantly higher odds of clinical success. After summarizing genomic evidence into overall scores, 6 million high-scoring gene-disease pairs were identified, with benchmarking indicating a 2.1 fold enrichment for clinical success (p = 5.5E-91). This approach was applied to GWAS for multiple sclerosis by intersecting genes near GWAS-associated loci with high-scoring genes based on genomic evidence and appending multiple sclerosis differential gene expression results. The intersection of these criteria resulted in the identification of 194 genes for further investigation, including genes with a well-known immune function.

High-confidence gene-disease pairs were identified by integrating multiple genomic data types and overlapping with genetic evidence. The framework used to score and benchmark these data types could be expanded to other types of genomic data. The combination of genetic and other genomic evidence matching a gene to a disease will likely result in the discovery of more robust disease-associated genes.

PB4390 The local portability of polygenic scores across populations varies significantly along the genome.

Authors:

A. Lupi, A. Vazquez, G. de los Campos; Michigan State Univ., East Lansing, MI

In the last fifteen years, thousands of Genome-Wide Association Studies (GWAS) have been published. These findings are increasingly used to develop polygenic risk scores (PGS). However, the overwhelming majority of participants in GWAS have European (EU) ancestry, and PGS derived from EUs have poor predictive performance in other populations. Many studies have evaluated the portability of whole-genome PGS across populations. However, no previous research has quantified how much the portability may vary along the genome. We hypothesize that the portability of SNP effects between populations varies significantly over the genome because of varying levels of genome differentiation. We developed a Monte Carlo-ANOVA (MC-ANOVA) method to estimate the portability of local PGS between populations. The method quantifies the impact of genome differentiation (allele frequency differences and imperfect linkage disequilibrium) on the portability of local PGS. We applied the methodology to data from the UK-Biobank to develop maps of the predicted portability of EU-derived marker effects in African, Caribbean, East Asian, and South Asian populations. Averaged over the entire genome, we estimate that genome differentiation alone leads to relative accuracies (RA, the ratio of PGS R-squared in non-EU relative to within EU prediction) ranging from 0.268 (African) to 0.771 (South Asian). However, we report a sizable variability in RA's along the genome, suggesting that even in populations with low overall portability of EU-derived SNP effects (*e.g.*, African) there are still chromosome segments with high portability of EU-derived PGS. We validated our findings using real PGS for six complex traits (height, serum urate, LDL and HDL cholesterols, BMI, and glucose). Our results show that EU-derived SNP effects from SNPs in regions where MC-ANOVA predicts RA have relatively high empirical RA of real PGS. We provide R-software that implements the proposed method and maps of the predicted RA (for 10 Kbp chromosome segments) for individuals of African, Caribbean, South Asian, and East Asian descent. The information in these maps can be used to prioritize variants to develop more accurate PGS for cross-population prediction.

PB4391 The pitfalls of overly parameterized polygenic risk scores and new diagnostics to combat overfitting

Authors:

A. Aw[1], J. McRae[2], E. Rahmani[3], Y. S. Song[1]; [1]UC Berkeley, Berkeley, CA, [2]Illumina, Inc., Foster City, CA, [3]UCLA, Los Angeles, CA

Polygenic risk scores (PRSs) are increasingly advocated as useful genetic instruments in clinical settings. Previous work has shown that predictability of PRSs is often improved by including thousands or even tens of thousands of variants, much more than the number of genome-wide significant variants based on GWAS.
Here, we challenge a commonly-held view that insignificant variants contributing to PRS predictability are causal yet insignificant at a genome-wide level owing to small effects. We argue, using statistical principles and empirical validation on the UK Biobank (UKB), that high-dimensional PRSs are in fact overparameterized, with the overparameterization capturing population stratification. We first show mathematically that (1) PRSs trained on a cohort can be represented as a linear combination of principal components (PCs), and (2) PRSs with random effect sizes (as one would get for insignificant non-causal variants; “random projection”) tend to capture leading axes of variation in the data. These facts imply concrete desirable checks of stratification-driven overfitting, including the evaluation of PRS predictability inflation and sensitivity to effect perturbations.
Applying our checks to 500,000 participants from the UKB across 141 quantitative traits, we find that 89% of all phenotypes have inflated predictability (incremental R^2) from PRSs constructed by random projections. Crucially, the degree of inflated predictability is significantly driven by the degree of phenotypic stratification along PCs.
Applying sensitivity analyses to PRSs constructed for 103 traits, we find that the performances (percentile-prevalence rank correlations) of more than 70% of PRSs are insensitive to shuffling or sign flipping of effects of weakly significant target variants. This suggests that the effects of insignificant variants typically do not correspond to true causal signals and therefore many PRSs are likely overparameterized. Further, the degree of insensitivity is not driven by homogeneity of the effects of these target variants; rather it is significantly driven by the strength of PRS stratification along PCs of the training cohort, the sum of effects of target variants, and the number of target variants. Focusing on 8 Lipoprotein(a) PRSs trained using various PRS methodology (source: PGS Catalog), we find that no PRS is uniformly sensitive, across 11 evaluation metrics considered, to effect shuffles or sign flips. Different PRSs also emerge as most sensitive depending on the metric of choice.
In summary, including insignificant GWAS variants often leads to overfitted PRSs, which can be avoided through inflation and sensitivity checks.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4392 The relationship between major psychiatric disorders, substance use behaviors, and longevity: A multivariable Mendelian randomization and multi-omics study

Authors:

A. Hamandi[1], D. Rosoff[2,1], A. Bell[1], L. Mavromatis[1], L. Park[1], J. Jung[1], J. Wagner[1], F. Lohoff[1]; [1]NIH, Bethesda, MD, [2]Univ. of Oxford, Oxford, United Kingdom

Observational studies suggest major psychiatric disorders, including bipolar disorder (BD), schizophrenia (SCZ) and major depressive disorder (MDD) reduce longevity; however, frequently co-occurring alcohol consumption and smoking have also been shown to impact longevity, making it difficult to disentangle which among the co-morbid disorders is driving this reduction. Here we deploy Mendelian randomization (MR) and transcriptomic imputation to parse the associations these disorders have to longevity. This study sourced existing summary-level genome-wide association study (GWAS) data from European-ancestry cohorts on psychiatric disorders, substance use behaviors, cardiometabolic diseases, multivariate longevity, and epigenetic aging acceleration (EAA).

MR analysis shows MDD, weekly alcohol consumption, and smoking negatively associate with longevity in a single-variable model; while only smoking negatively associates in a multivariable one. MR also shows a corresponding positive association between smoking and PhenoAge-measured EAA, and that these smoking associations are cardiometabolic disease-independent.

Transcriptome-wide association studies on smoking across several tissue types identified 118 novel gene-smoking associations not captured by the original GWAS. Colocalization analysis revealed several molecular features which share a causal variant with both lifetime smoking index placement and longevity, including PRMT6 transcripts and those for five genes in locus 17q21.31. Broadly, novel and colocalized genes were involved in cellular proliferation, learning, and neurodevelopment. Drug-target MR analysis identified genes upstream of smoking behavior whose protein products are amenable to drug targeting and involved in reward processing and nicotine metabolism.

Using genomic methods that enable the simultaneous assessment of major psychiatric disorders and substance use behaviors, we provide evidence that smoking—but not drinking, MDD, BD, nor SCZ—has a negative independent association with longevity that is recapitulated in the transcriptome. Our findings highlight the importance of developing smoking cessation therapies for the longevity of psychiatric populations, and identify prime drug-target candidates for such future translational research.

PB4393 The SNP rs6859 in NECTIN2 gene is associated with underlying heterogenous trajectories of cognitive changes in older adults.

Authors:

A. Lathika Rajendrakumar, K. G. Arbeev, O. Bagley, A. I. Yashin, S. Ukraintseva; Duke Univ., Durham, NC

Background: Functional decline associated with dementia, including in Alzheimer's disease (AD), is not uniform across individuals, and respective heterogeneity is not yet fully explained. Such heterogeneity may in part be related to genetic variability among individuals. In this study, we investigated whether the SNP rs6859 in *NECTIN2* gene (a major risk factor for AD) influences trajectories of cognitive decline in older participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI). **Method:** We retrospectively analyzed records on 1,312 participants from ADNIMERGE subset of the ADNI database. We used longitudinal measures of Mini-Mental State Examination (MMSE) scores in participants, who were cognitively normal, or having AD, or other cognitive deficits. Multiple linear regression analysis was conducted to investigate the association of SNP rs6859 with normalized lowest MMSE score recorded per participant. For trajectory analysis, the optimal number of latent classes was determined by Bayesian Information Criterion (BIC). We fitted a multivariate latent class regression model with SNP rs6859 both as fixed effects and as a mixture term with age, sex, education and ethnicity, as covariates for the optimal class model. **Results:** The SNP rs6859 was independently associated with MMSE in multiple linear regression analysis (-2.009, 95% CI: -3.596, -0.422, $p<0.05$). Three distinct subgroups performed best relative to the other latent groups during model selection (BIC: 56271.20). There was clear difference of MMSE trajectories across latent classes which was particularly evident for Class 1 (highest MMSE group with sharp decline). In the posterior classification, 54.57% (n=716), 43.75% (n=574), 1.68% (n=22) were classified as class 1 (highest MMSE group), class 2 (intermediate MMSE) and class 3 (low MMSE). In the heterogenous linear mixed model, the rs6859 - A risk allele was significantly associated with MMSE class membership and related decline; Class 1 (-4.633, 95% CI: -6.556, -2.711, $p<0.001$), Class 2 (2.573, 95% CI:0.121,5.026, $p<0.05$) and Class 3 (-3.974, 95% CI: -5.663, -2.286, $p<0.001$) respectively. **Conclusion:** This study found statistical evidence supporting the classification of three latent subclass groups representing complex MMSE trajectories in the ADNI cohort. The SNP rs6859 was associated with decreasing MMSE. It can, therefore, be suggested as a candidate genetic predictor of variations in MMSE trajectories between individuals. Functional studies may help further elucidate this relationship.

PB4394 The use of deep learning to alter and analyze facial expressions in syndromic facial diagnostics

Authors:

T. Patel[1], A. Othman[1], O. Sumer[2], F. Hellman[2], P. Krawitz[3], A. Elisabeth[2], P. Hu[4], C. Ngongang[1], L. Suzanna[1], R. Waikel[1], D. Duong[1], B. Solomon[1]; [1]NIH, Bethesda, MD, [2]Inst. of Computer Sci., Augsburg Univ., Augsburg, Germany, [3]Inst. for Genomic Statistics and Bioinformatics, Univ. of Bonn, Bonn, Germany, [4]NHGRI (NIH), Bethesda, MD

Deep learning is increasingly being used to examine genetic diseases. Aspects of the underlying datasets can impact results, therefore confounders should be studied and mitigated where possible. Stereotypically, Williams (WS) and Angelman (AS) syndromes are associated with a "happy demeanor," which includes a smiling face. Thus, clinical geneticists may be more likely to identify these conditions in images of smiling individuals.In our previous study we explored, aging as a confounder in syndromic facial diagnostics, (PMID: 35480315) and additionally found that clinical geneticists could more accurately classify WS in smiling individuals. To more fully study the impact of facial expression in facial diagnostics, we curated publicly available facial images of over 3500 individuals with genetic syndromes. We utilized ResNet, facial expression recognition categorization to determine whether or not that individual was classified as smiling. For WS and AS, images with neutral expressions had significantly lower prediction probabilities for the correct syndrome designation than those with smiling expressions. This was not seen for images of individuals with two conditions selected for comparison, 22q11.2 deletion and Noonan syndromes. To further explore this impact, we altered the facial expressions to compare the implications of a person smiling or not smiling. We trained Hyperstyle, the GAN-inversion technique to determine the vector representations of our images that are compatible with StyleGAN2. Then, using InterfaceGAN, we edited these vectors to make them capable of recreating the identical original images but with a new facial expression. Using surveys, eye-tracking, and DL methods, we examined how altering facial expressions affects predictions by human experts as well as neural net classifiers. Our findings show that altering the facial expression in pictures of people with WS and AS syndromes from smiling to neutral affects syndrome classification.

Training in Genomics Data Sci., Galway, Ireland, [4]Nantes Univ., Nantes, France, [5]Beaumont Hosp., Dublin, Ireland, [6]Queen's Univ. Belfast, Belfast, United Kingdom, [7]Queen s Univ. of Belfast, Belfast, United Kingdom, [8]Univ. of Groningen, Groningen, Netherlands, [9]Univ Minnesota, Minneapolis, MN, [10]Hennepin County Med Ctr, Minneapolis, MN, [11]UPenn, Philadelphia, PA, [12]Univ. of Manchester, Manchester, United Kingdom, [13]Finnish Red Cross Blood Service, Helsinki, Finland, [14]Helsinki Univ. Hosp., Helsinki, Finland, [15]Finnish Red Cross Blood Serv, Helsinki, Finland

Background

End Stage Renal Disease (ESRD) is a condition where an individual’s kidneys stop functioning on a permanent basis, thus requiring either transplant or dialysis. ESRD affects 800,00 individuals in the US alone, with 71% on dialysis and 29% with a kidney transplant. Multiple mechanisms have been implicated in the aetiology of kidney disease including monogenic and acquired conditions as well as polygenic factors. In cases of monogenic kidney disease, if the pathogenic mutation is known, some of the variation in age of onset of ESRD can be explained by pathogenic variant type, such as in the case of Polycystic Kidney Disease. However, most of the variation in age of onset is still largely unexplained. Here we test the hypothesis that polygenic risk scores (PRS) for a range of renal-related traits can predict age of onset of ESRD.

Methods

Using a dataset of 10,121 patients with ESRD from 9 European ancestry cohorts, PRS were calculated based on large GWAS for the following traits: hypertension, albuminuria, kidney volume, eGFR, and decline in eGFR. First, we investigated whether there was a difference in polygenic burden for each trait between individuals with ESRD and healthy controls. Next, we investigated the impact of PRS on age of onset of ESRD using a Cox PH mixed effects model. Finally, we compared the median survival between those in the highest and lowest tertiles of polygenic risk for each trait.

Results

Individuals with ESRD were found to have an elevated burden for albuminuria and for decreased eGFR in comparison to healthy controls (p-values 0.03, 0.04 respectively). Polygenic burden for decreased eGFR was also associated with earlier onset of ESRD (HR: 1.03 P = 0.02). Those in the lowest tertile of risk for reduced eGFR have a median survival of 49.1 years, compared to 48.3 years for those in the highest tertile (p=0.009).

Conclusions

These findings suggest that polygenic burden for albuminuria and reduced eGFR could explain some of the variation in age of onset of ESRD. Further investigation is required to combine this common variant burden with pathogenic variants and rare variant burden in order to build a more complete model to predict age of onset of ESRD.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4396 † Theoretical and empirical interpretation of heritability estimation in admixed populations.

Authors:

J. Huang[1], M. Shriver[2], A. Zaidi[3]; [1]Penn State Univ., University Park, PA, [2]Penn State Univ, University Park, PA, [3]Univ. of Minnesota, Minneapolis, MN

Estimating heritability in admixed populations is challenging due to their complex genetic diversity and population structure. Heritability is commonly estimated using genome-wide restricted maximum likelihood (GREML), which models the phenotypic resemblance between individuals as a function of genetic similarity. Despite the simple intuition, the accuracy and interpretation of GREML estimates remain a matter of debate, particularly in the presence of population structure and assortative mating. While much of the discussion has focused on the inflation of GREML estimates due to confounding effects of genetic and environmental stratification, there is comparatively little appreciation of the fact that population structure not only confounds but also contributes to heritability. This lack of clarity limits our understanding of the applicability of statistical genetics methods to diverse cohorts.
Here, we evaluated the behavior of GREML estimation in recently admixed populations using quantitative genetic theory and simulations. We showed that GREML estimates of heritability are biased in admixed populations, even in the absence of confounding. We traced the source of this bias to two assumptions: (i) that the effect sizes of causal variants are independent, and (ii) that the population mates randomly. These sources of bias can either inflate or deflate heritability estimates depending on the trait architecture and the degree of admixture structure in the population.
We sought to empirically understand the extent of this bias in admixed Americans using genetic data from the African Americans in the South West from the 1000 Genomes Project. We estimated the bias in the genetic variance explained by GWAS SNPs for 26 traits, including anthropometric traits, blood pressure, lipid levels, and blood cell counts using summary statistics from the GWAS catalog. We found that, despite incorrect assumptions, GREML estimates of heritability should, in practice, be close to the true parameter values, at least for the traits studied. However, for skin pigmentation and cholesterol (HDL and LDL), GREML should underestimate heritability in admixed populations because it does not take into account the fact that the effects of causal variants are correlated. As such, GREML estimates of heritability in admixed cohorts should be interpreted with caution.
We provide a clear interpretation of the GREML estimator of heritability in admixed populations and discuss its implications for genome-wide association studies and polygenic risk prediction in diverse cohorts.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4397 Three open questions regarding polygenic score portability

Authors:

J. Wang[1], M. Zietz[2], J. Mares[3], P. J. Rathouz[4], V. M. Narasimhan[1], M. F. Przeworski[3], A. Harpak[1]; [1]The Univ. of Texas at Austin, Austin, TX, [2]Columbia Univ. Irving Med. Ctr., New York City, NY, [3]Columbia Univ., New York City, NY, [4]Dell Med. Sch., Austin, TX

A major obstacle hindering the broad adoption of polygenic scores (PGS) is their lack of "portability" to people that differ—in genetic ancestry, environmental exposures or other characteristics—from the GWAS samples in which genetic effects were estimated. First principle considerations suggest some of the portability problem arises from differences in genetic ancestry; how much, however, remains unknown.

Here, we use the UK Biobank (UKB) to measure the change in individual-level PGS prediction accuracy as a continuous function of genetic dissimilarity to the GWAS sample from the White British subset of UKB. Through specific case studies, we highlight three major gaps in our understanding of PGS portability.

First, while previous studies have shown an average trend of decay in prediction accuracy in genetic ancestry groups other than that of the GWAS sample, such groupings confound differences in genetic similarity to the GWAS sample with many other factors, including distinct environmental and social exposures. We show that for many cases, continuous variation in prediction accuracy can be explained comparably well by socio-economic measures and by genetic ancestry.

Second, we show that trends of portability can be highly distinct across traits. While portability decays linearly with genetic dissimilarity for some traits such as LDL levels, this is not true across all traits, in contrast with previous reports. For BMI, portability is not monotonically decreasing with genetic dissimilarity. For several immune-related traits, prediction accuracy drops near zero quickly even at intermediate levels of genetic dissimilarity to the GWAS sample. We show that this quick drop is largely due to immune associations in the White British subset of the UKB being poorly reflective of genetic effects away from the GWAS sample.

Third, we show that even qualitative trends of portability can depend on the measure of prediction accuracy used. For some traits such as Hemoglobin levels (MCH), prediction accuracy at the group level (e.g., R^2) decays—while some measures of individual level prediction accuracy (e.g., reduction in mean squared error) increase with genetic dissimilarity.

Together, these results highlight the importance of considering characteristics specific to the trait, the GWAS sample and prediction samples, as well as the most relevant metric of prediction accuracy for the application of a given polygenic score, in order to understand and tackle the urgent problem of portability.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4398 Thyroid function and metabolic syndrome: a two-sample bidirectional Mendelian randomization study.

Authors:

N. Pleic, T. Zemunik, I. Gunjača, M. Babić Leko; Univ. of Split, Sch. of Med., Split, Croatia

Background: In clinical practice, metabolic syndrome (MetS) is often observed alongside thyroid dysfunction. MetS is defined as a cluster of cardiometabolic abnormalities including obesity, hypertension, hyperglycaemia and dyslipidemia. Multiple studies have suggested an association between thyroid dysfunction and MetS or its components, but the causality and direction of these associations remain yet to be proven. The aim of this study was to examine the causal effects of thyroid function on metabolic syndrome risk and its components, and vice versa, using a mendelian randomization (MR) approach. **Methods:** We performed a two-sample bidirectional MR study using summary statistics from the most comprehensive genome-wide association studies (GWAS) of thyroid-stimulating hormone (TSH, n=119,715), free thyroxine (fT4, n=49,269), MetS (n=291,107), as well as components of MetS: waist circumference (n=462,166), fasting blood glucose (n=281,416), hypertension (n=463,010), triglycerides (TG, n=441,016) and high-density lipoprotein cholesterol (HDL-C, n=403,943). We chose the multiplicative random-effects inverse variance weighted (IVW) method as the main analysis. Sensitivity analysis included weighted median and mode analysis, as well as MR-Egger, MR-PRESSO and Causal Analysis Using Summary Effect estimates (CAUSE). **Results:** Our results suggest that higher fT4 levels lower the risk of developing MetS (OR=0.96, P=0.037). Genetically predicted fT4 was also positively associated with HDL-C (β=0.02, P=0.008), while genetically predicted TSH was positively associated with TG (β=0.01, P=0.044). These effects were consistent across different MR analyses and confirmed with the CAUSE analysis. In the reverse direction MR analysis, genetically predicted HDL-C was negatively associated with TSH (β=-0.03, P=0.046) in the main IVW analysis. **Conclusions:** Our study suggests that variations in normal-range thyroid function are causally associated with the diagnosis of MetS and with lipid profile, while in the reverse direction, HDL-C has a plausible causal effect on reference-range TSH levels.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4399 Title:Deconvoluting Bulk RNA-seq Data of 1200 samples of Dorsolateral Prefrontal Cortex tissue using reference single nucleus RNAseq data of 400 samples for Cell-Type-Specific TWAS of AD Dementia

Authors:

S. Tang[1], A. S. Buchman[2], P. L. Jager[3], D. Bennett[2], S. Tasaki[2], J. Hu[1], J. Yang[1]; [1]Emory Univ., Atlanta, GA, [2]Rush Univ. Med. Ctr., Chicago, IL, [3]Columbia Univ., New York, NY

Recent transcriptome-wide association studies (TWAS) of Alzheimer's disease (AD) dementia have identified dozens of risk genes by integrating transcriptomic data with GWAS summary data. The potential genetic effects of the identified risk genes on AD dementia can be examined as mediated via transcriptome. Although cell-type-specific TWAS has been recently done for AD dementia using single nucleus RNAseq (snRNA-seq) data (n=400) of dorsolateral prefrontal cortex (DLPFC) tissue, most TWAS studies use transcriptomic data generated by bulk RNA-seq.

This study will compare three methods (TCA, bMIND, and BayesPrism) to identify the best one to deconvolute bulk RNA-seq data. Specifically, TCA utilizes a Tensor Composition Analysis (TCA) approach; bMIND is based on a Bayesian multivariable regression model with Gaussian priors; and BayesPrism assumes a Bayesian multinomial model. Both Bayesian methods use priors derived from reference snRNA-seq data. By using snRNA-seq data of 400 DLPFC samples which also have bulk RNA-seq data profiled, we will randomly select snRNA-seq data of 200 samples as reference data to deconvolute bulk RNA-seq data, and use the remain for testing the deconvolution accuracy with respect to cell-type-specific Pearson's correlation and mean squared errors.

We will then apply the best deconvolution method to a large-scale bulk RNA-Seq dataset of DLPFC tissue (n=1200), with reference snRNA-seq data of 400 DLPFC samples. The obtained sample-level cell-type-specific gene expression levels and their corresponding whole genome sequencing data (n=1200) will be used to train cell-type-specific gene expression imputation models, using the TIGAR tool developed by our lab (Nagpal et. al, AJHG, 2019). These trained expression imputation models will then be used with the most recent GWAS summary data (n=762K) of AD dementia to conduct cell-type-specific TWAS. We will use both penalized regression methods with Elastic-Net penalty and the nonparametric Bayesian Dirichlet process regression (both implemented in TIGAR) to train expression imputation models. For each test gene, the TWAS p-values based on expression imputation models trained using both regression methods will be combined by the aggregated Cauchy association method to produce a final omnibus TWAS p-value.

To summarize, by deconvoluting the bulk RNA-Seq data with available reference scRNAseq data, we expect to increase the sample size for training cell-type-specific expression imputation models to increase the TWAS power for studying AD dementia.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4400 TIVAN-indel a computational framework for annotating and predicting non-coding regulatory small insertions and deletions

Authors:

L. Chen[1], A. Agarwal[2], F. Zhao[1], Y. Jiang[3]; [1]Univ. of Florida, Gainesville, FL, [2]Indiana Univ., Bloomington, IN, [3]Univ North Carolina at Chapel Hill, Chapel Hill, NC

Small insertion and deletion (sindel) of human genome has an important implication for human disease. One important mechanism for non-coding sindel (nc-sindel) to have an impact on human diseases and phenotypes is through the regulation of gene expression. Nevertheless, current sequencing experiments may lack statistical power and resolution to pinpoint the functional sindel due to lower minor allele frequency or small effect size. As an alternative strategy, a supervised machine learning method can identify the otherwise masked functional sindels by predicting their regulatory potential directly. However, computational methods for annotating and predicting the regulatory sindels, especially in the non-coding regions, are underdeveloped. By leveraging labeled nc-sindels identified by cis-expression quantitative trait loci analyses across 44 tissues in Genotype-Tissue Expression (GTEx), and a compilation of both generic functional annotations and large-scale epigenomic profiles, we develop TIssue-specific Variant Annotation for Non-coding indel (TIVAN-indel), which is a supervised computational framework for predicting non-coding regulatory sindels. As a result, we demonstrate that TIVAN-indel achieves the best prediction performance in both with-tissue prediction and cross-tissue prediction. As an independent evaluation, we train TIVAN-indel from the 'Whole Blood' tissue in GTEx and test the model using 15 immune cell types from an independent study named Database of Immune Cell Expression. Lastly, we perform an enrichment analysis for both true and predicted sindels in key regulatory regions such as chromatin interactions, open chromatin regions and histone modification sites, and find biologically meaningful enrichment patterns.

PB4401 Towards fully automated polygenic risk score estimation from noisy data using a machine learning approach

Authors:

S. Squires[1], D. P. Fraser[1], S. Sharp[2], M. Weedon[1], R. Oram[1]; [1]Univ. of Exeter, Exeter, United Kingdom, [2]Stanford Univ., Palo Alto, CA

Introduction: Polygenic risk scores (PRSs) enable the summary of genetic data into a single number for research and clinical uses. A PRS often combines the number of effect alleles of single nucleotide polymorphisms (SNPs) in a weighted sum, but more complicated functions are also used. An impediment to the further use of PRSs is the difficulty in curating the data because if any of the SNPs are missing it can make the PRS less accurate, difficult to compare between datasets or unusable. Various methods including quality control, imputation and the use of proxy SNPs can be utilised to mitigate these issues, but they require technical expertise and may still produce poor results. As PRSs increasingly use more complicated functions these problems are likely to become more acute. Our aim is to produce a method that can produce an estimate of the PRS without substantial data curation even if the data has poor quality or missing SNPs.
Methods: We design and demonstrate a novel machine learning methodology (M-MLP) to estimate PRSs. We train a deep learning model with inputs that include proxy SNPs in addition to the PRS SNPs. We add in a masking and corruption procedure into the training to simulate poor quality input SNPs forcing the model to learn a robust representation which can handle noise in its inputs. We primarily use a 67-SNP PRS for type-1 diabetes (T1D) which includes pairwise interaction terms creating a complex nonlinear function between input SNPs and output PRS. We use UK Biobank (UKBB) imputed genetic data for training and testing our models, including keeping 387 T1D cases in our test set.
Results: We test our model and the PRS by simulating corruption of the input SNPs. By corrupting the input SNPs with uniform probability ranging from 0 to 0.25 the PRS sees its T1D cases to population AUC fall from 0.92 (95% CI 0.90-0.93) to 0.71 (CI 0.68-0.73) while the M-MLP sees a smaller fall from 0.92 (CI 0.90-0.93) to 0.89 (CI 0.88-0.91). We also altered specific numbers of non-proxy SNPs leaving the rest uncorrupted. With 12 of 67 SNPs corrupted (at a probability of 0.2) the PRS and M-MLP produces AUCs of 0.89 (CI 0.88-0.91) and 0.92 (CI 0.90-0.93), respectively. With 61 SNPs corrupted the PRS and M-MLP AUCs are 0.77 (CI 0.75-0.79) and 0.91 (CI 0.90-0.93), respectively. We further demonstrate the method using two other T1D PRSs and a Celiac PRS.
Conclusions: Our M-MLP method produces equivalent performance on uncorrupted data and improved performance on simulated corrupted data compared to the PRS. As the M-MLP model is resilient to corrupted or missing data it has the potential to be used with minimal data curation allowing wider use of PRSs and more confidence in the outputs.

PB4402 Towards improving access to autism clinical genetic testing: Estimating personalized genetic probabilities in over 3,000 autistic children

Authors:

S. Kuo[1,2], C. van der Merwe[1,2], J. M. Fu[1,2], M. E. Talkowski[2,1], A. Thurm[3], S. J. Sanders[4,5], S. L. Bishop[4], E. B. Robinson[1,2,6]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Natl. Inst. of Mental Hlth., Bethesda, MD, [4]Univ. of California San Francisco, San Francisco, CA, [5]Oxford Univ., Oxford, United Kingdom, [6]Harvard Sch. of Publ. Hlth., Boston, MA

Introduction: With 373 genes now associated with neurodevelopmental disorders (NDDs) like autism and intellectual disability, clinical genetic testing yields among autistic children will continue to rise. Despite the promise of clinical genetics for autism and the universal autism genetic testing guidelines from professional medical associations, clinical genetic testing remains vastly underutilized in autism. To help clinicians and families consider clinical genetic testing for autistic children, we aimed to develop an algorithm for predicting pretest probabilities of carrying a NDD-associated variant (NDAV).
Methods: Genetic probability prediction algorithms were developed in a large autism sample with whole exome sequencing and harmonized deep phenotyping data (N=3440 children aged 4-17 years from two independent cohorts). NDAVs were defined as de novo protein truncating variants, copy number deletions, missense variants (MPC>2), or genomic disorders in any NDD-associated gene. We first built logistic regression models predicting NDAV carrier status from LASSO-selected phenotypes, including demographic, clinical, developmental, and cognitive information. We stratified genetic probability predictions by >60,000 possible combinations of phenotypes, then compared each of these stratified probabilities to the average genetic probability in the general population.
Results: Genetic probabilities for carrying a NDAV were highly variable across autistic children, ranging from ~1% in children without intellectual disability or congenital heart problems who began walking by 12 months, to ~55% in children with co-occurring intellectual disability and congenital heart problems who began walking after 18 months. Because NDAVs overlap with clinically returnable variants and ~90% of the sample had estimated genetic probabilities greater than the average genetic probability in the general population, these data underscore the importance of recommending clinical genetic testing for autistic children. Our algorithm provides personalized genetic estimates with minimal burden and can easily be completed in <5 minutes.
Conclusions: The probability that an autistic child carries a potentially returnable genetic variant can be estimated from readily accessible phenotypes and used by clinicians and families in making decisions about clinical genetic testing. By working with diverse stakeholders in the autism community to translate our prediction algorithm into a public web resource, we hope to reduce barriers to accessing clinical genetic testing and to understanding autism's genetic influences and heterogeneity.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4403 Towards precision medicine: Factor analysis-driven phenome-wide data integration for enhanced polygenic score performance

Authors:

Y. Wang[1], Y. He[1], C. Fadil[2], K. Tsuo[3], S. Koyama[3], K. Paruchuri[1], Z. Yu[3], H. E. Leland[1], Z. Zheng[3], B. Truong[1], C. E. Carey[3], R. K. Walters[1], B. N. Neale[1], E. B. Robinson[1], P. Natarajan[1], A. R. Martin[1]; [1]Massachusetts Gen. Hosp., Boston, MA, [2]Harvard Univ., Boston, MA, [3]Broad Inst. of MIT and Harvard, Cambridge, MA

Polygenic scores (PGS) hold promise for stratifying patient disease risk, but they currently face critical limitations that preclude maximal accuracy and generalizability. Most PGS are developed from single-trait and single-ancestry genome-wide association studies (GWAS), missing opportunities to harness the phenome-wide breadth of modern multi-ancestry biobanks. We capitalized on factor analysis, a principled multidimensional distillation approach, to comprehensively model the interconnected landscape of human health.

Factor analysis unveiled 35 latent factors from 2,772 phenotypes in 361,144 White British individuals from the UK Biobank (UKB). Using GWAS on each of the 35 factors, we developed PGS, conducted PGS-pheWAS, and assessed predictive performance stratified by ancestry in three biobanks: UKB, Mass General Brigham Biobank (MGBB), and All of Us (AoU). Our analysis encompassed 52,946 African, 39,015 American, 10,809 Central and South Asian, 8,691 East-Asian, 158,413 European and 2,214 Middle Eastern individuals.

We identified a total of 142, 1,031, and 4,699 Bonferroni-significant associations out of 43,120, 115,235, and 190,785 comparisons in the UKB holdout, MGBB, and AoU, respectively. Notably, factors related to self-reported health and medical history showed the highest number of associations (2,203), followed by socio-demographics (1,192) and physical measurements (1,062). Importantly, directions of significant associations remained consistent across ancestries and biobanks, regardless of differences in recruitment strategies and geographic regions, highlighting the generalizability of factor-based PGS. Moreover, factor-based PGS demonstrated equal or superior accuracy and portability compared to PGS derived from several-fold larger case/control studies. For example, PGS based on a respiratory function factor (N = 360,406), specifically associated with diseases of the respiratory system among various phecode categories, outperformed an asthma PGS derived from multi-ancestry GWAS ($N_{Effective}$ = 715,234), with improvements of 19% in relative accuracy for African individuals.

Our findings highlight the power of modeling phenome-wide data from deeply phenotyped biobanks for accurate and generalizable prediction of patient outcomes in datasets lacking comparable depth or harmonization. We are integrating factor-based PGS with social determinants of health to develop comprehensive risk prediction models. These models are intended to further enhance performance, elucidate the most crucial factors underlying health outcomes, and identify key targets to improve health and reduce disparities.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4404 TraitScan: a trait subset scanning method for multi-trait GWAS

Authors:

R. Cao[1], E. Olawsky[1], E. McFowland, III[2], E. Marcotte[1], L. Spector[1], T. Yang[1]; [1]Univ. of Minnesota, Minneapolis, MN, [2]Harvard Business Sch., Boston, MA

Multi-trait analysis has been shown to have greater statistical power than single-trait analysis. Most of the existing multi-trait analysis methods only work with a limited number of traits and usually target achieving high statistical power instead of identifying relevant traits. We developed TraitScan, a powerful, summary-statistic-based, and fast algorithm that selects and tests a subset of traits from a moderate or large number of traits. We evaluated TraitScan using extensive simulations and found that it outperformed existing methods in terms of both testing power and trait selection under certain sparsity conditions. To demonstrate the utility of TraitScan, we applied it to search for traits associated with Ewing Sarcoma, a rare bone tumor in children, among 706 traits in UK Biobank. Our analysis revealed a few promising traits worthy of further investigation, highlighting the potential of TraitScan in enabling more effective multi-trait analysis as the deeply-phenotyped genome-wide association study databases emerge. Our algorithm is implemented in an R package ‘TraitScan’ available online.

PB4405 † Transcriptome-wide association study of whole blood lipid traits in a diverse population.

Authors:

J. Lundin[1], U. Peters[1], Y. Hu[1], J. Haessler[1], Y. Cai[1], K. North[2], L. Raffield[2], M. Graff[2], K. Young[2], S. Buyske[3], A. Reiner[4], T. Ye[4], R. A. Smit[5], Z. Wang[5], D. Levy[6], R. Joehanes[6], N. Heard-Costa[7], G. Peloso[8], Y. Wang[8], C. Kooperberg[1], PAGE Study; [1]Fred Hutchinson Cancer Ctr., Seattle, WA, [2]Univ. of North Carolina, Chapel Hill, NC, [3]Rutgers Univ, Piscataway, NJ, [4]Univ. of Washington, Seattle, WA, [5]Icahn Sch. of Med. at Mount Sinai, New York, NY, [6]Population Sci. Branch, Natl. Heart, Lung, and Blood Inst. of the NIH, Bethesda, MD, [7]Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA, [8]Boston Univ. Sch. of Publ. Hlth., Boston, MA

Background. Blood concentration of lipids including triglycerides (TRIG), high and low density lipoprotein cholesterol (HDL and LDL, respectively), and total cholesterol (TC) are well-established risk factors for cardiovascular disease and diabetes. In this study we evaluated whole blood gene expression associated with blood lipid levels to identify genetic regulatory mechanisms. This study, to our knowledge, is the first large-scale gene expression analysis of blood lipids.
Methods. We conducted and meta-analyzed transcriptome-wide association studies of four lipid measures (TRIG, HDL, LDL, TC) from peripheral whole blood among self-reported racially and ethnically diverse cohorts. The discovery participants were from the Cameron County Hispanic Cohort, two Framingham Heart Study (FHS) substudies, and one Women's Health Initiative (WHI) substudy [n=4,684; 43% European American (EA), 24% Black or African American (AA), 33% Hispanic or Latino/a (HL)]. The replication participants were from additional FHS and WHI substudies (n=2,405; 82% EA, 14% AA, 4% HL). After quality control, we performed mixed effects linear regression analyses on ~20,000 genes adjusted for age, sex, body-mass index, smoking, population structure, cell type composition, and technical covariates. Genes with $p<0.05/\sim20{,}000$ genes in the discovery stage were carried forward to an independent sample for replication ($p<0.05$/number of discovery genes). Gene Ontology for Biological Process was assessed for each lipid trait to gain mechanistic insight of differentially expressed genes. Two-sample bidirectional Mendelian randomization (MR) analysis was performed to determine whether differential expression was causal or consequential to blood lipid level.
Results. From the discovery meta-analyses, we replicated 1,419 genes significantly associated with TRIG, 511 with HDL, 5 with LDL, and 139 with TC. Functional enrichment categories for TRIG, HDL, and LDL included protein targeting to endoplasmic reticulum, oxidative phosphorylation, and cholesterol metabolic process. *FADS1*, a gene that regulates fatty acids and was enriched in the lipid metabolic process pathway for LDL, was significant in MR analyses identifying *FADS1* gene expression as causal for LDL, HDL, and TC blood lipid levels.
Conclusion. Overall, we identified multiple lipid-related genes in self-reported racially and ethnically diverse individuals that provide new insights into biological pathways and genetic regulatory mechanisms involved in modulating blood lipid concentrations. On-going work includes sensitivity analyses to evaluate clinical comorbidities and other potential confounders.

PB4406 Transcriptome-wide Causal Inference Identifies Potential Causal Genes for Male-pattern Baldness

Authors:

B. Kim[1,2], J. Shim[3], D. Kim[1], S-H. JUNG[4], M. Song[1,5], I. Shim[1], B. Jang[1,6], M. Woojae[2], C. Jeong[7], J. Lee[3], J-W. Kim[3], W-Y. Park[3,1], D. Lee[3], H-H. Won[1,3]; [1]Sungkyunkwan Univ., Seoul, Korea, Republic of, [2]Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of, [3]Samsung Med. Ctr., Seoul, Korea, Republic of, [4]Univ. of Pennsylvania, Philadelphia, PA, [5]Washington Univ. Sch. of Med., St. Louis, MO, [6]Icahn Sch. of Med. at Mount Sinai, New York, NY, [7]Seoul Natl. Univ., Seoul, Korea, Republic of

Male-pattern baldness (MPB) is a polygenic phenotype with subtype-specific causes. Although previous genome-wide association studies (GWASs) identified hundreds of genetic loci associated with MPB, it is challenging to prioritize potential causal genes for MPB. Here, we conducted a GWAS and transcriptome-wide Mendelian randomization (TWMR) of MPB subtypes to identify directly associated genes. A total of 186,093 male individuals of European ancestry from the UK Biobank were included in this study: no progression of hair loss (Pattern 1, n = 59,168), M-shaped hair loss (Pattern 2, n = 42,923), O-shaped hair loss (Pattern 3, n = 49,798), and severe hair loss (Pattern 4, n = 34,204). Phenotypes for MPB were defined as 1) severity of MPB (MPB0, continuous from the Pattern 1 to 4), 2) M-shaped baldness (MPB2, Pattern 1 versus 2), 3) O-shaped baldness (MPB3, Pattern 1 versus 3), and 4) severe baldness (MPB4, Pattern 1 versus 4). GWAS of each MPB subtype was performed using SAIGE adjusted for age, age^2, genotype batch, and the first 10 principal components. TWMR of each MPB subtype was conducted using SMR with expression quantitative loci (eQTL) in seven relevant tissues from the Genotype-Tissue Expression project: cell cultured fibroblasts, lower leg skin, suprapubic skin, skeletal muscle, prostate, testis, and thyroid tissues. For more reliable evidence of direct association, we performed a colocalization analysis between eQTLs on significant genes from TWMR. To investigate the potential pleiotropy of candidate genes, we conducted phenome-wide Mendelian randomization with 332 phenotypes from the pan-ancestry genetic analysis of the UK Biobank. A total of 539, 110, 176, and 379 lead variants that reached a genome-wide significant level ($P < 5.0 \times 10^{-8}$) were identified in GWAS of MPB0, MPB2, MPB3, and MPB4, respectively. We identified 61 directly associated genes that were significant in both TWMR and colocalization analyses; 52, 2, 18, and 37 genes for MPB0, MPB2, MPB3, and MPB4, respectively. Of the identified genes, 36.1% showed no significant potential pleiotropy. These candidate genes include Wnt/β-catenin signaling pathway-related genes such as *CTNNB1* (β-catenin), *HIC1*, *FTX*, *MSI1*, *IRF1*, *FAM53B*, *IQGAP1*, and *ZBTB38*. Notably, *EFEMP1*, a non-pleiotropic gene identified in this study, was directly associated with MPB4 and has been reported to be related to hair growth, but there is no medication targeting this gene. Our study provides directly associated genes for MPB that might be potentially causal for MPB and have less pleiotropic effects on other phenotypes. These candidate genes need to be further validated functionally as therapeutic targets.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4407 Transcript-specific rare-variant analysis identifies novel transcript-trait associations in the UK Biobank

Authors:

L. Ward[1], R. Hoffing[2], A. Deaton[3], A. Holleman[3], L. Krohn[4], P. LoGerfo[3], M. Plekan[3], S. Akle[3], P. Nioi[1]; [1]Alnylam, Cambridge, MA, [2]Alnylam Pharmaceuticals, Somerville, MA, [3]Alnylam Pharmaceuticals, Cambridge, MA, [4]Alnylam Pharmaceuticals, Montreal, QC, Canada

A single gene can produce multiple transcripts with distinct molecular functions. Rare-variant association tests often aggregate all coding variants across individual genes, without accounting for their presence or consequence in resulting transcript isoforms. To test the utility of transcript-aware variant masks, rare predicted loss-of-function (pLOF) variants were aggregated for 17,057 protein coding genes using 56,262 distinct transcript-specific variant masks. These masks were tested for their association with 318 quantitative phenotypes across 406,922 individuals in the UK Biobank. The transcript-specific approach resulted in 796 transcript-phenotype associations that were more statistically significant than the gene-based alternative, including *LDLR* transcript ENST00000252444 and medication-adjusted LDL (transcript-specific statistic, $p = 5.7x10^{-66}$, effect = 1.75 SD increase; gene-based statistic, $p = 1.1x10^{-27}$, effect = 0.80 SD increase). Of those associations, 256 were significant using the transcript-specific approach but not the gene-based approach, including *PCSK5* transcript ENST00000376752 and standing height (transcript-specific statistic, $p = 1.3x10^{-16}$, effect = 0.72 SD decrease; gene-based statistic, p = 0.02, effect = 0.04 SD decrease). This approach demonstrates the importance of considering the effect of pLOFs on specific transcript isoforms when performing rare-variant association studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4408 TransTWAS: A Multi-tissue Transcriptome-wide Association Studies with High Dimensional Transfer Learning

Authors:

D. Lai[1], H. Wang[1], T. Gu[2], Y. Zhang[1,3]; [1]Dept. of Statistics and Actuarial Sci., Faculty of Sci., The Univ. of Hong Kong, Hong Kong, China, [2]Dept. of Biostatistics, Columbia Univ., New York, NY, [3]Ctr. for PanorOmic Sci., Li Ka Shing Faculty of Med., The Univ. of Hong Kong, Hong Kong, China

Transcriptome-wide association study (TWAS) utilizes gene expression to examine the association between a patient's genotype and corresponding complex trait. TWAS imputes gene expression levels from genotypes through samples with matched genotypes and gene expression levels in a fixed human tissue; thus, the genetic architecture of complex traits is estimated by the imputed gene expression level. However, a major challenge is building a robust and accurate imputation model for tissues with a limited sample size. This paper introduced an imputation approach based on an efficient transfer learning algorithm (TransTWAS). TransTWAS leveraged information from external tissues to improve the prediction performance in the target tissue. It explicitly considered the concordance between external and target tissues; therefore, information from similar external tissues will contribute more to the information borrowing. Imputation models generated from GTEx and GEUVADIS panels are provided. Extensive simulations and analysis on multiple GWAS summary statistics datasets showed considerable improvements in statistical power and replication rate compared with existing single- (e.g., PrediXcan) or multiple-tissue methods (e.g., UTMOST).

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4409 Tree-based testing procedure for phenome-wide association studies

Authors:

D. Posner[1], E. D. Kolaczyk[2], K. Cho[1], P. W. Wilson[3], J. Dupuis[2]; [1]VA Boston Hlth.care System, Boston, MA, [2]McGill Univ., Montreal, QC, Canada, [3]VA Atlanta Hlth.care System, Decatur, GA

Biobanks have broadened the scope of epidemiological inquiries, enabling the discovery of shared genetic architectures between thousands of heritable traits. However, the increase in scope is accompanied by a commensurate increase in multiple testing. We propose a tree-based testing procedure (TreePCO) to lessen the multiple testing burden of large-scale biobank studies. Association of a biomarker with a broad trait group is tested at a less stringent significance level and, if rejected, the level is passed to tests of more specific trait associations. Extensive simulations for familywise error rate (FWER) and statistical power were conducted to test one genetic variant for association with each of 2000 traits. The traits were partitioned into 20 broad groups, then further into 5, 50, and 100 subgroups of increasingly specific hypotheses. FWER was controlled across all tree levels and various trait correlation structures. Simulations for power used an additive model with causal variant of allele frequency of 0.1, odds ratio of 1.29, case prevalence of 0.2, and sample size of 500,000. Power of TreePCO was greater than Bonferroni correction in all scenarios except weak pleiotropy (<0.5% of associated traits) with non-clustered causal associations. To validate TreePCO in practice, we re-analyzed UK Biobank (n=400,000) summary statistics for the associations between GCKR variant rs1260326 and 1380 phenotypes derived from electronic health records (PMID: 32504056). Using TreePCO, we found 6 new associations which were not identified by Bonferroni correction: substance addiction and disorders (β=-0.08, p = 1.9 x 10^{-4}), alcohol disorders (β=-0.05, p = 1.1 x 10^{-4}), noninfectious gastroenteritis (β=0.04, p = 2.4 x 10^{-4}), chronic liver disease and cirrhosis (β=0.08, p = 2.8 x 10^{-4}), cholelithiasis with acute cholecystitis (β=-0.15, p = 4.1 x 10^{-5}), and urinary calculus (β=0.07, p = 5.3 x 10^{-4}). All Bonferroni-significant associations were also identified by TreePCO. The associations for alcohol disorders (β=-0.04, p = 6.41 x 10^{-17}), chronic liver disease (β=0.09, p = 3.1 x 10^{-17}), and urinary calculus (β=0.04, p = 3.1 x 10^{-11}) were successfully replicated in European-ancestry participants of the Million Veteran Program (n=442,734). The associations with alcohol consumption and liver disease are well-documented, but less is known about rs1260326 and urinary calculus or kidney stones. Mediators of the association likely include triglyceride-glucose index (PMID: 34616176) and other metabolic biomarkers. In summary, TreePCO is a powerful testing procedure for large-scale biobank studies, including but not limited to phenome-wide association.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4410 Two-sample Mendelian Randomization of Major Depressive Disorder and Inflammatory Bowel Disease

Authors:

C. Simpson, S. R. Brant; Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN

Inflammatory bowel disease (IBD), including the subtypes Crohn's disease and ulcerative colitis, is a chronic, immune-mediated disease that is typically diagnosed in the late teens or twenties. However, it can begin at any age. Symptoms include persistent diarrhea, abdominal pain, cramping, loss of appetite, weight loss, and fever. A significantly lower quality of life has been reported in many patients. This effect appears to go beyond the simple burden of dealing with the disease as the complex relationship between the gut and the brain may increase the risk to patients with IBD of developing mental illness. Whether the effect is unidirectional, bidirectional, or caused by common external risk factors is unknown. This study aims to explore the causal relationship between IBD and major depressive disorder. Using publicly available genome-wide association study summary datasets, we selected SNPs from GWAS of Major Depressive Disorder (MDD) (N=480,359), Crohn's Disease (CD)(N=51,874), Ulcerative Colitis (UC)(N=47,745) and Inflammatory Bowel Disease (IBD)(N=65,642). We performed inverse-variance weighted (IVW) two-sample Mendelian randomization (TSMR). We observed an inverse association with the outcomes CD (beta=2.23E-02, P=0.04) and UC (beta=0.37, P=0.04) with MDD, but not with IBD (beta=-0.14, P=0.87). Analyses are ongoing and will be presented.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4411 Unbiased functional genomics-driven discovery of Alzheimer's Disease mechanisms via analysis of 382 independent GWAS loci

Authors:

Y. Leung, P. Kuksa, J. Cifello, O. Valladares, G. Schellenberg, L-S. Wang; Univ. of Pennsylvania, Philadelphia, PA

Most genomic loci identified by genome-wide association studies (GWAS) are in strong linkage disequilibrium (LD) with many nearby variants. Although all of these variants could be functional, they are non-coding and thus any underlying gene regulatory mechanisms must be context-dependent and hypothesized. This phenomenon is particularly true for complex diseases such as Alzheimer's Disease (AD).

We investigated non-coding regulatory mechanisms underlying AD GWAS variants (Bellenguez *et al* 2022) in enhancer regions using SparkINFERNO (Kuksa *et al* 2020), a recent non-coding variant analysis pipeline, and FILER (Kuksa *et al* 2022), an extensive functional genomics (FG) catalogue. SparkINFERNO performs direct analysis of full GWAS summary statistics in a genome-wide manner. This automated analysis is hypothesis-free, and provides a systematic report of all candidate causal variants at the SNP, LD block, locus, enhancer or eQTL (expression quantitative trait loci). This analysis identifies and aligns evidence for the nominated causal variants, context-specific regulatory mechanisms, and target genes underlying observed GWAS signals then links them to disease mechanisms.

SparkINFERNO facilitates biologists' ability to identify the tissue context for biological validation: a total of 7863 candidate variants (382 loci) were analyzed (compared to 75 variant/loci reported). Of the top 20% of the enhancer enrichments, 87% are immune/brain (known AD mechanisms). We also found digestive and adipose tissue enrichments (17% of all enhancer enrichments), indicating gut-microbiome or other metabolism-related mechanisms could play a role in AD pathophysiology.

SparkINFERNO can also pinpoint cell type/tissue specificity at the locus level: *CLNK*, *ERCC1*, *MME*, *PLCG2* and *RASA1* are blood/brain-specific. Two are novel plausible genes: 1) *ERCC1* is involved in multiple DNA repair pathways and is also a significant eQTL in the AMP-AD brain study; 2) *RASA1* is expressed highly in neurons (The Human Protein Atlas) and is also a brain eQTL. We also nominated *HS3ST5* and *MARK4* to be digestive-specific and related to the gut-microbiome. Independently, there is metabolomic support from AMP-AD on these two genes.

By integrating different FG datasets profiled in a variety of tissue contexts with GWAS signals, SparkINFERNO revealed relevant tissue contexts for AD. Insights yielded by SparkINFERNO in a hypothesis-free manner can help researchers design context-specific experiments on divergent/novel cell types to understand AD and other phenotypes from different perspectives.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4412 Unlocking missed structural variants: enhancing short-read data with haplotype-informed methods

Authors:

S. Rubinacci[1,2,3], P-R. Loh[1,2,3]; [1]Div. of Genetics, Dept. of Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [2]Ctr. for Data Sci., Brigham and Women's Hosp., Boston, MA, [3]Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Cambridge, MA

Structural variants (SVs) play a crucial role in genetic diversity and disease susceptibility. Current SV calling methods based on short-read whole-genome sequencing (WGS) have limitations in capturing the full spectrum of SVs, and recent analyses of long-read sequencing in the Human Pangenome Reference Consortium (HPRC) dataset have confirmed that only one-third of SVs are accessible with existing short-read-based methods. However, recent work (Mukamel et al. 2021, Science; Hujoel et al. 2022, Cell) suggests that it may be possible to unlock many more detectable SVs from short-read WGS by developing haplotype-informed methods that amplify read-level signals (e.g. read-depth, discordant read pairs and split reads) through data aggregation across distantly related samples. We therefore evaluated the performance of current SV calling pipelines by analysing 39 samples present in both the high-coverage 1000 Genomes SV callset and the HPRC dataset. Our focus was on identifying read-level SV signatures in short-read WGS for SVs called exclusively within the HPRC dataset. We utilised annotations from the Genome in a Bottle consortium, restricting our examination to unambiguously mappable regions.

Within the 1000 Genomes dataset, we observed an average of 1412 deletions per sample in the considered region (in contrast to 1931 in HPRC), with 76% of them exhibiting similar calls in the HPRC dataset. Notably, the use of long reads in HPRC enabled the detection of short deletions (average size of 325bp), whereas short-read sequencing primarily captured larger deletion events (average size of 727bp). We also identified an average of 1887 insertions (vs. 7047 in HPRC); however, only 42% of these insertions had a similar call in the HPRC dataset, highlighting the challenge of detecting and reporting accurate breakpoint insertions with short-reads.

Examining unique calls in the HPRC dataset, we found that approximately 20% of the identified insertions were mobile element insertions (MEI). These insertions showed discordant read pair signals in short-read sequencing data. Interestingly, among the MEIs present in the 1000 Genomes SV callset, 87% were found in HPRC, indicating the high precision of current methods in detecting MEIs, yet at the cost of lower recall. Furthermore, variable number tandem repeats, which accounted for nearly 40% of SVs in the HPRC dataset, were rarely found in the 1000 Genomes SV callset.

These findings motivate further work we will pursue to develop novel software capable of efficiently capturing these signals and integrating them across shared haplotypes within large biobank cohorts.

PB4413 † Unsupervised clustering revealed metabolic syndrome endophenotypes with differing phenotypic and genotypic traits in UK and Taiwan Biobanks

Authors:

A. Lim[1], E. Lim[2], P-L. Chen[3], C. Fann[4]; [1]Academia Sinica, Taipei, China, [2]Academia Sinica, Taipei, Taiwan, [3]Natl. Taiwan Univ. Hosp., Taipei, Taiwan, [4]Inst Biomed Sci, Acad Sinica, Taipei, Taiwan

Background: High heterogeneity of complex diseases impedes effective translational research from genetic findings.
Methods: As a proof-of concept, clinically-relevant endophenotypes were identified through unsupervised clustering in UK Biobank (UKB) metabolic syndrome (MetS) individuals. GWAS and associated post-GWAS analysis were performed to identify genotypic traits associated with each endophenotypes. Potential drug repurposing targets were established through unbiased identification of drugs targeting associated genes. Heritability and polygenic risk score models for each endophenotypes were calculated. MetS endophenotypes were further evaluated and validated in Taiwan Biobank (TWB).
Results: Five MetS endophenotypes were identified in UKB and TWB with similar proportion, comparable phenotypic traits and associated clinical outcomes: Cluster 1 (C1) non-descriptive, Cluster 2 (C2) hypertensive, Cluster 3 (C3) obese, Cluster 4 (C4) lipodystrophy-like, and Cluster 5 (C5) hyperglycaemic. *LPCAT2*, *NUDT21* and *OGFOD1* were associated with all clusters in UKB except C2, this finding was validated in C1 and C3 of TWB. When analysing the cluster-specific genes in UKB, C1 had 156 distinct genes while C2 had 16, C3 had 98, C4 had 133 and C5 had 8. C1 GWAS revealed cardiac-specific *TRIM63* and *MYBPC3*, skeletal muscle-specific *MYLPF* and *RAPSN*. C5 GWAS identified known T2D genes such as *TCF7L2*, *IRS1*, *BBIP1* and *GIN1*. C1, C3 and C4 were associated with genes highly expressed in brain tissues such as *CN1H2*, *TMEM151A*, *MT3* and *C1QTNF4*. Comparing genotypic traits between TWB and UKB, C1 of TWB overlapped at 43 genes, C3 overlapped at 21 genes and C4 overlapped at 112 genes with UKB. Example of overlapped genes for C1: *LPL*, *TOMM40*, C3: *FTO*, *SLC6A2* and C4: *LPL*, *APOA1*, *APOC1*, *PCSK7*, *GCKR*. C1-associated genes were enriched in gene-set targeted by cardiovascular system drugs such as diuretics targeting *SLC12A3* and *SLC12A4*; C3 by anti-obesity drugs targeting *SLC6A2* and antithrombotic drugs targeting *F2*, *TFPI* and *VEGFA*; C4 by lipid-modifying drugs targeting *APOB* and *LPL*; C5 by drugs of alimentary tract targeting *CES1*. With full sample size, our first-of-its-kind PRS for C4 performed the best at lower p-value thresholds. Based on subset of 3800 cases (as C5 with n=3869 was the smallest cluster), three out of five PRS models for MetS endophenotypes performed better than that of all MetS across p-value thresholds.
Conclusion: The novel combination of approaches from machine learning and genetic epidemiology allowed for identification of clinically important MetS endophenotypes across two populations, representing a key step towards precision medicine in complex diseases.

Hlth., Cambridge, MA, [12]Channing Div. of Network Med., Brigham and Women's Hosp., Harvard Med. Sch., Boston, MA, [13]Ctr Eye Res Aust, Brunswick, Australia, [14]Lions Eye Inst., Nedlands, Australia, [15]Dept. of Ophthalmology, Flinders Univ., Flinders Med. Ctr., Adelaide, Australia, [16]Harvard Med Sch, MEEI, Boston, MA, [17]QIMR Berghofer Med. Res. Inst., Herston, Australia

Background: Primary open-angle glaucoma (POAG) is often divided into two subtypes. High-tension glaucoma (HTG) is characterized by elevated intraocular pressure (IOP), while normal-tension glaucoma (NTG) is characterized by IOP in the normal range. However, this notion is still controversial as some studies argue that different tension subtypes could be part of the same pathogenic process while other studies claim that NTG represents a different etiological process where the neurodegeneration has a higher impact. This study aimed to elucidate the shared and specific genetic architecture for NTG and HTG.
Method: To identify risk loci specific to NTG we conducted a large multi-ethnic multi-trait meta-analysis of 7,942 NTG cases and 384,431 controls from studies from the United Kingdom, Canada, Finland, US, Hong Kong, Singapore and Japan, and a structural measurement of the integrity of the optic nerve, vertical cup-to-disk ratio (VCDR, N=282,100), adjusted for IOP using the mtCOJO method. We also performed an assessment of the genetic overlap between NTG and HTG (N HTG cases = 5144, N controls = 47,997) using the GWAS pairwise method (GWAS-PW).
Findings: This study identified 22 risk loci associated with NTG. Of these, 17 loci are novel for NTG, and two loci, *MIR5580* and *KPNB1*, have not previously been associated at the genome-wide significant level with glaucoma. Examination of each locus across the genome using the GWAS-PW method indicated that risk loci are shared across NTG and HTG. The magnitude of the effect of the genome-wide significant loci tends to be lower in NTG compared to their effects on HTG, particularly for IOP-related loci. Additionally, we identified 42 drug-gene interactions, including statins, with four genes (*ABCA1*, *CDKN2A*, *CDKN2B* and *ITGB3*) that were prioritized through our gene-based analysis.
Interpretation: This work expands our understanding of the genetics of NTG and highlights a strong genetic overlap between HTG and NTG. Despite the genetic overlap, we have shown that IOP-related loci tend to have a smaller effect size in NTG when compared with HTG whereas neurodegenerative loci independent of IOP have similar effect sizes on NTG and HTG. These results indicate that while there is a significant overlap in risk loci between NTG and HTG, a precise estimation of their effect sizes on NTG using larger studies could help develop genetic risk prediction models to identify individuals at a higher risk of developing NTG. We have also identified some potential targets for neuroprotective treatment through the interaction of four genes and multiple drugs.

PB4415 Unveiling novel endometriosis genetic associations through unsupervised, phenotypic clustering analysis of distinct clinical subtypes

Authors:

L. Guare, S. Senapati, Penn Medicine Biobank, Regeneron Genetics Center, S. Verma; Univ. of Pennsylvania, Philadelphia, PA

Endometriosis affects 10% of reproductive-age women, and yet, it goes undiagnosed for 3.6 years on average after symptoms onset. In spite of large GWAS meta-analyses, only a few dozen causal loci have been identified. We hypothesized that the challenges in identifying causal SNPs for endometriosis stem from heterogeneity across clinical and biological factors. We extracted known endometriosis risk factors, symptoms, and concomitant conditions from the Penn Medicine Biobank (PMBB) and performed t-SNE dimensionality reduction on 4,623 women with an ICD diagnosis for endometriosis. To mitigate artificial structure created by t-SNE, we performed 200 trials and averaged the resulting distance matrices. This averaged distance matrix was then utilized for hierarchical clustering. By considering distortion and silhouette score, we determined that the optimal number of clusters is 5. The 5 clusters were characterized by utilizing additional electronic health record (EHR) variables, such as procedure history, endometriosis-related comorbidities, and long-term conditions. We have designated the five subtype clusters as reproductive-health, uterine-health, EHR-asymptomatic, pain/inflammatory, and cardiometabolic based on enriched features from each group. The subtypes were observed in the discovery PMBB cohort, and we then performed an ancestry-stratified case/control GWAS for each cluster using a combined hold-out data from PMBB and eMERGE (N cases = 2,624). Two clusters had statistically significant associations in the PMBB+eMERGE dataset: the reproductive health endometriosis subtype was associated with *LOC105374621* (lead SNP rs60132896. P = 2.4x10-8) and the cardiometabolic subtype was associated with *SNORD28B* (lead SNP rs4464815. P = 4.5x10-8). Additionally, the cardiometabolic subtype was suggestively associated with one of the known endometriosis loci, *RNLS* (lead SNP rs61855396. P = 2x10-6). The statistically suggestive hits in this study were examined for previous associations in the GWAS catalog. The reproductive health subtype exhibited significant overlap with genes related to body measurements and neurological traits, while the EHR-asymptomatic, cardiometabolic, and pain/inflammatory subtypes showed suggestive associations with genes linked to blood protein measurements and asthma, DNA methylation, type 2 diabetes and smoking status, and hematological measurements and body weight, respectively. This study significantly enhances our understanding of the clinical presentation patterns of endometriosis subtypes, showcasing the innovative approach employed to investigate these complex diseases.

PB4416 Use of personalized reference sets for polygenic scores negates need for arbitrary groupings

Authors:

A. Sartori[1], Y. Ding[2], S. Buyske[3], C. Gignoux[4], C. Haiman[5], E. Kenny[6], C. Koopeberg[7], K. North[8], B. Pasaniuc[2], G. Wojcik[1]; [1]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [2]UCLA, Los Angeles, CA, [3]Dept. of Statistics, Rutgers Univ., Piscataway, NJ, [4]U Colorado, Anschutz Med. Campus, Aurora, CO, [5]Dept. of Population and Publ. Hlth.Sci., Keck Sch. of Med., Univ. of Southern California, Los Angeles, CA, [6]Icahn Sch. of Med. at Mount Sinai, New York, NY, [7]Div. of Publ. Hlth.Sci., Fred Hutchinson Cancer Ctr., Seattle, WA, [8]Univ North Carolina, Wake Forest, NC

Polygenic scores (PGS) helped translating GWAS results into clinical practice but with limited portability across individuals of different genetic backgrounds, especially for admixed populations with multiple recent genetic ancestries and often relying upon subjective groupings by race/ethnicity and/or “genetic ancestry groups”. This necessitates the use of a single-aggregate population reference set to estimate PGS performance, ignoring inter-individual variability. While this is meant to control for differences in allele frequencies and LD, it often combines non-comparable individuals. A personalized PGS reference set approach can overcome these problems by tailoring to single individuals. We used PGS for body mass index (BMI) and height in 41,586 individuals self-identified as African/African American (N=15993), Asian (N=4075), Hispanic/Latino (N=18950), Native Hawaiian (N=1970), and Native American (N=598) from the PAGE Study, and trained a k-nearest neighbors model (k=1,000) on PCA-based genetic distance to assess their relative position in the genetic ancestry continuum. For each index individual, we defined new reference clusters not reflecting continental-level genetic ancestry, nor racial/ethnic groupings, thus capturing inter-individual variation. After applying PGS models, we observed that PGS accuracy performed equally well with the new reference sets approach compared to grouping by racial/ethnic group (R^2=0.092 to R^2=0.093 for PGS_{BMI} and R^2=0.543 to R^2=0.545 for PGS_{Height}). In addition, when we compared all individuals to those at the top 10th percentile of the PGS distribution, no variation in the effect size magnitude was found (B=0.08 to B=0.08 for PGS_{BMI} and B=0.53 to B=0.53 for PGS_{Height}). Finally, we computed individual PGS accuracy, which has been previously shown to be highly correlated with genetic distance along the genetic ancestry continuum, within the new reference sets and assessed performance to explore potential benefits to those on the edges of previous groupings. Combining an individualized reference set approach with individual PGS will provide a robust tool for PGS estimation in a highly personalized way, holding the potential to benefit diverse individuals and translate clinically useful information into precision medicine without the need to create borders where none exist.

PB4417 Using a multivariate genotype-phenotype approach to measure endocrine-mediated masculinity and femininity in human faces.

Authors:

C. Da Silva[1,2,3], H. Hoskens[1,2,3], D. J. Aponte[4], B. Hallgrimsson[1,2,3]; [1]Univ. of Calgary, Calgary, AB, Canada, [2]Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada, [3]McCaig Inst. for Bone and Joint Hlth., Calgary, AB, Canada, [4]Deep Surface AI, Calgary, AB, Canada

Males and females have known differences in facial shape. This variation produces sex biases in congenital abnormalities, biting mechanics, and sleep-disordered breathing. Despite this, little is understood about the origins of these differences. The prevailing opinion is that facial sexual dimorphism results from testosterone-induced masculinization of the male face, with little consideration given to the role of estrogen. Moreover, facial femininity and masculinity are assumed to be mutually exclusive (i.e., femininity is the absence of masculinity), but this has never been tested formally. In this study, we address the current gaps by comparing patterns of endocrine-mediated facial femininity and masculinity in an independent sample of European descent. These include three-dimensional facial surface scans and genotype data for 1,000 individuals from the United States (500 males and 500 females). We begin by identifying the facial shape effects associated with the estrogen and testosterone pathways using a multivariate genotype-phenotype (MGP) approach. First, we select gene sets for the estrogen and testosterone pathways. The MGP method then identifies axes of shape variation that maximally covary with these sets of genes. Next, we use geometric morphometrics to quantify their respective shape effects and determine the dimensionality of the facial sexual dimorphism axis or axes by calculating the degree of correlation between the shape effects of estrogen-mediated femininity and testosterone-mediated masculinity. The degree of correlation indicates whether endocrine-mediated facial femininity and masculinity are on opposing sides of the same axis or on separate axes. Finally, we compare results between our male and female samples. This project presents a conceptually and methodologically novel approach to studying sexual dimorphism, combining techniques from statistical genetics and geometric morphometrics. Our method provides a biologically meaningful way of measuring morphological masculinity and femininity, which is an important first step toward understanding the developmental-genetic aetiology of sex differences in the human face.

Tecnologico y de Energias Renovables, Santa Cruz de Tenerife, Spain, [9]CIBERES - Inst. de Salud Carlos III, Madrid, Spain, [10]Univ. of Michigan, Michigan, MI, [11]Genentech, Pacifica, CA

Rationale: Idiopathic pulmonary fibrosis (IPF) is a rare progressive illness of the respiratory system with a poor prognosis and lack of therapeutic options. Studies have focused on the identification of genetic risk factors associated with IPF using genome-wide association studies (GWAS), which have highlighted new genes and pathways of interest. Objective: All prior GWAS of IPF have assumed an additive genetic model. We hypothesised that assuming non-additive associations may identify new IPF risk signals where the underlying causal effect is consistent with a dominant or recessive genetic model. Methods: We conducted the largest IPF risk GWAS using both dominant and recessive genetic models with data from seven independent studies (involving 5,159 IPF cases and 27,476 controls), imputed using TOPMed. We used logistic regression, adjusting for 10 principal components for ancestry, and meta-analysed results using inverse-variance weighted meta-analysis. We selected signals which were present in at least two studies and met genome-wide significance (p<5x10-8). We compared significant signals from the dominant and recessive models with results from an additive model GWAS using the same data. Results: Around 55 million SNPs were analysed using the dominant model, while 9 million SNPs were studied under the recessive models. We obtained 58 genome-wide significant signals using the dominant model and 25 for the recessive model. Of these, 18 signals were not genome-wide significant under an additive genetic model. Fourteen of the 18 signals were genome-wide significant under the dominant model (p varied between 3.76x10-8 - 1.65x10-11) and four under the recessive model (p varied between 4.51x10-8 - 5.11x10-12). Two of the recessive model signals were exonic signals located in the cell-cycle gene Polyamine-Modulated Factor 1 (*PMF1*) and in Epsin 3 (*EPN3*). EPN3 was previously found to be upregulated in lung tissue of IPF patients. Of previously reported additive signals, a SNP at desmoplakin (*DSP*) was most significant under a recessive model whilst the SNP at telomere gene, *RTEL1*, was most significant under a dominant model. Conclusion: The use of alternative genetic models in GWAS of IPF susceptibility enabled discovery of new signals that were not reported at genome-wide significance under the additive model. Understanding the causal model of association can inform downstream functional genomics studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4419 Using external reference panel and single-variant summary statistics for rare-variant aggregation tests.

Authors:

B. Ryan[1], R. Welch[1], M. Boehnke[1], C. Fuchsberger[2]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Eurac Res., Bolzano, Italy

Genome-wide association studies (GWAS) have identified hundreds of thousands of associations between common genetic variants and a range of human diseases and traits. These studies are often of low power to identify associations with rare genetic variants. To increase power, aggregation tests which pool the genetic signal across multiple variants in a gene or other region of the genome to test the cumulative effect of these variants on a disease or trait are often used. There are many publicly available GWAS summary statistics, and it has been shown that aggregation tests can be performed using only single-variant score statistics, their covariances, and the allele frequencies for each variant. Accurate estimates of single-variant test statistic covariances are required, and are easily obtained given individual-level genetic data. Due to privacy concerns, individual-level genetic data often cannot be shared. Sharing covariance matrices may also be infeasible due to data size. In this study, we apply a previously proposed method of estimating single-variant test statistic covariance from an external reference panel to perform aggregation tests. We use correlation between variants in the reference panel and allele frequencies from the original sample to estimate the test statistic covariances. We propose a two-stage approach by first filtering genes using a null covariance where covariance between all variants is set to zero to perform aggregation tests, and in stage two using an external reference panel to repeat aggregation tests only on those genes passing a p-value threshold. Using the null covariance generally overestimates association significance of genes, allowing us to confidently exclude non-significant genes in the first stage. As covariance computation is the most burdensome of the testing process, this leads to a substantial reduction in computation time. We investigate the properties of our method across ten traits from the UK Biobank, three variant annotation masks, and three different aggregation tests. When p-values on the log scale produced using individual-level data and our two-stage approach across all ten traits are compared, Pearson correlation coefficients are between 0.984 and 0.996 across all scenarios using a reference panel of 1,000 individuals. By using an African American reference panel (n=1,000) from the InPSYght study, we show that this approach is robust to misspecification of the reference panel ancestry. The two-stage approach results in substantial memory and computation savings and will be a useful tool for researchers wishing to perform rare-variant aggregation tests using publicly available summary statistics.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4420 Using F_{ST} to understand putative bias induced by population stratification in Mendelian randomization studies

Authors:

N. Khankari, P. Straub, A. Konkashbaev, F. Blostein, J. Hirbo, L. K. Davis, M. C. Aldrich, T. L. Edwards, N. J. Cox; Vanderbilt Univ. Med. Ctr., Nashville, TN

Two-sample Mendelian randomization (MR) relies upon existing GWAS summary statistics for the exposure and outcome from independent samples. A potentially causal association may be estimated via inverse-variance weighted (IVW) MR leveraging these readily available GWAS summary statistics. While the current GWAS landscape is changing with the advent of large-scale genomic studies conducted among diverse populations, many existing GWAS have focused solely on individuals of European ancestry. Given allele frequencies may vary even among individuals of a seemingly homogenous European population, resulting two-sample MR conducted in European populations may remain biased due to population stratification. We sought to understand the putative bias induced in two-sample MR studies when the existing GWAS summary statistics may be affected by population stratification. In this analysis, four scenarios were examined: (1) when neither the exposure (i.e., body mass index) nor the outcome GWAS (i.e., coronary artery disease) are affected by population stratification; (2) only the exposure GWAS (i.e., triglycerides) is affected by population stratification; (3) only the outcome (i.e., Celiac disease) GWAS is affected by population stratification; and (4) both exposure (i.e., triglycerides) and outcome (i.e., Celiac disease) GWAS are affected by population stratification. To compare how the estimated IVW MR effect varies according to population substructure in these scenarios, we conducted a fixation index (F_{ST})-weighted MR analysis to examine differences according to the four 1000 Genomes populations (i.e., FIN, GBR, IBS, and TSI). Pairwise F_{ST} was calculated comparing each European 1000 Genomes population with the CEU population, which was then used to weight the IVW MR estimate accordingly. We observed the largest differences between the estimated IVW MR [Beta (StdErr): -1.17 (0.63)] and F_{ST}-weighted population-specific MR effects (i.e., FIN: -2.22 (0.10), GBR:-3.79 (0.08), IBS: -2.71 (0.09), and TSI: -3.52 (0.10)] in the fourth scenario in which both exposure (i.e., triglycerides) and outcome (i.e., Celiac disease) were affected by population stratification bias. Using F_{ST}-weighted MR as a two-sample MR sensitivity analysis may help estimate ancestry-specific effects when GWAS summary statistics are affected by population stratification.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4421 Using information technology to optimise the differential diagnosis of rare genetic diseases

Authors:

H. Li[1], J. Yang[2], H. Duan[2], Q. Shu[1]; [1]Children's Hosp., Zhejiang Univ. Sch. of Med., Hangzhou, China, [2]Zhejiang Univ., Hangzhou, China

Rare diseases (RDs) are defined as conditions or disorders that affect a prevalence of less than 6.5 to 10 in 10,000 individuals. Despite being referred to as“rare”, there are over 7,000 RDs that collectively affect tens of millions of people in the general population. RDs are mostly genetic diseases. The diagnosis of RDs usually involves phenomic analysis and genomic analysis, the combination of which can lead to a definitive diagnosis. However, the diagnosis of RDs is of great challenge. Firstly, RDs often have complex phenotypic features. Secondly, RDs have extensive phenotypic overlap; In addition to the complex and overlapping phenotypic features of RDs, the limited knowledge and experience of clinicians, and the low quality of clinical records, also make it difficult to diagnose RDs. In response to the needs of the field, we have developed a range of new information technology methods and tools to help clinicians and researchers in the areas of knowledge presentation and phenotype retrieval, intelligent question and answer, and differential diagnosis using a variety of new information technologies:(1) RDmap (http://rdmap.nbscn.org): A rare disease map is built to visualize the knowledge of complex rare diseases and the relationships between RDs. Functions such as phenotype-based precision matching and similarity matching are provided to locate and retrieve RDs.(2)PheLR (http://phelr.nbscn.org): A Phenotype-driven Likelihood Ratio analysis approach (PheLR) assisting interpretable clinical diagnosis of RDs. With a likelihood ratio paradigm, PheLR estimates the posterior probability of candidate diseases and how much a phenotypic feature contributes to the prioritization result.(3)RDmaster (http://rdmaster.nbscn.org): a phenotype-oriented Q&A system, to gather important phenotypic features and assist doctors in the differential diagnosis of RDs.Benchmarked using simulated and realistic patients, these information tools show significant advantages over current approaches (Phenomizer, BOQA, PhenoPro, LIRICAL, Exomiser, GPT-3.5 and GTP-4) and is robust to noise and inaccuracy. The widespread dissemination of these IT tools can improve the accuracy and timeliness of diagnosis of rare genetic diseases.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4422 Using Polygenic Risk Scores to Investigate Inverse Genetic Associations Between Cancer and Cognitive Decline

Authors:

D. Chen[1], M. Glymour[2], P. Gilsanz[3], C. A. Schaefer[3], L. C. Sakoda[3], T. J. Hoffmann[1], P. Buto[1], M. Choi[1], J. S. Witte[4], R. E. Graff[1]; [1]UCSF, San Francisco, CA, [2]Boston Univ., Boston, MA, [3]Kaiser Permanente Northern California Div. of Res., Oakland, CA, [4]Stanford Univ., Stanford, CA

Epidemiological evidence suggests that there exists bidirectional inverse comorbidity between cancer and neurodegenerative diseases, including Alzheimer's disease (AD) and dementia. Biases do not fully explain the relationship, so it has become critical to explore the complex pathophysiology underlying connections between these two diseases. We thus assessed whether shared genetic risk factors partially drive the inverse association among 93,656 members of the Kaiser Permanente Medical Care Plan who had genetic information available. To do this, we constructed polygenic risk scores for all-cause cancer (PRS_{cancer}), 17 common cancer types, and AD, with (PRS_{AD}) and without ($PRS_{ADnoAPOE}$) representation of two variants comprising the APOE haplotype (rs7412 and rs429358). The study population included individuals of African (n = 3,304), Asian (n = 7,139), European (n = 74,949), and Hispanic/Latino (n = 8,264) ancestry. Within ancestry cohorts, we used Cox proportional hazards models to estimate hazard ratios (HR) and 95% confidence intervals (CI) for associations of PRS_{cancer} with dementia (all-cause, AD, and vascular) and associations of PRS_{AD} and $PRS_{ADnoAPOE}$ with each cancer type. Within Europeans, there were 16,780 incident all-cause cancer cases and 6,820 incident all-cause dementia cases. All-cause cancer and dementia cases were lower in other ancestry groups, ranging from 589 to 1,248 and 292 to 503, respectively. We did not identify any significant associations between the cancer or dementia PRS and the alternate disease after multiple comparison adjustment ($p > 2.78x10^{-3}$) in any of the ancestry groups. For example, all-cause PRS_{cancer} was not significantly associated with all-cause dementia in African (HR: 1.04, 95% CI: (0.92, 1.18)), Asian (HR: 0.97, 95% CI: (0.87, 1.07)), European (HR: 1.02, 95% CI: (0.99, 1.05)), and Hispanic/ Latino (HR: 0.94, 95% CI: (0.85, 1.03)) ancestry participants. All HRs estimating the association between individual PRS_{cancer} associations with dementia phenotypes in European ancestry participants were between 0.94 (95% CI: 0.88, 0.99) and 1.03 (95% CI: 0.99, 1.07). Associations of PRS_{AD} and $PRS_{ADnoAPOE}$ with varying cancer types were similarly non-significant. PRS_{AD} was not associated with all-cause cancer in African (HR: 0.97, 95% CI: (0.90, 1.05)), Asian (HR: 1.04, 95% CI: (0.98, 1.11)), European (HR: 1.00, 95% CI: (0.99, 1.02)), and Hispanic/ Latino (HR: 0.98, 95% CI: (0.93, 1.03)) ancestry individuals. Methods that improve cross-population polygenic prediction in diverse cohorts, such as PRS-CSx, will be explored in subsequent analyses.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4423 Using population data to assess significance of rare variants in WGS of n=1 disease cases.

Authors:

Marenne[1]; [1]Univ Brest, Inserm, EFS, UMR 1078, GGB, Brest, France, [2]Inst. of Translational Genomics, Helmholtz Zentrum München, Munich, Germany, [3]Université Paris Cité, Inserm, NeuroDiderot, Unité Mixte de Recherche 1141, Paris, France, [4]Aix Marseille Univ, INSERM, Marseille Med. Genetics (MMG), Marseille, France, [5]Assistance publique-Hôpitaux de Paris, Service de Génétique Moléculaire Neurovasculaire, Hôpital Saint-Louis, Paris, France, [6]Div. of Genetics, Oregon Natl. Primate Res. Ctr., Oregon Hlth.& Sci. Univ., Portland, OR, [7]Ctr. Hosp.ier Régional Univ.ire de Brest, Brest, France

High genetic heterogeneity in rare diseases poses the challenge of identifying an n=1 patient's causal variant using sequencing data and standard analysis methods. The PSAP (Population Sampling Probability) method uses gene-specific null distributions of CADD pathogenicity scores to assess the probability of observing a given genotype in a healthy population. Here, we propose an extension of the PSAP method to the non-coding genome, using as testing units predefined regions reflecting functional constraint at the scale of the whole genome. Our method broadens the spectrum of variants detectable by PSAP and improves the performance of PSAP in coding regions.

We simulated disease exomes and genomes by inserting coding and non-coding pathogenic ClinVar variants in 574 healthy exomes and in 10 whole genomes from the 1000 Genomes Project respectively, under both the autosomal dominant and recessive (AD and AR) models. Inserted variants were ranked based on their PSAP p-values using either genes or functional regions as testing units. The percentage of variants ranked at top positions was compared between the two PSAP strategies and against a ranking based only on CADD scores.

For the AR model, 89% of 2,680 coding ClinVar variants were ranked first when using PSAP on functional regions, as compared to 83% when using PSAP on genes and 0.04% when using CADD scores only. For the AD model, 38% of 4,965 coding ClinVar variants were ranked first when using PSAP on functional regions, as compared to 27% when using PSAP on genes, and 0.1% when using CADD scores only. For non-coding ClinVar variants, 54% of the 115 variants were ranked in the top 10 for the AR model and 21% of 218 variants for the AD model using PSAP on functional regions, against 3% using CADD scores only. Interestingly, among the non-coding ClinVar variants, PSAP performed best on splicing variants, which are often highly clinically relevant.

On real data from 6 patients with distinct known variants causing Cerebral Small Vessel Disease, a very heterogeneous disease, the prioritization of the causal variants was improved by using PSAP on functional regions as compared to genes and all variants were ranked within the top 100. Additional post-filtering (e.g, keeping only variants absent from the gnomAD database) improved this ranking.

The PSAP method extended to functional regions is an efficient agnostic prioritization tool, which offers promising results for the diagnosis of unresolved n=1 cases of rare diseases. Our method is implemented as a user-friendly and versatile Snakemake workflow, accessible to both researchers and clinicians.

PB4424 Using protein language model annotations to improve the power of exome-wide association studies.

Authors:

J. Mbatchou, C. Gillies, J. Kosmicki, M. Ferreira, G. Abecasis, L. Habbeger, J. Marchini, on behalf of the Regeneron Genetics Center; Regeneron Genetics Ctr., Tarrytown, NY

Advances in sequencing technologies have enabled the study of rare genetic variation which can play a key role in understanding complex diseases. Due to the low frequency of these variants and the need for very large sample sizes or effect sizes, gene-based tests have been developed to increase the statistical power of association tests over single variant tests by aggregating information across multiple variants. Several tools have been developed that also integrate functional annotations into the gene-based tests by applying different weighting schemes at each variant site with the goal of boosting the power of rare variant analysis (e.g., REGENIE, SAIGE, STAAR).
While many in-silico algorithms predict deleteriousness of genetic variants (e.g., Polyphen, SIFT), recent algorithms based on protein language models, which utilize many protein sequences to derive the functional impact of sequence mutations, were shown to have comparable or better performance than predictions based on supervised methods. Here we studied the use of ESM-1v, a deep learning algorithm trained on 98M protein sequences, to identify deleterious missense variants for inclusion in gene-burden tests. We generated qualitative functional groupings derived from continuous ESM-1v scores for missense variants.
We demonstrate the usefulness of using ESM-1v through real data applications in UK Biobank with ~400,000 exome sequenced samples where we run exome-wide gene-based association tests on 100 phenotypes. We compare gene-based tests derived from ESM-1v scores to those based on five in-silico algorithms. We discover 64 additional significant associations by utilizing functional groupings derived from ESM-1v scores. We show that these groupings can recover 98.7% of the signals found by functional annotations from in-silico algorithms . Thus, the use of state-of the art missense predictors to identify variants for inclusion in gene burden aggregation can improve power for exome-wide association studies.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4425 Utility of using elastic net models to impute gene expression in the anterior cingulate cortex and implications for network analysis.

Authors:

J. Drake[1,2], Z. Taylor[2], A. Denham[1,2], S-A. Bacanu[3], J. Shin[4], T. Hyde[4], V. Vladimirov[2]; [1]Texas A&M Univ., College Station, TX, [2]Univ. of Arizona, Phoenix, AZ, [3]Virginia Commonwealth Univ, Richmond, VA, [4]Lieber Inst. for Brain Dev., Johns Hopkins Univ., Baltimore, MD

Background: Given the cost and difficulty of measuring postmortem brain gene expression (GE), imputation methods have steadily gained traction in the field. However, a major drawback of GE imputation is the limited number of imputed genes, with even fewer of these imputed with sufficient accuracy, ultimately hindering the network analysis. To address these limitations, we expanded on PrediXcan's elastic net methodology by incorporating neuronal cell fractions in order to impute a higher number of genes and evaluate their utility in network analysis using weighted gene co-expression network analysis (WGCNA).
Methods: For our GE imputation, we used a large postmortem brain sample containing genotype and RNA-Seq data generated in the anterior cingulate cortex (ACC) from 196 neurotypical, 228 major depressive disorder (MDD), and 123 bipolar disorder (BIP) subjects, with a total N=547. By representing each phenotype, proportionally, we further split the sample into 70% training and 30% testing datasets to minimize overfitting. We used glmnet to create 19,948 mRNA elastic net models with 10-fold cross-validation. Considering the importance of cell-specific gene expression, we further used a single-cell reference dataset to deconvolute the bulk mRNA GE to estimate the specific brain cell fractions, which were then incorporated into our models for increased accuracy. We retained only models with an average coefficient of determination (R2) > 0, Z-score p-value < 0.05, and average correlation between the imputed and measured expression > 0.10. Genotype and cell fraction estimates of the testing dataset were used for network analysis to create modules, which were tested for preservation against the measured expression of the training dataset.
Results: At an average R2 of 0.13, 13,445 gene models survived, which were then used to generate a scale-free topology in WGCNA. WGCNA identified 18 imputed modules in the BIP subjects, one of which was associated with BIP at a nominal p-value ≤ 0.05 and 5 others, showing high preservation to the measured expression. In the MDD subjects, we identified 19 modules, with 5 imputed modules preserved between the measured and imputed expressions and 11 modules associated with MDD at a nominal p-value.
Conclusion: The inclusion of cell fractions greatly increases the number of quality models. However, the imputation of these models requires mRNA GE data to estimate cell proportions, which limits its utility.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4426 Variance of Age-specific Log Incidence Decomposition (VALID): Application to female breast cancer.

Authors:

J. Hopper[1], J. Dowty[2], T. Nguyen[3], S. Li[3], G. Dite[3], R. MacInnis[4], E. Makalic[3], D. Schmidt[5], M. Bui[3], J. Stone[6], J. Sung[7], M. Jenkins[3], G. Giles[4], M. Southey[8], J. Mathews[3]; [1]Univ. of Melbourne, Kew, Australia, [2]Univ Melbourne, Carlton, Australia, [3]Univ. of Melbourne, Carlton, Australia, [4]Cancer Council Victoria, Melbourne, Australia, [5]Monash Univ., Carlton, Australia, [6]Univ. of Western Australia, Perth, Australia, [7]Seoul Natl. Univ., Seoul, Korea, Republic of, [8]Monash Univ., Melbourne, Australia

Background: The extent to which known and unknown factors explain how much people of the same age differ in their risk of a disease is fundamental to epidemiology. Risk factors can be correlated in relatives, so familial aspects (genetic and non-genetic) must be considered. Historically, this has been addressed by estimating 'heritability' as a percentage based on a deterministic 'liability'. **Methods:** We developed a unifying model (VALID) by assuming that risk, defined as log(incidence) or logit(cumulative incidence), increases exponentially across risk scores which have standard normal distributions. The variance in risk is Δ^2, where Δ = log(OPERA) is the difference in mean between cases and controls and OPERA is the odds ratio per standard deviation. A risk score correlated r between a pair of relatives generates a familial odds ratio of $\exp(r\Delta^2)$ from which classic familial risk variance decomposition can be applied. There is an upper limit to variance in risk caused by genetic factors, determined by the familial odds ratio for genetically identical twin pairs, but no limit to variation caused by non-genetic factors. We applied VALID to published data on breast cancer risk factors. **Results:** Variance in breast cancer risk is explained by different factors to different extents at different ages. The familial risk ratio, and therefore the familial variance, is greater at younger ages. A substantial proportion of familial variance prior to, but not after, menopause is explained by high-risk mutations in the major genes *BRCA1* and *BRCA2*, a small proportion by the latest polygenic risk score, and a substantial proportion by non-genetic factors shared by sisters or undiscovered recessively inherited genetic factors. Risk factors identified from questionnaires such as reproductive factors and body composition explain little variance in risk. New mammogram risk scores explain as much variation in familial risk as the polygenic risk score and a similar amount of variation in non-familial risk. **Conclusions:** Much is unknown about the finite genetic and familial aspects of breast cancer risk, especially for young women, and very little is known about individual-specific variance in risk which is unlimited. These findings are contrary to those from applying the liability model.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4427 What underlies changes in physiological trait heritability with age?

Authors:

S. Smith, E. Tucker-Drob, **A. Harpak**; Univ. of Texas at Austin, Austin, TX

Understanding how genetic effects on clinically-relevant phenotypes vary with age may provide insights critical to the prevention, treatment and management of diseases of aging. The heritability of complex traits often varies with adult age. However, it is currently unclear whether these differences are driven by changes in genetic architecture, or alternative mechanisms, such as changes in the effects of environmental exposures or changes in the extent of environmental variance. We developed a method to evaluate competing hypotheses observed differences in heritability across age-stratified cohorts. Specifically, across birth cohorts composing the large age-heterogeneous cohorts from the UK Biobank and All of Us data sets, we identify the patterns of change in genetic and environmental variance that underlie age-related differences in the heritability of physiological traits. For instance, in traits related to body size, including height, weight and BMI, we find evidence that decreasing heritability with age is driven by consistent decreases in genetic variance. Conversely, for lipid biomarker traits we show that vanishing heritability with cohort age is primarily driven by increases in environmental variance against a backdrop of relatively stable genetic variance. Our results indicate that the patterns of change in the heritability are trait specific, but are shared within clusters of related phenotypes. Essential to the clinical management of these traits in aging individuals, we show that differences in the heritability estimates of age stratified cohorts can be due to differences in either genetic or environmental variance.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4428 When are aggregation tests more powerful than single-variant tests for rare-variant association studies?

Authors:

D. Bose[1], C. Fuchsberger[1,2], M. Boehnke[1]; [1]Dept. of Biostatistics & Ctr. for Statistical Genetics, Univ. of Michigan, Ann Arbor, MI, [2]Inst. for Biomedicine, Eurac Res., Bolzano, Italy

While single-variant tests have proven remarkably successful in identifying associations in common variant GWAS, their power is substantially less for rare variants. Aggregation tests were developed and shown to have greater power for rare variants in some situations. Despite this, most studies that have employed both types of tests have reported more associations through single-variant tests, even for rare variants. In contrast, recent studies of large biobank-scale datasets have yielded many significant results with aggregation tests. Given these findings, it is of interest to conduct a thorough investigation into the range of genetic models and sample sizes for which aggregation tests are expected to be more powerful than single-variant tests. We consider a normally distributed trait following an additive genetic model with c causal out of v total rare variants in an autosomal gene/region with region-specific heritability h^2, measured in n independent study participants. Under the assumption of independent variants, we calculate analytically the power of single-variant (SV), burden, and SKAT tests to detect associations. Assuming the same minor allele frequency (MAF) for all variants and the same effect size and direction for causal variants, we show that power for all three tests depends on nh^2, c, and v. Next, to account for linkage disequilibrium, we perform simulations based on 378,215 unrelated exome-sequenced White British UK Biobank participants. We investigate power of aggregation and SV tests to detect association for the 1,060 genes on chromosome 2 having at least 1 protein-truncating variant (PTV) over a range of probabilities of the variants being causal. Aggregation tests require us to choose which rare variants in the gene to include in the gene mask for the test with the aim to include causal variants and exclude non-causal ones. We find that power of aggregation tests is highly dependent on the choice of the mask and genetic model. For example, with n=100,000 and h^2=0.1%, when 80%, 50% and 1% of PTVs, deleterious missense, and non-deleterious missense variants respectively in a gene are causal, aggregation tests are more powerful than SV tests for at least 54% of genes with the mask containing only PTVs and deleterious missense variants, but are more powerful for only 24% and 9% of genes with the mask containing only PTVs or PTVs and all missense variants, respectively. Overall, aggregation tests are more powerful than SV tests only when a substantial proportion of variants in the gene is causal.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session III

PB4429 Whole exome sequencing of African-Brazilian extended families with essential hypertension reveals 30 candidate genes

Authors:

A. Nato[1], V. Magalhães Borges[1,2], N. Teruel[3], L. Kimura[2], A. Horimoto[4,5], E. M. Wijsman[5,6], R. Mingroni-Netto[2]; [1]Dept. of BioMed. Sci., Joan C. Edwards Sch. of Med., Marshall Univ., Huntington, WV, [2]Dept. of Genetics and Evolutionary Biology, Univ. of São Paulo, São Paulo, SP, Brazil, [3]Dept. of Pharmacology and Physiology, Faculty of Med., Université de Montréal, Montreal, QC, Canada, [4]Div. of Aging, Brigham and Women's Hosp., Boston, MA, [5]Dept. of Biostatistics, Univ. of Washington, Seattle, WA, [6]Div. of Med. Genetics, Dept. of Med., Univ. of Washington, Seattle, WA

Essential hypertension (EH) is a major risk factor for cardiovascular diseases. EH is a complex disease characterized by elevated systolic blood pressure (SBP) and/or diastolic blood pressure (DBP). In Brazil, the reference values for hypertension are SBP ≥ 140 and/or DBP ≥ 90 mmHg, with 24.3% of the population reported to have hypertension. Global estimates for heritability of EH range from 15-60%. For Brazilian partially-isolated populations of African ancestry (Quilombo populations), the estimated heritabilities of SBP and DBP are 36.1% and 42.9%, respectively. To identify genetic variants contributing to increased EH susceptibility in these Quilombo populations, we conducted whole exome sequencing (WES) analysis on 26 samples from 3 large pedigrees (167 affected, 261 unaffected, and 3 unknown). WES was performed utilizing the IDT xGen Exome Hyb Panel v2, Illumina TruSeq Exome Kit, and Illumina Nextera DNA Exome protocols. WES data obtained from different panels were curated to retain common variants and trimmed to comprise the top 5 chromosomal regions of interest (ROIs) derived from our admixture-adjusted genome-wide linkage analyses results. In this study, we present the findings from our WES analysis assuming the "common disease-common variant" hypothesis. Variant filtering was performed from the annotated VCF file using the following criteria: (1) autosomal, (2) has alternate allele, (3) within exonic/splice site, and (5) allele frequency (AF) ≤ 0.2. Variant AFs were obtained from several datasets, including gnomAD, ExAC, ESP6500, and ABraOM. Synonymous variants were excluded. Our analysis revealed the presence of 57 missense variants in 30 genes within each of the identified ROIs: 17 variants (82.1% marker completion rate (mcr)) within ROI1, 9 variants (90.4% mcr) within ROI2, 6 variants (27.5% mcr) within ROI3, 16 variants (69.2% mcr) within ROI4, and 9 variants (55% mcr) within ROI5. Subsequently, we are investigating the top variants to explore potential interactions of the translated proteins and associated mutations with certain ligands. Our approach allows us to capture and analyze the exonic regions of the genome, which may provide valuable insights about genetic factors underlying EH in these populations. Moreover, these findings not only underscore the genetic diversity and complexity within these genomic regions but also emphasize their potential role in contributing to EH susceptibility. By shedding light on the intricate interplay between genetic variants and their translated proteins, our study deepens understanding of the underlying mechanisms involved in the etiology of EH.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session I

PB4430 Whole genome sequencing interaction study identifies loci with sex-specific effects underlying platelet aggregation traits

Authors:

J. Ngwa[1], M-H. Chen[2], L. R. Yanek[3], B. Gaynor[4], K. Ryan[4], K. Kanchan[5], K. Kammers[1], L. C. Becker[3], M. Taub[1], J. P. Lewis[4], A. D. Johnson[2], N. Faraday[3], R. Mathias[3], I. Ruczinski[1]; [1]Johns Hopkins Univ. Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [2]NHLBI Population Sci. Branch, Framingham Heart Study, Framingham, MA, [3]Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [4]Univ. of Maryland Sch. of Med., Baltimore, MD, [5]Johns Hopkins Univ., Sch. of Med., Baltimore, MD

Platelets play a key role in both hemostasis and thrombosis, and in inflammation, atherogenesis, and cancer metastasis. Whole-genome sequencing (WGS) based association studies have successfully identified several single nucleotide polymorphisms (SNPs) associated with platelet aggregation phenotypes. However, despite strong differences in platelet aggregation between males and females, a comprehensive analysis to elucidate sex-specific genetic effects has not been conducted. In this study, we used sequencing data available through the NHLBI's Trans-Omics for Precision Medicine (TOPMed) program to analyze 19 harmonized platelet traits, in response to using ADP, epinephrine or collagen, in three family-based studies: the AMISH cohort (n=255 participants), GeneSTAR (n=857 participants of European and n=683 participants of African ancestry) and the Framingham Heart Study (n=1476 participants). Linear mixed effects models, as implemented in the GENESIS Bioconductor package, including an interaction term for bi-allelic SNPs and sex were conducted separately for each study using inverse normalized age- and sex- adjusted residuals of the platelet traits as dependent variables, followed by a fixed-effects inverse-variance weighted meta-analysis using METAL. In the primary analysis using a 1 degree of freedom test for the SNP by sex interaction we identified ten SNPs on chromosome 10 below the conventional genome wide significance threshold of $5x10^{-8}$ for two epinephrine aggregation phenotypes. The chromosome 10 peak SNP (rs116725046, $p=5.2x10^{-9}$), located in the long intergenic non-protein coding RNA gene LINC00702, had a mean minor allele frequency (MAF) of 1.5% across all studies. Association of the closest protein coding gene KLF6 with platelet phenotypes was previously reported in the GWAS catalogue, however an in-silico functional analysis based on RNA expression and chromatin accessibility implicates LINC00702 as the regulatory element. In addition, several loci on chromosomes 2, 3, 7 and 11 also showed significant interactions with sex in the genome-wide meta-analysis for epinephrine and collagen. A more targeted analysis also showed sex specific effects for a variant (rs17081713) in the Estrogen Receptor 1 (ESR1) gene on chromosome 6 for ADP aggregation traits. These results provide strong evidence for the existence of sex specific genotype effects for platelet aggregation phenotypes.

Session Title: Statistical Genetics and Genetic Epidemiology Poster Session II

PB4431 X chromosome association study of asthma

Authors:

A. Eslami[1,2], M. Deneus[1], Z. Li[1], N. Gaudreault[1], S. Thériault[1,3], Y. Bossé[1,4]; [1]Inst. universitaire de cardiologie et de pneumologie de Québec, Quebec, QC, Canada, [2]Dept. of Social and Preventive Med., Laval Univ., Qubec, QC, Canada, [3]Dept. of Molecular Biology, Med. Biochemistry and Pathology, Laval Univ., Quebec, QC, Canada, [4]Dept. of Molecular Med., Laval Univ., Quebec, QC, Canada

Context: Asthma is a common respiratory disease with both genetic and environmental risk factors. Heritability estimates for asthma range from 0.55 to 0.90. Numerous genome-wide association studies (GWASs) have been completed and have identified several single nucleotide polymorphisms (SNPs) associated with asthma. However, because of the difficulty in analyzing the X chromosome, these published asthma GWASs are mostly focused on autosomal variants (chromosomes 1-22, non-sex chromosomes) and ignore the sex chromosomes. The prevalence and course of asthma is known to be sex-specific. It is thus important to take into account the effect of the X chromosome in genetic studies. **Aim**: Our research aims to perform X chromosome ssociation in the Quebec City Case-Control Asthma Cohort (QCCCAC) which consists of 1,618 French-Canadian subjects (1,089 asthmatics [660 women and 429 men] and 519 healthy controls [330 women and 199 men]). **Methodology**: Genotyping performed using the Illumina Global Screening Array BeadChip. After filtering and imputation (TOPMed reference panel) , we tested more than one million variants in chromosome X for association analysis using SAIGE (Scalable and Accurate Implementation of GEneralized mixed model) adjusting for age, sex, and the first 20 ancestry-based principal components. **Results**: Five independent variants were identified at a suggestive association threshold of *P*-value less than 1×10^{-5} in the X chromosome analysis. The most significant variant is located in *NHS* gene. The allele frequencies in asthma cases and controls were 0.017 and 0.055, respectively. **Conclusion:** Performing genetic association analysis on the X chromosome is a valuable tool for researchers to gain a better understanding of complex diseases. We will compare several statistical methods to study the association in chromosome X.

PB4432 "Points to Consider" for International Genomic Data Sharing in the Health Technologies Industries

Authors:

B. Knoppers[1], S. Chase[2], Y. Joly[3], A. Thorogood[4]; [1]McGill Univ., Westmount, QC, Canada, [2]Illumina, La Jolla, CA, [3]McGill Univ., Montreal, QC, Canada, [4]Terry Fox Res. Inst., Montréal, QC, Canada

Health Technologies Industries (HTI) contribute unique resources, technologies, and expertise to translating genomic discoveries into improvements in human health. International sharing of human genomic and health data accelerates research and innovation by HTI, strengthening statistical power and reproducibility and facilitating collaboration and creative data re-use. Yet, data sharing raises important ethical issues, such as welfare and privacy risks, and evolving norms of data protection law, AI governance, research ethics, and data sharing.

A "Points to Consider" (PtC) for responsible sharing of genomic and related-health data was developed by the Centre of Genomics and Policy at McGill University in partnership with an Industry Core Group (participant members) from 10 companies. The PtC are tailored for HTI, building on the policies of the Global Alliance for Genomics and Health, namely the Framework for Responsible Sharing of Genomic and Health-related Data.

The Framework aims to activate the human right of everyone to benefit from scientific advancement and its applications, while also recognizing the moral and material interests resulting from any scientific production. The PtC were developed through: a systematic review of legislation, guidelines, and industry practices; 8 international, thematic briefs spanning from identifiability and consent to governance and intellectual property; and a series of consensus discussions.

The PtC aim to be concise and flexible, considering the diversity of HTI sectors, e.g., DTC, pharmaceutics, sequencing platforms, AI, and clinical genomics, as well as data sharing across jurisdictions. The PtC include the following:

- Promoting transparency in consent, data sharing, use of AI, and any return of results. - Assessing and mitigating identifiability risks, while preserving utility, quality and representativeness. - Conducting cross-border transfer impact assessments and employing data localization strategies to support compliance with local norms. - Ensuring data are kept securely, respect the FAIR principles, and are representative. - Balancing data control for legitimate commercial interests with data sharing for the public good ("responsible use"). - Establishing transparent partnerships with academia that respect scientific quality and freedom. - Meaningfully engaging with communities in the development of data sharing plans.

These "Points to Consider" for international genomic data sharing are intended for voluntary adoption by HTI, but can be customized into more prescriptive sectoral best practices or enforceable codes of conduct.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4433 "Think Rare": Harnessing electronic medical record data to shorten the rare disease diagnostic odyssey

Authors:

C. Chisholm[1], A. White-Brown[1,2], G. U. Ediae[3], J. Seymour[3], I. Terekhov[3], N. Mitsakakis[3], S. L. Sawyer[3,1], K. M. Boycott[3,1]; [1]CHEO, Ottawa, ON, Canada, [2]McGill Univ., Montreal, QC, Canada, [3]CHEO Res. Inst., Ottawa, ON, Canada

Rare genetic diseases (RGD) are often unrecognized by non-genetics health care providers, which can delay a patient's referral to a genetics clinic for appropriate evaluation and testing. These delays contribute to the diagnostic odyssey experienced by many patients with RGD. The recent availability of clinical genome-wide sequencing within Ontario has increased access to testing, but as ordering is limited to genetics providers, the current system still relies on non-genetics providers to suspect RGD and refer patients to a genetics clinic. We aimed to address this barrier to referral by developing a tool to search an electronic medical record (EMR) for patients with undiagnosed RGD.
In this retrospective study, we utilized our Epic EMR and the data warehouse at the Children's Hospital of Eastern Ontario to access the clinical health data already stored. Clinical judgement and data availability were used to identify data elements that would be suggestive of RGD: specific diagnostic codes as well as frequency of appointments with multiple subspecialty departments. The selected data elements were used in a rule-based system, to create a search algorithm (named ThinkRare) that was specific to patients with RGD. To evaluate the sensitivity, the algorithm was applied to patients previously evaluated in the genetics clinic known to meet the Ontario genome-wide sequencing eligibility criteria ("gold standard" cohort). The algorithm was then optimized through iteratively testing each version on a test dataset (patients not previously seen in genetics). A manual chart review was completed to confirm if selected patients were a true positive (appropriate selection) or false positive (inappropriate selection).
The algorithm had a sensitivity of 84% in the "gold standard" cohort (n=438). The algorithm was then applied to 262,296 unique patients, and identified 355 patients with data elements consistent with having RGD. Manual chart review revealed that 184 (52%) of those patients would be considered appropriate for a referral to the genetics clinic for evaluation and potential testing; the remaining 48% of patients had a non-genetics explanation for their phenotype. The next steps of this work include clinical evaluations for the 184 patients identified by the ThinkRare algorithm (summer 2023), further algorithm adaptations to improve specificity (ongoing), and ultimately creation of a real-time alert in the Epic EMR for providers to consider a referral to genetics if their patient meets the algorithm criteria (future). The algorithm shows promise in identifying patients suspected to have a RGD and ultimately help providers "ThinkRare".

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4434 † 20k T1d Exomes Cohort In Ukraine

Authors:

T. Oleksyk, W. W. Wolfsberger, K. Shchubelka; Oakland Univ. - Biology, Rochester, MI

Progress has been made in understanding how common genetic variants contribute to the risk of developing type 1 diabetes or T1D. Rare and local variants of low frequency are missed in global analyses but can be strong determinants of disease. In general, rare variants, as a group, have the potential to offer public health insights, explain disease onset and incidence, and represent an under-tapped reservoir of human-based drug discovery. We already collected and sequenced exomes of 3,000 type T1D patients and 3,000 matching controls in Ukraine, and conducted a genome-wide association study with the goal of discovering new genetic factors that affect the development and pathology which could help predict disease, identify therapies to delay progression, and/or improve the life those living with T1D in the region. We describe the progress of this work in the context of the current state of availability of genome data from Eastern Europe, the progress of our research from building a map of genetic diversity in Ukraine and bordering countries, explore ethical and logistic considerations of collecting DNA and consider challenges of big data analysis and sharing.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4435 A compendiumof manually annotated genetic variants for Alkaptonuria-AKUHub

Authors:

V. Radha Krishnan[1], A. Shanmuga Sundaram[1], S. Suresh[1], S. SOUCERADJOU[1], A. Chandramohan[1], R. Mehta[2], J. Jagamoorthy[1]; [1]Zifo Rnd Solutions, Chennai, India, [2]Zifo RnD Solutions, Chennai, India

Alkaptonuria or 'black urine disease' is a rare autosomal recessive disorder caused by dysfunctional homogentisate 1,2-dioxygenase (HGD) gene (3q13.33) leading to accumulation of homogentisic acid in the body. This inborn error in metabolism of phenylalanine and tyrosine causes accumulation of homogentisic acid leading to ochronosis, pigmentation in the sclera, ear cartilage, mitral valve calcification and osteoarthropathy. Advances in sequencing technologies have helped us to map genetic variants associated with alkaptonuria in diverse populations and regions. Currently, no centralized resource of all the reported actionable variants with uniformity in annotation exists for the HGD gene. We have compiled HGD exonic variants from various data sources and systematically annotated their pathogenicity according to American College of Medical Genetics and the Association of Molecular Pathologists (ACMG-AMP) variant classification framework. A total of 1686 exonic variants were catalogued and manually curated, creating one of the most comprehensive Alkaptonuria variant databases (AKUHub) which is publicly available.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4436 A database of genes and mutations associated with *chlamydia species* drug resistance.

Authors:

I. Benamri[1,2], A. Moussa[1], F. Radouani[2]; [1]Natl. Sch. of Applied Sci. of Tangier, Abdelmalek Essaâdi Univ., Tangier, Morocco, [2]Inst. Pasteur du Maroc, Casablanca, Morocco

Chlamydiae are intracellular bacteria responsible for redoubtable diseases in both human and animals. The commonly used drugs against *Chlamydiae* infections are antibiotics. However, the misuse and overuse of antimicrobial agents have resulted in an increase in the appearance of bacterial drug resistance, this phenomenon represents a growing public health problem worldwide. The main goal of this work is to implement a database for genes and mutations associated with *chlamydia species* resistance to drugs. This resource will be a user-friendly support to increase awareness of chlamydia species resistance to antibiotics, and provide support for potential inter investigator comparative studies. After a literature search targeting the collection of studies, we proceeded to a manual curation for all the papers gathered in order to extract the information needed to set up our database. Actually, our proposed database is presented as a web-based user-friendly interface to browse, search and visualise all the genes and mutations associated with *chlamydia species* resistance to drugs, in addition, it provides comprehensive information about *chlamydia species* and the genetic factors causing drug resistance. Hence, the users can easily retrieve and download all requested information.The developed portal is the first resource that gathers genes and mutations associated with chlamydia species drug resistance, it will be a relevant resource for drug resistance exploration based on bacterial genetic information. It will help investigators and physicians to improve the healthcare quality and infected patient’s therapeutic surveillance, to decrease the longer hospital stays, the higher medical costs and decrease the disease's complications. Finally, the database will be periodically updated to improve its services.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4437 A deep population reference panel of tandem repeat variation

Authors:

H. Ziaei Jam[1], Y. Li[1], R. Devito[1], N. Mousavi[1], N. Ma[1], L. Ibra[2], Y. Adam[3], M. Maksimov[1], B. Huang[1], E. Dolzhenko[4], Y. Qiu[4], F. Kakembo[2], H. Joseph[2], B. Onyido[3], J. Adeyemi[3], M. Bakhtiari[1], J. Park[1], S. Javadzadeh[1], D. Jjingo[2], E. Adebiyi[3], V. Bafna[1], M. Gymrek[1]; [1]Univ. of California San Diego, La Jolla, CA, [2]Makerere Univ., Kampala, Uganda, [3]Covenant Univ., Ota, Nigeria, [4]Illumina Inc., San Diego, CA

Tandem repeats (TRs) are elements in the human genome that consist of repeated sequences of motifs, typically one or more nucleotides, and exhibit high variability. The human genome contains approximately 2 million distinct TR loci. Despite their abundance, TRs have proven challenging to study extensively due to the technical difficulties associated with sequencing and genotyping. Several tools, such as HipSTR, GangSTR, adVNTR, and ExpansionHunter, have been developed to genotype TRs using short-read sequencing data. These tools have been utilized to investigate TR variation in population-scale studies involving multiple cohorts. However, the existing methods predominantly capture different sets of TRs, and none encompass the entire range of TR variation. Moreover, the TR callsets generated from these methods have shown a significant bias toward individuals of European ancestry.

In this study, we introduce EnsembleTR, a graph-based approach that combines genotypes from various TR calling methods to produce consensus genotypes for each TR. We utilized EnsembleTR to analyze high-coverage whole genome sequencing data from 3202 samples from the 1000 Genomes Project and 348 samples from the H3Africa Project. As a result, we created a comprehensive reference panel of TR variation across diverse global populations, encompassing approximately 1.7 million TRs. To validate our findings, we conducted fragment analysis on 48 TRs across 31 samples and observed a remarkable concordance rate exceeding 98% when compared with the genotypes obtained using EnsembleTR.

Using the improved data from EnsembleTR, we studied patterns of TR variation across populations. Our catalog recapitulates known patterns, such as higher variation rates in African populations and the relationship between repeat length/motif and heterozygosity rates. We also uncover novel findings, including (1) context sequence features in the immediate flanking regions of repeats influencing TR stability, (2) population-specific repeat expansions, including a CAG repeat in intron 4 of CA10 and a TTC repeat upstream of NEXN that both are specifically expanded in African populations and (3) TRs associated with gene expression. Finally, we generated a phased reference panel that allows accurate imputation of TR variants from SNP data. Our results and analysis provide a genome-wide TR catalog as well as population-level TR characterizations that will open the path for further studies.

PB4438 A familial, telomere-to-telomere (T2T) reference genome for human variation, recombination, and mutation

Authors:

D. Porubsky[1], G. A. Logsdon[1], N. Koundinya[1], W. T. Harvey[1], M. Noyes[1], Z. N. Kronenberg[2], K. M. Munson[1], K. Hoekzema[1], J. Knuth[1], G. Garcia[1], B. S. Pedersen[3], H. Dashnow[3], C. Nolan[2], E. Dolzhenko[2], C. Fanslow[2], C. Lambert[2], T. Mokveld[2], D. W. Neklason[4], W. S. Watkins[3], A. R. Quinlan[3], L. B. Jorde[3], M. A. Eberle[2], E. E. Eichler[1,5]; [1]Univ. of Washington, Dept. of Genome Sci., Seattle, WA, [2]PacBio, Menlo Park, CA, [3]Univ. of Utah, Dept. of Human Genetics, Salt Lake City, UT, [4]Univ of Utah, Dept. of Internal Med., Salt Lake City, UT, [5]Univ. of Washington, Howard Hughes Med. Inst., Seattle, WA

Telomere-to-telomere (T2T) chromosome assemblies generated from diploid samples provide access to complete genetic information, allowing us to revisit fundamental properties of mutation, transmission, and genetic recombination. We have generated deep Pacific Biosciences (PacBio) high-fidelity (HiFi), ultra-long Oxford Nanopore Technologies (ONT), Strand-seq, and Illumina whole-genome sequencing data to construct near-T2T, phased genome assemblies from primary material obtained from a 4-generation (G1-G4), 21-member CEPH reference family (1463). Using Verkko, a hybrid genome assembly pipeline, we created reference genome-grade assemblies that are highly accurate (QV>50) and contiguous (N50 >100 Mbp), resolving both the paternal and maternal haplotypes, including complete centromeres and complex regions of segmental duplications (SDs). We are constructing a comprehensive and validated catalog of >8 million single-nucleotide variants, indels, short tandem repeats, and structural variants for each haplotype from each member and assessing transmission characteristics, including a detailed assessment of inversion polymorphisms that associate with disease risk. In total, we have detected 121 inversions segregating in this family, of which 61 are larger than 50 kbp and flanked by SDs. We discover 72-110 de novo mutations per transmission and show that centromeres are remarkably stable when transmitted from generation to generation. We also sequence resolve the first de novo structural mutation of centromeres, consistent with higher-order repeat (HOR)-mediated changes of α-satellite DNA. We constructed a recombination map across the family and have identified 651 crossovers in G2 and G3 at high resolution (~17 kbp). Using Strand-seq, we are resolving the remaining gaps including complete resolution of the acrocentric arms and their mutation from generation to generation. The use of multiple orthogonal technologies, near-T2T phased-genome assemblies, and a multi-generation family to assess transmission as well epigenetic changes has the potential to create a “truth set” for all classes of human genetic variation upon which to test and benchmark new technologies and understand the most fundamental processes underlying human genetic variation.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4439 † A Gene EXPRESSION RESOURCE TO EVALUATE HUMAN LIVER CELL LINES AS MODELS FOR HUMAN LIVER BIOLOGY

Authors:

B. Halligan[1], Y. Chen[2], A. Oliveri[1], M. Tohme[1], E. Speliotes[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan-Ann Arbor, Saline, MI

Background: Liver disease may affect up to 54% of individuals in some populations. Liver disease is challenging to model in cell model. Primary hepatocytes can be difficult to obtain and dedifferentiate quickly in cell culture. Human hepatocellular carcinoma (HCC) lines can be easily propagated but are often aneuploid and important genes or biological pathways of interest may not be expressed. To aid in determining which cell lines may best human cell biology we used RNAseq to measure gene expression and compared these to normal human primary heptocytes. We also determined exonic variation in these cell lines. We created a new software application, CorrPaths, that reports gene expression and exonic variation across these cell lines to facilitate identifying cell lines suitable for modeling desired aspects of liver biology and diseases. **Methods:** RNAseq was performed on six primary hepatocyte datasets from GEO and compared with RNA seq from HepG2, HepG2-C3A, HuH-7, SNU-475 and THLE-1 cell lines. Gene expression levels for HCC lines were determined using TopHat and DESeq2 and compared to primary hepatocytes with CorrPaths. Select gene expression results were confirmed with Western blotting. Exome sequences from HCC lines were mapped to reference human genome sequences using GATK. **Results:** We found that many of the P450 cytochromes expressed by primary hepatocytes (CYP2E1, CYP2C8, CYP2C9, CYP3A4, CYP2A6) are nearly completely absent in all cell lines. Interestingly, we found all cell lines express the muscle form of glycogen synthase (GYS1) rather than the liver form of glycogen synthase (GYS2). This result was confirmed by Western blotting of GYS1 and GYS2 in HuH-7 cells compared with liver tissue extracts. Genotyping HuH-7 and HepG2 shows that both HuH-7 and HepG2 cell lines are homozygous for the PNPLA3 SNP (rs738409; I148M) known to increase NAFLD making them good models for this disease. The liver specific output from CorrPaths, LiverCellPath, can be used online or offline. It produces an Excel file that can be easily shared with other users, exported to HTML, and can be encrypted for use with sensitive data. **Conclusion:** Choosing the correct model biological system is critical for functional experimentation. Using LiverCellPath as an experimental design tool can guide users to chose a cell line suitable for their biology based on gene expression and exonic variation.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4440 A genome-first approach to cancer phenotypes, penetrance and survival rates of individuals who harbor concurrent pathogenic/likely pathogenic variants in*CHEK2*and other cancer predisposition genes.

Authors:

S. Kim[1,2], M. Ramos[2], J. Kim[2], J. Haley[3], H. Rao[3], U. Mirshahi[3], Discover EHR collaboration, B. Graubard[2], H. Katki[2], D. Carey[3], D. Stewart[2]; [1]Johns Hopkins Med. Inst., Baltimore, MD, [2]Natl. Cancer Inst., Rockville, MD, [3]Geisinger, Danville, PA

Introduction: Using two population-scale exome-sequenced cohorts linked to the electronic health record, we investigated the prevalence and risk of cancer in individuals who harbor a germline pathogenic/likely pathogenic (P/LP) variation in *CHEK2* plus at least one of 14 other cancer-predisposition genes. **Methods:** From Geisinger and UK Biobank (UKBB) (age>18 yr, Geisinger: n=167,060, UKBB: n=469,681), we investigated cancer phenotypes in individuals with concurrent P/LP variants in *CHEK2* and 14 other cancer predisposition genes: *ATM, BARD1, BRCA1, BRCA2, CDH1, MSH6, NF1, PALB2, PIK3CA, PTEN, RAD51C, RAD51D, RECQL* and *TP53*. Electronic health records, cancer, and death registries documented with ICD9 and ICD-10/ICD10-CM codes were used to retrieve cancer phenotypes. The risk of cancers in individuals carrying concurrent P/LP variants in *CHEK2* and 14 other cancer predisposition genes (Group A) were compared with that of total *CHEK2* heterozygotes (Group B) as well as noncarriers. Demographic variables, including age, sex, smoking, alcohol, and body mass index (BMI) were examined as possible confounders using logistic regression. Kaplan-Meier survival curves for survival analyses and reverse Kaplan-Meier curves for age-dependent cancer penetrance were constructed, and hazard ratios were computed based on the Cox Proportional-Hazards model. **Results:** The numbers of individuals were as follows: Group A (Geisinger: n=61, 0.04%, UKBB: n=34, 0.007%) and Group B (Geisinger: n=3,086, 1.9%, UKBB: n=3,192, 0.68%). In UKBB, cancer prevalence was higher in Group A compared to that of Group B (OR:2.32, CI: 1.13-4.75, *P*=0.022), and age-dependent cancer penetrance was significantly increased in Group A versus Group B (*P*=0.011). These observations were not replicated in the Geisinger cohort. Overall survival rate and cancer-related mortality were not significantly different between groups A and B in UKBB and Geisinger. **Conclusions:** Our results of the genome-first approach revealed that individuals who harbor concurrent P/LP variants in *CHEK2* and at least one of 14 other cancer predisposition genes may have an increased risk of cancer and age-dependent penetrance compared to those of *CHEK2* heterozygotes. We anticipate that these results will inform cancer surveillance and genetic counseling.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4441 A harmonized public resource of deeply sequenced diverse human genomes.

Authors:

M. Yohannes[1,2], Z. Koenig[1,2], L. Nkambule[1,2], J. Goodrich[1,2], H. Kim[1], X. Zhao[1,2,3], M. Wilson[1], G. Tiao[1], S. Hao[1,2,3], N. Sahakian[1], K. Chao[1], gnomAD Project Consortium, M. Talkowski[1,2,3], M. Daly[1,2,4], H. Brand[1,2,3], K. Karczewski[1,2], E. Atkinson[1,2,5], A. Martin[1,2]; [1]The Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [4]Inst. for Molecular Med. Finland, Helsinki, Finland, [5]Baylor Coll. of Med., Houston, TX

Underrepresented populations are often excluded from genomic studies due to limited resources supporting their analysis. The 1000 Genomes Project (1kGP) and Human Genome Diversity Project (HGDP), which have recently been sequenced to high coverage, are valuable genomic resources that capture global diversity and embrace open data-sharing policies. To harness the potential of these resources, we harmonized a set of 4,096 whole genomes from HGDP and 1kGP. We identified over 155 million high-quality single nucleotide variants (SNVs), insertions/deletions, and structural variants, revealing more variants compared to existing releases as a result of joint variant calling.

To explore ancestry compositions within geographical and genetic regions, we used global and subcontinental principal component analysis (PCA) and ADMIXTURE analysis. The SNV loadings were made freely available to enable the projection of user cohorts onto a unified reference PC space, allowing for ancestry modeling and inference. Additionally, we measured population genetic differentiation using common variants with Wright's fixation index, F_{ST}, while comparing rare variant sharing through pairwise doubleton counts using f_2 analysis. Comparisons of these divergence metrics provide insights into different historical time points, i.e. older population history with F_{ST} and more recent history with f_2. As expected, we identified more variants among individuals of African descent. Populations also clustered by geographical/genetic regions.

We also examined the relationship between F_{ST} and geographical distance based on great circle distances using the haversine formula, and pairwise geographic distances using five waypoints that reflect human migration patterns. The linear relationship between F_{ST} and distance was different between HGDP and 1kGP. The steeper slope observed in HGDP likely reflected the anthropological design intended to capture more divergent populations, whereas 1kGP represented some of the largest populations.

Importantly, we have publicly released this data without restriction. To facilitate community uptake of this invaluable genomics resource, we have also created two key resources for the genomics community: 1) a resource of haplotypes for phasing and imputation, and 2) detailed tutorials to facilitate common genomic analyses. This jointly called reference panel together with our detailed tutorials will empower genetic studies in diverse populations by equipping researchers with the necessary resources and tools that facilitate scalable and efficient analyses.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4442 A large-scale genomic survey of coding sequence variation in rhesus macaques reveals substantial numbers of predicted damaging variants in disease-related genes.

Authors:

J. Rogers[1], M. Raveendran[1], R. A. Harris[1], H. Doddapaneni[1], D. Muzny[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Coll. Med., Houston, TX

Rhesus macaques (*Macaca mulatta*) are the most widely used nonhuman primate models in biomedical research. This species is a well-documented and valuable model of infectious diseases such as HIV-AIDS, SARS-CoV-2, tuberculosis and others. In addition, rhesus macaques are widely studied as models of neurodevelopment, anxiety and affective disorders, diabetes, obesity, cognitive aging, reproductive biology, endometriosis and other human clinical disorders. We have generated deep whole genome or whole exome sequence data from 2,189 rhesus macaques bred in research colonies from more than 15 different US research centers. The dataset consists of 2,006 Indian-origin animals and 183 Chinese-origin animals. We mapped Illumina short read sequence data to the rhesus reference genome (Mmul_10) and called SNVs and small indels ($\leq$6 bp) using GATK and standard quality filters. The average read coverage for called variants was 42.7x. The Indian-origin animals exhibited 223,142 distinct missense, 3,618 stop gained and 778 splice donor or splice acceptor variants. The average number of SNVs analyzed per Indian-origin rhesus was 51,458. The total missense variants identified among Chinese-origin animals numbered 248,776, with 2,932 stop gained and 656 splice donor/acceptor variants. We mapped the macaque variants over to the hg38 reference genome and used CADD and ClinVar databases to assess the likely functional impact of each variant. There are 42 macaque variants observed more than once across the Indian-origin cohort and scored as "pathogenic" in ClinVar, including mutations that are known in humans to cause multiple myeloma, neurodevelopmental disorder, breast cancer, hypercholesterolemia and others. All the 42 variants have CADD scores of >22. The Chinese-origin rhesus macaques had 17 variants identified in ClinVar as pathogenic, with effects on kidney disease, adrenal disorder and intellectual development disorder among others. Overall, the Chinese-origin animals carry a similar array of predicted pathogenic variants to the Indian-origin animals but represent a smaller proportion of animals available for subsequent research. This dataset is the largest genomic survey reported to date for any laboratory nonhuman primate species. Our results illustrate the potential value of rhesus macaques as spontaneous models for the study of a wide diversity of human genetic diseases. Prior surveys by our lab and others of a smaller number of animals have led to the establishment of macaque models of disease that are currently being used to test novel therapies. These expanded data point towards further opportunities for similar pre-clinical studies.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4443 A novel genomics analysis pipeline identifies mitochondrial somatic variants.

Authors:

K. Patel, J. Kwan, A. Jha; Yale, New Haven, CT

Background: Mutations in mitochondrial DNA (mtDNA) can impair mitochondrial function and can lead to a range of diseases, including those impacting cardiovascular function. The accumulation of somatic mitochondrial variants also contributes to cardiovascular disease but determining somatic mitochondrial variants remains a challenge.
Research question: We sought to evaluate which variant calling algorithms or combinations of them would be able to call somatic mitochondrial variants.
Methods: We used four different variant calling algorithms to extract mtDNA variants from input genomes from the 1000 Genomes Project. Realignment was performed on the patient genetic sample to align their input genome to the "Genome Reference Consortium Human Build 38" (HG38) reference genome. Four algorithms were used to detect mitochondrial variants: Mutect2, DeepVariant, FreeBayes with BCFtools, and Mutserve.
Results: The results show that Google's DeepVariant and GATK Mutect2 are the most effective algorithms for detecting mitochondrial variants. FreeBayes with BCFtools failed to detect any mitochondrial variants. DeepVariant identified a total of 17 variants, 12 of which had a quality score greater than 30. Mutect2 detected the greatest number of mitochondrial variants with 407 variants detected. Mutect2 found all but one variant that DeepVariant detected.
Conclusions: Although the variants we found came from a healthy patient population, we were able to identify mitochondrial somatic variants. We are currently using machine learning methods to create a customized machine learning method and apply this on larger patient cohorts like the UK Biobank and TOPMed to detect somatic mitochondrial variants that are associated with CVD and can predict outcomes.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4444 A novel mouse model of uveal coloboma arises from genetic rearrangement on Chr13.

Authors:

Y. Wang[1], R. P. Alur[1], V. Kalaskar[1], A. George[1], E. Boobalan[1], A. Dutra[2], E. Pak[2], J. Thomas[2], L. Dong[1], M. Fruttiger[3], S. Pieke-Dahl[4], P. Hitchcock[4], B. Brooks[1]; [1]Natl. Eye Inst., Bethesda, MD, [2]NHGRI, Bethesda, MD, [3]Univ. Coll. London, London, United Kingdom, [4]Univ. of Michigan, Ann Arbor, MI

Purpose: Uveal coloboma is a congenital ocular malformation, caused by failure of the optic fissure to close at the 5th week of human gestation and at embryonic 11.5 days (E11.5) in the mouse. Currently, several genetic mutations that cause the disease have been identified. However, the genetic mechanisms by which the chromosomal rearrangement instigates optic fissure closure defects are poorly understood. Here we found that random insertion of a transgene (NSE-hVEGF) on chromosome 13 (Chr.13) of C57BL/6J mice generated an obviously retinal and iris coloboma (RICO). The region of insertion did not suggest any previously identified human coloboma genes. Therefore, it represents a novel dominant animal model of uveal coloboma. **Methods:** RICO mouse was generated by random insertion of transgene human VEGF driven by rat Neuron Specific Enolase (NSE) promotor on Chr.13. RICO mouse and embryos were analyzed via detailed histopathology. The insertion site was evaluated with the combination of Fluorescence In Situ Hybridization (FISH), Comparative Genomic Hybridization (CGH), BAC library construction, and whole-genome shotgun sequencing of RICO genomic DNA. The hVEGF RNA expression was detected by Basescope, and the inversional genes expression was evaluated by qRT-PCR at E11.5. **Results:** Transmission of RICO mice was autosomal dominant with nearly 100% penetrance. The uveal coloboma in mice are usually bilateral, affecting the retina, iris and optic nerve. FISH assay indicated the insertion site of the transgene at mouse Chr.13. Shotgun Sequencing analysis revealed that the chromosomal rearrangement occurred specifically between two distinct loci (4 Mb apart) in Chr.13, and about 20 copies of hVEGF transgene was inserted. The region of insertion did not suggest any previously identified human coloboma genes. CGH array shows no large duplications or deletions on Chr.13 after transgenic insertion. qRT-PCR results showed that a few development-related genes were altered in rearranged region. Basescope assay observed the specific hVEGF RNA expression in the margin of optical fissure at E11.5 of RICO mouse. Interestingly, insertion of hVEGF transgene into other chromosomes of independent lines of transgenic mice did not generate the RICO phenotype. **Conclusions:** Insertion of the hVEGF transgene into Chr.13 alter the genetic rearrangement and generate classic uveal coloboma in C57BL/6J mice. This transmission is autosomal dominant with nearly 100% penetrance. This result provides a new animal model to further understand the genetic and molecular mechanism of uveal coloboma.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4445 Accelerated workflows for analyzing long-read sequenced genomes in the NIH All of Us Program

Authors:

E. Dawson[1], L. Slim[1], L. Paulin[2], F. J. Sedlazeck[2,3,4]; [1]NVIDIA, Santa Clara, CA, [2]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [3]Human Genetics Ctr., Sch. of Publ. Hlth., Univ. of Texas Hlth.Sci. Ctr., Houston, TX, [4]Dept. of Computer Sci., Rice Univ., Houston, TX

The All of Us Project is a massive national sequencing initiative to gather health data from one million individuals in the US, with a focus on improving representation within genomic studies. This includes nearly 25,000 genomes to be sequenced using the Oxford Nanopore Promethion long read sequencing platform. To support the analysis of this data, we present a set of GPU-accelerated workflows that can be deployed locally or in cloud bioinformatics platforms. These workflows support basecalling, alignment of reads as well as variant calling of SNVs, indels and structural variants and phasing of small variants using a combination of best-practice tools. By incorporating a series of accelerated tools, we provide best-in-class performance and accuracy.

Leveraging these workflows in the cloud significantly increases the throughput of analyzing many genomes while also improving ease of use and the comprehensiveness across all variant classes. We demonstrate the accuracy of our workflows on the Genome-In-A-Bottle HG002 sample and provide runtime and cost numbers for a variety of depths of ONT data.

Standardized workflows provide an important community resource for reproducibility and a basis for further development. Cost-optimized workflows also make such analysis more accessible. These workflows can be adopted for Oxford Nanopore or PacBio data and scale from small to large labs. Our open-source workflows provide a best-practice starting point for long read studies and demonstrate the power of GPUs and workflows to democratize access to cutting edge bioinformatics analysis. They represent an approach for unifying and harmonizing variant calling across multiple larger consortia, generating a valuable resource for later studies relying on variant comparisons and allele frequency data. Furthermore, this harmonized workflow enables population merging of samples across ethnicities and as such represents a significant step forward for standardization for potential imputation servers to leverage the obtained long read data.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4446 An automated quality control system for the biochemical genetics laboratory.

Authors:

P. Tanpaiboon[1], D. Salazar[2], L. T. Xu[1], R. Sharma[1]; [1]Quest Diagnostics, San Juan Capistrano, CA, [2]Quest Diagnostics Nichols Inst, San Juan Capistrano, CA

Background: Quality control (QC) in any clinical laboratory is critical to ensuring quality and accuracy of patient results. However, QC monitoring is complicated in the multi-analyte, multi-instrument assays common to biochemical genetics laboratories. An ineffective QC review can impact laboratory productivity, data accuracy, troubleshooting, audit preparedness, and client satisfaction. Comprehensive off-the-shelf QC management systems optimized for such highly complex assays and platforms are relatively scarce. A manual QC review process can impact laboratory productivity and increase risk of errors. In contrast, commercially available software may lack the ability to nimbly adapt to new assay requirements, which is crucial for large laboratories with comprehensive test menus and various assay platforms. Here we describe a novel software application that integrates, processes, and displays QC statistical parameters from multiple instruments in real time. Methods and Results: A customizable, cloud-based software application was developed to automate QC review and monitor assay performance. This QC program has modules for different assay platforms including complex mass spectrometry, chemistry analyzer, ELISA, and fluorescence-based plate reader assays. The program's functions include automated collection and analysis of assay data, Levey-Jennings charts with integrated data from multiple instruments-multiple HPLC channels, graphical data visualization, instrument data consolidation and centralization, assay monitoring, tracking of tests not performed, and a time-stamped QC audit trail. The program also generates automated email notifications for pending QC lot expiration, weekly/monthly review reminders, and alerts about abnormal patient results that enable prompt communication to providers. The software was developed and has been maintained by the Quest Diagnostics Bioinformatics team. The program was written in PHP and JavaScript using the Symfony 4 framework and Microsoft SQL Server, and hosted on internal servers via a Docker container instance. The servers are securely connected to Quest's network, and all users must have a security clearance from Quest before gaining access. There are several access levels to limit what a user can do.Conclusion: This program may improve assay quality and provide significant time savings (approximately 4 hours/day) by automating data entry and eliminating clerical errors. One benefit of this software is the ease of updating program capabilities and customizing them to meet specific and changing needs.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4447 An imputation panel with disease-enriched variants for improving single-nucleotide and structure variants discovery on array data in Alzheimer's Disease

Authors:

P-l. Cheng[1], H. Wang[1], I. Horng[1], B. Dombroski[1], L-S. Wang[2], B. Vardarajan[3], G. Tosto[3], J. Farrell[4], B. Kunkle[5], G. Schellenberg[6], W-P. Lee[1]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]UPENN, Philadelphia, PA, [3]Columbia Univ., New York, NY, [4]Boston Univ Med, Laconia, NH, [5]Univ. of Miami, Miami, FL, [6]Univ Pennsylvania Sch Med, Philadelphia, PA

The discovery of structural variants (SVs) and short insertions/deletions (indels) is largely improved with the use of whole genome sequences (WGS) and has been demonstrated as a genetic factor associated with Alzheimer's disease (AD). Compared to WGS, genotype-array is cost-effective and has more data available than WGS for AD research. However, due to technology limitation, genotype-array is unlikely to support SV discovery. Although imputation could infer unobserved genotypes in a sample, current reference panels contain either none or a limited number of SVs, and thus disease-specific reference panels can outperform public reference panels when imputing disease causing variants. We first constructed an AD-specific panel including 51,459,037 single-nucleotide variants (SNVs) and 3,322,380 indels of 16,564 sequenced genomes from the Alzheimer's Disease Sequencing Project (ADSP). To assess the performance of our AD-specific panel, we performed imputation on 38,271 genotypes from Alzheimer's Disease Genetics Consortium (ADGC) and compared the imputation generated by our AD-specific panel with the one from TOPMed panel. Our AD-specific panel exhibited superior performance in rare variants. For example, rare exonic indels in ANO7, ZNF656, SCRT2, ABCA7, and PPDPF genes could only be imputed by our panel. Laboratory validation by PCR confirms the true imputation of these indels. To leverage the strengths of both the TOPMed and our AD-specific panels, we employed meta-minimac2 to combine imputations. The result shows that while the TOPMed panel demonstrated better performance in imputing common SNVs, our AD-specific panel was able to capture the rare disease-specific linkage disequilibrium (LD) structure that was overlooked by publicly available reference panels. Furthermore, we demonstrated extending the knowledge of indels gained from WGS to genotype-array data. To impute SVs, we incorporated 210,429 high-quality SVs, which were detected on ADSP WGS samples, into the panel. By using this SNP-SV panel, we successfully imputed SVs, ranging from 57bp to 39kb, located within AD risk loci, such as BIN1, PILRA, PLCG2, ADAM10, ABCA7, and APP, as well as genes found significant in association tests, such as NCK2, WDR12, TMEM106B, JAZF1, PLEKHA1, TPCN1, IGH, and WNT3/MAPT. The imputation quality of these AD related SVs on 38,271 genotypes was excellent in with R2=0.80±0.17. The project could effectively increase sample size for GWAS studies, enable SV discovery in numerous array data of AD, and facilitate finding novel genetic associations of AD.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4448 Analysis of targeted and whole genome sequencing of PacBio HiFi reads for a comprehensive genotyping of genic and phenotype associated Variable Number Tandem Repeats.

Authors:

S. Javadzadeh[1], A. Adamson[2], J. Park[1], S-Y. Jo[3], Y-C. Ding[2], M. Bakhtiari[1], S. Neuhausen[4], V. Bafna[5]; [1]Univ. of California San Diego, La Jolla, CA, [2]Beckman Res. Inst. of City of Hope, Duarte, CA, [3]Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of, [4]Beckman Res. Inst. of City of Hope, Duarte, CO, [5]Univ. of California, San Diego, La Jolla, CA

Variable Number Tandem Repeats (VNTRs) have repeat motif lengths greater than 5 bp. They have been associated with Mendelian and complex disorders but their complex structures are challenging to genotype. Of 10,529 gene-proximal VNTRs, nearly 40% exceeded Illumina short-read length (140 bp). Similarly, 60% of 53 phenotype-associated VNTRs (P-VNTRs) were long, requiring long-reads for precise genotyping. We explored the trade-off in scope (how many VNTRs) and coverage between targeted and whole genome HiFi sequencing for genotyping long VNTRs. We designed customized probes for 10,529 VNTRs and sequenced 7 samples for PacBio HiFi and Illumina sequencing followed by adVNTR genotyping. We compared these results with HiFi whole genome sequencing (WGS) data from 28 samples in the Human Pangenome Reference Consortium (HPRC).
Only 3,981 (38%) VNTRs and 4 of 53 P-VNTRs were spanned with > 15 reads using targeted probes. All 10,529 VNTRs showed high consistency of read coverage across the 7 samples (coefficient of variation CoV = 0.08), implying that the VNTR sequence, rather than individual samples, dictated the number of spanning reads. A smaller subset of 2,876 (1,422) VNTRs had very high median coverage of at least 50 (100) spanning reads. Among 5,638 VNTRs with low-coverage (<15), 67% were located within GC-rich regions (>60%). For another 16%, the closest probe was at least 1,000 bp from the VNTR possibly due to low-complexity intervening sequence. We also tested adVNTR genotype calls for overlapping VNTRs between Illumina and HiFi sequencing and obtained 97.4% consistency, with lack of spanning reads as the main reason for genotype discrepancy. Thus, good coverage is essential for accurate genotyping, but is possible only for a subset of targeted VNTRs.
In contrast, on the 40X WGS HiFi dataset, we captured 98% of all VNTRs and 49 (92%) P-VNTRs with > 15 spanning reads, albeit with a higher CoV (0.22). Among P-VNTRs,16% were highly polymorphic in repeat count (motif CoV up to 0.8), highlighting the importance of correct genotyping. Our findings demonstrate that targeted sequencing provides high and consistent coverage for a smaller subset of low-GC VNTRs, but WGS is more effective for broad sampling of a large number of VNTRs and P-VNTRs with sufficient coverage. The VNTR genotypes (repeat motif counts) for 10,529 VNTRs in 28 samples from the HPRC WGS cohort, will be provided as a resource for the community.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4449 Analyzing bivariate cross-trait genetic architecture in GWAS summary statistics with the BIGA cloud computing platform

Authors:

Y. Li[1], F. Xue[1], B. Li[1], Z. Fan[2], J. Shu[3], J. Lin[4], X. Wang[1], C. Copana[1], B. Zhao[5]; [1]Purdue Univ., West Lafayette, IN, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Purdue Univ., Lafayette, IN, [4]Yale Univ., New Haven, CT, [5]Univ. of Pennsylvania, Dept. of Statistics and Data Sci., Philadelphia, PA

As large-scale biobanks provide increasing access to deep phenotyping and genomic data, genome-wide association studies (GWAS) are rapidly uncovering the genetic architecture behind various complex traits and diseases. GWAS publications typically make their summary-level data (GWAS summary statistics) publicly available, enabling further exploration of genetic overlaps between phenotypes gathered from different studies and cohorts. However, systematically analyzing high-dimensional GWAS summary statistics for thousands of phenotypes can be both logistically challenging and computationally demanding. In this paper, we introduce BIGA (http://bigagwas.org/), a website that offers unified data analysis pipelines and centralized data resources for cross-trait genetic architecture analyses using GWAS summary statistics. We have developed a framework to implement statistical genetics tools on a cloud computing platform, combined with extensive curated GWAS data resources. Through BIGA, users can upload data, submit jobs, and share results, providing the research community with a convenient tool for consolidating GWAS data and generating new insights.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4450 Ancestry determination using REVEAL: VariantBank, an efficient storage, management, and computational analysis platform for VCF files

Authors:

M. Peterson, W. Jack, C. Garay, J. Zahiri, Z. Pitluk, S. Sarangi; Paradigm4, Inc., Waltham, MA

The growth in availability and accessibility of genomics data is transforming precision medicine and healthcare. Large genomic datasets provide numerous benefits such as targeted drug discovery, personalized treatment strategies based of pharmacogenomics, and expanding our understanding of disease, especially when ethnic cohorts can be created for complex diseases where multiple genetic factors are at play. However, conducting population genomics studies at scale present a variety of challenges such as - i) high-performance storage that is scalable, distributed, and supports both structured and unstructured data types; ii) efficient data management for querying, retrieval, and integration into existing pipelines; iii) versioning, security, and data provenance; iv) easy to use interfaces that employ elastic scaling for computational analyses; v) ability to query complementary multiomics data. In this work, we evaluated REVEAL, a bioinformatics platform developed by Paradigm4, for storage, management, and analysis of publicly available genomics data in the Variant Call Format (VCF). The VCF is a text file format generated during the variant calling process that contains genomic information, locations of variants in a group of sequenced samples, and associated metadata (e.g., version number, software, reference genome used). REVEAL facilitates easy loading of VCF files from cloud or local storage (e.g., AWS S3 bucket) into *flexFS*, a POSIX-compliant networked file system designed for high-throughput data transfer across thousands of nodes. Associated phenotypic data and sample metadata (e.g., biochemical measurements or prescription records) is also stored and organized into n-dimensional arrays, which are accessible via REST, R, and Python API's. REVEAL utilizes elastic scaling called Burst to run computational analyses such as VEP annotation or ancestry determination algorithms. The datasets that we loaded using REVEAL comprised of sample/ individual level gVCF files from the 1000 Genomes Project, Human Genome Diversity Project, and Simons Genome Diversity Project. Using the APIs we demonstrate querying of the VCF's for use cases such as identifying individuals with particular gene mutations, finding most frequent variants within gene regions, among others. We also show a scalable workflow for annotation with dbSNP using VEP, and finally we present results from implementing an machine learning algorithm, XGBoost, for ancestry determination in REVEAL.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4451 Annotation and scoring of the deleteriousness of individual genetic variants in the 4th release of the Alzheimer's Disease Sequencing Project

Authors:

N. Kannan[1], N. Wheeler[1], Genome Center for Alzheimer's Disease, L-S. Wang[2], Y. Leung[2], W. S. Bush[1]; [1]Cleveland Inst. for Computational Biology, Dept. for Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [2]Dept. of Pathology and Lab. Med., Penn Neurodegeneration Genomics Ctr., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

The Alzheimer's Disease Sequencing Project (ADSP) is a genetics initiative instituted by the National Institute of Aging to understand the genetic architecture of Alzheimer's Disease and related dementias. ADSP recently released its 4th (R4, latest) dataset consisting of 36,361 sequenced genomes, which contains genotype calls for 362 million genetic variants, the vast majority of which are rare.

Late Onset Alzheimer's Disease (LOAD) is highly polygenic, with much of its genetic architecture unknown. Predicting and scoring of the biological effects of individual variants provides valuable information when testing these variants for association with LOAD, and facilitates identification of novel associations.

We deployed CADD (Combined Annotation Dependent Depletion), SnpEff, and Ensembl VEP (Variant Effect Predictor) variant annotation and effect prediction tools locally to score potential impact and deleteriousness of ADSP R4 variants.

CADD provides both "raw" C-scores (that directly describe deleteriousness of a variant) and "scaled" C-scores (that describe the rank of deleteriousness of the variant relative to all other possible substitutions). A variant with a scaled C-score >= 10 is among the top 10% most deleterious substitutions possible for the human genome.

SnpEff was used to specifically predict potential LOF(Loss of Function) effects. We observed 1.9 million missense variants (0.76%), 76,672 frameshift variants (0.03%) and 754,927 splicing-related variants (0.3%) based on VEP consequence predictions. 443,333 variants (0.12%) were predicted to be LOF by snpEff.

Variants with predicted LOF had a average raw C-score of 1.98, while variants without predicted LOF had a significantly lower mean raw C-score of 0.40 ($t = 789.10$, $p < 0.001$), as expected. Conversely, among 443,333 variants with predicted LOF, 18,858 (4.25%) had C-scores >= 10, while 27,878,923 (7.68%) of variants without predicted LOF had C-scores >= 10 ($\chi^2 = 7377.20$, $df = 1$, $p < 0.001$).

Notably, the snpEff LOF designation only applies to coding variants, so the relative enrichment of higher C-scores for non-coding variants may indicate the presence of regulatory variants with equivalent deleterious effects to those observed in coding regions.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4452 Applying ACMG/AMP Variant Curation Guidelines for SCID - ClinGen SCID VCEP Recommendations

Authors:

M. Zelnick[1,2], V. Jacovas[1,2], K. Namrata[1], X. Pan[1], S. Martin[3], J. Ross[4], B. McLean[4], S. McNulty[5], M. Cowan[6], J. Puck[7], M. Hershfield[8], J. Verbsky[9], J. Walter[10], E. Chinn[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Texas Children's Hosp., Houston, TX, [3]Invitae Corp., Fort Lauderdale, FL, [4]Univ. of North Carolina Chapel Hill, Chapel Hill, NC, [5]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [6]Univ. of California San Francisco Benioff Children's Hosp., San Francisco, CA, [7]Univ California San Francisco, San Francisco, CA, [8]Duke Univ Med Ctr, Durham, NC, [9]Med. Coll. of Wisconsin, Milwaukee, WI, [10]Univ. of South Florida, Tampa, FL, [11]Seattle Children's Hosp., Seattle, WA, [12]UT Southwestern Med. Ctr., Dallas, TX, [13]NIH, Bethesda, MD, [14]Prevention Genetics, Marshfield, WI, [15]Human Genome Sequencing Ctr., Houston, TX

Introduction: The Clinical Genome Resource (ClinGen) has established Clinical Domain Working Groups (CDWG) across various medical subspecialties. The Immunology CDWG was created in 2019 to uncover the relationships between genes and variants connected with Inborn Errors of Immunity (IEI). Severe Combined Immunodeficiency Disease (SCID) is a rare IEI resulting in severe T- and B-cell immunodeficiency and heightened infection susceptibility. Without rapid diagnosis and definitive treatment, SCID typically results in mortality in the first year of life. Currently, variations in 19 genes result in SCID. The role of the Variant Curation Expert Panels is to provide evidence-based interpretations of genomic variants to aid in rapid SCID diagnosis and promote precision clinical care. The ClinGen SCID VCEP aimed to establish gene-specific guidelines for variant classification since there was a lack of gene-specificity in the 2015 guidelines provided by the American College of Medical Genetics and Genomics (ACMG)/Association for Molecular Pathology (AMP).
Methods and Findings: The SCID VCEP developed 20 rules from the 28 ACMG/AMP criteria to accurately interpret variants with seven SCID-associated genes. The genes of interest include those most commonly identified as defective in North American SCID cases: *IL2RG*, *JAK3*, *ADA*, *DCLRE1C*, *IL7R*, *RAG1*, and *RAG2*, with slight differences in rules applied between each gene. The new criteria were tested on both common and rare variants to ensure the effectiveness of the specifications. To confirm validity, all variants were curated in pairs, and reviewed by both Immunology and genetics experts. The feedback led to iterative refinements of the specifications during pilot testing of the specifications. This process resulted in comprehensive and finalized guidelines ready for implementation in the sustained phase of curation.
Conclusions: This standardized and evidence-based interpretation of genetic variants associated with SCID is essential to ensure accurate diagnosis, effective clinical management, and informed genetic counseling for affected families.The efforts of the SCID VCEP represent a significant step forward in our understanding of SCID and its associated genes. It has the potential to elucidate pathogenicity, enhancing clinical decision-making and improving overall patient outcomes significantly. The rigorous process of curation and expert evaluation has yielded specifications that are finely tuned and designed to meet the highest clinical standards of accuracy and precision.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4453 Assessing and addressing the burden of VUSs within adult medical genetics practices

Authors:

A. Stergachis, A. Folta, A. E. Sedeno Cortes, M. Jose, M. Horike-Pyne, A. E. McEwen, S. Fayer, L. Starita, M. Dubard-Gault, F. M. Hisama; Univ. of Washington, Seattle, WA

Genomic medicine aims to use patient-level genetic data to improve clinical care. However, the majority of clinically encountered variants are classified as variants of uncertain significance (VUS), which cannot be used for making clinical decisions given their unknown relationship to disease. To better understand the burden of VUSs within clinical medicine, we created the Brotman Baty Institute Clinical Variant Database (BBI-CVD), which is an electronic health record linked (EHR-linked) database of phenotype and clinical germline genetic variant information from ~4,000 patients with rare genetic disorders cared for at two adult tertiary medical centers. We demonstrate that the VUS burden is not equally shouldered across different patients at these centers. Specifically, certain testing indications result in >3-fold higher rate of VUS identification relative to pathogenic (P) or likely pathogenic (LP) variants. For example, 2.52 VUSs are returned for every P/LP variant identified in someone undergoing testing for cardiomyopathy, whereas the rate of VUSs to P/LP variants was 0.74 in individuals undergoing testing for sensorineural hearing loss. In addition, we found that individuals with different self reported ancestry had markedly different rates of VUS identification. For example, 2.49 VUSs are returned for every P/LP variant identified in individuals identifying as Black or African American, whereas the rate of VUSs to P/LP variants was 0.98 in individuals identifying as European ancestry. Finally, we demonstrate that we can leverage the BBI-CVD in conjunction with emerging variant-level functional data to enable the reclassification of VUSs for individual patients cared for at these medical centers. Specifically, integration of BRCA1 functional data with the BBI-CVD enabled us to reclassify one patient's VUS as LP and two patients' VUSs as likely benign, enabling updated care recommendations by their providers. Overall, the BBI-CVD helps illuminate the real-world burden of VUSs within adult tertiary medical genetics practices, and offers a resource to improve the diagnosis and care of patients with rare disorders.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4454 Assessing the Usage of Human Phenotype Ontology Terms in Facilitating Discovery of Disease Causal Genes

Authors:

J. Chan[1], K. Wang[2,3]; [1]The Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Phenotypic abnormalities are often associated with genetic disorders and analyzing these abnormalities can assist physicians in identifying potential disease-causing genes in patients with rare diseases. In this study, our objective is to evaluate the effectiveness of computationally generated Human Phenotype Ontology (HPO) terms in identifying disease causal genes in patients with genetic diseases. The CHOP Arcus database contains over 71,000 patients diagnosed with genetic diseases, each of whom has associated HPO terms generated by natural language processing algorithms on clinical narratives. By employing gene prioritization tools and leveraging the HPO terms, we conducted an analysis to determine the ability of using HPO terms to facilitate the discovery of causal genes or diseases. For a subset of patients, we also compared the results from computationally generated HPO terms with those generated by human experts during patient encounter. Our results suggest that phenotypic information can facilitate physicians to effectively narrow down their focus when assessing potential avenues for diagnosis or treatment.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4455 Barriers to Uploading Genetic Testing Report to Online Patient Data Sharing Registry

Authors:

B. VanHoute[1], J. M. Savatt[2], C. Cooney[3], A. M. Rossel[1], C. Ineke[1], A. Morgan[4], D. Azzariti[5], H. L. Rehm[6], C. L. Martin[2], E. R. Riggs[7]; [1]Geisinger, Lewisburg, PA, [2]Geisinger, Danville, PA, [3]Geisinger, Jersey City, NJ, [4]Geisinger, Kingston, PA, [5]ClinGen Resource, Cambridge, MA, [6]Broad Inst., Cambridge, MA, [7]Geisinger, Huntsville, AL

Purpose: GenomeConnect, the Clinical Genome Resource (ClinGen) patient registry, enables participants to share their genetic and health data. Structured genetic data collected from participant-uploaded reports, along with participant-provided phenotypes, are shared with databases, such as ClinVar, improving overall genomic knowledge. Participants are also able to learn about research opportunities, connect with others with similar variants and receive updates about their genetic results. Although many benefits of the registry rely on individuals sharing their genetic reports, to date only 1,656 of 4,778 participants (34.7%) have shared a report. This ongoing study aims to investigate barriers to report sharing.
Methods: A brief online survey was distributed to all consented and eligible participants that had not uploaded a genetic report as of May 2023 (n=2,351). The survey included skip logic, inquiries about the results of the participant's testing, recollection of reminder emails, demographic questions, an option to participate in a semi-structured interview, and instructions for how to upload a report.
Results: As of June 2, 2023, 102 participants completed the survey (4.3% response rate). This survey is ongoing with an expected end date of June 17, 2023. Of respondents, the majority recalled GenomeConnect participation (n=78/102, 76.5%) and were interested in sharing a genetic report (n=56/70, 80.0%). Many respondents indicated they did not have a copy of the report (n=17/70, 22.9%), did not know uploading was part of participation (n=18/70, 25.7%), forgot (n=11/70, 15.7%), experienced difficulty (n=25/70, 35.7%), or did not have time (n=7/70, 10%). Only 4 respondents (5.7%) reported privacy concerns, and other barriers such as a lack of benefit were selected by single participants. Since survey distribution, 69 recipients shared a report or indicated they would like GenomeConnect to directly request their results.
Conclusions: Our study demonstrates that the majority of respondents are willing to share their genetic report as part of GenomeConnect participation. Factors impacting sharing are related to report availability and the upload process. Future work, including semi-structured interviews, will further characterize barriers to report sharing and inform strategies to support participants. Survey data alone suggest a need to revisit current resources, such as email reminders, videos, and email instructions, and to explore the creation of additional report sharing supports. Ultimately, engaging as many patients in data sharing as possible will improve understanding of genes and genomic variants.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4456 Batch ClinVar Submission Support in ClinGen's Variant Curation Interface (VCI)

Authors:

M. Wright[1], C. Preston[1], G. Cheung[1], M. Mandell[1], B. Wulf[1], L. Babb[2], M. DiStefano[2], S. Harrison[3], C. Klein[1], R. Shapira[1], I. Keseler[1], D. Ritter[4], N. Shah[4], K. Riehle[4], A. Milosavljevic[4], S. Plon[5], T. Klein[1], Clinical Genome Resource (ClinGen); [1]Stanford Univ. Sch. of Med., Palo Alto, CA, [2]The Broad Inst., Boston, MA, [3]Ambry Genetics, Salt Lake City, UT, [4]Baylor Coll. of Med., Houston, TX, [5]Baylor Coll. Med., Houston, TX

The NIH-funded Clinical Genome Resource Consortium (ClinGen) Variant Curation Interface (VCI) is a global, open-source variant classification platform for supporting the application of evidence criteria and classification of variants based on the ACMG/AMP sequence variant classification guidelines. To facilitate evidence-based improvements in human variant classification, the VCI is publicly available to the worldwide genomics community. The VCI is among a suite of tools developed by ClinGen, and supports an FDA-recognized human variant curation process of ClinGen Variant Curation Expert Panels (VCEPs). ClinGen is expanding to involve more curators and teams of curators working today (affiliations) as part of an increasing scale of activities that will increase genetic variants across a greater number of genes. The variant curation workflow is intended to support dissemination of variant curations into two repositories: the ClinGen Evidence Repository (for approved ClinGen VCEPs) and ClinVar. Support for dissemination of curations into the Evidence Repository from the VCI is an API-driven process via the ClinGen Data Exchange; however, support for ClinVar submission from the VCI has been largely manual to date. Here we present the first in a series of planned software features to provide a better ClinVar submission experience for VCI users. This batch submission feature allows users to create an active batch of curated variants and then download a pre-formatted file of the curation data, which can easily be submitted to ClinVar. This provides a faster process for users submitting variant interpretations to ClinVar. It also allows VCI users to annotate which of their curations have been submitted to ClinVar. Future feature plans for ClinVar submission from the VCI include providing VCI users with real-time feedback on the status of their ClinVar submissions, as well as direct API-based submissions from the VCI. These features together will further streamline workflows for both ClinGen VCEP and non-ClinGen VCI users, and support the ClinGen goal of creating scalable curation workflows to support the clinical genomics community.

Title: Black and African American Connections to Parkinson's Disease Study

Aim: BLAAC PD is a multi-center study recruiting Black and African American individuals with Parkinson's Disease (PD) and healthy controls. BLAAC PD aims to provide a platform for replication studies to explore the relevance of genetic findings reported in other populations and investigate genotype-phenotype correlations. The ultimate goal is to create a foundational cohort to assess diverse aspects of PD in this historically excluded population and serve as a model for diversity and equity in research.

Background: Understanding genetic mechanisms across diverse populations can provide unique insights into complex traits like PD. Our current insights of the genetics underlying PD etiology has been disproportionately based on European ancestry populations. This has led to a significant gap in our knowledge about the disease's genetics and clinical characteristics in underrepresented populations, particularly individuals of African and African admixed ancestries.

Materials & Methods: BLAAC PD collects samples from six sites across the United States. A total of 147 cases and 174 controls have been collected. Following DNA extraction, samples are genotyped and imputed, followed by ancestry assessment through a pre-trained machine learning model based on reference sample series. A comprehensive assessment was conducted to investigate known and novel genetic contributors.

Results: Our analyses showed consistent differences in variant frequencies, magnitude of effects and risk alleles for disease-causing mutations in PD known genes including SNCA, VPS35, LRRK2, PRKN, PINK1, DJ1 and GBA. Additionally, we screened genetic risk loci known to be associated with PD in multiple ancestral populations including over 100 loci. We also assessed structural variants in early-onset and familial PD cases.

Discussion: These findings highlight the need for diverse representation in genetic research. Insufficiently diverse genetic data may exacerbate health disparities once translated to the clinic. BLAAC PD will help resolve the cross-ancestry applicability of drug targets, treatments and preventative measures by elucidating the genetic architecture of disease in African and African admixed ancestries and also providing a platform for replication studies of previous work in other populations. Looking ahead, BLAAC PD plans to continue recruiting and genotyping participants to serve as a foundational cohort for diverse genetic studies.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4458 Build the coordinates-compatible, consensus human reference genomes.

Authors:

L. Wang[1], T. Ma[1], J. Qi[2], E. Z. Prestano[1], Y. Asmann[3], J. Nie[4]; [1]Mayo Clinic, ROCHESTE, MN, [2]Hefei Inst.s of Physical Sci., Hefei, China, [3]Mayo Clinic, Jacksonville, FL, [4]Hefei Cancer Hosp., Hefei, China

Motivation:The current human reference genome (GRCh38) suffers from "reference bias" as approximately 70% of the sequences are derived from a single individual. This bias significantly affects the results of most next-generation sequencing-based genomic assays.
Methods:We have developed a tool called "genometa" for constructing consensus reference genomes (CRGs) using the standard reference genome as a template. Genometa achieves this by replacing minor alleles on the standard reference genome with non-reference major alleles (NRMAs). NRMAs are genomic variants that are dominant (allele frequency > 0.5) in specific populations but are not represented in the standard reference genome. Substitution variants were directly incorporated into the template without altering the original coordinates. For insertions and deletions (INDELs), genometa first identifies the Balanced Insertion and Deletion (BID) regions and then integrates these regions into the reference template using a dynamic programming algorithm that maximizes the utilization of INDEL variants.
Results:On average, we obtained approximately 2.35 +/- 0.072 million NRMA variants for each population from gnomAD, consisting of 84% SNVs and 16% Indels. We incorporated around 1.97 +/- 0.057 million substitution variants and 5133 +/- 584 BID regions into GRCh38 to construct population-specific CRGs. As a result, we generated CRGs for 10 populations (AFR, AMI, AMR, ASJ, EAS, FIN, MID, NFE, SAS, OTH) included in the gnomAD project.
To compare the CRGs with the standard GRCh38, we downloaded 42 whole-genome sequencing data of 6 AFR, 27 EAS, 6 NFE, and 3 MID individuals from the Human Genome Diversity Project (HGDP). Using the BWA-MEM, we aligned the WGS data of these individuals to both GRCh38 and the corresponding CRGs. Consistently across all tested samples, the alignment rates showed significant improvement when aligned to the respective CRGs. Compared to the alignment with GRCh38, for every 1 million read pairs, we observed an average increase of 2409 +/- 463 properly-paired reads. Additionally, there was an average increase of 30542 +/- 2939 mapped bases and a reduction of 63784 +/- 4591 mismatches.
Summary:Population-specific CRGs offer a substantial improvement in alignment rates, thereby significantly impacting genomic and epigenomic analyses. This enhancement enables the accurate identification of DNA variants and cis-regulatory elements, contributing to a more comprehensive understanding of genetic and human diseases. The compatibility of CRGs' coordinates also facilitates seamless cross-sample comparisons, data integration, and visualization.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4459 Building a phenotype for *ALPK3* loss-of-function mutation heterozygotes: Leveraging PheWAS to enhance reverse phenotyping studies

Authors:

N. Singh-Miller[1], A. Awan[1], C. Wilczewski[1], L. Hellwig[2], M. Haigney[2], L. Biesecker[1], H. Mo[1], C. Turner[1]; [1]Ctr. for Precision Hlth.Res., Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Ctr. for Military Precision Hlth.(CMPH), Uniformed Services Univ. of the Hlth.Sci., Bethesda, MD

Large patient datasets linking genomic data with clinical data, such as the *All of Us* (*AoU*) program, offer an invaluable opportunity to explore genotype-phenotype relationships and advance our understanding of heritable conditions. However, the limited depth of ICD-10 encoded electronic medical record (EMR) data coupled with restrictions on patient follow-up poses challenges to comprehensive phenotyping. Smaller cohorts of recallable patients available for targeted deep-phenotyping overcome these challenges. However, these cohorts are limited by their size and the cost of resource-intensive recall to phenotype traits with potentially small expected effect sizes. In this study we implemented an innovative phenotyping approach to address these challenges by using phenome-wide association studies (PheWAS) to improve the design of a targeted reverse phenotyping study aimed at investigating novel gene-disease relationships for *ALPK3*. Putative loss of function (pLoF) variants in *ALPK3* are known to cause a severe autosomal recessive cardiomyopathy phenotype. Currently there is an emerging phenotype associated with *ALPK3* pLoF heterozygosity, however the overall phenotype and penetrance in phenotypically-unselected genotype-positive individuals remains unknown.

We assembled a genotype-positive cohort of individuals from the *AoU* database based on their heterozygosity for a pLoF variant in *ALPK3*; clustering pLoF heterozygotes to increase the likelihood of identifying statistically significant features. We have initially identified fifteen such features for stop-gain mutations with a p-values less than 2×10^{-3}; including cardiac phenotypes such as cardiogenic shock (OR=16, p-value= 1.9×10^{-4}), as well as numerous inflammatory phenotypes such as mastoiditis (OR=23, p-value = 2.4×10^{-5}), optic neuritis (OR=8, p-value = 8.7×10^{-5}), postphlebitic syndrome (OR=32, p-value = 9.4×10^{-4}), and chronic pericarditis (OR=25, p-value = 1.6×10^{-3}). With this insight, we designed and initiated a phenotype-specific reverse phenotyping study with 10 genotype-positive patients in the NIH Reverse Phenotyping Core (RPC) cohort.

Through this methodology, we demonstrate that reverse phenotyping studies with re-contactable cohorts can be guided further with clinical informatics using large cohorts that, for now, are unavailable for follow-up phenotyping.

The Clinical Genome Resource (ClinGen) suite of microservices provides a platform to build applications within and outside of ClinGen by leveraging Application Programming Interfaces (APIs). The ClinGen APIs and messaging queues have been employed within ClinGen to support variant curation, which includes data aggregation, curation, and dissemination of published pathogenicity assertions. Version 1.0 of the Pathogenicity Calculator was aimed at non-ClinGen users, supported ACMG/AMP v3.0 2015 guidelines, and was utilized as a classic siloed application. Version 2.0 is upgraded to support an early draft of the ACMG/AMP/CAP/ClinGen SVC v4.0 2023 guidelines and leverages ClinGen API microservices, including the ClinGen Allele Registry, ClinGen Linked Data Hub, and ClinGen Criteria Specification Registry. In addition to the utility to the end-users, Version 2.0 thus provides a new model for how interfaces and workflows within and outside of ClinGen may leverage the ClinGen Resource.

Calculator 2.0 users first identify a variant of interest, uniquely identified by a stable canonical allele identifier (CA ID) obtained from free, open, on-demand registration within the Allele Registry. Supporting evidence is obtained and aggregated in the form of excerpts linked to a given CA ID in the Linked Data Hub, which facilitates open sharing of linked data from external sources and automated calculation of some evidence codes as Calculator input. ClinGen variant curation expert panel (VCEP) specifications are created, edited, and approved following the ClinGen expert panel process within the Criteria Specification Editor and are publicly-accessible via the Criteria Specification Registry. Criteria specifications are gene and disease specific structured data developed from a combination of empirical analysis and expert recommendations. Calculator 2.0 can use the tailored VCEP-specific gene-condition criteria specifications from the Criteria Specification Registry with a flexible user interface to solicit the required user input and calculate variant pathogenicity scores.

In conclusion, Version 2.0 of the ClinGen Pathogenicity Calculator exemplifies the power of ClinGen API microservices to serve as a platform for rapid development of new applications within and beyond ClinGen. This microservice-oriented model for interface development is particularly relevant for established variant curation and interpretation workflows outside of ClinGen, as they may tap into ClinGen API microservices to accelerate development, leverage ClinGen knowledge within their workflows, and adopt the latest professional guidelines.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4461 Calibrating CADD on a gene level for enhanced causal variant filtration

Authors:

B. Pusey[1], J. Fu[2], E. Macnamara[3], W. Gahl[4], D. Adams[5]; [1]Natl Human Genome Res. Inst., Homer, AK, [2]NHGRI, Rockville, MD, [3]NIH, Bethesda, MD, [4]NHGRI (NIH), Bethesda, MD, [5]NIH, Bethesda, MD

The NIH Undiagnosed Diseases Program (UDP), a member of the Undiagnosed Diseases Network (UDN), was established with the goal of conducting research for patients with significant illnesses that remain undiagnosed despite extensive medical evaluation. Genome sequencing approaches became available around the same time that the UDP started and are important tools for making diagnoses in some cases. Given the increasing prevalence of exome and genome sequencing in standard medical care, many current UDP applicants have been evaluated with this technology before they apply. As a result, a major focus of UDP genomic analysis is assessment of variants classified as “variants of unknown significance”. In this forest of variants it can be difficult to know which has a truly significant CADD (Combined Annotation Dependent Depletion) score, and the current practice has been to use an arbitrary or semi-arbitrary cut off based on a general view of the genome in its entirety. What can be determined to be a significant CADD score varies across genes dependent on a multitude of factors such as the gene size, and inherent genetic mutation burden etc.. Using gnomAD (Genome Aggregation Database) a standard distribution curve was calculated on a per gene basis. Using these distributions z-scores were calculated creating a calibrated score (cadd_z) that reflects the genes inherent biases given a large population in which individuals with severe disease have been culled from the cohort. Using these recalibrated cadd_z scores we then reanalyzed out cohort of more than 600 families and compared the score to those obtained using our original filters with a hard CADD score cut off. Diagnosed cases were used as controls to confirm that no causal variants were lost. The calibrated cadd_z score resulted in a reduction in noise from filtration results as well as providing candidate variants of interest that had previously been excluded. CADD scores can then be re-quantified to a per gene z-score allowing for filtering relative to the scores of the gene as a whole rather than an subjective value. Furthermore, this approach can be abstracted out to other genomic scoring methodologies. Using our new CADD threshold methodology, we identified new potential candidate variants of interest.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4462 Calypso: a comprehensive platform supporting team-based, longitudinal genomic diagnostic care

Authors:

A. Ward[1,2], I. Cooperstein[1], T. Di Sera[1], S. Georges[1], A. Pitman[1], M. Tristani-Firouzi[1], G. Marth[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]Frameshift Labs, Cambridge, MA

Patients presenting with complex phenotypes represent some of the most challenging diagnostic cases. To achieve a genetic diagnosis, large interdisciplinary teams are required to work collaboratively, sharing their own unique expertise and skills. Treating physicians provide detailed understanding of the clinical presentation and family history; medical geneticists brings a wide and deep knowledge of genetic diseases; bioinformaticians provide computational analysis skills and an ability to adjudicate the role of individual variants; and diagnostic pathologists synthesize all information to draw conclusions on the clinical significance of candidate variants. Currently available software tools cater primarily to those with computational expertise rather than clinical expertise and focus on diagnostic analysis at a single point in time, despite the fact that patient phenotypes can evolve over time. Consequently, treating physicians, or genetic counselors can be left out of the diagnostic process. Further, failure to follow a patient over a potentially lengthy diagnostic process where phenotypes and/or variant interpretations can change can potentially lead to missed diagnoses.
Calypso is a web-based software system being developed to address these concerns and comprises:

1. A computational backend to perform comprehensive annotation and filtering of incoming genomes and enable re-annotation and re-analysis of all variants on a periodic or user triggered basis,
2. User-friendly web tools including the iobio suite to ensure each case is summarized with quality statistics, clinical information and other analytics that ensures all team members can work as part of an effective collaborative team,
3. Case and cohort level dashboards that employ visual elements to summarize important case information (e.g. candidate variants and case history), as well as interactive analytics across cohorts of cases,
4. A robust communication infrastructure to support close collaboration between all diagnostic team members

Initial versions of Calypso have been deployed at the University of Utah, where it is used to aid team-based diagnostic analysis as part of the rapid NICU sequencing program and at the UDN.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4463 CARTaGENE PheWeb: presenting GWAS and PheWAS results in a Quebec cohort

Authors:

V. Chapdelaine[1,2,3], G. Lettre[4,5], S. Gagliano Taliun[4,5], D. Taliun[1,2,3]; [1]McGill Univ., Montreal, QC, Canada, [2]Canadian Excellence Res. Chair in Genomic Med., McGill Univ., Montréal, QC, Canada, [3]Victor Phillip Dahdaleh Inst. of Genomic Med. at McGill Univ., Montréal, QC, Canada, [4]Université de Montréal, Montreal, QC, Canada, [5]Montreal Heart Inst., Montréal, QC, Canada

CARTaGENE is a large longitudinal population-based cohort and a prospective health study with genetic data and a wealth of phenotypic information available to empower discoveries to better understand human health and disease. It currently includes 29,330 array-genotyped individuals recruited in the province of Quebec, Canada, of which 25,681 are of European genetic ancestry. Many of these individuals are French Canadians, a population that originated from immigration in the 17th century of 8,500 mostly French settlers to Quebec followed by serial founder effects. CARTaGENE thus provides a unique opportunity to better understand genetic risk in a founder population.

We performed a PheWAS on ~100M genetic variants imputed with the state-of-the-art TOPMed reference panel (R2 > 0.3) across 701 traits (326 binary, 375 continuous), including diseases, disease-related, behavioral, and various biochemical and anthropometric measurements. We used the regenie generalized mixed model association test to account for case-control imbalance (for binary traits) and relatedness among participants. Our analyses included sex-specific traits and chromosome X. We identified 30,678 significant associations (p-value < 5×10-8) within 1,327 independent loci. All summary statistics are publicly available to browse, visualize and download via the CARTaGENE PheWeb web-based interactive tool.

Our resource provides the most comprehensive view of genetic association results for the currently largest genotyped population cohort in Quebec. We have made these data publicly available to the worldwide research community to support a variety of downstream analyses, including replication, fine-mapping, construction of polygenic risk scores, and Mendelian randomization to better understand the genetic contributors to disease risk.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4464 Cavatica-based Variant WorkBench

Authors:

Y. Guo[1], Q. Li[1], J. Rozowsky[2], J. Costanza[3], M. Mattioni[2], J-P. Thibert[3], C. Botek[3], M. Brown[1], D. Higgins[1], Y. Zhu[1], B. Farrow[1], A. Heath[1], A. Resnick[1], V. Ferretti[3], Kids First Data Resource Center; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Velsera, Cambridge, MA, [3]Ctr. Hosp.ier Univ.ire Sainte-Justine, Montréal, QC, Canada

The Gabriella Miller Kids First Pediatric Research Program (Kids First) aims at facilitating researchers to uncover new insights into the biology of childhood cancer and structural birth defects, including the discovery of shared genetic pathways between these disorders. Kids First Data Resource Center developed the Kids First Data Resource Portal (KFDRP), which is a centralized data platform for both Kids First and collaborative cohorts. Currently, KFDRP facilitates data access for 37 studies with over 33,700 participants. To assist researchers and clinicians in identifying potential disease-causing germline variants in the human genome, KFDRP released the Variant WorkBench (VWB), which facilitates variant querying, manipulation, analysis, and visualization. Cavatica is a widely used bioinformatics analysis platform developed by Velsera (formally Seven Bridges). KFDRP-based VWB is now transitioned to a Cavatica-based version to have better support for data import/export, more convenient sharing of notebooks and data, and easier billing details, with the same level of scalable, cloud-based computing. Additionally, Cavatica-based VWB has incorporated multiple public reference databases, including Cancer Hotspots, ClinVar, COSMIC, dbNSFP, gnomAD, TOPMed, as well as gene-phenotype links provided by OMIM, HPO, Orphanet, and the Deciphering Developmental Disorders Project. These databases have been converted to parquet files, reducing process time and memory usage compared to regular text files, thus speeding up data retrieval and querying. Furthermore, Cavatica empowers users to create and share custom analysis workflows tailored to specific research questions and datasets, enhancing data utility and analysis accuracy. Here we present a gene-based variant filtering workflow that aggregates information from dbNSFP, HGMD, TOPMed, gnomAD, and ClinVar. We identified 1202 pathogenic/likely pathogenic variants in *NF1*, a gene that helps regulate cell growth, across 582 pediatric brain tumor samples within 6 mins. Among the variants, there are 21 protein-altering variants. Overall, the upgraded VWB is more powerful, user-friendly, and adaptable.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4465 Characterization of HLA variation in Quebec from whole-genome samples in the population-based CARTaGENE cohort.

Authors:

P. McClelland[1], K. Lo[2], G. Lettre[3], C. Bhérer[1], D. Taliun[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Montreal Heart Inst., Montreal, QC, Canada, [3]Université de Montréal, Montreal, QC, Canada

The human leukocyte antigen (HLA) system contains genes involved in many immunological processes, and genetic variation in this region is associated with many immune- and disease-related phenotypes, including type I diabetes, multiple sclerosis, and rheumatoid arthritis. Frequencies of genetic variants in the HLA region differ significantly across populations, making population-specific HLA characterization necessary to understand the prevalences and functional effects of HLA alleles within a given population. Here we characterize HLA alleles in individuals from the province of Quebec, Canada, using high-depth whole-genome sequencing (WGS) data from 2,180 participants from CARTaGENE, a population-based cohort that has collected high-quality biosamples and extensive health and phenotypic information from individuals across six different regions in Quebec. We performed HLA typing of class I and II classical alleles (HLA-B, -C, -DPA1, -DPB1, -DQA1, -DQB1, -DRB1, -E, -F, and -G) using HLA*LA. After quality checks, 43,189 alleles were retrieved from 2,173 participants. 286 individual HLA alleles were observed at least once in the CARTaGENE WGS dataset: 84 HLA-B, 42 C, 17 DPA1, 34 DPB1, 11 DQA1, 17 DQB1, 55 DRB1, 5 E, 2 F, and 19 G. Of these, 222 HLA alleles were also present in the most extensive publicly available multi-ancestry high-resolution HLA reference panel, HLA-TAPAS (n=21,546). 35 out of 222 HLA alleles were at a frequency significantly different in the CARTaGENE cohort (p < 2.25 x 10-4). Frequencies of 71 low-resolution (one-field) HLA allele types were also previously reported in the Hema-Quebec donor biobank in 17 administrative regions of Quebec. We compared allele frequencies by sampling site in CARTaGENE to the closest correlating administrative region in the Hema-Quebec cohort. In the CARTaGENE WGS dataset, frequencies of 38 shared HLA alleles correlated well with all regions combined in Hema-Quebec (Pearson's r = 0.9841); 2 alleles were at significantly different frequencies in CARTaGENE (p < 1.32x 10-3). For individual CARTaGENE sampling strata, HLA allele frequencies were well correlated with corresponding Hema-Quebec regions, with Pearson's r ranging from 0.88-0.93. This sequencing-based HLA allele data can be used in future to construct an HLA-specific imputation reference panel for imputing uncaptured HLA alleles into ~30,000 genotype-array samples also available within CARTaGENE, allowing for cohort-scale analysis into HLA-disease associations in the Quebec population.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4466 Characterization of human neuroblastoma cultured cells lines used for interpretation of coding and noncoding variation in neurodevelopmental diseases

Authors:

H. B. Heins, J. G. Manuel, J. K. Ng, T. N. Turner; Washington Univ. Sch. of Med., St. Louis, MO

Neurodevelopmental disorders (NDDs) affect >1% of the population. While there is an established contribution of rare protein-coding variants and large copy number variants to NDDs, the role of rare noncoding variation is an active area of investigation. From whole-genome sequencing (WGS) data in autism, we have identified a contribution of de novo variants in promoter and enhancer regions of the genome. We are now beginning to functionally characterize these variants in in vitro assays. To optimize these experiments, we are deeply characterizing available human cultured neuroblastoma cell lines including IMR-32, SH-SY5Y, and SK-N-SH as well as the commonly used HEK293 cell line. These cell lines have been utilized in several studies to assess coding and noncoding variation, but in-depth characterization of their genomic, epigenomic, and functional genomic characteristics are not available. This information is critical for determining the best cells for functional testing. We are utilizing several technologies including Hi-C sequencing, ATAC-Seq, short-read and log-read WGS, short-read and long-read RNA sequencing, and karyotype analysis to characterize these cell lines. By karyotype analysis, we found that each cell line exhibited aneuploidy with an IMR-32 karyotype of 48~49,XY,add(1)(p36.1),+add(1)(,add(2)(p21),+6,+12,der(16)t(15;16)(q11.2;q11.2)[cp11], a SH-SY5Y karyotype of 47,X,add(X)(p22.1),add(1)(q21),+7,add(8)(q24.1),add(9)(q34),add(14)(q22),add(22)(q13)[20], a SK-N-SH p36 karyotype of 47,X,add(X)(p22.1),+del(1)(p22),+7,add(8)(q24.1),add(9)(q34),add(14)(q22),add(22)(q13)[cp21], and a HEK293 karyotype of 67~74<3N>,XXX,+X,+X,add(X)(p22.1),add(X)(q26),add(1)(q42)x2,+2,-3,4,+5,+6,+6x2,add(6)(q25),-8,-8x2,+9,-10,+10,add(12)(p13),-13,-14,-15,-15x2,-16,+17,-18,+18,+21,+22,+22x2,+1-5mar,1~3dmin[cp16]. Another interesting aspect of our work beyond building the profiles for functional testing is our application of >40× long-read WGS. This work will provide new insights into de novo assembly generation of these aneuploid genomes and will be informative in other contexts (e.g., cancer). Our hope is to provide this data for our highly characterized HEK293 and human neuroblastoma cell lines to the research community to further the understanding of genomic and regulatory elements and noncoding variation in them.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4467 Characterization of long non-coding RNA and circular RNA in the aging human hippocampus across three library types.

Authors:

A. Knyshov[1], J. Hu[1,2], M. Lin[1], B. Zhou[1], J. A. Empawi[1], S. Puri[3], T. D. Stein[4], L. A. Farrer[1,5], B. Wolozin[3], X. Zhang[1,5]; [1]Dept. of Med. (BioMed. Genetics), Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA, [2]Bioinformatics Program, Boston Univ., Boston, MA, [3]Dept. of Anatomy & Neurobiology, Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA, [4]Dept. of Pathology and Lab. Med., Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA, [5]Dept. of Biostatistics, Boston Univ. Sch. of Publ. Hlth., Boston, MA

Ribosomal RNA depletion (ribo-minus) is commonly used for RNA sequencing to capture poly(A)+ mRNA, non-coding RNAs (ncRNAs), or protein-coding mRNAs that are not polyadenylated. The poly(A)-selected (poly(A)+) protocol enriches poly(A)+ transcripts including mRNAs and ncRNAs. However, many functional long transcripts (>200 nt) are known to lack poly(A) tails including circular RNAs (circRNAs), which are much less abundant than protein-coding mRNAs in human tissues.

In order to enrich these poly(A)- transcripts and estimate their function in aging brains, in this study, we first applied a polyA-depleted (poly(A)-) protocol to generate RNAseq data for 128 human hippocampus samples. For the same samples, ribo-minus and poly(A)+ RNAseq data were also generated in a similar manner (~40M 100bp paired reads per sample) using Illumina NovaSeq at the Genome Center at Yale University. We then systematically assessed the expression of linear long ncRNA (lncRNA), detected circRNA, and compared their expression levels across the three library types.

Our results show that both ribo-minus and poly(A)- sequencing perform well for linear lncRNA profiling in hippocampus, with poly(A)- libraries generally having a slightly higher number of detected expressing genes (per sample median n=2,661 at TPM > 0.1) compared to ribo-minus libraries (per sample median n=2,591 at TPM > 0.1). Similarly, the number of detected circRNA is only slightly higher in poly(A)- libraries (per sample median n=2,936 at FPB > 0.1) compared to the ribo-minus libraries (per sample median n=2,886 at FPB > 0.1). These results suggest that both strategies are effective for studying ncRNA in human tissue.

Additionally, we compared poly(A)- and poly(A)+ data generated from the same samples to predict the polyA status of protein-coding and lncRNA transcripts in human hippocampus. A ROC-based method was applied using a set of previously known status genes (n=6,104) to determine the classification cut-offs. Our results show that hippocampus samples have a higher proportion of non-polyadenylated transcripts, including more non-polyadenylated protein-coding mRNAs compared to what was reported before for other human tissues and cell lines. Our study offers a rich source of data for exploring the poly(A)- landscape of transcriptome in the human aging brain, but also suggests the importance of understanding the potential pitfalls of each sequencing strategy and making informed methodological choices, especially when studying non-coding RNAs.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4468 Characterizing the Natural History of *SYNGAP1*, *PCDH19*, and *CHD2* Disorders: Insights from the Ciitizen Database

Authors:

S. Sengupta[1], N. Chourasia[2,3], E. Bonkowski[4], H. Mefford[5]; [1]St. Jude Children's Res. Hosp., Memphis, TN, [2]Univ. of Tennessee Hlth.Sci. Ctr., Memphis, TN, [3]Le Bonheur Children's Hosp., Memphis, TN, [4]Univ. of Washington / St. Jude Children's Res. Hosp., Memphis, TN, [5]St. Jude Children`s Res. Hosp., Memphis, TN

Background:*SYNGAP1*-related intellectual disability, *PCDH19*-related epilepsy, and *CHD2*-related neurodevelopmental disorders are genetic disorders characterized by intellectual disability, epilepsy, and developmental delays. This study aims to conduct a comprehensive natural history analysis using electronic medical record data for *SYNGAP1*, *PCDH19*, and *CHD2*-related disorders gain insights into the clinical, demographic, and genetic characteristics of patients and understand the disease progression and outcomes.Methods:We use data generated through the Ciitizen®, a wholly owned subsidiary of Invitae Corporation, to acquire clinical information, genetic variants, demographic details, and longitudinal follow-up data of the participants. Descriptive analysis of the data summarizes the clinical and demographic characteristics, including age, sex, age of onset, seizure types, and comorbidities. Longitudinal analysis will investigate disease trajectories over time, assessing factors such as age at onset, seizure frequency, and cognitive development. Our ultimate goal is to further define the natural history to enable clinical trial readiness, to inform efficient treatment approaches, and to enhance clinical care for patients with these mutations.Results:We have obtained data for 205 patients (n=150 *SYNGAP1*, n=13 *PCDH19*, n=42 *CHD2*). Our preliminary analysis of 92 patients (median age 4 years) with known histories of epilepsy and primarily *de novo* *SYNGAP1* mutations show that more than 50% of pathogenic variants are SNVs, followed by deletions in 37%. For atonic seizures, we discovered a trend toward decreased mean seizure frequency over a period of 20 months following diagnosis. The downward trend is consistent with documented prescription of anti-seizure drugs. We are currently evaluating the association between age of seizure onset and developmental outcomes, longitudinal analysis of developmental milestone achievement, cognitive outcomes, and treatment response in to better understand the disease trajectory of *SYNGAP1*-related intellectual disability. We will perform parallel analyses for *PCDH19*- and *CHD2*-related disorders and subsequently perform comparative analyses across the disorders.Discussion:Comprehensive analysis of longitudinal medical record data will provide insights into the natural history and disease progression of *SYNGAP1*-, *PCDH19*-, and *CHD2*-related disorders. The implications for understanding disease mechanisms, identifying potential therapeutic targets, enabling clinical trial readiness, and informing clinical interventions will be discussed.

Young[5], D. A. Mackey[2,3], K. P. Burdon[3], A. Dubowsky[4]; [1]Flinders Univ., Adelaide, Australia, [2]Univ. of Western Australia, Perth, Australia, [3]Univ. of Tasmania, Hobart, Australia, [4]SA Pathology, Adelaide, Australia, [5]Univ. of Wisconsin-Madison, Madison, WI, [6]Garvan Inst. of Med. Res., Sydney, Australia, [7]L V Prasad Eye Inst., Hyderabad, India, [8]Univ. of Texas Southwestern Med. Ctr., Dallas, TX, [9]Univ. Erlangen-Nuremberg, Erlangen, Germany

Aim and Methods: Pathogenic variants in Myocilin (MYOC) are the most common cause of Mendelian open-angle glaucoma. The Clinical Genome Resource (ClinGen) Glaucoma Variant Curation Expert Panel (VCEP) recently published rule specifications for MYOC variant classification. Here we present the results of the curation of MYOC variants using the newly specified rules by the Glaucoma VCEP. **Results:** The Glaucoma VCEP curated 268 MYOC variants: 9 were classified as benign (B), 36 as likely benign (LB), 193 as variants of uncertain significance (VUS), 22 as likely pathogenic (LP) and 8 as pathogenic (P). All LP/P variants were located in the conserved olfactomedin domain in exon 3. A previous ClinVar classification was reported for 31.0% of variants (83/268). Fifty-eight (70.0%) reached an overall classification concordance with ClinVar (B/LB vs VUS vs LP/P), while 7 (8.4%) had discordance with clinical implications (LP/P downgraded to VUS). The VCEP rules led to the reclassification of 10 variants from VUS to B/LB and the resolution of 8 variants with conflicting interpretations in ClinVar. The majority of the VUS did not have functional evidence available (93.8%, 181/193). **Conclusions:** The refined variant curation guidelines for MYOC from the Glaucoma VCEP have improved variant classification and increased the number of variants listed in ClinVar. Additional functional evidence may further improve the classification by decreasing the proportion of VUS.

Introduction: Galactosemia type IV (MIM# 618881, galactose mutarotase [GALM] deficiency) is caused by a lack of GALM, an enzyme responsible for catalyzing the interconversion between β-D-galactose and α-D-galactose in the Leloir pathway. Given the recent identification, there is limited knowledge regarding GALM deficiency. This study aims to investigate the prevalence, genotypic characteristics, symptoms, and prognosis of GALM deficiency.Methods: A nationwide survey on clinical profiles of GALM deficiency was conducted between February 2022 and March 2023, targeting 529 core hospitals to cover positive cases through newborn screening.Results: A total of 41 patients with GALM deficiency were identified. The estimated prevalence of GALM deficiency in Japan was 1 in 164,333 individuals. Two pathogenic variants, c.294delC and c.424G>A, accounted for 73% of all identified variants. Four patients (10.3%) presented with infantile cataracts, which were successfully resolved through lactose restriction without surgical intervention. There was no significant association between cataract formation and mean galactose levels before the onset of cataracts. During the neonatal period, liver dysfunction, portosystemic shunt, cholestasis, and hepatomegaly were observed in 22.5%, 7.9%, 5.0%, and 2.6% of patients, respectively. The liver dysfunction manifested as an elevation in transaminase levels, which occurred within the first three months of life and spontaneously improved by 1-year-old. The median values of AST and ALT were 135.5 U/L and 163.5 U/L, respectively. In this population, only one patient (2.4%) developed attention-deficit/hyperactivity disorder. No patient was diagnosed with developmental delay, unlike GALK1 deficiency. No patients experienced hypoglycemia, encephalopathy, ovarian dysfunction, or fractures. The median of maximum galactose levels recorded was 27.9 mg/dL, which was lower than that observed in GALK1 deficiency. All patients with GALM deficiency were started on lactose restriction, and 24.4% of them completed the restriction.Conclusion: Our study indicates that GALM deficiency exhibits a milder phenotype compared to GALK1 deficiency. Early detection of GALM deficiency would hold significance meaningful because lactose restriction has proven to be effective in treating cataracts possibly associated with GALM deficiency.

PB4471 Cloud-scale training and education in the NHGRI Analysis, Visualization, and Informatics Lab-space (AnVIL)

Authors:

N. Kucher[1], M. Schatz[1], A. Philippakis[2], AnVIL Team; [1]Johns Hopkins Univ., Baltimore, MD, [2]Broad Inst. of MIT and Harvard, Cambridge, MA

As stakeholders in biomedical research increasingly adopt cloud computing, educational platforms and materials are needed to support the transition of genomic data science researchers to the cloud, for expert bioinformaticians and the next generation alike. Smoothly managing informatics training with software, data, and participant access as well as new elements relevant to the cloud, such as computing environment and billing are necessary for successful adoption.

The NHGRI Genomic Data Science Analysis, Visualization, and Informatics Lab-space or AnVIL, is a secure, cloud-based platform for storage, management, and analysis of genomic and related datasets that offers many opportunities for supporting genomics research training in the cloud. A major component of AnVIL is Galaxy, an interactive analysis platform that empowers users with and without programming experience to perform complex bioinformatics analysis from a user-friendly web interface. Galaxy in AnVIL offers participant and billing management, dedicated computing resources, and a consistent but customizable software environment all within a security perimeter necessary for use of protected and private datasets. These advantages result in faster jobs, reduced data transfer, tracked class activity and spending, and flexibility for in person and virtual training events.

Building on the rich resource of Galaxy training materials, we have developed scalable training and outreach content for AnVIL. Galaxy's extensive training network offers dozens of tutorials for the life sciences, including for genome assembly and variant analysis, functional genomics, proteomics, and epigenetics as well as other data intensive sciences such as climate research or machine learning. The AnVIL materials guide users in onboarding and explore the necessary building blocks for independent use of the AnVIL platform. In this presentation we will showcase the available AnVIL training resources, how they fit in the larger Galaxy Training Network, and summarize our experiences about lessons learned from onboarding users for using cloud resources.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4472 Combining national health register data with biobank's genomic resources enables selection of healthy controls for any disease.

Authors:

K. Silander, N. Eklund, K. Kantojärvi, P. Laiho, M. Sauramo, A. Kyttälä, T. Wahlfors; Finnish Inst. for Hlth.and Welfare, Helsinki, Finland

Background: The Finnish Institute for Health and Welfare (THL) is an independent state-owned expert and research institute promoting the welfare and health of the population. THL has maintained the national Care Register for Health Care since 1967. This register contains diagnosis data derived from hospitals and primary health care of all people living in Finland. Since 1996, the diagnoses have been recorded with ICD-10 codes. THL Biobank hosts samples and data from more than 230000 sample donors. The research collections include population-based health examination surveys, disease-specific cohorts, and other research cohorts collected nationwide. Imputed genome-wide SNP data is available for more than 130000 donors. The population-based cohorts (N=45000) include data on demographics, lifestyle and health status, clinical data and samples (DNA, serum, and plasma) collected during a baseline clinical visit, NMR metabolomics data and GWAS data. These cohorts also include a harmonized set of variables created for the study of healthy aging. **Material and methods:** To build better research resources, we have created an internal database that contains ICD-10 diagnosis codes and dates for all biobank sample donors, derived from the Care Register for Health Care. The register-based diagnosis data can be combined with omics and survey data stored in the biobank to identify different subsets of healthy sample donors. **Results:** We tested our resource for three common disease categories: cancer, diabetes, and dementia. Among 22000 donors from population-based cohorts who have reached the age of 70 years, we identified 18000 sample donors without a diagnosis of cancer (ICD-10 codes C00-C99) by age 70 and 14000 donors without any diagnosis of cancer so far. There are 19000 donors without diabetes diagnosis (E08-E11, and E13) by age of 70, and more than 20000 donors without any diagnosis of dementia (F00, F01, F03) so far. **Discussion:** Using this unique resource, different criteria can be used to identify sets of confirmed healthy controls for any given disease. It is also possible to select healthy controls for a combination of several different disease categories. The identification of confirmed healthy controls can be expanded to include all biobank sample donors with genomic data (130000 donors) using various selection criteria.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4473 Comprehensive molecular epidemiology of spinocerebellar degeneration in Japan based on J-CAT, a nation-wide patient registry

Authors:

Y. Hama[1], H. Date[1], H. Mizusawa[2], Y. Takahashi[1], J-CAT (Japan Consortium of Ataxias); [1]Natl. Ctr. Hosp., Natl. Ctr. of Neurology and Psychiatry, Kodaira, Japan, [2]Natl. Ctr. of Neurology and Psychiatry, Kodaira, Japan

Objective: Spinocerebellar degeneration (SCD) is a heterogeneous group of disorders presenting with ataxia. Approximately one-third of SCD patients are diagnosed as hereditary SCD in Japan. Many causative genes for SCD have been identified, particularly in whole genome/exome sequencing (WGS/WES) era. The aim of the study was to elucidate the comprehensive molecular epidemiology of SCD in Japan. **Methods:** From 2016 through May 2023, 2679 patients have been registered in J-CAT nation-wide with informed consent and 2197 subjected to mutational analysis. The number of patients with positive or negative family history was 1154 or 1043, respectively. Initial mutational analysis included PCR fragment analysis and repeat-primed PCR of SCA1, SCA2, MJD/SCA3, SCA6, SCA7, SCA8, SCA12, SCA17, SCA31, SCA36, DRPLA, and HD, followed by repeat-primed PCR for the pathogenic AAGGG or ACAGG repeat expansions in *RFC1* for 264 mutation-negative patients whose ages of onset were above 30 excluding those with autosomal dominant mode of inheritance (those who had an affected parent or children). WGS was conducted for 1058 mutation-negative patients and variant detection in 612 genes associated with ataxia has been completed in 838 patients. Candidates for pathogenic mutations identified in WGS were confirmed by Sanger sequencing method. **Results:** Mutational analysis established the diagnosis in 1048 patients (47.7%). The diagnostic rate of SCD patients with positive or negative familial history was 70% or 23%, respectively. In total, 41 genes were identified as causative in this cohort. The number of patients with major disease types were as follows: 311 with SCA31, 275 with SCA6, 184 with MJD/SCA3, 73 with DRPLA, 34 with SCA2, 31 with SCA1, 20 with SCA 36, 15 with SCA8, 14 with EA2, 13 with HD, 9 with SCAR8, 9 with CANVAS, 7 with SCA42, 6 with Spastic ataxia, Charlevoix-Saguenay type, 6 with SCA13, and 5 with SCA17. **Conclusions:** J-CAT has elucidated the latest and the most comprehensive evidence for molecular epidemiology of SCD in Japan. Next generation sequencing is a time and cost-effective method for genetic diagnoses, and an accurate diagnosis can result in better management. Even after WGS, a definitive diagnosis could not be provided for 52% of the patients. Further research is required for better diagnostic efficiency.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4474 Custom genome assembly of KOLF2.1J and its benefit across neuronal cell types.

Authors:

P. Alvarez[1,2], B. Walenz[1], A. Rhie[1], E. Lara[1], A. Beilina[1], D. Patel[1], F. Grenn[1], K. J. Billingsley[1], R. Genner[1,3], E. Gustavsson[2], M. Ryten[2], M. R. Cookson[1], B. Paten[4], M. Jain[5], A. M. Phillippy[6], C. Blauwendraat[1]; [1]NIH, Bethesda, MD, [2]Univ. Coll. of London, London, United Kingdom, [3]Johns Hopkins Univ., Baltimore, MD, [4]UC Santa Cruz, Santa Cruz, CA, [5]Northeastern Univ., Boston, MA, [6]Natl. Institues of Hlth., Bethesda, MD

Objectives To generate and characterize a custom genome assembly from the KOLF2.1J cell line and explore its impact on the analysis of omics data generated from derived neuronal and glial cell types.
Background While induced pluripotent stem cells have gained popularity to study neurodegenerative diseases (NDDs), the heterogeneity of stem cells results in difficulty when comparing results. The iPSC Neurodegenerative Disease Initiative (iNDI) identified the KOLF2.1J cell line and prioritized its use as a reference line for studying NDDs due to its high performance and neutral genetically encoded risk for Alzheimer's Disease (AD). This line, and its derivatives expressing >100 variants related to AD and other dementias, is publicly available. Current genetic analyses are limited by use of the human reference genome for sequence alignments. We present here a telomere-to-telomere draft of the custom genome assembly for KOLF2.1J to enable more accurate investigation of NDD genomics.
Methods KOLF2.1J IPSCs were sequenced using PacBio HiFi, Oxford Nanopore Technologies (ONT) Ultra Long sequencing and Hi-C. Verkko/1.2 assembler drafted a custom genome with this data. In parallel, KOLF2.1J was differentiated into neurons and microglia, and sequenced using ONT whole genome sequencing and bulk RNA sequencing, Illumina bulk RNA sequencing, and CAGE-seq. DNA and RNA were basecalled using Guppy and mapped to hg38, CHM13, and the new KOLF2.1J assembly using Minimap2. Variant calling was performed with Sniffles2 and transcript discovery and quantification was performed with Stringtie and Talon. Methylation from the ONT long-read genome sequencing data was plotted using Modbamtools.
Results We generated a complete genome of KOLF2.1J, and identified many structural variants including some impacting the coding structure of genes. We identified that RNA mapping increased unique mapping with the KOLF2.1J assembly compared to hg38 and CHM13v2.0 for both short-and long-read data, indicating that using a custom assembly generates more accurate genomics results compared to general reference genomes. Methylation data showed clear differences across neuronal cell types including in cell specific marker genes (i.e.TREM2 for microglia). Furthermore, we identified several positions in the genome with significant haplotype-specific methylation differences.
Conclusion Here we describe the path towards precision iPSC technology by generating a custom genome assembly of a widely used cell line. We show that a custom genome assembly greatly improves the accuracy of several types of omic data and recommend this approach for commonly used cell lines.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4475 *De novo* genome assemblies from two Indigenous Americans from Arizona identifies new polymorphisms in non-reference sequences

Authors:

C. Koroglu Altok[1], P. Chen[2], M. Traurig[1], C. Bogardus[1], L. Baier[1]; [1]NIH/NIDDK, Phoenix, AZ, [2]Jilin Univ., Changchun, China

The goal of improving disease prevention and treatment in all people generated a collective effort to increase diversity in human genetic studies, particularly among underrepresented populations. However, analysis of DNA sequence reads involves the initial step of alignment to the human GRCh38/hg38 reference genome, which does not adequately represent genomes of non-European ancestry. In this study we used *de novo* sequence assemblies to identify non-reference segments (NRSs) in genomes of an Indigenous American cohort from Arizona. These novel segments were then included in our whole-genome sequencing (WGS) variant calling pipeline. Two DNA samples (isolated from one female and one male) were sequenced using the HiFi SMRT method and the long sequence reads (mean length = 12 kb) were assembled using HiFiasm assembler. Each *de novo* assembly was compared to the hg38 reference genome using MUMmer software to identify NRSs > 100 bp. Each assembly included ~17 Mb of NRS which consists mostly of repeat elements. Forty NRSs totaling 240 kb were uniquely anchored to the primary assembly of hg38. These NRSs were enriched in gene regions with 17 segments positioned within introns. Among them, a 187 bp NRS that anchored 79 bp downstream of the *HCN2* third exon was the only instance where the reads in both *de novo* assemblies were identical. We then assessed the existence of the 187 bp NRS in 50 additional samples including those from other ancestries by Sanger sequencing; none of the five Caucasian genomes contained the *HCN2* NRS. In contrast, more than half of the Indigenous genomes (20 out of 34) and a few from Mexican and African American ancestries had the *HCN2* NRS. The *HCN2* NRS spans several putative transcriptional regulatory elements, and genotyping of this NRS in ~8,000 DNA samples to determine the frequency of the segment and any potential associations with metabolic disease in our Indigenous cohort is currently underway. In addition to characterizing the *HCN2* NRS, we are also determining the effect of all inserted NRSs on variant calling. We edited hg38 by inserting NRSs into their anchor sites. Alignment and variant calling using the GATK pipeline were performed on 387 WGS samples from our Indigenous cohort using either hg38 or the modified reference (hg38-NRS). Comparison of the annotated variants yielded >50,000 SNVs that were detected in at least 5% of the samples using hg38-NRS as reference which were not captured using hg38. In conclusion, this study showed that inclusion of population-specific NRSs dramatically changed the variant profile in an under-represented ethnic group, revealing common variation not detected by our previous population-level WGS and genotyping studies.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4476 De-identification of clinical notes using open source software and commercial cloud-based NLP service together

Authors:

H. Qiu[1], F. Mentch[1], J. Glessner[1,2], H. Hakonarson[1,2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Dept. of Pediatrics, The Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Unstructured free text in electronic health records captures rich phenotypic information. In our research setting, studies and analyses are typically conducted on anonymized datasets. For genomic researchers that require review of free text clinical notes by data analysts, de-identification needs to be performed to remove protected health information (PHI).

To address this, we utilized the open source MITRE Identification Scrubber Toolkit (MIST) for identifying and redacting HIPAA identifiers in free-text clinical notes. Since MIST is a type of supervised machine learning based on conditional random fields (CRF) model, a gold standard reference corpus composed of custom local data is required for optimal model building. The reference corpus is typically curated by human annotators. Construction of such a gold standard corpus is laborious and time consuming. Instead of human annotators, we tried Amazon's cloud-based natural language processing (NLP) service - Comprehend Medical - to extract potected health information (PHI) from the selected reference dataset. Comprehend Medical's output json files were transformed into MIST annotation files (in mat-json format) using custom scripts. The result mat-json files were subsequently treated as human-gold annotations for the model building and evaluation.

By combining commercial NLP service for initial reference dataset annotations and open source MIST tool for additional clinical notes de-identification, we established a scalable, time-saving and cost-effective automated de-identification workflow that demonstrated excellent performance. Here we present in detail how we implemented this method and share our experience and lessons learned. We successfully applied this method in multiple internal research projects with good user feedback.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4477 Developing a shareable HLA imputation reference panel for the Arab population

Authors:

H. Mbarek[1], C. Demay[1], G. Butler-Laporte[2], C. Saad[1], D. Velayutham[3], Z. Jan[3], P. Jithesh[3], Z. Calderone[4], S. Ismail[5], Qatar Genome Program Research Consortium; [1]Qatar Genome, Doha, Qatar, [2]Univ. of Oxford, Oxford, United Kingdom, [3]Coll. of Hlth.& Life Sci., Hamad Bin Khalifa Univ., Doha, Qatar, [4]American Red Cross, Holland Lab. for BioMed. Sci., Baltimore, MD, [5]Qatar Genome, Qatar Fndn., Doha, Qatar

The Human Leukocyte Antigen (HLA) complex is one of the most polymorphic regions of the human genome, showing significant diversity between different populations. Identifying HLA specific alleles is crucial for a wide range of research and clinical purposes, as the HLA system's genes are associated with susceptibility to over a hundred diseases, including infectious, inflammatory, and autoimmune conditions.
Although the genome-wide association studies (GWAS) and HLA allele imputation framework have revealed numerous associations between the HLA and human diseases, most of the shared imputation bases and tools have been generated from subjects of European origin.This method is known to be imprecise for individuals from ancestral groups poorly or not at all represented in imputation panels, running the risk of omitting potentially relevant HLA associations.
To solve it, we developed an HLA reference panel dedicated to the Arab population using 14,669 whole genome sequenced individuals from the Qatar Genome Program. After raw sequence quality control accounting for HG38 alternative HLA haplotypes, we designed a meta-algorithm combining HLA haplotype calls (IMGT/HLA v3.49) from three state-of-the art algorithms (HISAT-genotype, HLA-HD and T1K) to obtain high-quality HLA allele calls for 26 genes at a 3-field resolution (i.e. all protein-coding and synonymous variants). This includes all clinically relevant classical HLA genes, as well as non-classical HLA class I and II genes, including HLA-DRB3/4/5 and MICA/MICB. Then, these data trained a deep learning model for HLA genotype imputation using the cutting-edge HLA allelic imputation method DEEP*HLA. We obtained a shareable model that respects privacy requirements of both the reference and imputed samples.
Our reference panel and deep learning model are the first of their kind for the Arab population. They will help describe the genetic and phenotypic landscape of the HLA locus, improve understanding of HLA-associated diseases in Arab populations worldwide, and discover new alleles. It will also contribute to improving transplantation practices, mitigating or preventing transfusion-associated graft-versus-host disease, and discovering new host-pathogen interactions that may serve as potential therapeutic targets.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4478 † Developing and sharing polygenic risk scores for 4,206 brain imaging-derived phenotypes for 400,000 UK Biobank subjects not participating in the imaging study.

Authors:

X. Yang[1], B. Li[1], Z. Fan[2], D. Ding[2], J. Shu[1], M. Ritchie[2], G. Nave[2], P. L. Michael[2], T. Li[3], H. Zhu[4], B. Zhao[2]; [1]Purdue Univ., West Lafayette, IN, [2]Univ. of Pennsylvania, Philadelphia, PA, [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [4]M D Anderson Cancer Ctr, Houston, TX

The UK Biobank's brain imaging data is an essential resource for clinical research, but its cost and difficulty in obtaining limit the imaging study to only 100,000 participants, leaving the majority of UKB subjects without imaging data. However, because imaging-derived phenotypes (IDPs) are heritable, and most UKB subjects have genetic information available, it's possible to predict IDPs for UKB subjects outside the imaging study using genetic data. To this end, this study systematically developed and evaluated biobank-scale genetic polygenic risk scores (PRS) for 4,206 IDPs from multiple brain imaging modalities and processing pipelines. The results indicate that the majority of IDPs (64.76%, 2,774/4,206) were significantly predicted by PRS developed by subjects with both genetic and imaging data. Moreover, genetically predicted IDPs showed associations with a wide range of complex traits and diseases, with the patterns being consistent across different imaging pipelines. These findings suggest that genetic prediction through PRS is a cost-effective and practical way to make the UKB imaging study more beneficial to a broader population. The PRS data resources developed in this study have been made publicly available through Zenodo and will be returned to the UK Biobank.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4479 Development of a Korean imputation reference panel for imputing variants within the major histocompatibility complex locus

Authors:

C. Yu, K. Kim; Kyung Hee Univ., Seoul, Korea, Republic of

Genetic variants in the major histocompatibility complex (MHC) region are strongly associated with various human diseases. However, it is challenging to narrow down the causal variants mainly due to ancestry-specific long-range linkage disequilibrium in an extremely complex genetic architecture of the MHC region and the technical difficulty of typing HLA variants (= amino acids and classical alleles) and C4 variants (= C4 isotypes and structural variations) in large-scale populations. Here, our study aimed to construct a Korean MHC imputation reference panel for imputing HLA and C4 variants simultaneously, based on the neighboring SNP haplotypes. To this end, we obtained whole-genome sequencing data from 844 unrelated individuals and typed eight classical HLA genes (HLA-A, -B, -C, -DQA1, -DQB1, -DPA1, -DPB1, and -DRB1) at the G-group resolution by HLA-LA, which utilized a population reference graph. Additionally, we estimated the copy number of *C4*, its two alleles *C4A* and *C4B*, and viral sequences HERV within *C4* using a Gaussian Mixture Model by GenomeSTRiP. To determine the haploid-level copy number of these *C4*-related variants, haplotype clustering was conducted using a Gaussian Mixture Variational Autoencoder model with 733 pruned SNPs around *C4*. The haplotype clusters detected were assigned to the most likely haploid-level copy numbers through an iterative process to maximize the concordance rate between typed and estimated diploid-level copy numbers. Haploid-level HLA and *C4* variants were encoded in a binary format, along with the SNP genotypes using Beagle5. The Korean MHC imputation reference panel comprises 42,141 MHC SNPs, 570 HLA classical alleles at various resolutions, 1,399 HLA amino acid positions, and 17 binary-coded *C4*-related copy numbers. The reference performance was evaluated by measuring imputation accuracy through a leave-one-out cross-validation method. Haploid-level concordance rates were >99% for all eight HLA genes at the G-group resolution and >90% for all four *C4*-related copy number variations. In summary, we characterized the complex structure of *C4* and HLA genes in a Korean population and developed an MHC imputation reference panel that has great potential in future MHC association mapping studies in the Korean population. **Funding:** This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-2022R1A2C2092164).

Matsuda[3], T. Tomita[5], H. Nishihara[12], H. Nakae[13], J. Ikeda[13], H. Yokota[1], K. Ohneda[1], K. Noguchi[1], S. Nagaie[1], F. Nagami[1], T. Takagi[14]; [1]Tohoku Univ., Sendai, Japan, [2]Inst. of Med. Sci., Univ. of Tokyo, Tokyo, Japan, [3]Tokyo Univ., Tokyo, Japan, [4]Natl. Ctr. for Global Hlth.and Med., Tokyo, Japan, [5]Natl. Cerebral and Cardiovascular Ctr., Osaka, Japan, [6]Okayama Univ., Okayama, Japan, [7]Tokyo Med. and Dental Univ., Tokyo, Japan, [8]Kyoto Univ., Kyoto, Japan, [9]Tsukuba Univ., Tsukuba, Japan, [10]Kobe Univ., Kobe, Japan, [11]Shinshu Univ. Sch. of Med., Matsumoto, Japan, [12]Keio Univ., Tokyo, Japan, [13]CIBER, Tokyo, Japan, [14]Toyama Intl. Univ., Toyama, Japan

Biospeimen and data from quality-controlled biobanks are key for research and development in genomic medicine. In Japan, there exists over 50 biobanks, which stores over 1,210,000 biospecimen provided by over 730,000 doners. Biobanks hold quality-controlled biospeimen and data, but research institutions have had difficulty finding where to find the biospeimen and data they need for their own genomic medicine research and development. To address this issue, we established a Japanese biobank network connecting the three major biobanks (Tohoku Medical Megabank project, Biobank Japan, National Center Biobank Network and the university hospital's biobanks (Kyoto University, Tokyo Medical and Dental University, Tsukuba University, Okayama University, Kobe University, Shinshu University) in Japan. Our biobank network aims at research and development of operational support for promotion of utilization of biospecimen and data stored in biobank toward realization of genomic medicine. For this aim, we have developed a biobank crosssearch system on biospecimen and data stored in our biobank network. Research institutions can find biospeimen and data they need for their own genomic medicine research and development. To implement a cross-search service for biospecimens and data, we standardized the metadata of biobank holdings of biospecimen and data. The metadata was standardized by Minimum Information About BIobank data Sharing (MIABIS) in accordance with the biobank data model of the European biobank network BBMRI-ERIC. Now our biobank network stores 1,043,880 biospecimen and 321,112 molecular data provided by 583,773 donors. We also setup the web-based coordination system of fast access to biospecimen and data to meet the requests by academic/commercial users using the biobank cross-search system. Utilization across various biobanks will be promoted by our biobank crosssearch system and support of matching between academic/commercial users, and researches and developments toward realization of genomic medicine will be expected to be accelerated.

PB4481 Development of the ClinGen Rheumatologic Autoimmune Disease Clinical Domain Working Group (RAD CDWG) as an exemplar of complex disease curation

Authors:

R. Shapira[1], C. J. Klein[1], I. M. Keseler[1], G. Cheung[1], O. A. Garcia[1], M. A. Fernandez Vina[2], T. R. Merriman[3], A. Tin[4], S. E. Plon[5], M. W. Wright[1], I. Aksentijevich[6], S. Mack[7], S. L. Bridges, Jr.[8], T. E. Klein[1,9], on behalf of ClinGen Rheumatologic Autoimmune Disease Clinical Domain Working Group; [1]Dept. of BioMed. Data Sci., Stanford Univ., Stanford, CA, [2]Dept. of Pathology, Stanford Univ., Stanford, CA, [3]Univ. of Alabama at Birmingham, Birmingham, AL, [4]Univ. of Mississippi Med. Ctr., Jackson, MS, [5]Baylor Coll. Med., Houston, TX, [6]NIH - NHGRI, Bethesda, MD, [7]Univ. of California San Francisco, San Francisco, CA, [8]Hosp. for Special Surgery, New York, NY, [9]Dept. of Med., Stanford Univ., Stanford, CA

The Clinical Genome Resource (ClinGen) is an NIH-funded consortium dedicated to building a central resource that defines the clinical relevance of genes and variants for use in precision medicine and research. Until recently, gene curation efforts have focused exclusively on monogenic disease. The ClinGen Rheumatologic Autoimmune Disease Clinical Domain Working Group (RAD CDWG) was established to be an exemplar of curating complex genetic disorders.

The RAD CDWG has adopted a structure unique among ClinGen CDWGs, comprised of two framework development subgroups in addition to curation expert panels. Within this integrated and iterative model, disease area experts inform the development of and pilot new frameworks which can then be generalized by ClinGen for other domains.

The RAD CDWG is also addressing monogenic gene-disease relationships with two newly established ClinGen Gene Curation Expert Panels (GCEPs): the Monogenic Autoinflammatory Diseases GCEP and the Systemic and Incomplete Lupus Erythematosus GCEP. Future plans include the development of an Autoinflammatory Diseases Variant Curation Expert Panel (VCEP) in 2024.

The Human Leukocyte Antigen Working Group (HLA WG) was established to create an HLA-disease curation framework and develop a tool that can take in and process the complex HLA nomenclature for curation of HLA-disease associations and HLA-drug interactions. This nomenclature presents a unique challenge to biocurators, particularly given its evolution over time and inconsistent allele naming in the literature. To address this challenge, an extensive list of "common" HLA alleles (persisting at frequencies >0.0001 across multiple populations) is being built into the new curation interface. In conjunction with detailed documentation for mapping identifiers in the literature to the built-in list, this functionality will minimize the need for biocurators with HLA-specific expertise and help ensure data quality.

To fully address the breadth of complex disease inheritance within the RAD clinical domain, the Multigenic Disease Taskforce was established in 2023 with the goals of developing 1) a framework for determining what loci are important to curate, 2) a framework for curation of causal gene(s) at a locus, and 3) guidelines for determining the potential clinical utilities of causal genes of multigenic diseases. Gout has been selected as the test phenotype, as an exemplar complex disease that is not significantly attributable to monogenic or HLA associations. In subsequent phases, the framework will be extended to and tested on other diseases, first within the RAD clinical domain, and ultimately other clinical domains.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4482 Electronic phenotyping in the UK Biobank using the OMOP Common Data Model.

Authors:

D. Yang, W. S. Bush; Case Western Reserve Univ., Cleveland, OH

The UK Biobank (UKBB) is a large-scale registry containing medical, genetic, and lifestyle data from over 500,000 individuals from the UK, but its data is not in an easily usable format for research. Previously, an open-source tool called Delphyne was developed by the Hyve to perform extract, transform, and load (ETL) processing and to deploy the UKBB data using the Observational Medical Outcomes Partnership (OMOP) Common Data Model (CDM). Each time investigators access UKBB data, distinct participant identifiers are assigned to assure participant anonymity, therefore existing OMOP instances of the UK Biobank are not usable across projects or institutions. The ETL process, a crucial part of the data conversion to OMOP, can be a lengthy and complex task if not facilitated by effective tools like Delphyne. Here, we investigate the feasibility and efficiency of applying Delphyne to our local version of the UKBB. We first adapted and applied the published ETL to our UKBB dataset to create an OMOP version, documenting specific UKBB files and code modifications needed. Using electronic phenotyping of aging conditions including Alzheimer's disease (AD) and chronic kidney disease (CKD), we compare data distributions from mapped clinical data to summary diagnoses released by the UKBB and other published analyses of these phenotypes from the UKBB. To further validate the accuracy of our ETL process, we incorporated additional rounds of iterative testing and refinements, ensuring our electronic phenotyping aligns well with the original UKBB data context. OMOP helped to facilitate easier organization and manipulation of large and dense UKBB phenotype information and allowed increased use and harmonization of the data for our research projects. Existing OMOP tools such as the Data Quality Dashboard and the ATLAS web interface are connected to the UKBB OMOP instance to provide easier quality control and data browsing capabilities. We developed a comprehensive tutorial that serves as a guide for other investigators intending to undertake a similar adaptation of their UKBB datasets. This tutorial outlines the steps, challenges encountered, and potential solutions, thus reducing the learning curve and promoting a wider application of the OMOP CDM in future UKBB research. This work streamlines the use of UKBB for more efficient and reproducible research, potentially accelerating the discovery of better insights in the realm of aging and chronic diseases. In addition, our work also highlights the potential of effective data transformation tools like Delphyne, enabling large-scale studies to glean meaningful interpretations from vast datasets.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4483 † Empowering Researchers: Web-Based Repository for Tertiary Analysis of Public Bulk and Single-Cell RNA Sequencing Data.

Authors:

X. Zhang, D. Cheng, Z. Ouyang, Y. Zhu; BioInfoRx, Inc., Madison, WI

High-throughput RNA sequencing technologies (bulk and scRNA-Seq) have revolutionized the field of transcriptomics, providing insights into complex biological processes. The raw sequencing data files from primary data analysis are traditionally deposited to GEO or SRA databases. Recently, uniformly processed secondary analysis results from published RNA-Seq data (e.g., gene counts from ARCHS4 or recount2) have made reproducible analysis and massive data mining possible. However, tertiary data analysis, or interpreting the results in the context of the study, remains challenging for typical scientists without computational skills.
To overcome this challenge, we have developed web-based databases and data mining tools to enable scientists to conduct sophisticated tertiary analyses without requiring computational expertise. For bulk RNA-Seq data, >30,000 human and mouse projects encompassing >1 million samples from ARCHS4 are loaded into a web database. Researchers can easily access the projects and samples, utilize a streamlined workflow to perform differential gene expression analysis, and load the results in QuickOmics, a Shiny-based visualization system. QuickOmics includes a range of tertiary analysis tools such as PCA, gene expression plots, heatmaps, co-expression networks, functional enrichment, and pathway analysis.
For single-cell datasets, we collected published data reported by the authors and processed the results into h5ad format. In cases where important information, such as cell type annotation, is missing in public repositories, we have reached out to authors to obtain the required details. A standardized scRNA-Seq analysis pipeline has also been utilized to reprocess raw data for a subset of datasets. Currently, our database contains over 400 single-cell RNA-Seq datasets, comprising more than 17 million cells, with ongoing expansion. Researchers can explore these datasets visually using the interactive and scalable cellxgene VIP tool. This tool empowers researchers to gain insights into cell composition, gene expression profiles, and differentially expressed genes across cell types, utilizing over 20 commonly used plotting functions and high-level analysis techniques in single-cell research.
Comprehensive documentation is provided to assist users to fully utilize these tools. We will present several case studies where the databases and tools can quickly reproduce published results. The easy access to RNA-Seq tertiary analysis will foster collaboration, promote reproducibility and facilitate new discoveries.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4484 Enhancing dbSNP and ALFA for Genomic Research: Commemorating dbSNP's 25th Anniversary

Authors:

L. Phan, W. Qiang, H. Zhang, G. Shekhtman, E. Moyer, L. Ziyabari, R. Villamarin, T. Hefferon; NIH, NLM/NCBI, Bethesda, MD

Genomic research has witnessed remarkable progress over the past 25 years, and this year marks the 25th anniversary of the Single Nucleotide Polymorphism Database (dbSNP). In light of this significant milestone, this presentation outlines crucial improvements to dbSNP and the Allele Frequency Aggregator (ALFA) databases to meet the evolving demands of researchers and clinicians in precision medicine. The proposed enhancements encompass data integration, quality control, advanced annotation tools, expanded population-specific allele frequencies, improved web search tools, and an enhanced user interface. By incorporating these updates, we aim to provide researchers with reliable and comprehensive genomic information, enabling robust genotype-phenotype associations and accelerating discoveries in disease genetics and personalized medicine. As we celebrate the 25th anniversary of dbSNP, this presentation not only highlights its legacy but also showcases how these improvements will revolutionize healthcare practices, empowering the scientific community to unlock the full potential of genomics.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4485 Enhancing genomic understanding in the Taiwanese population: Individual-level Structural Variant profiling and HLA genotyping by WGS.

Authors:

J. Hsu[1], Y. Tseng[1], P. Chen[1], P-M. Chien[2], S-K. Lai[3], C-Y. Chen[2], P. Chen[1]; [1]Natl. Taiwan Univ., Taipei City, Taiwan, [2]Natl. Taiwan Univ., Taipei, Taiwan, [3]Natl. Taiwan Univ. Hosp., Taipei City, Taiwan

Accurately detecting genetic variations in Biobank-scale whole-genome sequencing (WGS) data is essential for precisely constructing a comprehensive variation profile and characterizing allele frequencies. This study focuses on improving genomic understanding in the Taiwanese population by addressing challenges related to individual-level structural variant (SV) profiling and human leukocyte antigen (HLA) genotyping. Previously published databases, such as gnomAD and HGSVC, have not adequately benchmarked SV calling using materials from the Genome in a Bottle (GIAB) consortium for their SV callsets. Moreover, the representation of Asians, including Taiwanese individuals, is limited in these databases. To overcome these challenges, we utilized the GIAB released workflow and callsets to evaluate nine SV callers, achieving an overall F1 score, precision, and recall of 0.85, 0.89, and 0.82, respectively, for large germline deletions. In parallel, this study compares WGS-based HLA genotyping algorithms, including HLA-VBSeq, Kourami, and HISAT-genotype. By analyzing miscall patterns using 800 samples with confirmed HLA genotypes, the study establishes the best available WGS-based HLA genotyping workflow and suggests complementary approaches for different HLA genes. We recommend using HISAT-genotype as the primary algorithm combined in-house checkpoints with HLA-VBSeq to reach at least 96% sensitivity for HLA class I genes at the two field resolutions. With an established WGS-based SV profiling and HLA genotyping workflow, individual-level SV and HLA genotypes can be resolved for samples from the Taiwan Biobank (TWB), facilitating improved clinical applications and personalized medicine. This research significantly enhances genomic studies in the Taiwanese population by integrating comprehensive SV analysis and improved HLA genotyping. The findings provide valuable insights into molecular diagnosis and the understanding of genetic variations, thereby offering essential information for healthcare applications in Taiwanese and Asian populations.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4486 † Enhancing Molecular Diagnosis of Mendelian Disorders: An Automated Phenotype-Genotype Database Using Large Language Models

Authors:

Z. Chen[1], J. Cai[1], Y. Yang[2], Z. Zhao[1], G. Li[1], K. Xu[1], Q. Li[1], N. Wu[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]Queen Mary Univ. of London, London, United Kingdom

Mendelian disorders affect millions of live births each year, underscoring the pressing need for molecular diagnoses provided by exome sequencing (ES). A typical ES analysis necessitates the interpretation of hundreds of variants, a task heavily reliant on phenotype-genotype databases such as The Human Gene Mutation Database (HGMD), ClinVar, and Online Mendelian Inheritance in Man (OMIM). However, these existing databases encounter two major challenges: 1) a lack of adequate phenotype-genotype associations; 2) an inability to accurately represent the probability of phenotype occurrences. To address these challenges, this study aims to establish an automated phenotype-genotype database of Mendelian disorders, capitalizing on recent advancements in large language models (LLMs). First, we developed a novel search strategy. Leveraging the similarity computation capabilities of LLMs, we employed semantic similarity searches instead of traditional keyword searches to identify all relevant literature on Mendelian disorders on Pubmed (a total of 34,957,128 articles). Using recall and precision as the evaluation metrics and HGMD as the "gold standard" (a total of 78,023 articles), semantic similarity search strategies notably outperformed keyword searches, yielding a relative increase ranging from 61.9% to 190.5% for recall, and -25.8% to 96.8% for precision. Second, leveraging the in-context learning and instruction-following abilities of LLMs, we developed a pipeline to efficiently extract phenotypes from the retrieved articles. When using recall and precision as the evaluation metrics, the LLMs-based pipeline successfully retrieved 79.7% of phenotypes with a precision rate of 90.3% in a manually curated test set of 208 articles. Here, we presented a prototype for a Marfan Syndrome phenotype-genotype database, developed through the LLMs-based strategies (Table 1, https://www.dropbox.com/s/eb4mzbxcsmb66fk/Table_1.csv?dl=0). Our approach has demonstrated enhanced precision and recall, as well as more accurate information extraction. This revealed considerable promise for the automatic construction of a phenotype-genotype database, and thus facilitating the molecular diagnosis of Mendelian disorders.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4487 Expanding the GENCODE geneset - addition of "non-canonical" ORFs to the Human reference annotation

Authors:

T. Hunt, J. M. Mudge, J. Gonzalez, J. Loveland, A. Frankish, The GENCODE consortium; EMBL-EBI, Hinxton, United Kingdom

The GENCODE consortium produces detailed reference annotation of all human and mouse protein-coding genes, pseudogenes, long non-coding RNAs and small RNAs. Accurate gene annotation is of fundamental importance for genome biology and clinical genomics; annotation that is incorrect or incomplete impacts downstream analysis and introduces potentially significant errors.

Recent work on enhancing the GENCODE geneset has focused on the identification of novel ORFs, including potential translations within lncRNAs and the UTRs of protein-coding genes. Extensive translation occurs outside of 'canonical' human protein-coding genes which can be readily identified by Ribosome Profiling. The first stage of this community-driven work involved making a consensus set of Ribo-seq ORFs identified by seven recent experimental publications mapped to GENCODE annotations. This resulted in the identification of 7,264 Ribo-seq ORFs which were recently published (PMID: 35831657).

However whether these ORFs are truly functional or simply molecular "noise" is open to discussion. Ribosome profiling does not demonstrate protein existence, and we have thus far classified only ~50 Ribo-seq ORFs as protein-coding by using evolutionary methods to distinguish protein-level constraint. Furthermore, our high stringency conventional mass spectrometry analysis finds little proteomics support for Ribo-seq ORF proteins. To investigate further, we have performed an extensive bespoke analysis of immunopeptidomics datasets. We observe that large numbers of Ribo-seq ORFs generate proteins that are presented by the HLA system within cell-lines or cancer samples, raising their potential utility as biomarkers or therapeutic targets. Finally, we recognize that translation can instead have a purely regulatory function. Around half of our Ribo-seq ORFs are uORFs within protein-coding genes, and these are also of emerging clinical interest.

Thus, we see great value in producing a reference GENCODE annotation of 'non-normal' translation. We will discuss our efforts to expand our current "non-canonical" ORF catalog, with a community-focused approached, including the expansion of our 5' UTR annotation with state-of-the-art transcriptomics data to ensure that it encompasses putative uORFs; the development of a new evolutionary approach to infer their function; and the development of gold standard approaches to analyse Ribo-seq data.

Combined, this expansion and improvement of the GENCODE catalog will provide a gold standard resource for both basic genome biology research and clinical genomics applications.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4488 Exploring Genetic Polymorphisms of Amino Acid Concentrations in a Community-Based Japanese Cohort of 10,000.

Authors:

R. Toki[1], S. Harada[1], S. Kojima[1,2], S. Fushiki[1,2], A. Hirata[1], M. Iida[1], N. Miyagawa[1], S. Edagawa[1], A. Miyake[1], Y. Sutoh[3,4], H. Ohmomo[3,4], Y. Otsuka-Yamasaki[3,4], A. Shimizu[3,4], T. Okamura[1], T. Takebayashi[1]; [1]Dept. of Preventive Med. and Publ. Hlth., Keio Univ. Sch. of Med., Tokyo, Japan, [2]Konica Minolta, Inc., Tokyo, Japan, [3]Div. of Bioinformation Analysis, Iwate Tohoku Med. Megabank Organization, Iwate Med. Univ., Yahaba, Japan, [4]Div. of Bioinformation Analysis, Inst. for BioMed. Sci., Iwate Med. Univ., Yahaba, Japan

Introduction: Plasma amino acid concentrations have been recognized as vital markers for various diseases and these are influenced by a complex interplay of genetic and environmental factors. Although genome-wide association studies (GWAS) have successfully identified genetic variants affecting plasma amino acid concentrations, most predominantly focus on European populations. Therefore, there is an unaddressed need for further exploration of these genetic associations in the Japanese population. **Objective:** Our study aims to identify genetic polymorphisms associated with plasma amino acid concentrations in a Japanese population, comprising 10,000 individuals. **Methods:** We genotyped 10,933 participants from the Tsuruoka Metabolomics Cohort Study (TMCS) baseline surveillance using the Axiom™ Japonica Array™ NEO (Thermo Fisher Scientific). Following quality control, we conducted cross-imputation with impute4 using the 3.5KJPNv2/1000 genome phase3 panel in line with our prescribed pipeline. Subsequently, we conducted a GWAS using BOLT-LMM (v2.3.6) with 20 common amino acid concentrations in plasma measured by capillary electrophoresis-mass spectrometry as traits. We then fine-mapped the obtained summary statistics and cross-referenced our lead single nucleotide polymorphisms (SNPs) with previous reports in the GWAS Catalog. **Results:** Association analysis of 11,584,837 SNPs identified polymorphisms significantly associated ($p < 5 \times 10^{-8}$) with 18 of the 20 plasma amino acid concentrations, excluding glutamic acid and leucine, and detected 85 significant locus-to-metabolite associations at 43 genes. Of these associations, 43 loci had no reported one-to-one association with the trait, and 14 loci had no reported association with any plasma metabolite in the previous metabolome GWAS. For instance, SNPs in *AGXT* and *MTHFR* were shown to be significantly associated with plasma serine concentrations for the first time in this study, and both were identified as genes encoding necessary metabolic enzymes involved in serine metabolism. In addition, polymorphisms commonly associated with multiple amino acid concentrations were detected at 15 loci where associations were noted, further suggesting the possibility of pleiotropy. **Conclusion:** Our study focused on genetic factors on plasma amino acid concentrations by identifying multiple genetic polymorphisms in the Japanese population. The unique findings, including potential novel mutations and pleiotropy, call for further validation and underline the need for more comprehensive studies in different ethnicities to fully understand the global genetic architecture of these traits.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4489 ExtCodonIslands: A novel algorithm for extracting outlier regions in translational efficiency.

Authors:

M. Cloward, E. Nysetvold, P. Ridge; Brigham Young Univ., Provo, UT

Codon bias is the unequal distribution of synonymous codons across a gene or genome. Codon choice is subject to selection and is non-random. Codon choice is highly correlated with the most abundant tRNA. This is energetically desirable because the anticodons bind more efficiently to the codon during translation, unlike codons that do not bind in the wobble position. Codons may be labeled as efficient (i.e., their cognate tRNA is highly expressed) and translated quickly, or inefficient and translated more slowly. Groups of consecutive, inefficient codons appear in many genes. For example, a ramp sequence is consecutive inefficient codons at the 5' end of the coding region. Here we name outlier regions of efficient or inefficient codons "codon islands." Like ramp sequences, the presence or absence of codon islands is conserved. Efficiency-altering mutations in these codon islands may have phenotypic consequences even when the mutation is synonymous (e.g., inefficient regions may slow the ribosome to allow for protein folding that must occur before downstream translation). We present ExtCodonIslands, an algorithm to identify codon islands, and we describe the frequency, locations, and conservation of codon islands.
ExtCodonIslands uses codon efficiencies provided by the user or calculates efficiencies from a CDS file. Each codon in each sequence in the input file is assigned an efficiency. ExtCodonIslands uses a sliding window mean to remove noise and simulate ribosome movement along the transcript. Outliers are identified if window mean clusters exceed the interquartile range multiplied by plus or minus 1.5.
We ran ExtCodonIslands on 144,412,469 sequences from 69,224 archaea, bacteria, fungi, invertebrates, plants, protozoa, mammalian vertebrates, other vertebrates, and viruses. We identified 100,113,205 codon islands or 0.73 islands per transcript. Islands per transcript ranged from 0.29 in mammals to 1.04 in fungi. Islands were more abundant at the 5' and 3' ends of transcripts that contained them and less abundant in the center. Excluding viruses, the tool ran at about 1.7 seconds per 1000 transcripts on a standard laptop. Our study provides important insights into codon efficiency clustering patterns in all domains of life.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4490 Extending Pan-UK Biobank to rare variants through systematic gene-based association testing across continental ancestry groups in the UK Biobank.

Authors:

J. Sealock[1,2], W. Zhou[1,2], K. Tsuo[2], M. Kanai[2], W. Lu[3], Y. Wang[1], Y. He[4], R. Gupta[5], R. Grant[2], P. Darnowsky[2], M. Solomonson[2], R. Walters[1], E. Atkinson[6], B. Neale[1], A. Martin[1], K. Karczewski[7]; [1]Massachusetts Gen. Hosp., Boston, MA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA, [3]Broad Inst., Cambridge, MA, [4]Harvard Med. Sch., Boston, MA, [5]Harvard Med. Sch. / Broad Inst., Cambridge, MA, [6]Baylor Coll. of Med., Houston, TX, [7]Broad Inst., Medford, MA

Rare-variant association studies (RVAS) provide new opportunities to directly assess phenotypic effects of gene disruption by aggregating rare damaging variants, particularly predicted loss-of-function (pLoF) variants, within a gene. We previously conducted RVAS on thousands of phenotypes in the UK Biobank (UKB); however, analyses were performed using only individuals with European ancestry (EUR), thus limiting the detection of rare variants to a single ancestry. Here, we make use of the full UKB dataset to conduct RVAS on all genetic ancestry groups.
We performed gene burden testing in the two largest non-EUR ancestries in UKB, CSA (Central/South Asian; N = 8,471) and AFR (African; N = 6,281), using SAIGE-GENE+ on pLoF, missense, and synonymous variants. These analyses included some of the largest gene burden tests for a subset of phenotypes in these ancestries. In CSA, we discovered 284 significant associations among 468 phenotypes. Notable associations included changes in blood biomarker levels with pLoF variants in *HBB*, such as red blood cell count. We found 12 pLoF associations not seen in EUR, including an association between *HBB* and direct bilirubin. Analyses in AFR identified 575 significant associations across 353 tested phenotypes. We replicated a known association between decreased LDL levels and damaging variants in *PCSK9*. There were 20 pLoF associations not seen in EUR, including between *UGT1A3* and total bilirubin. Among significant hits, the correlation of effect estimates with EUR was 0.50 ($p = 2 \times 10^{-7}$) for CSA and 0.40 ($p = 2 \times 10^{-4}$) for AFR, suggesting that these effects are directionally consistent, but in some cases providing additional information on top of EUR effects.
Inclusion of non-EUR samples in genetic studies is imperative to maximizing scientific discoveries. While some of the analyses conducted here remain underpowered, the results represent some of the largest RVAS of non-EUR populations to date. Effect estimates were not perfectly correlated between EUR and AFR/CSA, and several associations not seen in EUR emerged, indicating the potential for uncovering new genes by using the full dataset. Our results illustrate the utility of incorporating diverse populations for RVAS and provide a step forward for creating equitable and diverse population genetics resources.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4491 FinnGen PGS Browser: a platform for polygenic risk score analyses and interpretation from a cohort of 400,000 Finns.

Authors:

N. Kolosov[1], FinnGen, V. Llorens[2], T. P. Sipilä[2], M. Aavikko[2], M. P. Reeve[2], S. Ripatti[2], A. Palotie[2,3,4], M. J. Daly[2,3,4], M. Artomov[1,5]; [1]Nationwide Children's Hosp., Columbus, OH, [2]Inst. for Molecular Med. Finland (FIMM), Helsinki Inst. of Life Sci. (HiLIFE), Univ. of Helsinki, Helsinki, Finland, [3]Broad Inst. of Harvard and MIT, Cambridge, MA, [4]Massachusetts Gen. Hosp., Boston, MA, [5]The Ohio State Univ. Coll. of Med., Columbus, OH

Polygenic scores (PGSs) have become a vital resource for biomedical research due to the increasing availability of genome-wide association study results, genetic data, and electronic health records from large biobanks such as FinnGen. PGSs have a broad range of applications, such as predicting a patient's disease status, estimating the age of disease onset, identifying phenome-wide associations, or assessing shared etiology between phenotypes. However, for researchers and medical professionals to easily comprehend and utilize this information, it is crucial to present it in a clear and concise manner.

To address this need, we've created a "FinnGen PGS browser" - a web-based application that allows researchers to access a variety of PGS-based experimental results conducted in 392,649 participants and offers advanced filtering, visualization, and risk prediction capabilities.

We analyzed 129 polygenic score models (PGSs) derived from external genome-wide association studies (GWAS) and 4,995 traits from FinnGen (n=392,649). For each PGS model, we conducted a phenome-wide association study to investigate its association with 4,995 phenotypes for case/control status using logistic regression, and age of disease onset using Cox proportional hazards. On average, we observed 349 significant (p-value < $2*10^{-6}$) associations per PGS model for case/control status and 127 for age of onset. For each phenotype, we presented the corresponding odds ratios, hazard ratios, and area under receiver operating characteristic curve (ROC AUC) for all PGSs.

Additionally, we identified 15 phenotypes with ROC AUC values for PGS models exceeding 0.6 and trained corresponding Cox proportional hazards deep neural networks using polygenic scores and clinical data to provide the predictions for the external samples. The performance of these models was evaluated on test samples using the time-dependent concordance index (C^{td}-index), ranging from 0.63 to 0.89.

We envision that the PGS browser presented in this study will inspire future hypothesis generation for researchers and help facilitate further integration of PGSs into clinical practice.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4492 † Gene Expression and Splicing QTL Analysis of Blood Cells in African American Participants from the Jackson Heart Study

Authors:

J. Wen[1], Q. Sun[2], L. Huang[3], L. Zhou[1], M. F. Doyle[4], L. Ekunwe[5], N. C. Olson[6], A. P. Reiner[6], Y. Li[7], L. M. Raffield[8]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]UNC-Chapel Hill, Chapel Hill, NC, [3]Univerisity of North Carolina at Chapel Hill, Chapel Hill, NC, [4]Univ. of Vermont, Burlington, VT, [5]Jackson Heart Study, Jackson, MS, [6]Univ. of Washington, Seattle, WA, [7]Univ North Carolina, Chapel Hill, NC, [8]UNC - Chapel Hill, CHAPEL HILL, NC

Most gene expression and alternative splicing quantitative trait loci (eQTL/sQTL) studies have been biased toward European ancestry individuals. Here, we performed eQTL and sQTL analysis using TOPMed whole genome sequencing-derived genotype data and RNA sequencing data from stored peripheral blood mononuclear cells in 1,012 African American participants from the Jackson Heart Study (JHS). At a false discovery rate (FDR) of 5%, we identified 4,798,604 significant eQTL-gene pairs, covering 16,538 unique genes; and 5,921,368 sQTL-gene-cluster pairs, covering 9,605 unique genes. About 31% of detected eQTL and sQTL variants with a minor allele frequency (MAF) $gt 1% in JHS were rare (MAF $lt 0.1%), and therefore unlikely to be detected, in European ancestry individuals. We also generated 17,630 eQTL credible sets and 24,525 sQTL credible sets for genes (gene-clusters) with lead QTL p $lt 5e-8. Finally, we created an open database, which is freely available online (http://jhsqtl.genetics.unc.edu/), allowing fast query and bulk download of our QTL results.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4493 GeneMatcher and VariantMatcher, tools designed for phenotypic and genomic data sharing

GeneMatcher (genematcher.org), is a freely available, web-based tool designed to facilitate connection of individuals around the world with interest in a specific gene with options to tailor matches using phenotype criteria. It has been used primarily to establish collaborations aimed to identify novel disease gene candidates. Over the last ~10 years it has been acknowledged in more than 747 publications describing more than 560 novel disease gene discoveries. GeneMatcher is also a founding member of Matchmaker Exchange (MME; www.matchmakerexchange.org), that allows GeneMatcher submitters to match genes across MME. As of June 1st, 2023, there are 17,132 GeneMatcher submitters from 105 countries who have made 74,420 submissions involving 15,392 unique genes, with 10,775 genes having > one match.VariantMatcher (variantmatcher.org) is also a freely available web-based tool developed to connect individuals around the world with interest in a specific variant. It enables sharing of de-identified variant-level and phenotypic data from research participants for discovery of disease-causing variants and genes. The database contains rare (MAF < 1% in gnomAD), nonsynonymous SNVs identified in 6,827 VCF files (957,249 unique variants) of affected and unaffected individuals sequenced as part of multiple projects along with their phenotypic information. Users are able to query the database upon registration and administrator approval. Queries are made on "chr:coordinate refAllele > altAllele" format using hg19 assembly (hg18 and hg38 will be lifted over to hg19 prior to matching). Matches are based on genomic coordinates, although phenotypic features can be added and shared in the email notifying the match. VariantMatcher is also connected to the Beacon Network through the Beacon protocol. As of June 1st, 2023, VariantMatcher had 901 submitters from 50 countries; 11,265 variants in 252 genes (224 of which are known disease genes). 281 variants have matched to 1 of more of 2,199 individuals. Among these 281 variants, 24 were classified as pathogenic or likely pathogenic in ClinVar, 155 were classified as variant of uncertain significance (VUS) and 42 were classified as benign or likely benign. To date, most of the matches helped to rule out the queried variant as causative for the phenotype being investigated.GeneMatcher and VariantMatcher have been widely used around the globe and have enabled researchers, health care providers, and patients to share their phenotypic and genomic data and build new connections to increase discovery rate of novel etiologies for diseases of unknown cause providing insights into both human biology and disease.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4494 † Generation of a multi-ancestry Leukocyte Telomere Length resource in the Million Veteran Program

Authors:

K. Iyer[1,2], P. Vembu[2], R. Guarischi-Sousa[1,2], P. Billing-Ross[3,2], P. Tsao[1,2], S. Clarke[1,2], T. Assimes[1,2]; [1]Dept. of Med., Stanford Univ., Palo Alto, CA, [2]VA Palo Alto Hlth.Care System, Palo Alto, CA, [3]Dept. of Genetics, Stanford Univ., Palo Alto, CA

Telomeres, repetitive DNA sequences that protect chromosomal ends, shorten with age, and have been associated with several age-related chronic illnesses. Both genetics and environmental factors impact telomere length. However, telomere length has been predominantly studied in European populations, due to the scarcity of multi-ancestry biobanks that could facilitate such comprehensive investigations. This gap poses a great risk of exacerbating disparities in aging research.

The Million Veteran Program (MVP) presents a unique and unparalleled chance to bridge the existing gaps in telomere research concerning diversity and aging demographics. We leveraged the pre-existing sequenced data of 78,385 diverse MVP participants to generate the aging phenotype of leukocyte telomere length (LTL) using the widely implemented bioinformatics tool in the field - TelSeq. These participants with a mean age of 65 years, exhibited a demographic distribution of approximately 69% European ancestry, 24% African ancestry, 6% Hispanic ancestry, and 1% Asian ancestry. LTL estimates for this analytic sample set showed a median of around 2kb (IQR_{all} = 1.7kb - 2.3kb; $Median_{EUR}$ = 1.97kb, IQR_{EUR} = 1.67kb - 2.28kb; $Median_{AFR}$ = 2.03kb, IQR_{AFR} = 1.73kb - 2.36kb; $Median_{HISP}$ = 1.97kb, IQR_{HISP} = 1.64kb - 2.35kb; $Median_{ASN}$ = 1.86, IQR_{ASN} = 1.55kb - 2.3kb). Among these participants, we observed a statistically significant inverse correlation between age and estimated LTL (r= -0.26, p<2E-16), which was consistent across all ancestry groups (r_{EUR} = -0.27, p_{EUR}<2E-16; r_{AFR} = -0.23, p_{AFR}<2E-16; r_{HISP} = -0.21, p_{HISP}<2E-16; r_{ASN} = -0.21, p_{ASN}<2E-16). To further investigate this relationship, within each ancestry group we stratified the participants into 20-year age intervals and examined the correlation within each bin. We observed a marginally declining correlation with increasing two decades intervals, corroborating the fact that rate of telomere attrition decreases in older individuals.

Next steps include making the resource available to active MVP investigators for the (1) identification of genetic determinants of LTL, and (2) association of LTL with common chronic diseases encountered by veterans. Considering that majority of MVP samples have undergone sequencing using the Illumina's NovaSeq platform and processed exclusively at a single center, we expect minimal batch effects that could compromise the accuracy of our LTL estimates. Therefore, we plan to expand the scale of LTL data generation by including additional 75,000 samples. This expanded dataset will likely contribute to a more comprehensive understanding of LTL and its associations with diverse populations and aging.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4495 Genome in a Bottle benchmarks in the era of complete human genomes

Authors:

J. Zook; Natl. Inst. of Standards and Technology, Gaithersburg, MD

Recent advances in genome sequencing, assembly, and polishing have made high-quality, nearly-complete diploid genome assemblies possible. The Genome in a Bottle Consortium (GIAB) is using these diploid assemblies to generate benchmark sets for evaluating accuracy of challenging small variants and structural variants. Previous versions of the GIAB benchmark sets relied primarily on variant calls from mapped reads. These mapping-based benchmark sets excluded regions with large variants and complex variants, excluding ~8% of the GRCh38 reference genome plus 7% of sequence missing from the reference. Initial exploratory work in assembly-based variant calling provided promising results, first with the development of a benchmark for the difficult, highly variable but medically relevant MHC region, then with a benchmark set targeting 273 medically relevant genes not sufficiently covered by our existing mapping-based benchmark sets. Building off this initial work we developed a framework for generating and evaluating assembly-based benchmarks sets. We form these benchmarks using the assembly-based variant caller dipcall, followed by excluding regions with potential assembly errors, alignment errors, and variant types problematic for current benchmarking tools. This framework enables the automated generation of small and structural variant draft benchmark sets for high-quality diploid assemblies aligned to multiple references (GRCh37, GRCh38, and T2T-CHM13). We are currently working with the GIAB community to evaluate draft assembly-based benchmarks for tandem repeats and for X and Y chromosomes, with the latter derived from complete chromosome assemblies. For the X and Y benchmark, we found it reliably identifies errors across a variety of high-quality variant callsets from different technologies, though we needed to exclude assembly errors in very long homopolymers as well as a complex gene conversion-like event containing the gene TSPY2 where assembly-assembly alignment is not standardized. As we include increasingly complex variants in the benchmark, we are also developing new tools to compare these variants, e.g., enabling robust benchmarking in tandem repeats. The GIAB and T2T Consortia are also working towards a near-perfect assembly with homopolymer errors corrected, as well as methods to form benchmarks for regions with complex variants. These new curated benchmarks will be valuable as the community moves towards variant calling in the most challenging regions, spurring development of increasingly accurate sequencing technologies and bioinformatics methods.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4496 GenomeConnect: Patient completed health surveys can increase phenotypic data available in the public knowledge base

Authors:

C. Cooney[1], J. M. Savatt[2], D. R. Azzariti[3], H. L. Rehm[4], C. L. Martin[2], E. R. Riggs[5]; [1]Geisinger, Danville, NJ, [2]Geisinger, Danville, PA, [3]ClinGen Resource, Cambridge, MA, [4]Massachusetts Gen. Hosp., Boston, MA, [5]Geisinger, Huntsville, AL

ClinGen's patient registry, GenomeConnect, has recognized that patients can serve as an important source of genomic and health data. GenomeConnect collects data from genetic reports and health surveys from participants who consent to de-identified data sharing and recontact. All participants are encouraged to complete a general health survey; some are offered additional sub-surveys based on their responses. Responses from participant surveys are mapped to Human Phenotype Ontology (HPO) terms to enable structured data sharing. Detailed phenotypic information can be valuable when evaluating gene-disease validity and variant pathogenicity. GenomeConnect, in consultation with ClinGen's curation expert panels, designed 8 detailed sub-surveys to capture additional phenotypic data: developmental milestones, developmental services and family history, cardiomyopathy, seizures, arrhythmia, RASopathy, cancer, and heart defects. To assess the value of participant completed health surveys, we reviewed the number of completed surveys and HPO terms collected for all GenomeConnect participants. Of 4,588 participants, 3,459 (75%) completed the general health survey resulting in an average of 2 HPO terms per participant (0-258). Based on their responses, 2,236 (49%) participants were eligible to complete at least one sub-survey. Nine hundred and twenty-seven participants (41%) completed at least one sub-survey with a complete rate of: 35% developmental milestones and developmental services and family, 39% cardiomyopathy, 28% seizures, 45% arrhythmia, 7% RASopathy, 44% additional cancer, and 40% heart defect. Preliminary data suggest that the sub-surveys provide an additional HPO term per participant (range 0.8-8.5) though the number of potential HPO terms varies per sub-survey. GenomeConnect surveys also provide additional data that cannot be described using HPO terms, such as treatment, family history, age of symptom onset and diagnosis. The development of additional sub-surveys is advancing patient-provided phenotypic data collection, which can be used to inform gene and variant classification efforts including those of ClinGen expert curation panels. Further, GenomeConnect surveys are publicly available, and modified versions are being used by other advocacy groups thus increasing detailed phenotypic data collection. GenomeConnect participants continue to provide valuable genetic and health data to the public knowledge base. In future work, we plan to compare GenomeConnect's ClinVar submissions to those from other submitters and determine the number of variants where GenomeConnect is the only source of structured phenotype data.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4497 † Genome-wide maps of regulatory enhancer-gene interactions across human cell types and tissues.

Authors:

K. Mualim[1,2]; [1]Stanford Univ., Stanford, CA, [2]Carnegie Inst. for Sci. - Dept. of Plant Biology, Stanford, CA

Identifying transcriptional enhancers and their target genes is essential for understanding gene regulation and the impact of human genetic variation on disease. Here we create and evaluate a resource of >13 million regulatory enhancer-gene interactions across 352 cell types and tissues, by integrating predictive models, measurements of chromatin state and 3D contacts, and large-scale genetic perturbations generated by the ENCODE4 Consortium. We first create a systematic benchmarking pipeline to compare predictive models, assembling a dataset of 10,411 element-gene pairs measured in CRISPR perturbation experiments, >30,000 fine-mapped eQTLs, and 569 fine-mapped GWAS variants linked to a likely causal gene. Using this framework, we develop a new predictive model, ENCODE-E2G, that achieves state-of-the-art performance across multiple prediction tasks, demonstrating a strategy involving iterative perturbations and supervised machine learning to build increasingly accurate predictive models of enhancer regulation. The ENCODE-E2G atlas of regulatory enhancer-gene interactions across the genome reveals global properties of enhancer networks, identifies differences in the functions of genes that have more or less complex regulatory landscapes, and improves analyses to link noncoding variants to target genes and cell types for common, complex diseases. By interpreting the model, we find evidence that, beyond enhancer activity and 3D enhancer-promoter contacts, additional features guide enhancer-promoter communication including promoter class and enhancer-enhancer synergy. Altogether, these genome-wide maps of regulatory enhancer-gene interactions, benchmarking software, predictive models, and insights about enhancer function provide a valuable resource for future studies of gene regulation and human genetics.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4498 Genome-wide prediction of dominant and recessive neurodevelopmental disorder risk genes

Authors:

A. Zoghbi[1], B. Weido[1], J. Dhindsa[1], A. Shetty[1], C. Sands[1], S. Petrovski[2], D. Vitsios[3], R. Dhindsa[1]; [1]Baylor Coll. of Med., Houston, TX, [2]AstraZeneca, Fulbourn, United Kingdom, [3]AstraZeneca, CAMBRIDGE, United Kingdom

Despite great progress in the identification of neurodevelopmental disorder (NDD) risk genes, there are thousands that remain to be discovered. Computational tools that provide accurate gene-level predictions of NDD risk can significantly reduce the costs and time needed to prioritize and discover novel NDD risk genes. Here, we first demonstrate that machine learning models trained solely on single-cell RNA-sequencing data from the developing human cortex can robustly predict genes implicated in autism spectrum disorder (ASD), developmental and epileptic encephalopathy (DEE), and developmental delay (DD). Strikingly, we find differences in gene expression patterns of genes with monoallelic and biallelic inheritance patterns. We then integrate these expression data with 300 orthogonal features in a semi-supervised machine learning framework (mantis-ml) to train inheritance-specific models for ASD, DEE, and DD. The models have high predictive power (AUCs: 0.84 to 0.95) and top-ranked genes were up to two-fold (monoallelic models) and six-fold (biallelic models) more enriched for high-confidence NDD risk genes than genic intolerance metrics. Across all models, genes in the top decile of predicted risk genes were 60 to 130 times more likely to have publications strongly linking them to the phenotype of interest in PubMed compared to the bottom decile. Collectively, this work provides highly robust novel NDD risk gene predictions that can complement large-scale gene discovery efforts and underscores the importance of incorporating inheritance into gene risk prediction tools (https://nddgenes.com).

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4499 Genomic and Clinical Correlates of Plasma Urate in the "All of Us" Cohort

Authors:

O. Shchelochkov[1], A. Awan[2], T. Ferrara[2], S. Goleva[2], D. Schlueter[3], J. Keaton[4], J. Denny[5], H. Mo[2]; [1]Purine and Pyrimidine Metabolism Unit, NHGRI, Bethesda, MD, [2]Cohort Analytics Core, NHGRI, Bethesda, MD, [3]Cohort Analytics Core, NHGRI, BETHESDA, MD, [4]Ctr. for Precision Hlth.Res., NHGRI, Bethesda, MD, [5]All of Us, NIH; Cohort Analytics Core, NHGRI, Bethesda, MD

Variations in blood urate are associated with clinical, genomic, and environmental factors, but their causal interactions require further clarification. Using a population-scale dataset ("All of Us"), we explored causal relationships between urate levels, genomic correlates, and co-morbidities. The All of Us cohort currently includes 245,400 participants with genome sequencing, demographics surveys, and electronic health records, including lab measurements. Blood urate level was extracted from electronic health records, formatted and standardized for analysis using the QualityLab pipeline (PMID: 33441150). Participants with end-stage renal disease, blood cancers, or urate levels exceeding 3 standard deviations from the mean were excluded. 25,261 participants met the inclusion/exclusion criteria. Using a trans-ancestry GWAS analysis to identify polymorphisms associated with urate levels, we replicated several known GWAS associations. Blood urate was associated with SNPs in *SLC2A9* (rs13115469-C, beta = 0.39 mg/dL, p = 1.24e-119); *ABCG2* (rs1481012-G, beta = 0.22 mg/dL, p = 1.18e-19); *SLC22A12* (rs524023-T, beta = 0.12 mg/dL, p = 6.95e-15); and *SLC17A1* (rs1165154-C, beta = 0.11 mg/dL, p = 1.17e-12). We then used PheWAS to explore the association between clinical phenotypes and urate level (direct-PheWAS). After Bonferroni correction, 387 phecodes with significant associations were identified, of which 30 were related to the cardiovascular system. We then used the genetic risk scores (GRS) calculated from the four identified SNPs to perform GRS-PheWAS as a comparison. Only gout and its sub-phecodes were significant in the GRS-PheWAS, of which none were in the cardiovascular system. Urate was associated with gout with an OR = 1.70 (1.64 - 1.76) per 1 mg/dL increment in the direct-PheWAS, while the uric acid level estimated by GRS had OR = 3.01 (2.58 - 3.51) per 1 mg/dL increment. We conclude that genetic determinants of urate had a larger effect size on the risk of gout than the actual urate measurements; and that other, likely non-genetic factors linked to urate have a larger effect size on the risk of cardiovascular diseases. Replication of these findings are required in an independent cohort.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4500 † Genomic, Epigenomic, and Functional Genomic Characterization of Mouse Neuronal Cell Lines.

Authors:

J. G. Manuel, H. B. Heins, J. K. Ng, T. N. Turner; Washington Univ. Sch. of Med., St. Louis, MO

Neuronal cell lines are used to study the function of genes and variation. In-depth molecular characterization of these cell lines is crucial to research. In our study, we focus on two commonly used mouse neuronal cell lines called HT-22 and Neuro-2a. These lines have not been studied in-depth for genomic, epigenomic, and functional genomic features. Characterization of the cell lines will help determine genomic variation, gene expression, methylation, open chromatin regions, and chromatin interactions. These can be beneficial in prioritizing genes and noncoding regions that can be studied in a specific cell line. We characterized the HT-22 and Neuro-2a cell lines by performing karyotype, Illumina whole-genome sequencing (WGS), PacBio WGS, Hi-C, ATAC-seq, Illumina RNA-seq and PacBio Iso-Seq. Karyotyping, Illumina WGS, and PacBio WGS were used to identify the genomic variation within these cell lines with PacBio WGS also providing information on 5mC methylation. PacBio Iso-Seq was used to generate full length RNA isoforms, and Illumina RNA-seq was used for quantification of expression levels. ATAC-seq was used to identify regions of open chromatin, and Hi-C identified chromatin interactions. By using the methods previously stated, we were able to generate an in-depth characterization of each cell line with long-read and short-read sequencing data. Our unpublished data is available through NCBI BioProject (PRJNA938057) with a UCSC genome browser trackhub and other information available at https://github.com/TNTurnerLab/HT22_genome_epigenome_functional_genomics_project. This type of characterization had not been done before for these cell lines even though they have been used extensively in studies of genes and therapeutics. One particularly innovative aspect of our work is our long-read WGS (98X coverage) of the Neuro-2a cell line using the newly released PacBio Revio sequencer. In our sequencing of Neuro-2a on three Revio SMRT cells, we identified “expected” coverages of at least 30X with 30X, 32X, and 36X genome coverage per SMRT cell, respectively. Variant calling was highly consistent across all three SMRT cells with >98% concordance comparing SMRT cells for small variants and >88% concordance for structural variants. The correlation of methylation features was $r > 0.94$ in comparisons of the three SMRT cells. This is just one interesting aspect of our work and in our presentation, we will discuss several others. In-depth characterization of the HT-22 and Neuro-2a cell lines will be a resource to other researchers to identify whether their gene or noncoding regions of interest can be studied using these cell lines as a model.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4501 Genomics 2 Proteins portal: A discovery tool to link genetic screening outputs to protein sequence and structure

Authors:

S. Iqbal[1], J. Safer[1], D. Nguyen[1], S. Kwon[1], P. May[2], D. Hoksza[3], A. Campbell[1], A. Burgin[1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA, [2]LCSB, Esch-belval, Luxembourg, [3]Charles Univ., Prague, Czech Republic

We live in the era of big biological data where on the one hand, deep learning methods and experimental techniques have made millions of high-quality protein structures accessible to the biomedical community, and on the other hand, an unprecedented number of genetic variations in the general population and those associated with monogenic and complex diseases have been identified and accumulated in multiple databases. Efficient computational tools are needed to connect these multi-omics data of disparate types (e.g., genomic vs. transcripts vs. protein structural data), for a holistic interpretation of the molecular effect of inherited clinical and population genetic variations, as well as those generated by functional genomics approaches (e.g., base editing, multiplexed assay). Toward this goal, we developed an integrated bioinformatic method established by programmatic access and linking of APIs to dynamically query, retrieve, and connect genetic variations and transcripts to protein sequence annotations and structures, wrapped within an interactive web interface, called Genomics 2 Proteins portal (G2P; g2p.broadinstitute.org). Using the method, we mapped over 18,000,000 human genetic variations from all protein-coding genes (20,271 genes; 49,675 Ensembl and 53,389 RefSeq transcripts) onto protein sequences and structures, with comprehensive annotations such as physicochemical properties of amino acids, structural information, functional features from UniProt, post-translational modifications, and readouts from multiplexed assays of variant effect. By exploiting experimentally solved (Protein Data Bank) and predicted (AlphaFold database) protein structures, G2P covers 99% of human proteins corresponding to 75,573 structures. Additionally, the portal includes an “Interactive Module” that allows users to securely upload genetic variation annotations at the protein residue level along with other protein sequence annotations, e.g., domains, drug-binding pockets, and conservation scores, and map them over to the target protein’s structure, essentially generalizing this capability of linking genomics to proteins beyond the genetic variations and protein structures available in the databases. The portal will serve as an easy-to-use, discovery tool for researchers and scientists from different subfields of biology and medicine to understand the relationship between genetic variations and their molecular phenotype, i.e., how variations map to protein structures, modulate structure-function relationship and cause diseases, and thereby design better therapeutics.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4502 GWAS SVatalog: a visualization tool to aid fine mapping of GWAS loci with structural variations.

Authors:

S. Chirmade, Z. Wang, S. Mastromatteo, B. Thiruvahindrapuram, D. Roshandel, T. Nalpathamkalam, F. Lin, K. Keenan, J. Whitney, S. Allana, L. Strug; The Hosp. for Sick Children, Toronto, ON, Canada

Structural variants (SVs) are large polymorphisms that range from 50 bp to several megabases. These genomic modifications have been shown to impact different diseases through a variety of mechanisms by affecting gene expression, regulation and function. SVs have been notoriously difficult to genotype but advances in sequencing methods, particularly the emergence of long-read technologies, have progressed the understanding of genome-wide characteristics and frequencies of these alterations. Genome-wide association studies (GWAS) conventionally use single nucleotide polymorphisms (SNPs) and have significantly enhanced our understanding of contributing loci and the disease model for common traits. However, SNPs explain only a small percentage of phenotypic variation and may be tagging other types of polymorphisms that could fill this gap in variation.

Motivated by a GWAS of cystic fibrosis (CF) disease severity, we identified a suggestive locus tagging a SNP-SV pair, rs10273639 and 20-kb deletion, and discovered its contribution to the risk of intestinal obstruction at birth (meconium ileus) in CF. We hypothesized that other disease-associated loci reported in the literature are tagging unknown or unexplored SVs and could be the cause of GWAS signals.

We developed GWAS SVatalog, an open-source web tool that uses GWAS Catalog's vast amount of trait-associated SNP data to visualize SNP-SV pairs in high linkage disequilibrium (LD). Using 101 samples sequenced by Pacific Biosciences long-read technologies, we merged SVs from two different calling pipelines, pbsv and Sniffles2, and combined them with SNP data. This workflow was benchmarked using Genome in a Bottle's HG002 public datasets. LD between SVs (MAF > 0.1) and GWAS Catalog SNPs was then calculated using SHAPEIT4, generating R2 and D' statistics.

We found 35,855 SVs to be in high LD (D' >= 0.9) with 64,955 GWAS SNPs, accounting for over 26% of the total SNPs found in the GWAS Catalog. This suggests the impact of SVs at GWAS loci requires further bioinformatic and functional investigation to determine whether the SVs explain the GWAS signal.

GWAS SVatalog allows the user to visualize the SNP-SV relationships at a specific locus in the form of an interactive plot by filtering for their specified criteria (genomic region or phenotype). The corresponding GWAS Catalog, SV and LD data can also be downloaded by the user for subsequent analysis.

Understanding the existence of common SVs at GWAS loci will provide a source of putative causal polymorphisms that have yet to be explored. GWAS SVatalog will facilitate this understanding, guiding future functional investigation and disease mechanism studies.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4503 High resolution characterization of known pathogenic repeat expansion loci in over 1,000 long-read genomes

Authors:

I. Xu[1], M. Danzi[1], S. Fazal[1], E. Dolzhenko[2], M. Eberle[2], AllOfUS Long Reads Working Group, S. Zuchner[3]; [1]Univ. of Miami, Miami, FL, [2]Pacific BioSci.s, Oceanside, CA, [3]Univ. of Miami Miller Sch. of Med., Miami, FL

Tandem repeats (TRs) are highly polymorphic, repetitive stretches of DNA motifs. Expansion of TRs cause over 50 diseases, many with neurological symptoms. Due to the limits of short-read genome sequencing in resolving large tandem repeats and a lack of normative genome-wide high-quality data in control populations, TRs are largely understudied. TRs are likely implicated in many more disease phenotypes. Working as part of the Long Reads Working Group within the All Of Us Research Project program, we have genotyped over 1.7 million TR loci in 1,027 phased control genomes using long-read PacBio Hifi sequencing. This resulted in an unprecedented three billion TR allele sequences, complete with length, motif composition, motif purity, and flanking sequence variation. Here, we characterize the ~50 known pathogenic TR loci in this control cohort. We show the distributions of repeat lengths, motif compositions, repeat purity, and flanking sequence variation, as well as estimates of premutation allele frequencies and carrier frequency for autosomal recessive disorders. We utilize the RFC1 locus as an example to showcase the extreme length and motif polymorphism present at some pathogenic TR loci which can be studied with this dataset. This data resource will aid in the identification of new pathogenic TR expansions.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4504 Highly faceted scientific management model catalyzes large scale team science to help build the future of genomic medicine.

Authors:

L. Antonacci-Fulton, S. Cody, T. Lindsay, H. Lawson, T. Wang; Washington Univ., St. Louis, MO

Washington University School of Medicine has a long history in the field of genomics contributing to the generation of the original human genome project and it is now home to organizational centers that drive large-scale, team-based genomic research.

• Human Pangenome Reference Consortium (HPRC) - Building human pangenome resources will lead the scientific and clinical communities from a linear human reference to a reference comprised of many genomes which better represent human variation, leading to improved outcomes in the clinic.

• Impact of Genomic Variation on Function (IGVF) - Study of genomic variation on function leading to the creation of a catalog of results and resources utilized to understand phenotypes

• Somatic Mosaicism Across Human Tissue (SMaHT) - a systemic study of genetic differences within the body to create a catalog of variation to understand how they impact biology and disease.

HPRC will allow for the development of a multi-allelic reference comprised of many genomes that better define diversity. This new reference landscape along with information about somatic variation will allow for a broader investigation of genomic variation on function. The resulting information will be a full collection of functionalized germline and somatic variations.

Funded components comprise the consortia, including an organizational unit, data producers, analysis core, and groups funded for tool and technology development. Resources are regularly cataloged and made available to the scientific community. Outreach activities include publications, presentations, public-facing websites, and social media. The organizational framework for each consortium includes a steering committee and working groups focused on specialized work streams.

Our organization center employs Wiki software, allowing for the collaborative organization and management of information and resources generated by the consortium. Google and Box store and retain files. Communication tools enhance daily interactions and involve SLACK and email. Many consortia also have mid-year virtual and annual, in-person meetings that allow the consortia researchers to come together to take stock of their current work and make plans for the future.

Centralizing activities within a multi-consortium support center yields the quick start of consortiums, an operational economy of scale, quick adoption of new organizational methods and policy changes, systematic in-reach and outreach methods, and the straightforward cross-pollination of systems, ideas and interactions between the consortia.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4505 hipFG: Harmonization and Integration Pipeline for Functional Genomics

Authors:

J. Cifello, P. P. Kuksa, N. Saravanan, O. Valladares, Y. Leung, L-S. Wang; Univ. of Pennsylvania, Philadelphia, PA

Functional genomics (FG) data such as genomic interactions, quantitative trait loci (QTLs), and epigenetic markers provide insightful biological context to genome-wide association study (GWAS) hits. However, the inclusion of such FG data within genomic workflows is often hindered by inconsistent standards, file formats, and metadata vocabularies. For example, effect sizes for expression QTLs will correspond to alternate alleles in some studies but tested alleles in others. We developed the Harmonization and Integration Pipeline for Functional Genomics (hipFG) to normalize heterogeneous FG datasets via standardization of both data and metadata, and organization of the standardized outputs for rapid datatype-specific indexing and access. Applicable FG datasets may include chromatin interactions, QTLs, and other annotated genomic intervals. This is achieved via automatic generation of customized datatype-specific pipelines. For example, QTLs are corrected to have effect sizes always with respect to non-reference alleles, and chromatin interactions are reformatted such that both anchors of each interaction are searchable.

Harmonized FG outputs have uniform (BED) file standards and are organized into output folders by assay, datatype, and more. These FG outputs are compatible with rapid query of genomic regions of interest via tools such as Bedtools, Giggle, and BEDOPS. hipFG pipelines are scalable and executable sequentially or in parallel. Lastly, hipFG generates standardized metadata describing FG outputs, expanding upon a user-provided minimal data descriptor table. To test hipFG, we processed three disparate data sources -- all of eQTL catalogue, EpiMap, 3DGenome 988 datasets, >18B records -- to functionally annotate and prioritize 10,823 variants of genome-wide or suggestive significance from the Bellenguez, et. al. '22 Alzheimer's Disease GWAS. This yielded a 1 MB locus at chr17 (q21.31) with the most variants-tissue-assay combinations of all tested loci.

In conclusion, hipFG allows users to quickly integrate genome analysis workflows with diverse FG datasets spanning many cell types, tissues, and assays. hipFG is freely accessible at https://bitbucket.org/wanglab-upenn/hipFG/.

PB4506 How Open Targets resources use Genetics data to facilitate target identification and prioritisation

Authors:

A. Buniello[1,2], D. Suveges[1,2], C. Cruz[1,2], M. Bernal[1,2], P. Uniyal[1,2], I. Lopez[1,2], J. Xiangyu[1,2], Y. Tsepilov[1,2], D. Considine[1,2], H. Nicholls[1,2], K. Tsukanov[1,2], C. Mehta[1,2], L. Fumis[1,2], R. Martinez Osorio[1,2], E. Barkhordari[1,2], H. Cornu[1,2], S. Horswell[1,2], S. Young[1,2], M. Ghoussaini[3,2], D. Ochoa[1,2], D. Hulcoop[4,2], I. Dunham[1,2], E. McDonagh[1,2]; [1]EMBL-EBI, Hinxton, Cambridge, United Kingdom, [2]Open Targets, Cambridge, United Kingdom, [3]Wellcome Trust Sanger Inst, Cambridge, United Kingdom, [4]GSK, Stevenage, United Kingdom

Open Targets is an innovative industry-academia partnership that uses human genetics and genomics data to facilitate systematic drug target identification and prioritisation. Its two flagship open source bioinformatic resources are Open Targets Genetics (https://genetics.opentargets.org/), identifying targets based on GWAS and functional genomics and the Open Targets Platform (https://platform.opentargets.org/), integrating public domain data to enable target identification and prioritisation. Genetics evidence is of key importance for identifying and prioritising targets for novel drug development, as drugs developed to modulate target-disease associations with supporting genetic evidence are more likely to succeed; however, the challenge arises with connecting evidence from all genome wide association studies (GWAS) loci to the likely disease-causing genes in a systematic way. Open Targets Genetics was established as a resource to address this challenge and provide post-GWAS analysis for the scientific community. It brings together data from 36,224 human GWAS from the GWAS Catalog, FinnGen and UK Biobank with functional genomics datasets (eQTLs, pQTLs and sQTLs). 3.7 million colocalisation tests are performed and made available for GWAS-GWAS and GWAS-quantitative trait loci. These large scale genetics and functional genomics datasets feed into a machine learning model, developed to provide a predicted locus-to-gene (L2G) score to help prioritise the most likely disease-causing genes from GWAS. Open Targets Genetics is a key source of genetic evidence that is integrated with >20 different data sources feeding into the Open Targets Platform to provide target-disease associations for the context of drug discovery. As well as L2G predictions for common traits from Open targets Genetics, rare disease and somatic variation evidence from clinical resources such as ClinVar, PanelApp and ClinGen are integrated, scored and combined into the Platform to provide extensive genetic evidence for target-disease associations. Gene Burden test results that aggregate rare and ultra-rare variants at the gene level to provide gene to phenotype associations. The Platform integrates a comprehensive set of burden test results that aggregate rare and ultra-rare variants at the gene level to provide gene to phenotype associations. We have also shown that two thirds of drug approvals have underlying genetic evidence for the target-disease hypothesis. We believe these systematic, open source approaches address a fundamental need for the community to utilise rare and common variation results for target discovery.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4507 Hypotonia: The Co-Existence and Patterns of Human Phenotype Ontology Terms in Neonatal and Pediatric Patients.

Authors:

Z. Liu[1], M. K. Higashi[1], y. liu[1], K. Wain[1], N. P. Melanie[1], P. Kruszka[1], A. scheurer-Monaghan[2]; [1]GeneDx, Gaithersburg, MD, [2]Western Michigan Univ., Kalamazoo, MI

Background: Congenital hypotonia is a relatively common diagnosis in the newborn period. Diagnosing an underlying cause for neonatal hypotonia is challenging since the classic presentation of "floppy infant" is associated with a large differential diagnosis and a myriad of tests and procedures for evaluation. Recent studies have concluded that exome sequencing as a first-tier test for neonates with unexplained hypotonia is warranted, but this has not been implemented universally into clinical care. Ontology-based search methods interrogating phenotypes associated with hypotonia during and beyond the neonatal period may yield new insights into clinical outcomes. Intuition into phenotype associations over the lifespan may aid the clinical adoption of exome sequencing as a first-tier test for neonatal hypotonia.**Objective:**This study's purpose was to develop a knowledge graph describing the association between hypotonia and other HPO terms within age group cohorts in neonatal and pediatric patients.**Methods:**Using a de-identified historical dataset of genetic testing data, the hypotonia cohort was identified via keyword search for "hypotonia" in any HPO field. These fields were previously converted from clinical notes. Cytoscape software developed a knowledge graph to map co-existing HPO terms at the patient-level. R package wordcloud2 and Stats was used for enrichment analysis (comparing hypotonia to those without) and to develop word clouds stratified by age categories. **Results:**Among 222,525 cases referred for exome or genome sequencing, a cohort of 51,912 cases (23.3%) were identified with hypotonia. From newborn (1-30 d) to pediatric (1-4 y), the total number of phenotypes associated with hypotonia increase by 201.0%. Enrichment analysis revealed that the main phenotypes changed across age cohorts, with seizures most common in neonatal hypotonia (35%) and global developmental delay (GDD) most common in pediatric hypotonia (93%). Co-existence analysis revealed 979 HPO pairs from 232 HPO terms are present in 1% or more of the patients. Rare phenotypes only coexist with hypotonia but are not associated with any other phenotypes (N=51, 22.0%). A constellation of phenotypes (34.1%) are shared jointly between patients that exhibit both GDD and hypotonia. **Conclusions:**Our goal was to make available pairwise HPO correlations for 51,912 hypotonia cases. We observed changes in the pattern of reported HPO terms between age categories of patients with hypotonia, which provides evidence for complex comorbidity relationships. These findings support the implementation of exome sequencing into diagnostic workflows for infants with hypotonia.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4508 Identification and characterization of genomic variationsfrom population scale whole genome sequencing inIndia

Authors:

B. Kahali[1], K. Subramanian[1], S. CHAKRABORTY[2], A. Rajesh[1], S. Vinod[1], S. Jani[1], N. Kalita[1], S. Adhya[1], TLSA study team, SANSCOG study team; [1]Ctr. for Brain Res., Indian Inst. of Sci., Bangalore, India, [2]Indian Inst. of Sci., Bangalore, India

India's population of 1.3 billion comprising >4,500 well defined ethnic groups could have numerous distinct genetic variations resulting from the country's rich genetic and social diversity, multiple waves of migration over the past thousands of years, and unique socio-cultural practices followed by extant population groups. However, representation of Indians in human genetic studies has been limited so far. Thus, population-specific reference genome datasets and genome-wide association studies in Indian population are warranted. Here, we present a comprehensive analysis of SNVs and InDels in 800 individuals from the TATA Longitudinal Study of Aging (TLSA) and Srinivaspura Aging Neurosenescence and Cognition (SANSCOG) population-based cohorts. We identify and characterize about 30 million SNVs and 4.5 million InDels from 40X short-read whole genome sequencing. The rare variants hugely outnumber the common variants, and about two-thirds of our identified SNVs and InDels are present in <1% individuals in our dataset. 3% of identified variations are present in coding regions. Out of ~12,000 frameshifts, ~4000 are rare. On average, each individual carry 20 variants intolerant to protein coding loss of function changes. We discover ~36,000 structural variants (SV), consisting of ~24,550 deletions, ~2900 duplications, ~8700 insertions, and 13 inversions. 1.4% of these SVs disrupt coding regions. 0.23% of total SVs are highly conserved and exhibit high intolerance to loss-of-function. The identified SNVs, InDels and SVs exhibit specificity to population groups. We elucidate the population structure inferred from coding and non-coding variants. We constructed a reference imputation panel using our discovery set variations merged with 1000Genomes SAS genotypes, and observe increased accuracy (~5%) compared to other standardized imputation panels. We have conducted rare-variant kernel-based association studies for commonly occurring age-associated phenotypes, highlighting novel suggestive associations. Our findings ameliorate the representation of South Asian populations in worldwide genetic studies. This dataset will be a resource for designing and interpreting large scale association and functional genomic studies in Indian population that could pave the way for devising better diagnosis and treatment strategies for a substantial proportion of world population.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4509 Impact of Masking the Reference on Germline Variant Calling utilizing GPU Accelerated BWA, HaplotypeCaller and Deepvariant

Authors:

P. Vats[1], A. Sethia[1], H. Clifford[1], G. VACEK[1], M. Gatzen[2], M. Samadi[1]; [1]NVIDIA, Santa Clara, CA, [2]Broad Inst. of MIT and Harvard, Cambridge, MA

The human reference genome is a foundational resource enabling advances in genomic research. It provides a reference framework for mapping and analyzing DNA sequences from individuals and populations. The major applications of the reference genome are mapping, genome assembly, variant calling, functional annotation, and interpretation of genetic variation in individuals. Here, we explore the impact of human reference on variant calling. Variant calling involves identifying the differences between the reference genome and a given sample's DNA sequence. This is crucial for detecting genetic variation that may be associated with disease or other population specific traits. However, the choice of reference genome can impact the accuracy of variant calling as different versions of reference genome with false duplication of specific genes can lead to ambiguous mapping and can affect the ability to call a variant. The GIAB consortium (Genome in a Bottle) recommends masking the duplicated regions to remove false duplication which can improve variant calling accuracy. In this study, we show the impact of using the masked reference genome which results in higher accuracy than the un-masked reference genome. The overall accuracy is higher than any of the current state-of-the-art methods used for SNP variant calling. In this study, we focus on the guideline to use Illumina alt masked GRCh38 reference genome compared to GRCh38 reference genome. We performed germline variant calling utilizing the GIAB HG001 30x, HG002 30x, HG003 45x, and HG004 52x whole genome sequencing (WGS) dataset. Alignment was performed using GPU (Graphical Processing Unit) accelerated BWA-MEM and variant calling was attained by running GPU accelerated HaplotypeCaller and Deepvariant; these GPU accelerated applications are part of the Parabricks v4.1 release. For Single nucleotide variants (SNVs) on HG001-HG004 dataset, the HaplotypeCaller achieved on average recall 99.27%, precision 98.84%, and F1 score of 99.05% using unmasked reference, whereas for masked reference the average recall 99.32%, precision 98.84% and F1 score of 99.08% respectively. Similarly, on HG001-HG004 dataset Deepvariant achieved an average recall of 99.38%, precision 99.87%, and F1 score of 99.63% using unmasked reference, and for masked reference the average recall 99.40%, precision 99.88% and F1 score of 99.64%. The results from the two variant callers on HG001-HG004 dataset indicate that the variant calling was improved while using Illumina alt masked reference genome GRCh38 versus using the non-masked GRCh38 reference genome.

PB4510 Implementing precision medicine on a nationwide scale

Authors:

P. Johansen, M. Bøgehus Rasmussen, B. Nybo Jensen; Danish Natl. Genome Ctr., Copenhagen S, Denmark

The Danish National Genome Center (DNGC) is a government agency established by law in 2019 as described in the Danish strategy for personalized medicine. The aim of the DNGC is, in cooperation with a wide range of stakeholders, to implement, facilitate and expand the use of whole genome sequencing (WGS) for Danish patients with rare diseases and cancer and to build a national safe high-performance computer infrastructure to store and exhibit large genomic datasets to clinicians and researchers. Patient groups, eligible for WGS, have been chosen through two recommendation rounds. This has resulted in the selection of 17 patient groups from several different medical specialties and falls within the broader categories of rare diseases (14 groups) and cancer (4 groups). For each group DNGC has facilitated and hosted a national specialist network, that have been tasked with making recommendations and describing the clinical indications and criteria for the use of WGS for their patient group. The patient groups contain 88 distinct indications of patients eligible for WGS as a first-tier diagnostic test. Currently the DNGC in collaboration with regional healthcare facilities sequences app. 1,100 samples a month in a population base of app. 5,8 million. These samples include, WGS, total RNA sequencing of cancer samples (solid and hematological) as well as a germline WGS for tumor-normal and heritable disease analysis. The total number of samples in the Danish Genome database is currently app. 16,000. DNGC have recently implemented a national genomic interpretation platform where interpreters from the healthcare sector can gain access to the relevant software and bioinformatic tools. Interpreters have access to software for both germline and somatic analysis as well as more than thousands of bioinformatic packages. Three technical working groups advise the DNGC on developments for the interpretation platform. The access to this platform raises the level of collaboration, knowledge sharing and makes genomic interpretation more uniform on a national scale for the advantage of patients receiving clinical WGS. DNGC have facilitated a national governance structure that includes technical and clinical leadership on how to implement WGS into a national public healthcare system. This governance relies on clinical experts, health professionals and decision makers in the Danish healthcare system to come together, participate, collaborate and take ownership to elevate precision medicine for the benefit of Danish patients. The DNGC has received funding for 5 years by a 147.000.000$ grant from the Novo Nordisk Foundation

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4511 Improved phasing and imputation accuracy using a harmonized resource of high-coverage diverse human genomes.

Authors:

L. Nkambule[1,2], Z. Koenig[1,2], M. T. Yohannes[1,2], J. K. Goodrich[2,3], H. A. Kim[1], X. Zhao[3,4,5], M. W. Wilson[3], G. Tiao[3], S. Hao[3,4,5], N. Sahakian[6], K. R. Chao[3], gnomAD Project Consortium, M. E. Talkowski[1,3,4,5], M. J. Daly[1,2,3,7], H. Brand[3,4,5], K. J. Karczewski[1,2,3,4], E. G. Atkinson[1,2,8], A. R. Martin[1,2,3,4]; [1]Stanley Ctr. for Psychiatric Res., The Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Analytic and Translational Genetics Unit, Massachusetts Gen. Hosp., Boston, MA, [3]Program in Med. and Population Genetics, The Broad Inst. of MIT and Harvard, Cambridge, MA, [4]Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [5]Dept. of Neurology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [6]Broad Genomics, The Broad Inst. of MIT and Harvard, Cambridge, MA, [7]Inst. for Molecular Med. Finland, Helsinki, Finland, [8]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX

The 1000 Genomes Project (1kGP) and Human Diversity Genome Project (HGDP) resources have existed for more than a decade but have only recently been sequenced to high coverage. These resources are often used independently for genomic analyses, despite various efforts showing how invaluable larger and more diverse resources are. We have jointly-called the 1kGP and HGDP datasets to generate a harmonized high quality public haplotype reference panel, HGDP+1kGP, which consists of 4,091 high-coverage whole genomes. This harmonized resource contains almost twice as many variants as the 1kGP reference panel alone. Compared to the 1kGP reference panel, we show that our HGDP+1kGP panel achieves higher phasing accuracy across different ancestries, with more pronounced improvement in African ancestry, and also higher imputation accuracy, particularly for rare variants. Specifically, our reference panel outperforms the 1kGP panel for genotype imputation in African individuals in both low coverage and array data and also in both SNPs and INDELs. These phased haplotypes are freely available through Google Cloud Storage. We believe this resource will be invaluable in supporting genomic research particularly in diverse ancestry cohorts.

PB4512 Improved validation of conditions for variant classifications in ClinVar

Authors:

M. Landrum[1], S. Chitipiralla[1], G. Brown[1], C. Chen[1], J. Hart[1], D. Hoffman[1], C. Liu[1], Z. Maddipatla[1], R. Maiti[1], J. Mitchell[1], T. Rezaie[1], G. RILEY[1], G. Song[1], J. Yang[1], G. Zhou[1], V. Lyoshin[1], K. Kaur[1], A. Russette[1], B. Kattman[2]; [1]NCBI/NLM/NIH, Bethesda, MD, [2]NCBI/NLM/NIH, Fort Collins, CO

The ACMG/AMP guidelines for the interpretation of sequence variants (Richards et al, 2015) are intended "to determine whether a variant in a gene with a definitive role in a Mendelian disorder may be pathogenic for that disorder. Pathogenicity determination should be independent of interpreting the cause of disease in a given patient." These guidelines are often cited in submissions to ClinVar as the assertion criteria, or classification rules, used by the submitter to classify variants. These rules are consistent with the most typical case in ClinVar, *i.e.* a germline variant classified for a single Mendelian disease. The ClinVar team also sees other less common, less straightforward scenarios in submitted data. First, some variants are classified for a set of clinical features not a disease; without additional information, it can be difficult to distinguish whether the data describes a patient's specific phenotype or a novel disease that currently is only defined by the set of features. Second, disease definitions are not always discrete, so a variant may be classified for several diseases that are considered parts of a phenotypic spectrum. Third, not all laboratories that submit to ClinVar indicate the disease for the classification; this leads to many variants classified for a condition that is "not provided" or "not specified". These scenarios reflect the complexity of both biology and data management for clinical genetics; however, they can create confusion and uncertainty for ClinVar users. The ClinVar team has added more checks to pre-submission validation to help submitters provide the clearest and highest quality data as the condition for the classification. First, variants that are classified for a set of clinical features are only accepted when the features define a novel disease; a patient's phenotype is described elsewhere in the submitted record (SCV). Second, if the condition is described by multiple identifiers from a disease database, such as multiple OMIM IDs, the submitter must provide the "explanation for multiple conditions". Options for the explanation are "uncertain", meaning that the variant is classified for several diseases that may represent a spectrum of disease and it's uncertain if the variant is associated with one or more of the diseases; and "co-occurring", meaning that the variant causes two distinct diseases (expected to be rare). Third, submitters will now get an error if they provide more than one SCV classified for a disease and for no disease ("not provided" or "not specified"). These validations are expected to reduce the number of variants with conflicting classifications and to clarify the rarer, more complicated cases.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4513 Improving the imputation quality of the cohort in the Department of Veterans Affair's Million Veteran Program (MVP) by leveraging the TOPMed reference panel.

Authors:

Y. Shi[1], B. Gorman[2], D. Dochtermann[3], X. Gong[1], T. Webster[4], A. Mittal[5], M. Sullivan[6], J. Schmidt[7], P. Karnam[8], P. Devineni[8], C. Cai[9], P. Tsao[10], S. Pyarajan[11], on behalf of MVP program; [1]VA Boston Hlth.care System, Jamaica Plain, MA, [2]Booz Allen Hamilton, Lexington, MA, [3]Boston VA Hlth.Care, Boston, MA, [4]Thermo Fisher Scientific, Olga, WA, [5]ThermoFIsher Scientific, San Jose, CA, [6]Thermo Fisher Scientific, New York, NY, [7]Thermo Fisher Scientific, Santa Clara, CA, [8]Boston VA Hlth.Care System, Boston, MA, [9]VA Palo Alto Hlth.Care System, Palo Alto, CA, [10]VAPAHCS/Stanford Univ., Palo Alto, CA, [11]VA Boston Hlth.Care System, Jamaica Plain, MA

The Million Veteran Program (MVP) was initiated by the U.S. Department of Veterans Affairs (VA) to implement personalized medicine in the care of U.S. veterans. The current tranche of high-quality genotype data contains 664,479 highly diverse patients assayed at 668,029 unique markers in a custom Applied Biosystems™ Axiom™ MVP1.0 microarray. Here we described the improvement of imputation quality of the MVP cohort with the TOPMed reference panel over the combined African Genome Resources (AGR) and 1000 Genomes (IKG), which was validated by using 10,375 whole genome sequences.We first performed pre-imputation variant QC by removing variants with high missingness (>20%), that failed an ancestry-aware Hardy-Weinberg Equilibrium test, or were monomorphic. We used SHAPEIT4 (v.4.2.0) to phase the variants, followed by Minimac4 (v 1.0.2) to impute phased genotypes. We evaluated imputation quality with empirical R^2 at different MAF bins across ancestries. We performed a height GWAS and compared height association p-values for genome-wide significant GIANT exome array associations to further validate imputation quality. To investigate whether the empirical R^2 in TOPMed imputation is inflated, we converted 10,375 whole genome sequences (EUR, AFR, HIS) into genotype dosages and calculated true R square (r^2) between the imputed genotype dosages and the WGS dosages. The TOPMed reference panel improved imputation quality (empirical r^2) for both common and rare markers, across all ancestries (EUR, AFR, AMR, ASN) in the MVP cohort. The number of well imputed markers (empirical $R^2 >= 0.7$) in the rare spectrums were greatly increased: the 0.01%-0.1% MAF bin increased from 45.8 to 67.4% and the 0.1%-1% MAF bin increased from 80.38 to 93.21%. Imputation in non-PAR X chromosome was also significantly improved. Common variant associations were similar between 1000 Genomes and TOPMed reference panels. The mean empirical r^2 of common markers (0.01, 0.5] across the ancestry spectrum was high: AFR was the highest (0.98 ± 0.007) followed by EUR (0.96 ± 0.013), and AMR (0.95 ± 0.009), and ASN (0.84 ± 0.01). The average difference between true r^2 and the empirical r^2 across the MAF bins was 0.55 ± 0.05, -0.03 ± 0.005, 0.029 ± 0.002 for EUR, AFR, and AMR, respectively. The mean empirical r^2 of rare markers ((0.001,0.01]) was above 0.86 and had the same population order as the common markers. We could not evaluate ultra-rare variant (MAF<0.1%) for AFR and AMR due to limited number of NGS samples. In conclusion, the TOPMed reference panel significantly improved the imputation, and imputation quality of all four ancestries and AFR and AMR benefit the most from the panel.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4514 Increase the training dataset for disease-specific variant prioritization by combining SNVs in related diseases

Authors:

Q. Liang, D. Kostka; Univ. of Pittsburgh, Pittsburgh, PA

Better characterizing and prioritizing non-coding genetic variants have the potential to facilitate insights into molecular mechanisms underlying complex disease. Previously, we developed a disease-specific variant prioritization method and applied it to 111 disease terms in the NHGRI-EBI GWAS Catalog. Here, we build on this approach by systematically evaluating if information sharing between different disease terms leads to better variant prioritization performance. Specifically, we exhaustively screen all pairs of disease terms in the NHGRI-EBI GWAS Catalog, combine annotated SNVs, and assess the effect of variant prioritization. We combine SNVs between terms with a range of disease-term-specific sample weights and determine performance improvement of variant prioritization (or the lack thereof) using nested cross-validation. We find, for example, that SNV prioritization performance as measured by average precision increased 30% for “multiple myeloma” when combined with disease term “multiple sclerosis”, and 17% when combined with disease term “systemic lupus erythematosus”. More generally, we find that it is possible to quickly identify suitable term pairs and achieve an average increase of SNV prioritization performance of 5% across the GWAS catalog. These experiments show that combining SNVs across disease terms can be beneficial for disease-specific variant prioritization and suggest that data sharing is a promising avenue for improving the performance of disease-specific models and expanding their applicability to a wider range of diseases.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4515 Initial modified ACMG criteria for *RPGR* variant curation from the ClinGen X-linked inherited retinal disease gene Variant Curation Expert Panel

Hosp., Ghent, Belgium, [6]Janssen R & D, LLC, South San Francisco, CA, [7]Cincinnati Children's Hosp., Cincinnati, OH, [8]NEI Office of Data Sci. and Hlth.Informatics, Natl. Eye Inst., Bethesda, MD, [9]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [10]Baylor Coll. Med., Houston, TX, [11]Blueprint Genetics, OY, Keilaranta, Finland, [12]McGill Univ Hlth.Ctr., Montreal, QC, Canada, [13]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [14]Stanford Univ, Stanford, CA, [15]Ophthalmology & Vision Sci., Univ. of California Davis, Davis, CA, [16]Univ Texas HSC Houston, Houston, TX, [17]Invitae, San Francisco, CA, [18]Sorbonne Univ. Inst. de la Vision Dept. of Genetics, Paris, France

The X-linked Inherited Retinal Disease Variant Curation Expert Panel (XLIRD VCEP) was established in 2020 as part of the Clinical Genome Resource (ClinGen), to address the need for consistent variant interpretation in inherited retinal disease (IRD) genes with an X-linked inheritance pattern. These genes account for ~15% of all IRD cases reported in large cohorts and several are targets for genetic therapeutics. *RPGR* is one of the most commonly mutated genes in retinitis pigmentosa.

The XLIRD VCEP implements the ClinGen variant curation practices that have been recognized by the U.S. FDA to assess individual variants in seven X-linked genes (*CACNA1F*, *CHM*, *NPD*, *OFD1*, *RPGR*, *RP2*, and *RS1*). By combining experience from clinical and laboratory researchers with expertise in phenotypes and molecular mechanisms of IRD, a set of variant curation rules customized to each gene is specified to assess the pathogenicity of the variants. Variants in the seven genes will be scored systematically following these rules and categorized into five classes, including pathogenic, likely pathogenic, variant of uncertain significance (VUS), likely benign, and benign, according to ACMG/AMP guidelines.

We established the XLIRD VCEP, with membership and curation protocols available on the ClinGen website (https://www.clinicalgenome.org/affiliation/50086/). Starting with *RPGR* (OMIM 312610), in which variants account for 9% of rod-cone and cone-rod dystrophies, we generated gene-specific curation rules. Performance of various computational prediction tools are evaluated, and thresholds have been defined for allele frequencies in population databases consistent with benign or disease-causing variant effects. To facilitate the curation process, in addition to published variants, private variant data from genetic testing laboratories are also collected. Pilot curation exercises performed will be evaluated to refine the initial rules, which will then be applied to curate variants in the *RPGR* gene. This process will be repeated for the other XLIRD genes, and the curations reviewed iteratively to refine the processes further.

Systematic and consistent curation of variants from FDA-recognized gene-specific guidelines supported by sharing genomic data and expertise will evaluate the current classification of variants and decrease the numbers of VUS within these XLIRD genes. This will improve the specificity and accuracy of the molecular diagnoses of patients with variants in these genes and increase the value of genetic testing as a diagnostic tool and a guide for patient eligibility for genetic therapies for these inherited retinal disorders.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4516 Insights into digenic mechanisms through DIVAs, an Explainable-AI phenotype-driven approach for digenic variant interpretation.

Authors:

F. De Paoli, G. Nicora, E. Rizzo, I. Limongelli, S. Zucca; enGenome srl, Pavia, Italy

Background
The challenge of identifying the genetic cause of Rare Diseases is even more demanding in the context of non-Mendelian inheritance. Due to the lack of guidelines for digenic variant interpretation (DVI), Artificial Intelligence (AI) tools could greatly support this process and Explainable-AI (XAI) allows further investigation of digenic mechanisms. We curated a dataset of pathogenic digenic combinations and we expanded DIVAs, a phenotype-driven AI-based approach for DVI, to dissect the digenic mechanisms into True Digenic or Composite (TD/CO) versus Dual Molecular Diagnosis (DM).
Methods
We gathered almost 800 pathogenic combinations from public databases, internal cases and manual curation and translated the phenotypic description reported in the corresponding study or provided by clinicians into a set of Human Phenotype Ontology (HPO) terms. DIVAs has been trained on *bona fide* data and integrated with an additional layer of XAI that exploits Shapley values to subclassify digenic combinations by mechanism. We tested the prioritization ability of DIVAs and other DVI tools (ORVAL, DiGePred and DIEP) on 9 confirmed digenic WES cases collected within international collaboration. DIVAs was then applied on a cohort of undiagnosed patients affected by disorders of the immune system provided by the Clinical Immunogenomics Research Consortium Australasia (CIRCA). Furthermore, a cohort of unsolved samples belonging to the Rare Genome Project (RGP) of the Broad Institute and 12 patients affected by Shwachman-Diamond syndrome (SDS) provided by the University of Pavia were analyzed.
Results
On a test set of about 400 combinations, our approach shows 80% sensitivity in pathogenic prediction. On the same data, the XAI approach used to dissect the digenic mechanism reports an accuracy of 91%, while ORVAL has almost 70% accuracy. On the WES data, DIVAs pinpoints the causative digenic combinations in the first 25 positions in 77% of the cases while the other DVI solutions show lower prioritization performances (11%). Furthermore, DIVAs identifies the genetic diagnosis of a patient affected by SDS caused by a *SBDS* mutation with a second mutation on *KMT2A* gene explaining additional phenotypes, including developmental delay, horseshoe kidney and bone abnormalities. The *SBDS-KMT2A* combination was correctly subclassified as a DM (PMID:35893049). CIRCA and RGP results review is still ongoing.
Conclusion
We improved DIVAs by including an XAI layer that predicts the digenic mechanism of pathogenic combinations. The integration of an oligogenic approach, exploiting biological networks, is ongoing.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4517 *Integrating PacBio and Illimina producdes nearly complete* phased human genome references for six trios from Middle Easten ancestries

Authors:

M. Ghorbani[1], S. Moosa[1], Z. Siddig[1], R. Farhad[1], I. Alazwani[1], R. Mathew[1], M. Al Hashmi[1], A. El Khouly[1], S. Tomei[1], K. Fakhro[2], E. Eichler[3], Y. Mokrab[1]; [1]Sidra Med., Doha, Qatar, [2]Sidra Med. and Res. Ctr., Doha, Qatar, Qatar, [3]Univ of Washington, Seattle, WA

The genetic diversity of the Middle Eastern region is poorly captured in the various reference genomes published to date including the pangenome form HPRC. Genomic analysis of SNV and SV calls for both disease association studies and rare gene discovery has been shown to significantly improve with the use of population-specific genomic references and annotations. Based on six families (2 Qatari families, and one family from Sudan, Jordan , Syria and Afghanistan), we built de novo reference genomes using a combination of PacBio Hifi reads (30-50x), and Illumina short-read sequencing (30X). For 12 (father and mother) individuals from these trios, we generated high quality haplotype-resolved phased assemblies using hifi-asm and for 6 childs we used trio-hifi-asm to generate phased assemblies. Haplotypes were resolved accurately using independent assessment of assemblies by parental inherited short reads k-mers. Also, high Quality Value (QV) values in the range of 44-59 were achieved for the haplotypes. In terms of contiguity, we obtained N50 values between 50 and 100 Mb and a maximum contig length of more than 130 Mb. We managed to achieve telomere to telomere assembly of chromosomes 6,8,11,12,18 for three individuals combined (one contig per chromosome). Our best assembly achieved T2T assembly of chromosome 8 and 12 for both haplotypes. These high quality genome references will provide valuable resource for population specific gene discovery, variant calling, and disease association studies for underrepresented region of Middle East.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4518 Integrative Analysis of miRNA and mRNA (MIMR): a web tool for identification of hidden pathological mechanisms

Authors:

d. kim, Y. Ko; Hankuk Univ. of Foreign Studies, Seoul, Korea, Republic of

MicroRNAs (miRNAs) are small non-coding RNAs that intricately regulate target gene products, resulting in the inhibition of gene expression. Although these miRNAs play crucial roles in essential biological processes, encompassing immunity, metabolism, and cell death, their specific impacts on diseases remain unknown. Recent studies have been focused on the integration of miRNA and mRNA expression to reveal the underlying biological pathways and mechanisms responsible for disease manifestation. Traditional approaches are involved in miRNA target relationships incorporated from TargetScan, PicTar, or PITA, and mRNA and miRNA expression data are utilized to identify disease-associated pathways, However, these methods consider only direct interactions between proteins or genes and may miss significant indirect regulatory effects, leading to the failure of identification of hidden pathological mechanisms.To address these limitations, we have proposed the novel approach for integrative analysis of miRNA and mRNA expression data and developed MIMR (Integrative Analysis of miRNA and mRNA), a web-based application that leverages Random Walk with Restart (RWR) algorithm. MIMR incorporates both direct and indirect interactions by harnessing protein-protein interaction (PPI) networks and experimentally validated mRNA-miRNA target interactions. MIMR provides extensive results, including pathological pathways associated with a specific disease, interactive network diagrams representing the mRNAs and miRNAs. Our method applied to mRNA-miRNA expression data for nephrotic syndrome patients and successfully identified the biological pathways related to the manifestation of symptoms in patients with nephrotic syndrome. In summary, MIMR offers a deeper insights into the hidden mechanisms of diseases and identify potential therapeutic strategies through integrated analysis of miRNAs and mRNAs.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4519 † Introduction to the Health and Medical Research Resources Information center in Korea National Institute of Health:focusing on Clinical & Omics Data Archive (CODA)

Authors:

Y. Lee, J-E. Kim, H. Chai, H-Y. Park; Korea NIH, Cheongju-si, Korea, Republic of

The Clinical & Omics Data Archive (CODA) is established in Aug, 2016 by Korea National Institute of Health (KNIH). CODA is a central data repository for integrating and sharing Korean multi-omics data produced from the research projects sponsored by the Ministry of Health and Welfare (MoHW). It aims to construct a trust based archive for bio-medical infrastructure. It collects various biomedical data (epidemiological information, health records etc al) and multi-omics data (microarray, whole-exome, whole-genome, transcriptome, metabolome). To date, an unprecedented amount of data (about 226,955 samples, 2,972TB) from national research projects are collected in CODA. We have collected genetic data (Whole Genome sequencing data, >30X) from more than 20,000 Koreans. With these 20,000 samples, we are working on cataloging genetic variations specific to the Korean population and the results will include information about genomic variations, such as single nucleotide variants, insertions, deletions, and structural variations. It will be a valuable resource for researchers and medical professionals studying genetics and genomics by providing a comprehensive and accurate dataset of genetic variants that can be utilized for a variety of purposes, including disease research, precision medicine, and population genetics studies. CODA had shared qualified data to researchers for data-driven studies. It also provides analysis infrastructure with various pipelines for facilitating analysis. We expected to contribute to the advancement of personalized medicine and enhance the understanding of the genetic basis of diseases, ultimately leading to improved diagnosis, treatment, and prevention strategies specific to the Korean population.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4520 Investigating the complex genomic structure of the low-affinity *FCGR* locus under different copy number states in healthy donors using long-range sequencing.

Authors:

S. Frampton[1], J. Forster[1], M. Armand[1], H. Parker[1], K. Hussain[1], C. Hargeaves[1], R. Foxall[1], R. Smith[1], D. Bryant[1], S. Beers[1], M. Cragg[1], J. Gibson[2], J. Strefford[1]; [1]Univ. of Southampton, Southampton, United Kingdom, [2]Univ of Southampton, Southampton, United Kingdom

Therapeutic monoclonal antibodies rely on FcγRs for efficacy. The low-affinity FcγR genes (*FCGR2A, FCGR2B, FCGR2C, FCGR3A, FCGR3B*) are in a highly polymorphic 200k locus, challenging to analyze with short-read methods. We used long-range technologies (Oxford nanopore (ONT) and Bionano (BN) for accurate study of this locus in poorly defined copy number regions (CNRs).

Using a healthy human cohort (n=22) with different *FCGR* SNPs and CNV states, ONT adaptive sampling and cas9-mediated enrichment (chr1:161490622-161690621) enabled SNP and SV calling, phasing, de novo assembly, and methylation calling. *FCGR* maps from ONT data were compared to BN optical maps from matched samples.

ONT sequencing (mean coverage 200x, 35Kb N50), identified a total of 16,326 high-quality SNPs and indels across 2,296 unique genomic locations, averaging 742 variants per sample. Most variants were found in intergenic regions (60.5%), followed by intronic regions (26.7%). Variants were also observed in 3'-UTRs (3.3%), downstream of genes (2.9%), upstream of genes (2.8%), exons (1.8%), splicing sequences (0.8%), and 5'-UTRs (0.8%).

The intergenic region between *FCGR3B* and *FCGR2B* exhibited the highest polymorphism frequency, accounting for 22.5% of all variants (n=3673). Among the genes, *FCGR2C* had the highest number of variants (34.5%, 2036 total), closely followed by *FCGR3B* (31.9%, 1881 variants). Interestingly, *FCGR3B* had the highest polymorphic index (variants/gene length) and proportion of homozygous variants (51.5%), while the remaining genes had 20-35% homozygous variants.

Most of the variants (88.6%) were associated with an rs ID and we identified 114 variants (5%) that were shared across all 22 samples. *FCGR2C* had the highest count of variants (148, 7.3%) without rs IDs. Successful phasing of 92.8% of the heterozygous variants enabled genotyping of clinically-relevant SNPs and identification of extended haplotypes.

Eight polymorphic short tandem repeat (STR) regions were detected that have the potential to be of functional relevance to FcγR expression. Leveraging Bionano and ONT technologies, we refined the locations of breakpoints for CNR1 (5.4kb), CNR2 (14.5kb), CNR3 (7.9kb), and CNR4 (4.7kb). Notably, we reported a novel case of CNR4 duplication involving the entirety of *HSPA7* and *FCGR3B* with its breakpoints within the proximal region of *FCGR2C* and *FCGR2B.*

In conclusion, long-range technologies offer a powerful solution to characterize *FCGR* genomic variants. This enhances our understanding of the region's regulation, potentially leading to targeted therapeutic approaches for cancer patients and improved patient stratification.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4521 † JOB : Japan Omics Browser provides integrative visualization of multi-omics data.

Authors:

Y. Takahashi[1], Q. Wang[2], Y. Okada[3], Japan COVID-19 Task Force; [1]Osaka Univ., Suita, Japan, [2]The Univ. of Tokyo, Tokyo, Japan, [3]The Univ.Tokyo / Osaka Univ. / RIKEN, Tokyo, Japan

In recent years, a wealth of human genome, transcriptome, proteome and other omics data has become available. Integrative analysis of different omics layers is effective in elucidating disease mechanisms. Here, we present the Japan Omics Browser (JOB), which enables visualization of regulatory effects of millions of variants to nearby genes. JOB offers visualization of per-variant regulatory effects in the human blood at mRNA and protein level distinctively, quantified from statistical fine-mapping of mRNA-expression quantitative loci (eQTL) and protein QTLs (pQTLs) in 1,405 samples from the Japan COVID-19 Task Force (JCTF ; extended from Wang QS. et al. Nat Commun 2022). In addition, JOB shows per-tissue regulatory effect prediction score (EMS), trained via multi-task learning utilizing hundreds of features (Wang QS. et al. Nat Commun 2021). More than 10% of the putative regulatory variants available in the browser are validated through massively parallel reporter assay (MPRA), where the full data over 20,000 variants are planned to be added to the browser by the time of presentation. This will be accompanied with further additions of omics data, including micro RNA expression QTLs and fine-mapped cell type-specific eQTLs from single cell RNA-seq experiments, all aiding functional interpretation of trait associated variants at single variant resolution. We summarize a set of examples demonstrating the utility of JOB. First is the example of rs74953707, where all the EMS, MPRA, and eQTL signal colocalize to clearly highlight the regulatory effect on gene *FAM189B* (posterior inclusion probability : PIP=1.0). Notably, this variant is rare (MAF~=0.003) in European and the association has not been reported in other major database, highlighting the value of JOB. Second is the example of rs35083095, which shows high pQTL signal and affects genes *SETMAR* (PIP=0.78) and *SUMF1* (PIP=0.73) through changes in protein expression levels, providing further characterization of its previously known eQTL effect. Finally, as an example of interpreting complex trait-associated locus with JOB, we highlight the regulatory effect of rs10411704 on *CD22* expression (50< fold enrichment of EMS and pQTL PIP=0.37) co-localizing with hematopoietic traits (PIP=0.28) in the UK Biobank. JOB, an intuitive and interactive web tool friendly for both experts and non-experts, is freely accessible at (https://optical-hexagon-384504.an.r.appspot.com/), on desktop, smartphones or any other devices.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4522 Landscape of Colorado Center for Personalized Medicine Research Freeze 3

Authors:

N. Rafaels[1], S. Chavan[1], M. Fisher[1], J. Shortt[1], N. Pozdeyev[1], H. Smith[2], M. Lin[1], E. Todd[2], K. Crooks[1], C. Gignoux[1]; [1]Univ. of Colorado Anschutz Med. Campus, Aurora, CO, [2]Univ. of Colorado Anschutz Med. Campus, AURORA, CO

IntroductionThe Colorado Center for Personalized Medicine (CCPM) has recently completed a research freeze incorporating 73,346 individuals genotyped or imputed at 46,264,610 sites from 49,372 samples from whole exome sequencing (WES) and 24,079 samples genotyped on the Multi-Ethnic Genotyping Array (MEGA). Filtering of the WES and MEGA data to the American College of Medical Genetics (ACMG) Recommendations for Secondary Findings revealed 1793 and 522 patients, respectively, identified for confirmatory genotyping. GWAS summary statistics are available for 1563 phecodes derived from electronic health records (EHR), as well as imputed blood type and HLA type. **Methods**Briefly, 49,496 samples were sequenced using hg38 Twist comprehensive exome kit with additional non-exonic regions sequenced at low coverage (GxS) to yield genomic backbone coverage sufficient for whole-genome imputation. After removing 124 samples for quality control, we performed variant QC on 10,452,242 and 1,414,694 variants from WES and GxS, respectively, keeping 9,741,141 and 1,139,510 variants, respectively. We then merged 24,079 non-overlapping samples genotyped on MEGA (QC methods: https://www.medrxiv.org/content/10.1101/2022.06.09.22276222v1) keeping only sites genotyped in both datasets with concordant alleles, after which principal component analysis was performed. We then performed imputation against TOPMed reference panel, restricting to variants with MAF>0.00005 or inclusion on the Illumina Global Diversity Array to achieve sufficient overlap, leaving 1,853,339 autosomal variants in 2 batches. After filtering to variants with R2>0.55, we then merged the two RGC imputed batches with previously imputed data from MEGA using IMMerge keeping variants in common. We then re-inserted genotype calls from RGC that passed QC for imputed variants in common, reset R2=1 and recalculated allele frequency. **Conclusions**Our current research freeze consists of one of the largest Biobank GWAS datasets spanning the entire United States, and genotyping samples from additional whole exomes and GWAS array is underway. In the future, we hope to enrich our database with PRS, MetaXcan results, set based tests, as well as mine whole exome data for CHIP, telomere length, and more. We collaborate openly on numerous initiatives including the Global Biobank Meta-Analysis Initiative, the PAGE Study, and the PRIMED Consortium. We provide a list of best practices for merging array and NGS-based datasets as calibrated for biobanks and other institutional resources.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4523 Leveraging distributed cloud infrastructure to analyze genetic data at scale.

Authors:

M. Khanna, B. Alexander; Pfizer, Cambridge, MA

The quantity and quality of genetic data has been increasing at an exponential rate over the last few decades. These increases present new challenges for both the storage and analysis of genetic datasets. Systems such as High-Performance Computing environments allow for increased computational power for genetic analyses but are ultimately bottlenecked by their shared and limited resources. Further, computational algorithms are increasing in complexity, but parallelization can be difficult and time-consuming to implement. Variability in algorithm implementation, underlying libraries, and hardware stacks can lead to artifacts and unreproducible results. Therefore, a new paradigm is required to meet the demands of these challenges. The Genetic Informatics Platform provides a framework for scientists to ingest genetic data and to build reproducible workflows utilizing the power of cloud infrastructure. Our cloud-based approach addresses these challenges by providing the following solutions: dynamic scalability and distributed computing; improved performance through the utilization of multiple database types; and workflow reproducibility and transparency through containerized algorithms. Using this framework, we have ingested 35,813 public genome wide association studies, standardized to a common human genome build and integrated into a distributed database cluster. These datasets reference 32,845 distinct traits, across a total of 72 populations. Further, we provide a user interface to query and visualize this database through interactive plots. Additionally, containerized algorithms can retrieve data from cloud services and local locations. This cloud framework enables researchers to create reproducible workflows that scale both vertically and horizontally, meeting the demands of the future of genetic datasets and analysis.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4524 † Long-read sequencing of 1000 Genomes Project samples to catalog normal patterns of human genome structural variation.

Authors:

J. Gustafson[1], K. Hoekzema[2], M. Galey[3], J. Goffena[3], N. Damaraju[4], S. B. Gibson[2], W. De Coster[5,6], C. Reeves[7], A. Helland[7], A. Raval[7], A. Snead[8], C. Sci., Antwerp, Belgium, [7]New York Genome Ctr., New York, NY, [8]Dept. of Biology, New York Univ., New York, NY, [9]Intl. Lab. for Human Genome Res., Univ. Natl. Autónoma de México, Queretaro, Mexico, [10]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [11]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [12]Dept. of Computer Sci., Rice Univ., Houston, TX, [13]DeepSeq, Sch. of Life Sci., Univ. of Nottingham,, Nottingham, United Kingdom, [14]Dept. of Bioengineering, Dept. of Physics, Northeastern Univ., Boston, MA, [15]Howard Hughes Med. Inst., Chevy Chase, MD, [16]Brotman Baty Inst. for Precision Med., Univ. of Washington, Seattle, WA, [17]Dept. of Lab. Med. and Pathology, Univ. of Washington, Seattle, WA

Over 50% of individuals with a suspected Mendelian condition remain undiagnosed after a comprehensive clinical evaluation, limiting their ability to benefit from precision or N-of-1 therapies. This has led to growing interest in using new technologies such as long-read sequencing (LRS) in challenging unsolved cases to identify precise molecular diagnoses. However, use of these new technologies is hindered by the limited availability of comprehensive datasets from healthy controls, which are crucial for filtering, categorizing, and prioritizing identified variants. Per genome, LRS-based approaches identify approximately 25,000 structural variants (SVs) larger than 50bp, including insertions, deletions, duplications, inversions, and translocations. This is more than three times the number of SVs detected by short-read genome sequencing (srGS). Filtering and prioritizing variants identified by LRS becomes challenging without an appropriate annotation dataset,.
The 1000 Genomes Project was an international endeavor to identify patterns of human variation among diverse populations, using samples consented for broad sharing of both materials and data. A range of technologies, including microarray, exome sequencing (ES), and srGS have been employed to characterize these samples, and the data generated have been used for variant filtering and prioritization both in the research and clinical settings. Building upon that project, the 1000 Genomes ONT Sequencing Consortium is an international effort to sequence at least 500 samples (~40% African, 40% Asian, 10% European, and 10% American ancestry) from the 1000 Genomes Project using the Oxford Nanopore Technologies (ONT) platform. Our goal is to better characterize normal genome-wide SV patterns as well as to identify variants in regions of the genome difficult to evaluate using srGS (e.g. hard-to-map regions).
Here, we present preliminary data from the first 250 genomes sequenced to 30x coverage with an average read N50 of 50 kbp. Our analysis includes both alignment and de novo assembly-based approaches. Shasta-based de novo assembly resulted in contig N50 values of more than 30 Mbp and enabled phased variant calling with DeepVariant and phased SV calling using both Sniffles2 and cuteSV. We used joint SV callsets from this dataset to filter and prioritize SVs in unsolved clinical cases. The data generated as part of this project are publicly available and analysis efforts are open to all. We anticipate that this dataset will be of broad utility to the human genetics community, and lead to discovery of disease-causing variants among individuals being sequenced with the ONT sequencing platform.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4525 Long-read sequencing of hundreds of human brains provides insight into the impact of structural variation and methylation

Authors:

K. Billingsley[1], K. Daida[1], M. Meredith[2], P. Alvarez Jerez[1], R. Genner[1], L. Malik[3], B. Baker[1], M. Mastoras[2], m. abdelhalim[1], M. Jean[2], R. Lorig-Roach[2], M. Asri[2], S. Behera[4], K. Shafin[5], T. Pesout[6], T. Pesout[2], P. Carnevali[7], J. Yang[8], A. Rhie[1], K. Miga[9], M. Nalls[10], W. Timp[11], A. Phillippy[12], M. Chaisson[8], X. Reed[1], M. Jain[13], F. Sedlazeck[14], M. Kolmogorov[1], B. Paten[9], C. Blauwendraat[1]; [1]NIH, Bethesda, MD, [2]UCSC, santa cruz, CA, [3]NIH, bethesda, MD, [4]Baylor Coll. of Med., Houston, TX, [5]Google Hlth., Mountain View, CA, [67]Chan Zuckerberg Initiative,, Redwood City,, CA, [8]Univ. of Southern California, Los Angeles, CA, [9]UCSC, Santa Cruz, CA, [10]datatechnica, glen echo, ME, [11]Johns Hopkins Univ., Baltimore, MD, [12]NIH/NHGRI, Bethesda, MD, [13]Univ. of California Santa Cruz, Santa Cruz, CA, [14]Baylor Coll. Med., Houston, TX

Structural variants drive gene expression in the human brain and are causative of many neurological conditions. However, most existing genetic studies have been based on short-read sequencing methods which poorly capture these regions of the genome. Long-read sequencing significantly increases our power to detect disease-associated and functionally relevant structural variants but has not been a feasible option for large-scale genomic projects because it was low throughput and too costly. Here, we leverage a new scalable wet-lab protocol and computational pipeline for Oxford Nanopore Technologies (ONT) and apply it to neurologically normal control samples from the North American Brain Expression Consortium (NABEC) cohort. Through this work, we present a publicly available long-read resource from the frontal cortex of 222 human brain samples (average N50 ~30kb and 44X coverage). We discover 86,440 structural variants, consisting mainly of insertions (n=46,434) and deletions (n=38,602). Utilizing matched expression datasets for these samples including CAGE-seq and bulk and single-cell RNA-seq we apply quantitative trait locus (QTL) analyses and identify structural variants that impact gene expression in post-mortem frontal cortex brain tissue. Further, we determine haplotype-specific methylation rates of millions of CpGs and with this data identify cis-acting structural variants. In summary, these results highlight that long-read sequencing at population scale can identify disease-relevant regulatory loci that were inaccessible using previous technologies. We believe this new resource will provide a critical step toward understanding the biological effects of genetic variation in the human brain. Expanding on this, as part of the NIH's Center of Alzheimer's disease and Related Dementias (CARD) long-read sequencing initiative, we are currently applying this framework to sequence a total of 4000 human case and control brain samples to catalog structural variants in Alzheimer's and related Dementias.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4526 Mass General Brigham Biobank - Insights from a New England Healthcare Biobank

Authors:

S. Koyama[1,2], Y. Wang[2,1], K. Paruchuri[2], M. Uddin[1], S. J. Cho[1], S. Urbut[1], S. Haidermota[2], W. Hornsby[2], R. Green[3], B. M. Neale[2], J. W. Smoller[2], M. Lebo[4], E. W. Karlson[2], P. T. Ellinor[2], A. R. Martin[2], P. Natarajan[2]; [1]The Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]Harvard Med. Sch., Boston, MA, [4]Mass Gen. Brigham Lab for Molecular Med., Cambridge, MA

Mass General Brigham (MGB) is an integrated healthcare system in the Greater Boston area, Massachusetts, United States, serving 1.5 million patients annually. Within MGB, we analyzed genetic and phenotypic data from over 65,000 patients in a volunteer patient cohort with the goal of discovering the interplay between disease and genomics with a particular emphasis on understanding the impact of ancestral diversity in real-world medical practice through comprehensive phenotyping and genotyping.

We used a network-based clustering genetic algorithm within the MGB Biobank to reveal a detailed population structure, including substructures within European ancestry. These population structures mirror the sequential immigration to the Greater Boston area throughout American history. The genetic ancestral clusters we identified exhibited distinct geographical distributions, allele frequencies of pathogenic variants, and polygenic load. These findings suggest that granular ancestral assessment has the potential to enhance personalized care for patients.

The use of the MGB Biobank offered a notable advantage over general population biobanks, as it demonstrated a relative enrichment for a breadth of uncommon conditions. Using genome-wide phenome-wide association analysis, we associated genotypes and 1,416 PheCodes identifying 114 Bonferroni-significant associations ($P < 1.6 \times 10^{-11}$). We identified several highly penetrant variants such as rs35004220 and Hereditary hemolytic anemias, rs72660908 and Rhesus isoimmunization in pregnancy, that were consistent with prior studies while expanding our understanding of the associations between specific genetic variants and their corresponding phenotypic manifestations.

Our research highlights the power of large-scale, unbiased analyses within a hospital-based biobank to understand the complex interplay between genotypes, geographical location, and phenotypes, paving the way for tailored interventions.

PB4527 Matched Annotation from NCBI and EMBL-EBI (MANE): Towards completion of MANE Select set and beyond.

Authors:

S. Pujar[1], J. Loveland[2], A. Astashyn[1], R. Bennett[2], A. Berry[2], E. Cox[1], C. Davidson[2], O. Ermolaeva[1], C. Farrell[1], R. Fatima[2], T. Goldfarb[1], J. Gonzalez[3], D. Haddad[1], M. Hardy[2], T. Hunt[4], J. Jackson, D[1], V. Joardar[1], M. Kay[2], V. Kodali, K[1], K. McGarvey[1], J. Mudge[2], M. Murphy[1], S. Rangwala[1], F. Thibaud-Nissen[1], A. Vatsan[1], C. Wallin[1], D. Webb[1], A. Frankish[2], F. Cunningham[2], T. Murphy[1]; [1]NCBI/NLM/NIH, Bethesda, MD, [2]EMBL-EBI, Hinxton, United Kingdom, [3]EMBL-EBI, Bethesda, United Kingdom, [4]EMBL/EBI, Hinxton, United Kingdom

Accurate and consistent genome annotation is a prerequisite to leveraging genomic sequence information for various applications. In clinical genomics where annotation products are used to report clinical variants, the lack of a reporting standard may cause confusion and inconsistency in reporting and clinical interpretation of variants. Matched annotation from NCBI and EMBL-EBI (MANE), a collaboration between National Center for Biotechnology Information (NCBI) and European Molecular Biology Laboratories-European Bioinformatics Institute (EMBL-EBI), provides a representative transcript (MANE Select) and the associated protein for every protein-coding gene to serve as a universal standard for variant reporting and for display in commonly used genomic resources. For a small number of genes where the MANE Select alone is not sufficient to report all known clinical variants, a second transcript called MANE Plus Clinical is provided after consultations with clinical experts. Each MANE Select and Plus Clinical transcript represents an exact match in the exons of a RefSeq transcript and the corresponding Ensembl transcript such that two identifiers can be used synonymously. MANE transcripts are intended to be stable and will not be updated to cause a change in the sequence accession or version, except in rare instances when egregious errors are identified. MANE transcripts are chosen based on biological criteria such as transcript expression and coding region conservation and perfectly match GRCh38. MANE v1.1 released in April 2023 covers almost 99% of protein-coding genes including all genes in the ACMG SF v3.1 set. Eleven MANE Select transcripts are annotated on a patch representing an alternate locus because the gene could not be accurately represented on the chromosome. Five MANE Plus Clinical transcripts were also added in this release. This year, we are working to add the remaining protein-coding genes and achieve near-100% coverage. MANE data is available on FTP and multiple RefSeq and Ensembl resources. Detailed information about the MANE dataset is available at https://www.ncbi.nlm.nih.gov/refseq/MANE/. We welcome your feedback or requests on specific MANE transcripts at MANE-help@ncbi.nlm.nih.gov. As a next step, we plan to include non-coding genes in MANE. We have begun work towards converging on annotation of a set of non-coding genes associated with disease phenotypes and hope to include them in a MANE release this year. The work is funded in part by the National Center for Biotechnology Information of the National Library of Medicine. Additional support is from Wellcome Trust-WT200990/Z/16/Z, EMBL-Core-Funds and NIH-U24HG007234.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4528 MedGenome's genomics solutions for large-scale genetics studies

Authors:

K. Suryamohan[1], R. Gupta[2], M. Corbo[1], R. Menon[3], M. Muraleedharan[1], E. Ramesh[1], H. Gowda[1], H. G.H[1], V. Ramprasad[4], S. Seshagiri[1]; [1]MedGenome Inc., Foster City, CA, [2]MedGenome Labs Ltd., Bangalore, India, [3]MedGenome Labs Pvt ltd, Bangalore, India, [4]MedGenome Inc., Bengaluru, India

Genomics has revolutionized biomedical research, transforming our understanding of human health and disease. MedGenome, a leading provider of sequencing and bioinformatics solutions, offers a comprehensive range of services, including whole genome and whole exome sequencing, transcriptome sequencing, liquid biopsy, immune repertoire analysis, and single-cell sequencing. Our proprietary solutions effectively support pre-clinical research, biomarker discovery, and early drug development pipelines for academia, pharmaceutical and biotechnology companies. With state-of-the-art laboratories in India and the US, our team of highly skilled and experienced scientists can process a wide array of sample types using established best practices, ensuring the generation of high-quality sequencing data. MedGenome has developed an array of cutting-edge bioinformatics tools and optimized wet lab workflows to meet the ever-evolving needs of research and diagnostics. We have created a user-friendly, cloud-based analytics platform that facilitates scalable genomic data analysis and can generate publication-ready figures and reports. This interface was specifically designed for ease-of-use and does not require any prior programming or bioinformatics expertise. MedGenome has spearheaded the development of several proprietary technologies including VarMiner, an AI-enabled variant interpretation software, and HiTmAb, an innovative high throughput antigen-specific monoclonal antibody discovery platform that harnesses the power of single-cell B-cell receptor (BCR) sequencing for identification of antigen-specific B-cell antibodies.MedGenome has also positioned itself as a frontrunner in human genetics research. Through collaborations with over 500 hospitals in India, we routinely generate large-scale genomic data to identify novel human genetic variants to enable drug discovery and diagnostics. As a founding member of the GenomeAsia 100K project, we have curated an extensive catalog of population-level genomic sequencing data from across South Asia, thus creating a vital resource for identifying novel genetic risk factors and rare variants that are underrepresented in public databases. As part of our ongoing efforts, we have successfully launched several clinical tests, including Kardiogen, a Polygenic Risk Score test used to determine an individual's risk of developing coronary artery disease. Our expertise in diagnostics, sequencing and bioinformatics positions us at the forefront of biomedical research, driving groundbreaking advancements and empowers scientists to address complex genomic questions.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4530 MitoNet1.0: A genetic interaction network of the human mitochondrion.

Authors:

N. Mikolajewicz[1,2], S. Masud[1,2], D. Thomson-Taylor[1,2], K. Chan[1], K. Brown[1], O. Sizova[1], A. Habsid[1], R. Climie[2], M. Billman[3], C. Myers[4], B. Andrews[2], M. Costanzo[2], C. Boone[2], J. Moffat[1]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]Univ. of Toronto, Toronto, ON, Canada, [3]The Univ. of Bonn, Bonn, Germany, [4]Univ. of Minnesota, Minneapolis, MN

Background. The human mitochondrion is a complex organelle involved in numerous functions beyond its indispensable role in aerobic respiration. This complexity has resulted in challenges in defining what exactly a mitochondrial gene is. Various strategies (e.g., protein-protein interactions, protein localization, bioinformatics) have resulted in complementary, yet discordant mitochondrial catalogs, including gene ontology (GO), DepMap, GeneDX, and MitoCarta, among others. ***Methods***. We performed >200 genome-wide CRIPSR/Cas9 screens using a diverse library of isogenic mutant HAP1 cells to identify genetic interactions. Library-side co-essentiality (Pearson correlation and topological overlap matrices) and latent features identified through machine learning (ensemble classifier) were used to annotate mitochondrial genes. Mitochondrial gene recovery was benchmarked using existing mitochondrial catalogs and summarized using area under the precision-recall curve (AUPRC). Novel mitochondrial genes predicted by MitoNet1.0 were functionally validated in orthogonal CRISPR/Cas9 screens and *in vitro* assays. ***Results***. We present MitoNet1.0, a genetic interaction-based network of human mitochondrial genes. We identified >1500 known and novel mitochondrial genes with an AUPRC of 0.718 (DepMap), MitoCarta (0.663), 0.512 (GO), and 0.309 (GeneDx). MitoNet1.0 recovered core mitochondrial processes, like OXPHOS/ETC pathway, as well as associated mitochondrial processes, like intrinsic apoptosis. We highlight several novel mitochondrial genes as case examples demonstrating the utility of MitoNet1.0 for improved gene annotation efforts. ***Conclusions***. MitoNet1.0 is a relational mitochondrial network defined using genetic interaction co-similarities profiles. It represents an invaluable resource that can be used to query the function and relationship of candidate mitochondrial genes.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4531 Mucopolysaccharidosis Type VII (MPS VII): *GUSB* gene variant database

Authors:

S. Daugherty[1], T. Hamazaki[2], M. Hegde[3], R. Giugliani[4], T. MacKenzie[5], M. Kiel[6], O. K. Japalaghi[1], B. Lianoglou[5], D. Marsden[1], D. McKnight[7], J. L. Merritt, II[1], N. Tatiele[1], L. Pollard[8], V. Rangel Miller[1], T. Sparks[9], N. Miller[1]; [1]Ultragenyx Pharmaceutical Inc., Novato, CA, [2]Osaka Metropolitan Univ., Osaka, Japan, [3]PerkinElmer, Waltham, MA, [4]HCPA/UFRGS, Porto Alegre, Brazil, [5]UCSF Sch. of Med., San Francisco, CA, [6]GENOMENON, Ann Arbor, MI, [7]Invitae Corp., San Francisco, CA, [8]Greenwood Genetic Ctr., Greenwood, SC, [9]Univ. of California, San Francisco, San Francisco, CA

Background: Mucopolysaccharidosis type VII (MPS VII) is an ultrarare, autosomal recessive, lysosomal storage disease caused by beta-glucuronidase (GUSB) enzyme deficiency. Patients present variably with fetal effusions, skeletal dysplasia, dysmorphology, and cardio-pulmonary signs. MPS VII is diagnosed clinically in association with GUSB enzyme deficiency and/or in association with two disease-associated variants in the *GUSB* gene. Urinary glycosaminoglycans are elevated in patients with MPS VII. MPS VII is the most common lysosomal storage disorder associated with non-immune hydrops fetalis (NIHF). Molecular testing is used to determine the etiology of NIHF in order to reduce risk of poor postnatal outcomes.
Methods: We tabulated data from multiple clinical laboratories, ClinVar, and from a consolidated literature search to develop a comprehensive landscape of variants found in the *GUSB* gene.
Results: As of 17 May 2023, we report 318 unique *GUSB* variants distributed as: 221 (70%) missense, 21 (7%) nonsense, 21 (7%) splicing, 16 (5%) frameshift, 9 (3%) UTR, 7 (2%) intronic, 6 (2%) CNV, 3 (<1%) deletion, 1 (<1%) insertion, 2 (<1%) start-loss, and 11 (3%) synonymous. 314 variants were associated with clinical classifications distributed as 65 Pathogenic, 39 Likely Pathogenic, 209 Variants of Uncertain Significance (VUS), and 1 conflicting variant. Of the variants in this study, 110 were recurrently encountered having been identified from at least two of the sources: ClinVar, clinical labs, and literature review. Of the remaining variants, 138 were uniquely identified from ClinVar, 32 from clinical labs and 38 from literature review.
Conclusions: We recently found that approximately half of the patients with MPS VII had one or more VUS. These data highlight the value of timely submission of novel and previously observed variants to public databases in association with clinical and biochemical evidence. Cataloguing and disseminating information about *GUSB* variants is essential to improve timely and accurate diagnosis of this ultrarare disease. Moreover, clinical study of *in utero* fetal therapy for MPS VII relies heavily on molecular diagnosis of MPS VII. With the advent of genome-based newborn sequencing, timely reporting and classification of MPS VII disease associated variants is also necessary to ensure an accurate diagnosis. These data highlight the value for rapid reporting of novel and previously observed variants to public databases for more ready access by clinicians to promote timely, accurate diagnosis of MPS VII.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4532 Navigating the Path to Diagnosis: An Efficient Workflow for AADC Deficiency Assessment.

Authors:

N. Liu[1], J. Odom[1], C. Gijavanekar[1], T. Wilson[1], Q. Sun[2], L. Emrick[2], R. Sutton[2], K. Hyland[3], N. Blau[4], K. Glinton[1], S. Elsea[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Coll. Med., Houston, TX, [3]Med. Neurogenetics Lab., a LabCorp company, Atlanta, GA, [4]Univ. Children s Hosp. Zurich, Zurich, Switzerland

Aromatic L-amino acid decarboxylase deficiency (AADCD) leads to a combined deficiency of neurotransmitter biosynthesis, resulting in a broad and heterogeneous phenotypic spectrum including developmental delays, hypotonia, autonomic dysfunction, and movement disorder with/without oculogyric crises in infancy. Early diagnosis is necessary to allow prompt therapeutic interventions. However, diagnosis is often delayed or missed due to the limitation of historical diagnostic approaches that require targeted analyte testing of cerebrospinal fluid and the rarity of the disorder, which necessitates access to specialized clinical expertise. Furthermore, genomic data alone are often insufficient for diagnosis and require additional testing to assess the pathogenicity of the variants identified. Toward improving diagnostic processes, a comprehensive review of the published literature on AADCD was conducted to document all reported AADCD cases to date. We then retrospectively assessed clinical and research genomic (>20,000 exomes) and metabolomic (>6,000 plasma & urine samples) databases and curated 343 unique AADCD cases to create a comprehensive database of metabolo-genomic and phenotypic variation to support efficient diagnostics for AADCD. This comprehensive review identified 102 *DDC* variants representing 117 unique genotypes. The presence of only 30 of these disease associated *DDC* variants in ClinVar further highlights the diagnostic challenge. AADC enzyme testing and targeted testing for 3-O-methyldopa (3-OMD) were commonly used to confirm diagnosis; however, results may be confounded by treatment with dopamine or vitamin B6 supplementation. Using untargeted metabolomics, our laboratory showed that biomarker profiles from both plasma (3-OMD, VLA, 3-methoxytyramine sulfate, dopamine-3-O-sulfate, VMA) and urine (3-OMD, VLA, vanilloylglycine, VMA) effectively distinguish affected individuals from carriers, and from patients taking dopamine medications and/or vitamin B6 supplements. This supports the efficacy of untargeted metabolomic screening for early diagnosis of AADCD. Current guidelines for AADCD diagnosis are invasive, costly, burdensome, and limit access to care. For AADCD and other inborn errors of metabolism with non-specific clinical presentations, implementing a non-invasive metabolo-genomics diagnostic workflow early in clinical evaluation will shorten the diagnostic journey, alleviate concerns regarding misdiagnosis, and importantly, will decrease health disparities and broaden access to effective treatment.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4533 NCBI clinical resources to support genetic testing result interpretation and clinical action

Authors:

A. Malheiro, M. Kane, M. Hoeppner, T. Venkatapathi, B. Kattman; NCBI, NLM, NIH, Bethesda, MD

Expanded access to genetic testing prompts the need to educate the whole spectrum of the healthcare community about phenotypes with a genetic component. Healthcare providers are faced with genetic test results from clients that undertook consumer-initiated options or that participated in research studies like the All of Us program and need to discuss clinical implications. A suite of clinical resources at NCBI exists to support healthcare professionals who receive non-clinical testing results that may impact a variety of areas of clinical care. These reports may indicate risk alleles for cancer predisposition, complex diseases, genetic diseases, carrier status for prenatal planning, or variants that impact drug metabolism. Clinicians may need to confirm the test results via a suitable clinical genetic test. The NIH Genetic Testing Registry (GTR) is a free resource with over 75,000 clinical tests from more than 500 laboratories in 48 countries. Clinicians can search for tests by gene or disease, filter results by lab location and CLIA certification, then review the test details including methodology, clinical utility, and analytical validity. The clinician may need to research diseases or phenotypes that have been uncovered during testing. Information including diagnosis, prognosis, and treatment for many conditions is available in MedGen. MedGen compiles disease terminology, definitions, clinical features, and highly relevant literature from PubMed and the NCBI Bookshelf, including clinical practice guidelines. MedGen links to authoritative sources for genetic disease information, including OMIM and OrphaNet. For pharmacogenomics, NCBI has a dedicated resource: Medical Genetics Summaries (MGS), which includes concise, structured reviews on genetic variants and drug responses along with recommendations from authoritative sources including the FDA, Clinical Pharmacogenetic Implementation Consortium (CPIC), and PharmGKB. Each expert-reviewed chapter discusses one drug and uses standardized terminology. MedGen, GTR, and MGS link to molecular resources like ClinVar as well as patient-focused resources like MedlinePlus Genetics and NCATS Genetic and Rare Diseases to support clinicians in test interpretation and patient education. By making relevant, data-rich information readily available, NCBI aims to better equip healthcare providers to incorporate genetics into their patients' care and be well informed when faced with genetic test results they did not initiate themselves. This work was supported [in part] by the National Center for Biotechnology Information of the National Library of Medicine (NLM), National Institutes of Health.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4534 NCBI Variant Databases for Identification and Analysis of Common and Somatic Variants

Authors:

T. Hefferon, Q. Wang, H. Zhang, J. Garner, G. Shekhtman, R. Villamarin-Salomon, L. Phan; NIH/NLM/NCBI, Bethesda, MD

Accurate identification and filtering of somatic mutations, including single nucleotide variants (SNVs) and structural variations (SVs), are crucial for precision medicine in genetic diseases such as cancer. Common genetic variation databases like dbSNP and NCBI ALFA have been instrumental in this process. Additionally, the incorporation of the Database of Genomic Structural Variation (dbVar) enhances the analysis of somatic SVs.
dbSNP catalogs genetic variations, allowing differentiation between germline and somatic mutations. Comparing genomic data with dbSNP enables the exclusion of germline variants, focusing on pathogenic somatic SNVs. The database's extensive variant collection and population frequency annotations aid in identifying clinically relevant somatic SNVs. NCBI ALFA, within dbSNP, provides curated data on somatic mutations, particularly in cancer, improving the accuracy of somatic mutation analysis. It integrates information from sources like The Cancer Genome Atlas (TCGA), facilitating the identification and filtering of cancer-specific somatic mutations. In addition to dbSNP and NCBI ALFA, dbVar is crucial for analyzing somatic SVs. It catalogs SVs associated with various diseases, including insertions, deletions, duplications, and chromosomal rearrangements. Incorporating dbVar data enhances the identification and filtering of somatic SVs implicated in disease development.
By integrating dbSNP, NCBI ALFA, and dbVar, researchers achieve comprehensive analysis of somatic mutations (SNVs and SVs) for precision medicine. These databases serve as reliable references for identifying and filtering somatic mutations, ensuring accurate interpretation and facilitating personalized treatment strategies.
In conclusion, the combination of dbSNP, NCBI ALFA, and dbVar databases significantly enhances the analysis of somatic mutations in precision medicine. Leveraging these resources enables the identification and filtering of somatic SNVs and SVs, leading to improved patient outcomes and a deeper understanding of genetic diseases.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4535 New developments in the RD-Connect GPAP facilitate research on diagnosis and gene discovery for rare diseases

Authors:

I. Gut[1], M. Bayes[1], A. Blanco[1], G. Bullich[1], A. Corvo[1], S. Chaves[1], J. Dieguez[1], M. Fernandez-Callejo[1], A. Garcia[1], L. Kraatz[1], S. Laurie[1], H. Lochmuller[2], L. Matalonga[3], I. Paramonov[4], A. Papakonstantinou[1], G. Parra[1], D. Pico[1], S. Medrano[1], I-D. Teoc[1], R. Thompson[2], R. Tonda[1], O. Torres[1], J-R. Trotta[1], G. Vazquez[1], L. Zalatnai[1], D. Piscia[1], S. Beltran[5]; [1]CENTRO NACIONAL DE ANALISIS GENOMICO (CNAG-CRG), Barcelona, Spain, [2]Univ. of Ottawa, Ottawa, ON, Canada, [3]CNAG-CRG, Barcelona, Spain, [4]Centro Natl. de Analisis Genomico, Barcelona, Spain, [5]Centro Natl. de Análisis Genómico (CNAG), Barcelona, Catalonia, Spain

The RD-Connect Genome-Phenome Analysis Platform (GPAP) is an IRDiRC recognised resource that facilitates collation, discovery, sharing, and analysis of standardised genome-phenome data within a collaborative environment. The platform aims to facilitate Rare Disease (RD) research on diagnosis and gene discovery to non-bioinformaticians. The RD-Connect GPAP is an integral part of the European Joint Programme on Rare Diseases (EJP-RD) Virtual Platform and is a key component of the EU Solve-RD project, which has contributed to the diagnosis of hundreds of patients with previously inconclusive genomic tests. The RD-Connect GPAP securely hosts pseudonymized data from over 28,000 patients and relatives. Pheno-clinical data may be batch submitted or entered through user friendly interfaces. The data is standardized with the Human Phenotype Ontology (HPO), the Orphanet Rare Disease Ontology (ORDO), and OMIM. Raw or aligned sequencing data can be submitted in FASTQ, BAM or CRAM format. Data can be exported as GA4GH VCF and Phenopackets, among others. The submitted datasets are made accessible to the rest of the validated users after a maximum of 6 months, although justified extensions might be granted. The RD-Connect GPAP is connected to both the Beacon and the MatchMaker Exchange networks.
The RD-Connect GPAP is in continuous development. As part of these efforts we have recently launched a new graphical user interface (GUI) to improve general usability, as well as data submission, collation, analysis and interpretation. The new and intuitive GUI is fully integrated with the other RD-Connect GPAP modules, such as data management, pheno-clinical information, cohort analysis and the integrated IGV Browser. Among other features, the genomics analysis module now better supports reproducible research, with extended functionalities to save and share studies, and to label and tag variants of interest. New annotations such as REVEL, Splice-AI and InterVar ACMG classification have been added. Cohort analysis has been simplified so that users can create *in silico* cohorts and run gene discovery analysis across hundreds of patients with only a few steps.
The RD-Connect GPAP hosted by the Centro Nacional de Análisis Genómica (Barcelona, Spain) and is available at https://platform.rd-connect.eu. We welcome registration and data submission from international RD researchers complying with EU General Data Protection Regulation.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4536 NIA Genetics of Alzheimer's Disease Data Storage Site (NIAGADS): 2023 Update.

Authors:

L. Armus[1,2], A. Kuzma[1,2], O. Valladares[1,2], H. Nicaretta[1,2], J. Manuel[1,2], P. Gangadharan[1,2], Z. Katanic[1,2], M. Kirsch[1,2], Y. Ren[1,2], N. Saravanan[1,2], A. Wilk[1,2], Y. Greenfest-Allen[2,5], P. P. Kuksa[1,2], Y. Leung[1,2,6], W-P. Lee[1,2], G. Schellenberg[1,6], L-S. Wang[1,2,6]; [1]Penn Neurodegeneration Genomics Ctr., Dept. of Pathology and Lab. Med., Philadelphia, PA, [2]Inst. for BioMed. Informatics, Philadelphia, PA, [3]Dept. of Economics, Lehigh Univ., Bethlehem, PA, [4]Dept. of Epidemiology, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [5]Dept. of Genetics, Philadelphia, PA, [6]Inst. on Aging, Philadelphia, PA

Background: NIAGADS is a national genomics data repository that facilitates access of genotypic and sequencing data to qualified investigators for the study of the genetics of Alzheimer's disease (AD) and related neurological diseases. Collaborations with large consortia and centers such as the Alzheimer's Disease Genetics Consortium (ADGC), Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, the Alzheimer's Disease Sequencing Project (ADSP), and the Genome Center for Alzheimer's Disease (GCAD) allow NIAGADS to lead the effort in managing large AD datasets that can be easily accessed and fully utilized by qualified investigators in the research community.
Methods: NIAGADS is supported by National Institute on Aging (NIA) under a cooperative agreement. All data derived from NIA funded AD genetics studies are expected to be deposited in NIAGADS or another NIA approved site. NIAGADS manages a Data Sharing Service (DSS) that facilitates the deposition and sharing of genomic data and association results with approved users. In addition, researchers may freely use the NIAGADS Alzheimer's Genomics Database (www.niagads.org/genomics/) to search annotation resources that link published AD studies to AD-relevant sequence features and genome-wide annotations.
Results: As of June 2023, NIAGADS houses 99 datasets comprised of >172,000 samples including GWAS, sequencing, gene expression, annotations, deep phenotypes, and summary statistics. Qualified investigators can retrieve ADSP sequencing data with ease and flexibility through the NIAGADS DSS. To date, the ADSP and other contributing studies have completed whole exome sequencing (WES) of 20,503 samples and whole genome sequencing (WGS) of 36,361 samples. Raw WES and WGS files, quality controlled VCF files, and phenotype data files are available via qualified access. The next round of sequencing currently underway will generate around 25,000 additional genomes to be released in late 2023.
Conclusion: NIAGADS is a rich resource for AD researchers, with the goal of facilitating advances in Alzheimer's genetics research by sharing diverse datasets from a myriad of projects and institutions for secondary analysis by qualified researchers. Datasets, guidelines, and features are available on our website at https://www.niagads.org.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4537 Omics Research in the Environmental influences on Child Health Outcomes (ECHO)-wide Cohort Study (EWC)

Authors:

G. Page, ECHO Program; RTI Intl., Atlanta, GA

The goal of the Environmental influences on Child Health outcomes (ECHO) Program (www.echochildren.org) is to understand the effect of a broad range of early environmental and omics influences on child health and development. ECHO is dedicated to both learning what factors affect child health and to finding ways to enhance it. ECHO has a collaborative research design comprising 69 cohorts in 31 consortia and was funded by the National Institutes of Health in 2016 and is renewed through at least 2030. Surveys, interviews, standardized examinations, laboratory analyses, and medical record abstraction are used to obtain information in five main outcome areas: pre-, peri-, and post-natal outcomes; neurodevelopment; obesity; airways; and positive health. Exposures include place- (e.g., air pollution, socioeconomic status), family- (e.g., parental mental health), and individual-level (e.g., diet, genomics) factors. The inclusion of children at different life stages allows for the evaluation of time-varying effects of exposures and critical periods of development. As of May 26, 2023, the EWC has data from 67,757 children and 35,559 have been consented for the EWC data and biospecimen collection. While the EWC was being implemented, the extant omics data that had been generated by the individual cohorts were aggregated and harmonized across cohorts. Extant genome wide methylation data are available on 8,387 samples from 5,990 participants including 614 parent-offspring pairs. Many participants have multiple tissues' data (n = 1,077 participants) or the same tissue at different ages (n = 1,742 participants). Extant genetic data are available on 5,794 participants from 13 cohorts. Data were generated on multiple single-nucleotide polymorphism (SNP) microarray platforms with 370,150 to 1,730,897 SNPs per sample. All the data have been cleaned to the same standard and mapped to the human genome build 38 and imputed using the TOPMed (Version r2 2020) reference panel. 11,681 microbiome samples from 5682 EWC participants, primarily 16S, are also available. This includes paired samples from 650 mother-infant dyads. Thousands of EWC participants have multi-omics data. Additional genetic, epigenetic, microbiome and metabolomics data on the EWC participants are being generated. ECHO investigators are conducting numerous omics-based studies on the EWC participants including studies of genetics of early childhood growth, robustness of epigenetic clocks across age and tissue, and effects of air pollution on the epigenome. The EWC is a powerful collaborative resource for studying child health and development whose power and utility will continue to increase over time.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4538 Pan Genomic Analyses and GWAS of *Mycobacterium fortuitum from different isolation sources*

Authors:

B. Yakubu; Kwame Nkrumah Univ. of Sci. and Technology, Kumasi, Ghana

Mycobacterium fortuitum is a specie of rapidly growing non-tuberculous mycobacteria that can be found in soil, water, and various environmental sources including endoscopes, and prosthetic devices. *M. fortuitum* causes infections in humans, especially in those with compromised immune systems, such as individuals with cystic fibrosis, cancer, or HIV/AIDS. However, treatment of *M. fortuitum* infections involving a combination of antibiotics sometimes fail due to development of novel strains, virulent/antibiotic resistant genes and inadequate knowledge on the specific genes which have strong association with its virulence. To unravel the interplay of these genomic features of the bacterium on disease onset, Pangenome and GWAS analyses was conducted using Roary pangenome pipeline, including Prokka, Abricate, SCOARY. Downstream statistical analyses and visualizations were also performed using R-programming, Uniprot Ugene, Phandango and google sheets. Five different clusters were constructed along a nine-layer phylogenetic tree for similarity and evolutionary analyses. A total of 22526 pan genes were identified with 41.99% of them strongly associated with the identified traits. Mirage of both virulent and AMR genes found whiles some obsolete antibiotics were detected. In conclusion, we noted that *M. fortuitum* bacterium is quite diverse with the potential of increasing the diversity in future, relatively virulent and may continue to resist a number of Antibiotics.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4539 PangyPlot: A Visualization Tool for Exploring Pangenomes

Authors:

S. Mastromatteo, F. Lin, K. Keenan, S. Chirmade, B. Thiruvahindrapuram, Z. Wang, D. Roshandel, J. Whitney, S. Allana, L. J. Strug; The Hosp. for Sick Children, Toronto, ON, Canada

A persistent issue with traditional linear reference genomes is that they fall short in capturing the full genetic diversity present in populations. Dependency on a singular reference sequence introduces reference bias — under-representation of alleles that differ from the reference genome — leading to a skewed and inaccurate understanding of genetic variation. Pangenomes (often implemented as graph genomes) overcome this limitation by incorporation of all genetic variations and structural variations found in a population into a single unified representation. Recent improvements in long-read sequencing technologies have reduced the complexity of assembling reference-quality genomes, making the construction of a graph genome viable.

Use of a graph genome in practice is challenging because the landscape of supporting bioinformatics tools remains sparse. Particularly, visualizing the structure of a graph genome is unintuitive despite being a critical part of linear genome-based analysis. Software such as Bandage and Sequence Tube Maps can visualize local regions of a graph but are less effective with complex structures and lack a robust annotation system.

Here we present PangyPlot, a novel browser-based tool designed to facilitate the exploration of pangenome structures. PangyPlot provides a dynamic and interactive visualization of graph genome structure at different resolutions. Users can view complex structural variation and zoom in to annotated SNP-level details. Unlike existing tools, PangyPlot incorporates annotations within the visualization as well as the ability to collapse complex structures and highlight paths along the graph corresponding to haplotypes.

We evaluated PangyPlot using the Human Pangenome Reference Consortium (HPRC) data along with 101 hybrid genomes assembled using Pacific Biosciences long-read sequencing and linked-reads (average N50=45Mb, L50=20) from individuals with cystic fibrosis (CF). We demonstrate the potential of the tool by visualizing the *PRSS1-PRSS2* CF modifier locus that contains a common 20 kb deletion polymorphism as well as the *SLC9A3* locus that is dense with large tandem repeats. Both regions impact CF severity and are difficult to characterize using traditional linear reference-based approaches.PangyPlot provides powerful and intuitive visualization for exploring pangenome structures. Leveraging graph-based representations provide deeper visual insights into genetic diversity and identification of genomic features that would be commonly missed due to reference bias. A version of PangyPlot that visualizes HPRC and our 101 genomes is being made available as a public web application.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4540 PhenoDB and CAVATICA: Container-Based Annotation and Analysis

Authors:

L. Vail[1], S. Griffith[1], R. Martin[2], M. Brown[3], D. Miller[4], Y. Guo[5], A. Heath[3], Y. Zhu[6], N. Sobreira[2]; [1]Johns Hopkins Genomics, Baltimore, MD, [2]Johns Hopkins Univ, Baltimore, MD, [3]Children's Hosp. of Philadelphia, Philadelphia, PA, [4]Childrens Hosp. of Philadelphia, Philadelphia, PA, [5]Children s Hosp. of Philadelphia, Philadelphia, PA, [6]The Children s Hosp. Of Philadelphia, Havertown, PA

PhenoDB, a web-based tool, provides methods to annotate and analyze the variants of patients and their family members for links to diseases. CAVATICA is a cloud-based data analysis platform that allows users to run various analyses over their genomic data in a HIPPA complaint environment.
To provide access to some of the PhenoDB analysis tools in CAVATICA, the PhenoDB, CAVATICA, and D3b/CHOP teams have collaborated to create a CAVATICA app that provides a baseline variant analysis extracted from PhenoDB.
CAVATICA apps are built by encapsulating functionality into Docker containers, which run using the Common Workflow Language (CWL) to collect parameters from users. The encapsulated PhenoDB workflow was split into two containers so that each step can be run independently.
The first step is the ANNOVAR annotation, which is the input for PhenoDB analysis. As parameters, it accepts the user's choice of assembly (Hg19 or Hg38), the VCF files to be annotated, and the ANNOVAR reference data. The second step is a PhenoDB analysis based on the output of the first step. The parameters for the second step are: the characteristics of each individual included in the analysis (affected status, relationship to the proband, sex, and annotated VCF file), inheritance patterns, minor allele frequency, and RefGene gene location (variant type).
The PhenoDB app on CAVATICA provides a graphical user interface to configure the analysis, which can be run using any file stored on CAVATICA. All jobs executed on CAVATICA are retained, can be edited, and rerun. For collaboration, users can share their CAVATICA projects with other users.
This initial collaboration between the PhenoDB, CAVATICA, and D3b/CHOP teams is a starting point that we expect will lead to further PhenoDB functionality being added to CAVATICA. The creation of containers encapsulating PhenoDB analysis functionality also provides a gateway for collaborations on other cloud-based genomics analysis platforms.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4541 Polygenic Interactive Discovery System: an interactive knowledgebase for exploring complex genetics networks

Authors:

M. Milojevic[1], R. Z. Marandi[1], B. Sherman[2], W. Chang[2], J. D. Lundgren[1], D. D. Murray[1], C. R. Macpherson[1], P. Leung[1]; [1]Ctr. of Excellence for Hlth., Immunity and Infections (CHIP), RigsHosp.et, Copenhagen, Denmark, [2]Lab. of Human Retrovirology and Immunoinformatics, Frederick Natl. Lab. for Cancer Res., Frederick, MD

Genome Wide Association Studies (GWAS) are used to assess the impact of single nucleotide polymorphisms (SNPs) on a specific phenotype. While widely used and beneficial, this method has limitations, namely strict control for type 1 error at the expense of type 2 error and an inability to account for pleotropic effects at the gene or pathway level. Further, GWAS output is not easy to explore in connection with existing literature to identify supporting/contradicting studies and develop new hypotheses. To address these concerns, we developed the Polygenic Interactive Discovery System (PIDS), an interactive genetics knowledgebase that facilitates the study of genetic effects on disease with the knowledge of relevant molecular pathways and prior studies. Data from Ensembl, GWAS Catalog, ClinVar, PGS Catalog, and Reactome were extracted and merged into a single, searchable data structure to form the knowledgebase. Users of PIDS are also able to upload their own SNP level association data. Output from any of the resources outlined above is mapped to the network generated from the knowledgebase, which can then be explored and added to using an interactive R shiny interface. The current version of PIDS contains a comprehensive biological network with 19496 genes and biologically relevant small molecules, connected by 353,889 edges. All resources were harmonized to a combined total of 326,948 SNPs with single-nucleotide effects studied across 4901 studies, 1775 PRS studies describing pleiotropic effects for 390,235,794 rsID-gene pairs. SNP co-ordinates were cross-checked with Ensembl's human gene list (N = 40,785 genes, genome build: GRCh38) and variation file for rsID matching. To showcase PIDS, networks were created for two existing datasets and explored through the graphical interface. First, we created a network using an existing polygenic risk score (PRS) for Type 1 diabetes and mapped results from a separate GWAS study, observing commonality between these two studies. Second, we created a network from an existing HIV GWAS and mapped other GWAS exploring the same phenotype and other viral infections, showing that genetic variation in HLA-B is important across these independent studies. In conclusion, PIDS is a versatile tool that leverages data from five distinct databases to complement genetic association studies with knowledge of biological function and enhance them by connecting with existing studies in related areas. The system aids the interpretation of SNPs at the resolution of one or more genes and may be used to explore functions of SNP at a gene and pathway level by providing a deeper, more connected view for overall interpretation and hypothesis generation.

PB4542 Practical recommendations for TOPMed metabolomics data.

Authors:

F. Ockerman[1], L. Zhou[1], E. Drzymalla[1], T. Alkis[2], M. Grove[2], B. Yu[2], L. Raffield[1]; [1]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [2]Univ. of Texas HSC at Houston, Houston, TX

The Trans-Omics for Precision Medicine (TOPMed) program expects to soon release over 90,000 samples with broad-spectrum metabolomic data, representing over a dozen studies. However, investigators using this resource face potential challenges in pre-processing and integrating data across studies. Differing metabolomic platforms and analysis centers may cause technical variation. Likewise, missing metabolite values may vary in their distribution and source between studies. Consistent protocols for pre-processing and integration are thus necessary to unlock the potential of this rich resource. We compare several strategies and offer recommendations for the TOPMed community, with the goal of guiding and facilitating future genetic and phenotype-specific analyses.

As a pilot phase, we are currently analyzing data from 25,058 participants from diverse case-control and population-based cohort studies, including 15,633 participants from 3 cohort studies on the Metabolon platform and 9,425 participants from 5 cohort studies on the Broad/BIDMC platform. This dataset includes 1,730 named metabolites, including 364 metabolites measured in at least some cohorts across both platforms. With within-study rank-based inverse normal transformation, we demonstrate that estimates of age-metabolite associations are highly concordant ($r > 0.999$), and generally consistent with the existing literature, between pooled and inverse variance meta-analyzed data, although 36 metabolites are significant only in the meta-analysis. Most named metabolites had very low missingness in our dataset, and we found that metabolite associations with age and sex were highly consistent across all missingness imputation strategies (zero, min, half-min, k-nearest neighbors, random forest, quantile regression imputation of left censored data). We recommend replacing missing values with zero in metabolites characterized as xenobiotics. For other metabolites, we will compare imputation strategies with an analysis of metabolite quantitative trait loci (mQTLs).

In summary, we find largely consistent results in pooled and inverse variance meta-analysis. We recommend inverse-normal transformation to enable integration between studies. We recommend left-censored imputation for xenobiotics and will soon release recommendations for imputation in other metabolites. To aid investigators, we will release scripts for implementing these recommendations. Such pre-processing steps are necessary to optimize power in cross cohort metabolomic analysis, including planned QTL studies.

PB4543 Profiling senescent cells in snRNA-seq data.

Authors:

M. Koutrouli[1], J. Bendl[2], D. Lee[3], P. Fnu[4], G. E. Hoffman[5], V. Haroutunian[6], J. F. Fullard[4], J. J. Lars[1], P. Roussos[5]; [1]Univ. of Copenhagen, Copenhagen, Denmark, [2]Icahn Sch. of Med. at Mount Sinai, New York City, NY, [3]Ctr. for Disease Neurogenomics and the Icahn Inst. for Data Sci. and Genomic Technology and the Dept.s of Psychiatry and Genetics and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY, USA, New York, NY, [4]Ctr. for Disease Neurogenomics, Icahn Sch. of Med. at Mount Sinai, New York, NY, [5]Icahn Sch. of Med. at Mount Sinai, New York, NY, [6]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Aging is a complex phenomenon with many factors, or hallmarks, contributing to its advancement. These hallmarks include cellular senescence, genomic instability, telomere attrition, epigenetic alterations, loss of proteostasis, deregulated nutrient sensing, mitochondrial dysfunction, stem cell exhaustion, and altered intercellular communication. Among these potential causes, cellular senescence stands out as having a particularly significant role in the aging process and age-related diseases, including Alzheimer's disease.Cellular senescence is a process in which cells permanently stop dividing and enter a state of permanent growth arrest. It is triggered by a variety of stressors, including DNA damage, telomere shortening, oxidative stress, oncogene activation, and changes in chromatin structure. Senescent cells (SNCs) can secrete pro-inflammatory molecules, chemokines, and growth factors that are thought to influence the surrounding cellular environment, ultimately leading to a range of age-related pathologies, including Alzheimer's disease.Excitatory neurons are one of the most abundant types of neurons in the brain and play a critical role in cognitive functions. Recent studies have shown that cellular senescence also occurs in excitatory neurons, leading to their dysfunction. The accumulation of senescent excitatory neurons is believed to contribute to the development and progression of Alzheimer's disease.To gain a deeper understanding of the role played by senescent excitatory neurons in Alzheimer's disease, our research aimed to identify and analyze these neurons within the PsychAD cohort. This cohort comprises a vast collection of 8,342,664 cells obtained from 1,495 unique donors. Our specific focus was on establishing biomarkers and characterizing excitatory senescent neurons in both Alzheimer's disease and healthy brain tissue.Our preliminary findings have revealed a significant correlation between the concentration of excitatory senescent neurons and Alzheimer's disease. By characterizing these senescent excitatory neurons, we hope to shed light on the underlying mechanisms that lead to their dysfunction and demise in the context of Alzheimer's disease as well as identify potential therapeutic targets for intervention and treatment.

PB4544 Quantifying the incredible pleiotropy of microRNAs: focusing ChatGPT on the literature

Authors:

M. McGeachie[1], S. Begum[1], R. Sharma[2], K. R. Wang[3]; [1]Brigham & Womens Hosp., Boston, MA, [2]Harvard Med. Sch. & BWH, Boston, MA, [3]Roxbury Latin, Boston, MA

MicroRNAs (miRNAs) are recognized as key regulatory factors in numerous severe diseases, with the same miRNA often involved in several diseases simultaneously or being identified as biomarker for dozens of separate diseases. While of evident biological importance, miRNA pleiotropy remains poorly understood, and a robust measure of pleiotropy could greatly aid in understanding the broader role miRNAs play in health and disease. To this end, we introduce miRAIDD (miRNA Artificial Intelligence Disease Database), a comprehensive database of miRNA-disease causal associations constructed using OpenAI's ChatGPT model and describe its implications for understanding the general pleiotropy of miRNAs in human disease.

We employed ChatGPT to read over 60,000 abstracts from PubMed mentioning miRNAs and used it to determine if the abstract described evidence of a causal role for the miRNA in the condition or trait described therein. We aggregated these results into miRAIDD, totaling 85,454 annotations, 51,410 unique papers, and 23,346 unique papers that demonstrate a causal miRNA-disease relationship; these represent a marked increase over existing human-curated miRNA-disease collections. The performance of the AI model in generating the database was found to be comparable to human annotators and existing miRNA-disease association databases.

We combined miRAIDD with other publicly available sources of data on miRNA to identify factors influencing the pleiotropy of miRNAs, defined as the number of diseases a miRNA is reported to have caused. The most important factor influencing pleiotropy of a particular miRNA is the number of publications featuring the miRNA. The number of tissues a miRNA has been observed in and the number of validated and predicted gene targets were also significant predictors. After adjusting for publications, the date of discovery, evolutionary conservation, and number of gene targets predicted by computational algorithms (but, importantly, not the number of experimentally validated gene targets) were the strongest indicators of number of diseases caused. We identified over 100 miRNAs causing more than 50 distinct diseases each, which suggests that many miRNAs have substantial pleiotropy.

While much has been written about the potential future impact of strong AI models like ChatGPT impacting biomedical research, our investigation represents one of the first such implementations. The miRAIDD database is freely available for download, with the anticipation that it will further expedite research about miRNA publications, results, and pleiotropy.

PB4545 † RefSeq Annotation and Curation of the T2T-CHM13 Human Genome Assembly

Authors:

T. Goldfarb, S. Pujar, J. Jackson, V. S. Joardar, V. K. Kodali, K. McGarvey, M. Murphy, A. Vatsan, D. Webb, F. Thibaud-Nissen, T. D. Murphy; Natl. Ctr. for Biotechnology Information, Natl. Library of Med., NIH, Bethesda, MD

The RefSeq project at the National Center for Biotechnology Information (NCBI) manually curates the publicly available reference genomes to represent a standard reference set of well supported and non-redundant reference sequences used by the medical and scientific communities. A large focus of RefSeq curation has been on the human reference genome, GRCh38. While the availability of this sequence has revolutionized science and medicine during the last two decades, the technology used at the time of its assembly resulted in some gaps and repeat regions that could not be properly sequenced, and therefore regions of the genome that could not be annotated, curated, and represented.
Recently, a new human assembly was released by the Human Pan Genome Consortium (HPRC), T2T-CHM13, using long-read sequencing technologies that overcomes some of the limitations of sequencing complex and repeat regions of the genome that cannot be sequenced using clone-based techniques. RefSeq annotation of the T2T-CHM13 assembly was made available in April 2022 and includes 82,862 curated RefSeq transcripts with experimental evidence for the annotation drawn from 9.7 billion RNA-seq reads, nearly 83 million PacBio and Oxford Nanopore long transcriptome reads, 8.6 million ESTs, and 345,700 GenBank cDNAs and corresponding proteins. This annotation is expected to provide valuable information and transcript sequences on some of the regions missing in the GRCh38 assembly. Preliminary analysis of the annotation suggests that there are more than 400 protein-coding genes uniquely annotated on T2T-CHM13, including important disease-related genes. Presented here are the results of RefSeq curation of the T2T-CHM13 annotation, including new RefSeqs for genes that are novel to the T2T-CHM13 assembly compared to the GRCh38 assembly. In addition, RefSeq has curated and represented transcripts found on T2T-CHM13 that represent alternate alleles of genes, including differences in coding potential (e.g. unitary pseudogenes), polymorphic splice sites, and some cases in which the T2T-CHM13 allele represents the major allele found within some populations. RefSeq will continue curation of the T2T-CHM13 assembly and expect that this effort will help users get the maximum use and benefit of this assembly in years to come.

PB4546 Repository of Alzheimer's Disease and Related Dementia (RADR) and its application to diverse populations

Authors:

R. Vaza, A. Elmas, H. Wu, V. Subramaniam, A. Renton, A. Goate, P. O'Reilly, K-l. Huang; Icahn Sch. of Med. at Mount Sinai, New York City, NY

Alzheimer's disease and related dementias (ADRD) present significant public health challenges, and understanding their genetic underpinnings is crucial for developing effective interventions and risk prediction strategies. However, existing genetic resources are largely fragmented, limiting the development of genomic medicine for ADRD. We introduce the Repository of Alzheimer’s Disease and Related Dementia Variants (RADR), a curated database of 3530 rare genetic variants associated with ADRD. The database standardizes and integrates data from various sources, including Alzforum, ClinVar, and DNA-seq studies. Additionally, we explore the distribution and pathogenicity of genetic variants within RADR with a focus on pathogenic, likely pathogenic, and risk factors/modifiers. We demonstrate the application of RADR to two large-scale biobanks, BioMe (n = 30813) and the UK Biobank (n = 201,136), for genotype-phenotype correlations with ADRD-related phenotypes. The findings highlight incomplete penetrance, enrichment of certain variants, and potential population-specific differences. Overall, RADR provides a comprehensive and unified resource for researchers and clinicians studying ADRD, facilitating genetic variant analysis and the potential to aid in the development of personalized approaches for diagnosis, prevention, and treatment.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4547 Resources for archiving and analysis of human data in Japan

Authors:

Y. Kodama[1], A. Fukuda[1], T. Tokimatsu[1], J. Mashima[1], T. Hachiya[2], M. Ishii[2], M. Kawashima[3], N. Mitsuhashi[3], T. Fujisawa[1], T. Tanjo[1], O. Ogasawara[1]; [1]Natl. Inst. of Genetics, Mishima, Shizuoka, Japan, [2]Genome Analytics Japan Inc., Tokyo, Japan, [3]Database Ctr. for Life Sci., Chiba, Japan

The Japanese Genotype-phenotype Archive (JGA, https://www.ddbj.nig.ac.jp/jga) as a centralized repository in Japan has been maintained jointly by the National Bioscience Database Center (NBDC) (https://humandbs.biosciencedbc.jp) and DDBJ. NBDC is responsible for the ethical guidelines and its Data Access Committee (DAC) grants data submission and data access requests to JGA. DDBJ accepts metadata, genotype and phenotype data associated with data samples, and assigns stable, unique accession numbers prefixed with ‘JGA’. JGA studies are indexed at the DDBJ Search (https://ddbj.nig.ac.jp/search). As of 5 June 2023, 339 studies (585,632 samples and 980 terabytes of data files) are available. DDBJ also provides a secured supercomputing environment for analyzing personal genome data. The secured system is connected with the JGA server through a high-speed network, and users can smoothly download and analyze JGA datasets as in a cloud environment. For the convenience of users, we pre-process raw genome sequencing data deposited at JGA by using the workflow "jga-analysis" (https://github.com/ddbj/jga-analysis), and provide alignment and variant call data along with the original raw data from JGA. Allele frequencies of analyzed variants are available at the DBCLS TogoVar (https://togovar.org), which is a database for variant annotation with allele frequencies among Japanese populations, without restriction.. We also provide the NBDC-DDBJ imputation server to enable researchers to execute imputation analysis by simply uploading their data and selecting an imputation panel dataset in the web interface. Researchers can use Japanese imputation panel datasets distributed by JGA upon a NBDC DAC approval.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4548 Shared loci between post-traumatic stress disorder and cardiovascular phenotypes using EHR and heart imaging data from more than 1 million participants

Authors:

J. SHEN[1,2], W. Valentim[2,3], D. Koller[2,4], M. B. Stein[5], J. Gelernter[6], R. Polimanti[2], G. A. Pathak[2]; [1]Children's Hosp. of Soochow Univ., Suzhou, China, [2]Yale Univ. Sch. of Med., New Haven, CT, [3]Faculdade de Med. da Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil, [4]Univ. of Barcelona, Catalonia, Spain, [5]Univ. of California San Diego, San Diego, CA, [6]Yale Univ Sch. of Med., West Haven, CT

Objectives: The aim of this study is to investigate the shared loci between post-traumatic stress disorder (PTSD) and cardiovascular disease (CVD) phenotypes, utilizing electronic health records (EHR) and heart imaging data, to gain a deeper understanding of the underlying mechanisms. Methods: We analyzed 76 autosomal loci associated with PTSD from the recent genome-wide association study (GWAS; N=1,307,247) of the Psychiatric Genomics Consortium (PGC). CVD EHR phenotypes (circulatory system -141 phecodes; endocrine/metabolic - 105 phecodes) were obtained from the Million Veteran Program (MVP; N=458,061). Cardiac and aortic structural and functional imaging traits were derived from UK Biobank (UKBB, N=26,893). We estimated global and locus-level genetic correlations (rg) between PTSD and CVD traits, using LDSC and LAVA respectively. To estimate probability of shared causality between PTSD and CVD traits we applied the coloc method. For replication, we also tested PGC-PTSD data with respect to phecodes from UKBB (N=420,531) and similar phenotypes available from other GWAS consortia (N=915,868). Statistical significance was defined considering false discovery rate (FDR-q<0.05). Results: Significant globalrg were found between PTSD and circulatory phecodes (100 traits, globalrg 0.107~0.661), endocrine/metabolic phecodes (53 traits, globalrg 0.072~0.551), and heart imaging (8 traits, globalrg 0.207~0.190). Of the 76 PTSD-associated loci, we observed 33 loci to be genetically correlated with 59 traits (absolute [localrg] - 0.159 ~ 1). Considering loci with evidence of local PTSD-CVD rg, we investigated shared causality using probability of (i) having the same causal variant for the two traits [H4-PP>80%]; and (ii) two LD-linked causal variants for the two traits [H3-PP>80%]. We found 20 CVD traits that shared the same causal SNP with PTSD at 12 loci, and 27 CVD traits where causal variants were different but LD-linked at 9 loci. Of these results, we found colocalizations for 18 traits at 12 loci that replicated in UKBB phecodes or similar phenotypes available from other GWAS consortia. We found eight traits including coronary atherosclerosis, atrial fibrillation, obesity, diabetes, and ischemic heart disease at four loci (3p21.31,7p22.3,17q21.32, 19p13.11) that shared causal variants with PTSD in all three cohorts. Conclusion: Overall, our study provides new insight by prioritizing specific loci that share potential causal variants between PTSD and several CVD conditions. These loci will be further investigated as drug repurposing targets and their molecular function, which may explain their shared mechanism.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4549 Spit take: Improving high molecular weight DNA extraction from shelf-stable saliva for long-read sequencing.

Authors:

L. Morina[1], J. Hosea[1], C. Montano[2], W. Timp[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Natl. Human Genome Res. Inst., Bethesda, MD

Single-molecule, long-read sequencing technologies have enormous potential in population genetics and epigenetics. Single-molecule platforms (PacBio/ONT) can generate reads long enough to span low-complexity genomic regions and distinguish covalently modified nucleotides directly on individual DNA molecules. However, these methods require high DNA input, and retaining high molecular weight (HMW) DNA fragments is required to best leverage these platforms' advantages. These limitations are particularly relevant when dealing with limited-quantity patient samples, whether whole blood, buffy coat, or saliva. In recent years, saliva samples have seen an increase in use for large-scale genetic studies. This is partly because saliva samples are ideal for clinical studies - collection does not require a trained individual, samples are stable at room temperature, and collection tubes can be shipped for collection. However, this leads to a unique set of challenges: contamination, an uncharacterized DNA degradation rate for room temperature samples, and a variable cellular composition within the sample. Our goal is to overcome these obstacles so that saliva can be more widely used for single-molecule sequencing of high molecular weight (HMW) DNA in large-scale genetic studies. We are developing a DNA sequencing protocol specifically tailored for HMW DNA from saliva, primarily for use with the Oxford Nanopore Technologies (ONT) PromethION platform. The protocol, which includes DNA extraction, shearing and size selection, and library prep, has been tested on a medley of saliva samples gathered within the past five years. So far, we have tested two HMW DNA extraction methods, two size selection methods, and two shearing methods and sequenced all samples with PromethION. In the future, we plan to assess three more extraction methods. We also plan to process whole blood and buffy coat samples gathered around the same time as the saliva samples for comparison. The initial saliva samples exhibited varying bacterial contamination but were sequenced regardless. Contamination was evaluated by visual inspection or after sequencing by percent mapping to the human genome by *minimap2*. We have established a basic filtering pipeline to accompany the final protocol using alignment (*minimap2)* and k-mer based classification (*kraken2)*. This experimental and computational workflow will be useful for the wider community to apply to saliva specimens, a convenient and cost-effective source of DNA for sequencing.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4552 Telmisartan reduces T2D incidences in electronic health records

Authors:

A. Tiwari[1], Q. Wang[1], Q. Wei[1], R. Chen[1], Y. Tan[1], Y. Yan[1], B. Li[1], X. Zhong[2]; [1]Vanderbilt Univ., Nashville, TN, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Background: Essential hypertension and Type 2 Diabetes (T2D) are common conditions that often coexist. Some medications treating blood pressure have been found to also affect diabetes due to shared targets. Our previous work suggested that telmisartan, an anti-hypertensive medication, may protect against T2D as the drug reversed the disease signature of T2D based on an integrative analysis of T2D genetics and drug-induced perturbation experiments. **Objective:** In this project, we use electronic health records (EHR) from Vanderbilt University Medical Center (>3 million de-identified individuals) to validate the potential therapeutic effect of telmisartan on T2D.**Methods:** We first constructed a telmisartan drug user cohort including 40,241 adults diagnosed with essential hypertension, and two types of control cohorts: 1) non-telmisartan user cohort, and 2) comparator cohorts of hypertensive patients taking other anti-hypertensive medications. Each control cohort was matched by age, gender, body mass index (BMI), and disease comorbidities to the telmisartan cohort using propensity score. We then estimated the hazard ratios (HRs) and 95% CIs using stratified Cox proportional hazard models, adjusting for age at diagnosis, gender, BMI, and disease comorbidities. **Results:** Among the hypertension patients, we found that usage of telmisartan was associated with a reduced risk of T2D (HR 0.48; 95% CI 0.44 to 0.52; P<2e−16) compared to the non-telmisartan user control cohort. Telmisartan was also significantly associated with a decreased risk of T2D for all three comparator cohorts (clonidine (HR 1.33; 95% CI 1.22 to 1.45; P<1.07e-10), metoprolol (HR 1.22; 95%CI 1.12 to 1.34; P<6.33e-06), and timolol (HR 1.29; 95% CI 1.14 to 1.47; P<8.8e-05)). **Conclusions:** Our analysis of EHR data provides further evidence supporting the protective effect of telmisartan against T2D. Further validation such as randomized clinical trials is needed. **Keywords:** hypertension drug, T2D, drug repurposing, electronic health records, insulin resistance, clinical outcomes.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4553 The Alzheimer's Disease Sequencing Project - Discovery, Discovery Extension and Follow Up Study ADSP-FUS: *APOE* genotype status and demographic characteristics across datasets.

Authors:

P. Mena[1], A. Zaman[1], K. faber[2], L. Adams[1], J. Inciute[1], P. Whitehead[1], T. Foroud[3], D. Reyes-Dumeyer[4], A. Kuzma[5], H. Issen[6], A. Naj[7], E. Martin[8], C. Dalgard[9], G. Schellenberg[10], L-S. Wang[11], R. Mayeux[12], B. Vardarajan[13], J. Vance[1], M. Cuccaro[14], B. Kunkle[1], M. Pericak-Vance[8]; [1]Univ. of Miami, Miami, FL, [2]Natl. Centralized Repository for ADRD, Indianapolis, IN, [3]Indiana Univ Sch Med, Indianapolis, IN, [4]Columbia Univ., New York City, NY, [5]Univ Pennsylvania, Philadelphia, PA, [6]Univ. of Pennsylvania, Glenside, PA, [7]Univ. of Pennsylvania, Philadelphia, PA, [8]Univ. of Miami Miller Sch. of Med., Miami, FL, [9]USUHS - TAGC, Bethesda, MD, [10]Univ Pennsylvania Sch Med, Philadelphia, PA, [11]UPENN, Philadelphia, PA, [12]Columbia Univ, New York, NY, [13]Columbia Univ., New York, NY, [14]John P. Hussman Inst. for Human Genomics, Miami, FL

Background: The ADSP is a National Institute on Aging (NIA) initiative focused on identifying genetic risk and protective variants for Alzheimer Disease (AD). Initial phases (Discovery and Discovery Extension) were predominantly non-Hispanic Whites of European Ancestry (NHW-EA). The ADSP expanded the population diversity in the Follow Up Study (ADSP-FUS) where existing ethnically diverse and unique cohorts underwent whole genome sequencing (WGS). The recent phase, ADSP-FUS 2.0: The Diverse Population Initiative, continues focusing on non-European populations, Hispanic/Latino (HL), non-Hispanic Black with African Ancestry (NHB-AA), and Asian populations.
Methods:ADSP cohorts consist of studies of AD, dementia, and age-related conditions. Clinical classifications are assigned based on standard criteria and derived from clinical measures and history, as well as additional neuropathologic data. In addition to production of WGS, APOE genotyping is available for all ADSP samples.
Results: The ADSP currently consists of 40 cohorts comprised of ~36,300 individuals, with plans to sequence >120,000 individuals from diverse ancestries. Genotyping, sequencing, and clinical adjudication has been performed on 36,361 participants (cases N=12,133, median age=72; cognitively-unimpaired(CU) individuals N=17,116, median age=74; ADRD N=7,112, median age=71). Mean ages for cases and controls vary across cohorts, from 57.0+5.6 to 86.5+4.2 for cases and 63.3+7.8 to 90.0+0 for controls. 61% of participants are female that are distributed as follows: cases (60.3%), CU(63.7%), and ADRD (55.8%). The most prevalent APOE genotype is APOE ?3/?3 (% by cases/CU for ?2/?2=0.2,0.5; ?2/?3=4.7, 9.4; ?2/?4=2.2, 1.8; ?3/3=41.2, 63.2; ?3/?4=40.9, 23.0; 4/4=10.8, 2.1). These proportions differ by ethnicities, with the highest for APOE ?4/?4 observed in Amerindian participants (18.3%) and the lowest in NHW-EA participants (1.7%).
Discussion: The results provide an overview of clinical features in ADSP cohorts. The continued growth of the ADSP-FUS 2.0 is central to the ADSP. Expanding in size and diversity, this genomic resource, available via NIAGADS, will be integrated with ADSP programs focused on phenotype harmonization, association analyses, functional genomics, and machine learning. In concert with these programs, the ADSP-FUS 2.0 will accelerate the identification and understanding of potential genetic risk and protective variants for AD across all populations with the target of developing new treatments that are globally effective.

PB4554 The Association to Function Knowledge Portal enables forward- and reverse-genetics analyses of human genetic and functional genomic data

Authors:

T. Nguyen[1], M. Costanzo[2], M. Brandes[1], M. Duby[1], Q. Hoang[1], D. Jang[1], R. Koesterer[1], P. Kudtarkar[3], A. Moriondo[1], O. Ruebenacker[1], P. Smadbeck[1], S. Ying[3], K. Gaulton[4], M. Boehnke[5], J. Flannick[6], N. Burtt[7]; [1]The Broad Inst. of MIT and Harvard, Cambridge, MA, [2]Broad Inst. of MIT & Harvard, Cambridge, MA, [3]Univ. of California San Diego, San Diego, CA, [4]UCSD, San Diego, CA, [5]Univ. of Michigan, Ann Arbor, MI, [6]Boston Children s Hosp., Boston, MA, [7]Broad Inst., Cambridge, MA

Genome-wide association studies (GWAS) provides valuable insights into the genetic architecture of diseases; however, most functional effects of GWAS signals remain unknown, hindering the understanding and treatment of diseases. We have created the Association to Function Knowledge Portal (A2FKP; a2fkp.org) to address this obstacle on a large scale. The unique values of the A2FKP lie in the inclusion of 669 phenotypes in 11 disease systems across 11 ancestries, the integration of 8 data types (genetic and functional genomic) totaling more than 4,500 datasets, 8 bioinformatic methods that allow for integration and visualization of these data, and the capacity for both single-trait and multi-trait analysis. The A2FKP connects closely with a sister resource, Common Metabolic Diseases Genome Atlas (CMDGA; cmdga.org) that houses more than 7,200 epigenomic and functional genomic datasets. In addition, we have developed 8 community portals tailored to disease-specific research communities. The A2FKP includes tools for multi-trait analysis on both the variant level and the gene level. In a forward genetics approach, on the variant level, the Signal Sifter allows for clustering genetic associations by sets of traits, accounting for linkage disequilibrium, which can reveal novel pathways underlying complex traits. Users can search for variants associated with multiple traits, and filter the results based on direction of effect and strength of associations. Similarly, on the gene level, the Gene Finder enables assembling sets of genes with significant gene-level associations for a custom list of traits. It queries gene-level associations from both common and rare variant data, Human Genetic Evidence Calculator scores calculated by a novel statistical method that evaluates the strength of evidence for associations, tissue-specific gene expression levels, and effector gene predictions curated by experts. Starting with a list of traits, users can filter the results based on any of those criteria. In a reverse genetics approach, using the Variant Sifter, researchers can explore genomic regions of interest to prioritize potentially causal variants and genes. They can choose one or more phenotypes and opt to see relevant credible sets, both contributed by our collaborators and curated from the literature, and multiple types of epigenetic annotations for 48 tissue types, including accessible chromatin, chromatin states, binding sites, and target gene predictions. To build the A2FKP, we work directly with disease communities who provide their expertise, data and methods; we welcome future collaborations.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4555 The Baylor College of Medicine Center for Precision Medicine Models

Authors:

D. Lanza, J. Rosenfield, S. Yamamoto, M. Wangler, H. Bellen, O. Kanca, J. Rogers, M. Roth, R. Darshoori, V. Ramanathan, U. Ramamurthy, J. Posey, S. Nagamani, M. Dickinson, J. Seavitt, L. Burrage, A. Milosavljevic, J. Heaney; Baylor Coll. of Med., Houston, TX

Precision animal models are critical tools for interpreting variants of uncertain significance and for pre-clinical investigation of personalized medicine approaches. To assist clinicians, researchers, patient support groups, and large research consortia (*e.g.*, Undiagnosed Diseases Network and GREGoR) with the development of precision animal models of undiagnosed, rare and Mendelian disorders, we have established the Baylor College of Medicine (BCM) Center for Precision Medicine Models (CPMM). Our center combines the expertise of fly, mouse, and nonhuman primate modeling programs with the clinical, gene discovery, and informatics expertise at BCM. Variants nominated for modeling through the Center website are reviewed for the feasibility and applicability of creating a precision fly or mouse model that can address the clinical question with consideration of existing model, variant, and clinical data. The Center also searches a database of genome and exome data from nonhuman primates in National Primate Research Centers to identify potential models with spontaneous mutations relevant to the nominated variant. To support the pathogenicity of a nominated variant the Center can query the Baylor Genetics clinical exome database for similar variants, perform RNA-seq using patient-derived cells, or reanalyze the patient exome or genome data. Nominations not accepted for modeling are accompanied by a clinical review summary including suggestions for other collaborations or existing modeling data that would support variant pathogenicity. If a nomination is accepted for modeling, Center members work closely with the nominator to develop a modeling plan that will address critical clinical questions. The Center leverages the resources and infrastructure of the Undiagnosed Diseases Network Model Organism Screening Center's Fly Core and Knockout Mouse Phenotyping Project (KOMP2) site at BCM to generate and characterize its precision fly and mouse models. To date, the Center has reviewed 70 nominations encompassing over 111 variants and accepted 18 variants for modeling in mouse, 19 variants for modeling in fly, and 2 variants for modeling in both organisms. The precision models currently being generated by CPMM are helping to uncover new disease mechanisms, reveal new disease biomarkers and phenotypes, and identify and test potential new therapeutic strategies for patients.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4556 The Brain Gene Registry: A collaborative resource of the Intellectual and Developmental Disabilities Research Centers (IDDRC's) to promote advances in translational science.

Authors:

V. Lanzotti[1], A. Gupta[2], I. Y. Oh[2], D. Baldridge[1], M. Thompson[1], L. Kaster[2], A. Abbacchi[1], A. Lai[1], A. Sveden[3,4], S. Mahida[4], M. Chopra[3,4], S. Srivastava[3,4], H. Hazlett[5], E. R. Riggs[6], J. M. Savatt[6], J. Piven[5], M. Sahin[3,4], C. Gurnett[1], J. Constantino[7], P. R. O. Payne[2], Brain Gene Registry Consortium, B. Minor[2]; [1]Intellectual and Dev.al Disability Res. Ctr., Washington Univ. Sch. of Med., St. Louis, MO, [2]Inst. for Informatics, Data Sci. & Biostatistics Washington Univ. in St. Louis, St. Louis, MO, [3]Rosamund Stone Zander Translational NeuroSci. Ctr., Boston Children's Hosp., Boston, MA, [4]Dept. of Neurology, Boston Children's Hosp. Intellectual Disability and Res. Ctr.; Harvard Med. Sch., Boston, MA, [5]Dept. of Psychiatry, Univ. of North Carolina Intellectual and Dev.al Disability Res. Ctr., Chapel Hill, NC, [6]Autism & Dev.al Med. Inst., Geisinger, Danville, PA, [7]Ctr. for Behavioral and Mental Hlth., Children's Hlth.care of Atlanta, Dept.s of Psychiatry and Pediatrics, Emory Univ., Atlanta, GA

Monogenic disorders account for a significant proportion of population-attributable risk for intellectual and developmental disabilities (IDD), but the data necessary to establish a causal relationship between a given genetic variant and a neuropsychiatric disorder is often lacking. Recognizing this scientific roadblock, investigators from 13 Intellectual and Developmental Disabilities Research Centers (IDDRC's) formed a consortium, and using their collective resources, created a Brain Gene Registry (BGR); a repository which pairs genomic data from participants with variants in putative brain genes with high-quality neurophenotypic data. Phenotypic profiles are developed using a combination of data elements extracted from participants' electronic health records (EHR) and through a battery of standardized assessments, collectively referred to as the Rapid Neurophenotypic Assessment Protocol (RNAP). The RNAP was developed by this group and adapted for virtual administration; it comprises information on cognitive, neuropsychiatric, and sensorimotor function, including symptoms of dysmorphology, and neurodevelopmental conditions such as attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD). BGR participants also co-enroll with GenomeConnect which enables the co-registered information to be assimilated in ClinVar. As of June 2023, the BGR contains data on 378 participants who are 55% male, 79% White, 7% Asian, 5% Black, and 11% Hispanic/Latine. The registry contains data for >80 genes with cohorts of more than 10 participants in CACNA1A, DNMT3A, SLC6A1, SETD5, and MYT1L, and 38 genes with cohorts between 3 and 10 participants. Most variants are *de novo;* 43% are classified as Pathogenic, 20% are Likely Pathogenic and 37% are Variants of Uncertain Significance, according to ACMG criteria. Cognitive standard scores on the Developmental Profile 4 (DP4) are shifted relative to a neurotypical population, with most participants scoring between 40 and 100 (*M= 67.69, SD=9.75*). EHR data show that symptoms of the muscle are the earliest and most prevalent diagnoses, followed over time by speech and language disorder, autism and ADHD. BGR-derived data has been used to accelerate and enrich curation for 15 brain genes evaluated by ClinGen's BGR ID-ASD Gene Curation Expert Panel. The BGR consortium welcomes referrals of participants with VUS or newly described variants in IDD genes and encourages the use of the evolving BGR data set to advance discoveries in translational science. Referrals, collaboration and data access requests can be submitted directly through the BGR website (https://braingeneregistry.wustl.edu/).

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4557 The Ferrome: A curated list of iron-related genes with brain-specific sex differences in expression.

Authors:

K. Sharma[1], N. R. Wheeler[2], W. S. Bush[2,3], A. R. Kallianpur[1,4]; [1]Dept. of Genomic Med., Cleveland Clinic, Cleveland, OH, [2]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [3]Cleveland Inst. for Computational Biology, Case Western Reserve Univ., Cleveland, OH, [4]Dept. of Molecular Med., Cleveland Clinic Lerner Coll. of Med. of Case Western Reserve Univ., Cleveland, OH

Iron is essential for myelination, neurotransmitter synthesis, and energy production, and its dysregulation in the brain is likely to influence neurophysiology, cognition, and social behavior. Iron stores/utilization and brain iron transport differ by sex due to heightened demands during the female reproductive years. Furthermore, for unknown reasons, cognitive/neurodegenerative and neuropsychiatric disorders often show a sex predilection. This study assessed sex differences in brain expression of critical iron-related genes using a newly created resource. We manually curated an up-to-date, comprehensive database of 822 iron-regulatory and iron-metabolic genes and genes regulated by iron or that encode proteins dependent on iron for their function, which we collectively term the "ferrome". This database includes genes involved in iron-uptake/transport (336), iron-sulfur-cluster biogenesis and mitochondrial function (103), and essential oxidoreduction reactions (185); ferroptosis, a type of iron-mediated programmed cell death, involves at least 198 genes. Using a 100 KB window flanking each gene and the TOPMed genomic reference panel, ferrome genes were found to contain approximately 3 million common genetic variants. Based on data from the Genotype-Tissue Expression (GTEx) project, 715 ferrome genes (87%) are expressed in one or more brain regions. The liver, an organ central to systemic iron regulation, is also a major producer of iron-related transcripts and protein products, with 663 (81%) of genes expressed. Utilizing a recent analysis of sex-biased gene expression within GTEx, we performed gene-set enrichment analyses to determine whether ferrome genes are more or less likely to show differences in expression in the brain by sex. Of 20,013 genes expressed in the brain, ferrome genes were 1.21 times more likely to exhibit sex-biased gene expression ($p = 0.038$) than non-iron-related genes; 164 ferrome genes (20%) showed sex-biased expression in brain. No significant enrichment was observed, however, for sex-biased gene expression in the liver ($p = 0.304$). Top pathways enriched in these 164 sex-biased ferrome genes included: Metabolism (including biological oxidations and iron uptake/transport), Neurodegenerative Disorders, Ferroptosis, and Oxidative Phosphorylation. The ferrome and its genetic variants will be useful for targeted analyses of the role of iron-related genes in many neurological and neuropsychiatric phenotypes. A surprising proportion of these genes shows significant brain expression differences by sex, suggesting that such targeted analyses may lead to novel sex-specific associations in brain disorders.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4558 The German Human Genome-Phenome Archive (GHGA) - A national infrastructure for secure archival and community-driven analysis of omics data

Authors:

C. Mertes[1,2,3], A. Benet-Pages[4,5], J. Winkelmann[4,3], J. Gagneur[1,2,3], on behalf of the GHGA Consortium; [1]Technical Univ. of Munich, Munich, Germany, [2]Munich Data Sci. Inst., Munich, Germany, [3]Inst. of Human Genetics, Sch. of Med., Technical Univ. of Munich, Munich, Germany, [4]Inst. of Neurogenomics, Helmholtz Ctr. Munich, Oberschleissheim, Germany, [5]Med. Genetics Ctr. Munich (MGZ), Munich, Germany

The German Human Genome-Phenome Archive (GHGA) is building a secure national omics data infrastructure, aiming to enable the secondary use of human omics data for research purposes. It is part of the German National Research Data Infrastructure (NFDI) and will serve as the national hub of the Federated European Genome-Phenome Archive (FEGA). GHGA strives to provide the necessary computing infrastructure, an ethical-legal framework to handle omics data in a data-protection-compliant and FAIR (Findable, Accessible, Interoperable, Reusable) manner, a harmonized metadata schema, and standardized workflows to uniformly process the incoming data. GHGA will be based on cloud computing infrastructures managed in a network of data generators. Utilizing the Global Alliance for Genomics and Health (GA4GH) standards, researchers will have controlled access to raw and processed sequence data.

We will showcase the first set of tools GHGA has developed to support our communities: a FEGA-compliant metadata model that links omics data with experimental and phenotypic information to make data traceable, and tools to help overcome challenges such as legacy consent forms, consent to share secondary data, and GDPR compliance. Furthermore, GHGA has co-developed workflows (together with the nf-core community) for data analysis, benchmarking, statistical analysis and data visualization.

Initially focusing on stakeholders that drive the national efforts for research and clinical sequencing at scale (cancer, rare and infectious diseases), GHGA will enable cross-project analysis and hence promote new collaborations and research.

This project is funded by the Deutsche Forschungsgemeinschaft (DFG) - project number 441914366 (NFDI 1/1).

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4559 The Incontinentia Pigmenti Genetic Biobank: an example of fruitful partnership with patients

Authors:

M. Ursini[1], A. Pescatore[1], E. Spinosa[1], C. Casale[1], M. Lioi[2], F. Fusco[1]; [1]IGB ABT CNR, Naples, Italy, [2]Basilicata Univ., Potenza, Italy

The Incontinentia Pigmenti Gene Biobank (IPGB) is a facility that stores and manages biological samples from patients with the rare genetic disease Incontinentia Pigmenti for use in research. The IPGB research program collects blood, urine and saliva samples from participants. The IPGB research program seeks to construct a cohort studies to improve health of participants by characterizing the disease natural histories, identifying risk factors and revealing biomarkers. The biobank supports the collection, analysis, storage, and distribution of the biosamples that the program collects for research purposes. The IPGB program aims to make the research results accessible to participants, and it is developing new approaches to generate, access, and make data available to approved researchers.The IPGB is powered by participants that come from a group generally overlooked in biomedical research. Participants have been involved in defining the IPGB program since its inception. IPGB has built trust with patients and their families through continuous collaboration with patient associations (IPASSI ONLUS https://incontinentiapigmenti.it/). The association support and participate into the research and improve the quality of data collection.Participants are digitally registered through the IPGB website (https://www.igb.cnr.it/ipgb/). After completing the consent forms and registration, participants are provided with several basic health surveys and, where appropriate, the surveys can be enhanced to include additional questions as they have been developed in the event of the COVID pandemic.Consent and surveys are available in English, Italian, French and Spanish, and all the contents for the participants are provided in a simple and immediate language. IPGB has a high level of privacy and security standards developed in accordance with the BBMRI-ERIC consortium of which IPGB is a member. A particular effort has been put into transparency. The IPGB was created to allow participants to have access to their own data and most research test results. We are developing protocols for the return of genetic, laboratory tests, to participants; this development is guided by feedback from participants and internal and external experts.We plan to follow participants' health and outcomes for decades, to enable research that provides a better understanding of the disease, which in turn would support accurate molecular diagnoses, disease prevention strategies, treatment selection, and development of targeted therapiesThe IPGB research protocol has been published previously (Fusco et al. EJHG. 2019).

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4560 The Mouse Peroxisome Research Resource for Basic and Preclinical Research

Authors:

J. Hacia[1], L. l. Arayan[2], N. Braverman[3], A. Zuberi[2]; [1]Univ of Southern California, Los Angeles, CA, [2]The Jackson Lab., Bar Harbor, ME, [3]MUHC-RI, Montreal, QC, Canada

Peroxisomes are a hub of cellular metabolism and signaling pathways and play essential roles in the development and functions of mammalian organ systems. Inherited defects in genes involved in peroxisome assembly, structure, replication, and functions are responsible for a group of multisystemic monogenic disorders that include X-linked adrenoleukodystrophy and Zellweger spectrum disorder. Based on genome-wide association studies (GWAS) and lipidomic data, peroxisome activities have been proposed to contribute to the pathophysiology of common disorders including diabetes, cancer, Alzheimer's disease, and infectious diseases. Despite their relevance to human health, the limited number of publicly available mouse models and antibody resources to investigate peroxisome biology and test targeted therapies for peroxisomal disorders has hindered progress within the translational science spectrum. Here, we discuss the NIH-funded Mouse Peroxisome Research Resource (MPRR) that provides a central resource for mouse models and antibodies for peroxisome research. The MPRR works with the peroxisome basic and preclinical research communities and patient advocacy groups to accelerate the creation, distribution, and proper use of high-impact mouse models and immunological reagents. It solicits for and ensures that all deposited mouse models are placed on standardized genetic backgrounds to control for the presence of genetic modifiers that influence phenotypes of interest, such as disease severity. It also produces novel high-priority mouse models with defined genotypes on standardized genetic backgrounds, cryopreserves them, and distributes them to the public. The MPRR assists in the targeted phenotyping of these mouse models, including the measurement of relevant peroxisome metabolite levels in tissues of interest. Moreover, it produces, publicizes, and distributes validated antibody reagents for peroxisome research, including characterizing relevant mouse models. Overall, the MPRR seeks to develop and distribute well-annotated resources to accelerate basic science research and the preclinical testing of therapeutic interventions for disorders caused by peroxisome dysfunction.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4561 The NHGRI Sample Repository for Human Genetic Research: biospecimens and a new multi-variant search tool for PGx and PRS

Authors:

A. Liautaud, D. Kusic, G. Calendo, J. Madzo, S. Sampson, J. Schulz, L. Willis, E. Horton, M. Mitchell, N. Gharani, L. Scheinfeldt; Coriell Inst. for Med. Res., Camden, NJ

The NHGRI Sample Repository for Human Genetic Research (NHGRI Repository) housed at the Coriell Institute for Medical Research facilitates studies of human genetic and genomic variation by establishing, characterizing and distributing a large (over 3,700) and diverse publicly available collection of renewable biospecimens obtained from human populations living around the world, including biospecimens associated with the HapMap and 1000 Genomes Projects as well as the Human Pangenome Reference Consortium. Participants that have generously donated to the NHGRI Repository consented to their biospecimens and associated data being used for a wide range of general research and to broad data sharing of largescale genomic data. Through the 1000 Genomes Project, the majority of this collection has been characterized with publicly available whole genome sequencing data and other large-scale genomic data. We recently developed a user-friendly and integrated multi-SNP search tool that allows catalog users to dynamically query 1000 Genomes Project whole genome sequencing data (30x). A set of up to 100 variants at a time can be searched by individual variant (rsid). The multi-SNP search returns an interactive table of each subject id, population descriptor, genotype for each SNP included in the search, and sex that can be filtered or exported to an excel file. This tool is intended to support researchers interested in identifying biospecimens with particular multi-variant profiles such as those used in pharmacogenetics (PGx) and polygenic risk assessments. For example, a researcher interested in identifying cells or DNA that carry one or two copies of the CYP2C19*2 allele can simultaneously search the three haplotype defining SNPs (rs12769205, rs4244285, rs3758581) according to PharmVar. Similarly, researchers interested in identifying cells or DNA that carry high or low numbers of polygenic risk alleles can search up to 100 variants at a time; for example, 23 of the 34 variants that define the ROOT PRS model for breast cancer are included in the WGS dataset and can be searched together in a single batch. This tool adds to the growing number of web-based genomic search tools affiliated with the NHGRI Repository, including a Gene search tool and a Gene Expression search tool. These tools are intended to enable researchers a fast and simple way to identify biospecimens with the most appropriate variation profiles for their research goals. Our Genomic Data Search tools can be accessed at https://www.coriell.org/1/Browse/Genomic-Data-Search, and more information about the NHGRI Repository can be found at https://catalog.coriell.org/NHGRI.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4562 The NIH Comparative Genomics Resource: Maximizing the impact of research organisms to human health.

Authors:

V. Schneider[1], N. A. O'Leary[1], S. H. Rangwala[2], F. Thibaud-Nissen[1], T. L. Madden[1], T. D. Murphy[1]; [1]NIH/NLM/NCBI, Bethesda, MD, [2]NCBI/NLM/NIH, Bethesda, MD

NCBI is developing the NIH Comparative Genomics Resource (CGR) to maximize the impact of eukaryotic research organisms and their genomic data to biomedical research. Comparative genomics involves the evaluation of genomic features from diverse organisms to systematically explore and evaluate biological relationships. Because all biological processes rely on genes, proteins, and the biochemical pathways they belong to, and these fundamental elements are shared across the tree of life, this approach can inform nearly any aspect of biology- and help identify new model organisms that may be used to address issues in human health. However, the relevant data and applications for the growing number of sequenced organisms are often siloed, challenging their use. Additionally, assembled genomes often contain contaminating sequences and lack annotations that inform comparisons. CGR facilitates reliable comparative genomics analyses for all eukaryotic organisms through community collaboration and an NCBI genomics toolkit. The toolkit offers high-quality genomics-related resources impactful to users' research, including interconnected databases with access points enabling seamless navigation of NCBI content and interoperable data and tools that can integrate into users' workflows. We will present our recent developments on several of these resources, including a new public cloud-ready tool suite for removing foreign sequence contamination, a new web-based graphical tool supporting the visual comparison of two genomes based on alignments, and NCBI Datasets, which provides web and programmatic interfaces that help users search, browse, and download genome-related data. We will illustrate the value of CGR in the context of health-related workflows. We will also demonstrate how connecting community-supplied genome-related content to the organism-agnostic CGR can make it easier for researchers to use data from sources and organisms they may not have known about, and how community feedback has impacted CGR development. Through CGR, we can assist researchers in using genomic data available from thousands of organisms to answer questions involving human health.
This work was supported by the National Center for Biotechnology Information (NCBI) of the National Library of Medicine (NLM), National Institutes of Health (NIH).

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4563 The NINDS Human Genetics Resource Center: publicly available resource of large and clinically well-characterized cells and DNA

Authors:

L. Scheinfeldt[1], A. Green[2], A. Amberson[2], S. Sampson[2], T. Cutts[2], R. Zhang[3]; [1]Coriell Inst. for Med. Res., Philadelphia, NJ, [2]Coriell Inst. for Med. Res., Camden, NJ, [3]NIH/NINDS, Rockville, MD

Established in 2002, the National Institute of Neurological Disorders and Stroke (NINDS) Human Genetics Resource Center is a public biorepository of DNA and lymphoblastoid cell lines available to promote neurogenetics research. Specimens donated by over 42,000 individuals can be accessed through an online catalog (http://catalog.coriell.org/NINDS), and over 70,000 catalog samples have been distributed to researchers around the world. The collection includes samples from individuals diagnosed with cerebrovascular diseases (N>12,800), Parkinsonism (N>5,600), motor neuron diseases (N>2,500), Epilepsy (N>6,100), Tourette syndrome (N>4,200), Dystonia (N>3,800), and neurologically normal controls (N>7,500). Each patient biospecimen is annotated with standardized clinical and demographic common data elements (CDEs) specifically designed for each disease subcollection (https://catalog.coriell.org/1/NINDS/Downloads2/Clinical-Data-Forms). This resource thereby facilitates large, multi-site studies of genetic risk factors with consistent clinical data that would not otherwise be possible. Indeed, over 900 publications have used samples and data from the NINDS Human Genetics Resource Center, and these publications have been cited over 90,000 times. These publications include genome-wide association studies of Parkinson's disease, ALS, Epilepsy, Stroke, Tourette Syndrome, and Dystonia. This collection, therefore, has made a substantial impact on research around the world.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4564 The PhenX Toolkit: Recommended measurement protocols to standardize data collection for COVID-19 studies

Authors:

D. Williams, M. C. Krzyzanowski, J. Abedini, P. Ceger, B. Cook, I. Glaze, W. Huggins, C. Ives, M. Mandal, H. Pan, T. Reeve, G. Swank, P. West, L. G. Wood, X. Wu, T. Hendershot, C. M. Hamilton; RTI Intl., Research Triangle Park, NC

The PhenX (Phenotypes and eXposures) Toolkit is a web-based catalog of recommended measurement protocols to assist with the design of studies with human participants and to facilitate cross-study data integration and analyses. PhenX protocols are recommended by domain experts using a consensus-based process that includes community input. The PhenX Toolkit currently includes measurement protocols across 30 research domains (e.g., Demographics) that add breadth to the Toolkit and six collections (e.g., Social Determinants of Health) that add depth to the Toolkit. The Toolkit site has over 4,700 registered users and has been recommended for use as a NIH Common Data Elements (CDEs) resource in over 600 NIH Funding Opportunity Announcements (FOAs).
In 2020, to assist NIH with their response to the COVID-19 pandemic, the PhenX Toolkit began releasing protocols into the COVID-19 Protocol Library to facilitate sharing of COVID-19 surveys. The goals were to reduce the proliferation of additional COVID-19 related surveys and to identify protocols that could be recommended for use and release into the PhenX Toolkit. Initially, 20 protocols from the COVID-19 Library were included in six COVID-19 Specialty Collections. The collections were decided based on the results of a crowd-sourcing effort and guidance from the PhenX Steering Committee, enabling "rapid release" of these protocols into the Toolkit. Use of these protocols helps investigators understand the symptoms and treatments of COVID-19 in the context of social determinants of health, the impact of the pandemic on mental health and behavior, and the effects of infection on health and daily living. Later, the recognized need for protocols describing the emerging longer-term effects of the COVID-19 pandemic led to the development of a Long COVID collection. The Long COVID Collection contains 25 protocols that address Long COVID in the context of an individual’s quality of life, daily living, comorbidities and COVID impact, multisystem inflammatory syndrome, physical functioning, vaccination, and symptoms.
The COVID-19 Variable Compare Tool (VCT) enables investigators to compare COVID-19 Specialty protocols and COVID-19 Library instruments. The VCT allows investigators to explore survey questionnaires and questions within the questionnaires, which are referred to as "variables". Through the interface, an investigator may perform a keyword search of variables, view a side-by-side comparison of questionnaires, or generate a heatmap visualization that shows the variable-based similarities between multiple questionnaires.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4565 The POPGEN project: building a French reference panel of genomes

Authors:

A. Herzig[1], G. Marenne[1], M. Guivarch[1], A. Saint Pierre[1], T. Ludwig[1,2], I. Alves[3], D. Christian[3], R. Redon[3], J-M. Sebaoun[4], L. Gressin[4], J-C. Beaudoin[4], V. Morel[4], B. Fin[5], C. Besse[5], R. Olaso[5], D. Bacq[5], V. Meyer[5], F. Sandron[5], A. Ferrane[6], A. Boland[5], H. Blanché[4], M. Zins[7], J-F. Deleuze[4,5], G. Le Folgoc[1], E. Génin[1,2]; [1]Univ. Brest, Inserm, EFS, UMR 1078, GGB, IBSAM, F-29200, Brest, France, [2]CHU Brest, F-29200, Brest, France, [3]Nantes Université, CHU Nantes, CNRS, INSERM, l'institut du thorax, F-44000, Nantes, France, [4]Fondation Jean Dausset, CEPH, Paris, France, [5]Université Paris-Saclay, CEA, Ctr. Natl. de Recherche en Génomique Humaine (CNRGH), 91057, Evry, France, [6]Inst. de Santé Publique, Pôle de recherche clinique, INSERM, F-75013, Paris, France, [7]Université de Paris Cité, Université Paris-Saclay, UVSQ, Inserm, Cohortes Epidémiologiques en Population, UMS 11, F-94807, Villejuif, France

Background/Objectives: The POPGEN project was launched as part of the French genomic medical initiative to build a catalogue of variants found in the different regions of metropolitan France and provide allele frequencies in order to help filter out neutral variants from patient genomes.
Methods: Individuals from the population cohort Constances were asked to complete a questionnaire on birthplaces and birth years of their parents and grandparents. Based on their answers, 15,000 individuals were selected to cover the different regions of metropolitan France and were posted saliva collection kits. Genotyping was successful for 9,772 individuals and 4,000 individuals were selected for whole-genome sequencing. Different methods were used to study fine-scale population structure and rare variants were imputed using public reference panels enriched by 856 whole genomes from the FranceGenRef project.
Results: We demonstrate the fine-scale population structure of French populations and show how it relates to geography. Using these results, we show how the performance of imputation panels can vary across the territory; driven by patterns in haplotype sharing. We also investigate the important impact for downstream genetic epidemiological study designs.
Conclusions: This study proposes a design to sample individuals from the general population to create reference panels that could help improve imputation accuracy for geographically clustered variants. The POPGEN project will contribute to the "Genome of Europe" project.
Grant: French Ministry of Research PFMG2025 and ANR IA-10-LABX-0013 FranceGenRef

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4566 † The World's Largest Methylation Data Cohort: The Million Veteran Program increases its multi-omics capability by profiling 45,460 on a methylation array to provide novel insights and to serve as a rich data resource.

Authors:

K. Markianos[1], P. Schreiner[1], B. Despard[1], S. Gautam[1], B. Barnes[2], W. Zhou[3], B. Gorman[1], P. Devineni[1], Y. Shi[4], P. Tsao[5], S. Pyarajan[1]; [1]VA Boston, Boston, MA, [2]Illumina, Inc., San Diego, CA, [3]Ctr. for Computational and Genomic Med., The Children's Hosp. of Philadelphia, Dept. of Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA, [4]VA Boston Hlth.care System, Jamaica Plain, MA, [5]VAPAHCS/Stanford Univ., Palo Alto, CA

The Department of Veterans Affairs (VA) Million Veteran Program (MVP) is one of the world's largest databases of genomic and clinical data. MVP has already proven to be a valuable precision medicine research resource. It has the potential to develop into a multi-omic resource with significant implications for veteran health research. To this end, we introduce the new MVP methylation dataset. We describe quality control and analysis of 45,460 methylation samples released by the Million Veteran Program using the Illumina Infinium Methylation EPIC Array (~850k genomic sites). We developed a Dockerized, high-throughput SeSAMe-based quality control and preprocessing pipeline incorporating common preprocessing steps that calculate metrics describing the reliability of methylation detection, which are necessary to validate probes and define sample inclusion. In addition, we developed a high-precision fingerprinting process that allows unambiguous matching of methylation assays to genotype and sequencing assays from the same individuals. We present demographic distributions of the data set (ancestry, gender) and we perform exemplary analysis: HIV+ age acceleration and Body Mass Index (BMI) EWAS. We compare our analysis with published literature and comment on the sensitivity of the results to technical covariates such as DNA storage length. This data release represents the largest methylation data set to date. Our results illustrate the potential of this dataset for elucidating the role of epigenetic variation in human disease, particularly when combined with MVP's large genomic and clinical datasets.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4567 UCSC Genome Browser: Instantly lift annotations between human genomes.

Authors:

L. Nassar, B. J. Raney, G. P. Barber, J. Casper, H. Clawson, C. Fischer, J. Navarro Gonzalez, A. S. Hinrichs, C. M. Lee, G. Perez, M. Haeussler, W. J. Kent; UC Santa Cruz, Genomics Inst., Santa Cruz, CA

With the rapid increase in sequencing accessibility, combined with consortium projects such as T2T and HPRC, we are seeing an exponential trend in the number of human genomes not only becoming available but actively researched. Unfortunately, many databases are singularly mapped to the reference such as GRCh38/hg38, leaving these new assemblies with sparse annotations.

Here we present liftOver-on-the-fly, a process by which annotations from one assembly can be quickly displayed on another. To do this we leverage our annotation lifting pipeline, which we have operated for over a decade, to lift any desired annotations from one assembly, such as hg38, to any number of target genomes including T2T and HPRC assemblies. The liftOver tool works best when lifting between closely related assemblies, so human-to-human lifts are often 100% matches.

LiftOver-on-the-fly is still in active development, and the types of data that can be lifted, as well as the origin and target assemblies, are expanding. We anticipate that the demand for features such as this will continue to increase and annotation transfers such as these will eventually become commonplace.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4568 Understanding the role of structural variants in Alzheimer's Disease: Building a reference imputation panel across 4,699 samples to drive SV-GWAS

Authors:

M. Byrska-Bishop[1], A. Corvelo[1], A. O. Basile[1], W. E. Clarke[1,2], U. S. Evani[1], R. Musunuri[1], A. Runnels[1], B. Vardarajan[3,4], G. Narzisi[1], M. C. Zody[1]; [1]New York Genome Ctr., New York, NY, [2]Outlier Informatics Inc., Saskatoon, SK, Canada, [3]Taub Inst. for Res. on Alzheimer's Disease and the Aging Brain, Coll. of Physicians and Surgeons, Columbia Univ., New York, NY, [4]Dept. of Neurology, Coll. of Physicians and Surgeons, Columbia Univ. and the New York Presbyterian Hosp., New York, NY

The role of structural variants (SVs) in Alzheimer's disease (AD) is not well understood. While the majority of AD research has focused on the contribution of single nucleotide variants (SNVs) and short insertions and deletions (INDELs), SVs have received comparatively less attention. SVs refer to larger-size (>50 bp) alterations in the genome that have the potential to impact gene expression and disrupt regulatory elements, thus likely contributing to disease state. Understanding the role of SVs in AD could potentially shed light on novel mechanisms and therapeutic targets for this devastating neurological disorder. Here, we describe variant calling and generation of a reference imputation panel consisting of SNVs, INDELs, and SVs (large insertions and deletions) discovered across 4,669 Illumina WGS samples from 700 multiplex AD families (EFIGA and NIA LOAD) and unrelated case-control samples (ROS/MAP). We called and genotyped 105,874,088 SNVs and INDELs using GATK HaplotypeCaller. In parallel, we produced a call set containing 123,094 SVs by combining: 1) Illumina calls discovered using Manta, MELT, and Absinthe across 4,669 AD samples; 2) Oxford Nanopore (ONT) calls discovered using Sniffles2 across 4 AD samples; and 3) genotyping on the AD samples of an external PacBio call set produced by the Human Genome Structural Variation Consortium from 32 diverse human genomes. All SVs were genotyped at the cohort-level using either Paragraph or Pangenie. To make the variants accessible for future association studies, we generated an integrated haplotype-resolved reference imputation panel. First we filtered the SNV/INDEL and SV call sets, selecting non-singleton sites in Hardy-Weinberg equilibrium with low missingness rate which resulted in 64,386,896 small variants and 82,594 SVs. Next, we phased the SNV/INDEL call set using statistical phasing, as implemented in the SHAPEIT4 software. We then used the phased SNV/INDEL panel as a scaffold onto which we phased the SVs. We computed the switch error rate (SER) of SNV/INDELs using ONT-based phasing information, available for 4 of the AD samples. The SER ranged from 0.11% to 0.52%, indicating high phasing accuracy. Similarly, to evaluate the accuracy of SV phasing, we computed their flip rate relative to flanking SNVs, against the ONT-based phased call sets. The flip rate of SVs ranged from 0.48% to 0.88%, suggesting high accuracy of SV phasing as well. Finally, we show examples demonstrating how the reference panel including SVs can be used to accurately impute genetic variants across the size spectrum and enable discovery of new associations improving our understanding of the genetic architecture of AD.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4569 Unveiling hidden transcripts using a T2T human reference genome

Authors:

J. Kim[1], E. Tseng[2], A. Phillippy[3], A. Rhie[4]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Pacific BioSci.s, Menlo Park, CA, [3]NIH/NHGRI, Bethesda, MD, [4]NIH, Bethesda, MD

A complete human reference genome (T2T-CHM13v2, hereby CHM13) was recently released, including an additional 200 million base pairs of sequence. It corrects thousands of structural errors and unlocks the most complex regions of the human genome. With the inclusion of numerous genes not present in the widely used GRCh38 reference, there is a chance to discover novel transcripts that have been excluded from prior analyses.In this study, we utilized long-read RNA sequencing data derived from the HG002 cell line as a biological replicate for the identification and annotation of full-length isoforms in the CHM13 reference. To evaluate the applicability of CHM13 as a reference for transcriptome data, we compared mapping statistics between the CHM13 and GRCh38 references. We found 4,900 transcriptome reads that mapped to CHM13 but not GRCh38. These reads mapped to 62 regions on CHM13, among which 19 loci (30.6%) were found to be in non-syntenic regions with respect to GRCh38. The remaining transcripts mapped to sequences that exhibited better concordance to CHM13, which could be attributed to corrections made in CHM13 or better agreement between the HG002 and CHM13 haplotypes. Our results also showed that over 200,000 reads were mappable to CHM13 with a higher mapping quality compared to GRCh38. In contrast, only 900 reads were unmappable to CHM13 but alignable to GRCh38, encompassing 8 non-overlapping gene loci in total. Predominantly, most of these transcripts were found in the intronic regions of 4 genes and one exonic region of the hypervariable HLA-DQA1 gene.We conclude the more complete CHM13 reference improves overall transcript mappability, which is essential for accurate isoform identification and discovering potentially novel transcripts. Future work will include comparisons to a personalized, diploid HG002 reference as well as a pangenomic reference.

PB4570 Unveiling the spectrum of genetic variants intheKorean population: whole genome sequencing of 8,100 Korean participants

Authors:

Y. Kim, N-H. Choi, M. Hwang, D. Shin, K. Yoon, H-Y. Park, B-J. Kim; Korea NIH, Cheongju-si, Korea, Republic of

Recent extensive sequencing projects have catalogued an immense number of genetic variants, offering potential targets for drug development and valuable resources for precision medicine research. However, the majority of the datasets consisted of individuals of European ancestry, highlighting the need for additional sequencing datasets encompassing diverse ethnicities. The Korean Reference Genome (KRG) project was initiated by the National Institute of Health, Republic of Korea, with the aim of identifying variants in the whole-genome sequences of approximately 20,000 Korean participants. During the interim phase of the Korean Reference Genome (KRG) project, approximately 8,100 Korean participants were subjected to sequencing with an average depth of 30x. The obtained reads were aligned to the hg19 reference genome, and variant calling was performed using DRAGEN™. The resulting 8.1K KRG dataset comprised around 46 million variants, with approximately 84.6% being single nucleotide polymorphisms (SNPs) and the remaining 15.4% being insertions and deletions (indels). Among these variants, 22.9% were classified as common (with a minor allele frequency, MAF, of 1% or higher), while 77.1% were categorized as rare (with an MAF below 1%). Within the 791K protein coding altering variants identified, the majority were rare, while 10.6% were common. The KRG project expanded the repertoire of predicted loss-of-function (pLOF), encompassing around 36K pLOF variants. Additionally, 2,276 variants were annotated as pathogenic or likely pathogenic based on information from the ClinVar or LOVD databases. The KRG significantly improved the accuracy of imputation for the Korean population. When imputing independent 499 Korean samples using different reference panels, including the KRG, the KRG demonstrated the highest level of accuracy with a mean imputation accuracy of r^2=0.996. Furthermore, the KRG offered extensive genomic coverage for common variants (MAF >= 1% & r^2>=0.8, 84.5%) and rare variants (MAF 0.1~1% & r^2>=0.8, 51.5%). This study represents a valuable genetic resource for the East Asian population along with a comprehensive imputation server for imputation analysis.

PB4571 Utilizing targeted TSO500 ctDNA NGS assay and Seer Proteograph to study genome and proteome changes in various cancer types

Authors:

N. Prasad; Discovery Life Sci., Huntsville, AL

Liquid Biopsy in recent year have emerged as a valuable sample to understand the comprehensive genome and proteome in oncology patients. It provides a unique opportunity to diagnose, monitor and evaluate response to therapy using a non-invasive blood draw. New emerging Next Generation Sequencing (NGS) and proteomic technologies allow researchers to investigate key changes within the genome and proteome in these patients to enable patient centric care and treatment. We have utilized the TruSight Oncology ctDNA (TSO 500ct DNA) assay paired with Seer Proteograph, an automated liquid handling and nanoparticle-based enrichment technology assay along with SCIEX's Zeno TOF 7600 Mass Spec, to enable deeper genomic and proteomics profiling from plasma samples of oncology patients. This workflow was used to generate deep, unbiased genomics and proteomic data from a plasma sample sets from donors with various cancer types and stages. The NGS and proteomic data from these sample sets were then correlated to underscore the importance of using a multiomic approach to fully understand the underlying drivers of disease in oncology patients.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session III

PB4572 Validating gene-disease relationships in Charcot-Marie-Tooth disease through a robust curation effort: The Clinical Genome Resource Charcot-Marie-Tooth gene and variant curation expert panels.

Authors:

K. Latchman[1], J. Raposo[1], D. Bis-Brewer[2], A. Rebelo[3], K. Johnson[4], J. Medina[5], M. Dohrn[6], D. Beijer[7], L. Van de Vondel[8], G. Spurdens[1], I. Xu[7], R. Le Shay Araujo[1], H. Elloumi[9], R. Seyedsadjadi[10], A. Cortese[11], J. De Winter[12], D. Hermann[13], S. Mohan[14], T. Stojkovic[15], S. Scherer[16], S. Zuchner[5]; [1]Univ. of Miami Dept. of Human Genetics, Miami, FL, [2]Geisinger, Danville, PA, [3]Univ Miami, Miami, FL, [4]The Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA, [5]Univ. of Miami Miller Sch. of Med., Miami, FL, [6]RWTH Aachen Univ., Aachen, Germany, [7]Univ. of Miami, Miami, FL, [8]Univ. of Antwerp, Antwerpen, Belgium, [9]GeneDx, Rockville, MD, [10]Harvard, Cambridge, MA, [11]Univ. Coll. London, London, United Kingdom, [12]Univ. of Antwerp and Antwerp Univ. Hosp., Brussels, Belgium, [13]Univ. of Rochester, Rochester, NY, [14]Univ. of North Carolina At Chapel Hill, Apex, NC, [15]Inst. of Myology, Paris, France, [16]Univ. of Pennsylvania, Philadephia, PA

The Clinical Genome Resource's Charcot-Marie-Tooth Gene Curation Expert Panel (ClinGen CMT GCEP) was established in December 2019 to evaluate the proposed gene-disease relationships of more than 90 genes reported to cause CMT. CMT is the most common inherited neurological disorder, affecting approximately 1 in 2500 individuals and the goal of the CMT GCEP is to use the ClinGen gene-disease clinical validity framework to evaluate the strength of evidence for these gene-disease relationships. ClinGen's curation process is uniquely recognized by the FDA and thus will contribute to regulatory considerations of gene-based diagnosis and therapies. To date, the CMT GCEP has completed an evidence-based classification of 55 genes and more than 40 genes have been classified as having definitive evidence for robust gene-disease relationships based on current literature. With more than 50% of reported CMT genes having been curated, we recently gained approval to begin a ClinGen CMT Variant Curation Expert Panel (CMT VCEP). The process of gene and variant curation is in accordance with ClinGen's gene-disease clinical validity framework whereby biocurators within the CMT GCEP and VCEP review the literature, score genetic and experimental evidence to support or refute a claim of gene-disease relationship, and make a final decision among an expert panel regarding the determining evidence category, such as definitive, moderate, or limited. Evidence supporting the gene-disease relationship include case-level data, co-segregation analyses, and functional experiments. A standardized pre-curation process (lumping or splitting criteria) to define the disease entity according to MonDO (Monarch Initiative) is followed when more than one phenotype is indicated for a gene. Pre-curations and curations are thoroughly discussed by the expert panels and final classifications, based on cumulative score and replication over time, are published on the ClinGen website. The CMT GCEP and VCEP are an internationally collaborative effort, comprised of recognized experts in Charcot-Marie-Tooth disease, and whose primary goals are to analyze and define the clinical relevance of known CMT genes, improving our knowledge of genomic variations, and providing valuable resources to further guide precision medicine and research.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session I

PB4573 VanDyPlot, an interactive gene-specific variant visualization interface.

Authors:

M. Marhabaie[1], S. Ramadesikan[1], I. Showpnil[1], U. Gurusamy[1], A. C. Herman[1], K. Voytovich[1], D. M. Gordon[1], H. C. Kuck[1], G. E. Lammi[1], R. K. Wilson[1,2], D. C. Koboldt[1,2]; [1]The Steve and Cindy Rasmussen Inst. for Genomic Med. at Nationwide Children's Hosp., Columbus, OH, [2]Dept. of Pediatrics, The Ohio State Univ. Coll. of Med., Columbus, OH

The advent of high-throughput sequencing and exponential growth of genetic testing has dramatically increased the catalog of human genetic variation in disease genes and led to the discovery of novel disease-causing genes. Variant interpretation, particularly for novel variants, remains a major challenge in both clinical and research settings. Understanding patterns of known disease-associated variants can play an important role in the pathogenicity classification of the variant. Thus, there is an increasing need for a robust user-friendly interface that can be used to visualize large datasets. Unfortunately, currently available tools are either not user-friendly or heavily geared toward cancer research, thus, do not have an exhaustive representation of germline genetic variants in genes associated with constitutional disease conditions. To fill this gap, we developed VanDyPlot, a React-based web application that utilizes Amazon Web Services to visualize variant information across genes. It features (1) a lightweight application that (2) encompasses all RefSeq transcripts (with MANE transcript indicator) and (3) can handle multiple tracks from diverse databases with (4) protein domain annotations and (5) various preset variant filters. The current release (accessible at https://vandyplot.igmdev.org) focuses on variants reported in the ClinVar database. As of May 2023, VanDyPlot contains information for more than 2,178,000 variants (317,827 pathogenic/likely pathogenic, 828,893 benign/likely benign, and 1,016,514 variants of uncertain significance) from more than 22,740 genes. Functional domains, motifs, and active sites of proteins are also annotated on the plot using the Pfam database and the UniProt knowledgebase. By visualizing genomic variation data in a compact and accessible way, VanDyPlot offers a comprehensive view of variation across a gene and helps to consolidate and understand patterns of disease-associated variants.

Session Title: Genetic, Genomic, and Epigenomic Resources and Databases Poster Session II

PB4574 We do know what we don't know: variant assessment across *All of US* long read efforts

Authors:

F. Sedlazeck[1,2], Y. Zhu[1], M. Izydorczyk[1], M. Mahmoud[3], L. Paulin[1], Z. Khan[3], G. Metcalf[3], D. Muzny[1], R. Gibbs[1], All of Us Research Program consortium; [1]Baylor Coll. Med., Houston, TX, [2]Rice Univ., Houston, TX, [3]Baylor Coll. of Med., Houston, TX

The All of Us Research Program seeks to generate whole genome data on at least 1M diverse participants in the US with clinical return of results. While this resource will provide the evidence needed to make clinical sequencing more applicable to non-Caucasian populations, it does not address the full spectrum of variation. The precision enabled by short reads does not extend to larger classes of variants (e.g. SVs, tandem repeats etc). These variants are documented to have a role in disease and impact more nucleotides than SNVs so additional methods to resolve are required.

All of Us recently launched an initiative to produce ~15,000 long read genomes using PacBio and Oxford Nanopore. This endeavor will enhance our understanding of the full spectrum of variation across understudied populations, and serve as a valuable annotation resource for many subsequent studies involving medically relevant and challenging genes (e.g *LPA*). While long read data does enable full variant characterization, using these data for population analyses requires new computational methods.

In response, we have developed tools to identify all classes of variants and enable their comprehensive representation. For SV calling, Sniffles outperforms other methods in speed and accuracy and can produce a fully genotyped population variant file that can be directly utilized in SV association studies. Further, Sniffles enables identification of mosaic SVs in bulk sequencing. Here, we found multiple candidates that we could already validate.

To improve our understanding for repeats in the genome, we have co-developed TRGT. TRGT can call complex alleles (e.g. in *FMR1* or *RFC1)* that are often inaccessible by other methods and known to be pathogenic. TRGT reports length designation with sequence resolved alleles, which are important for interpretation (e.g. fragile X syndrome). Further, we extended Truvari to operate in tandem repeat regions where the allelic representation is challenging. Truvari allows us to merge variant types and accurately compare them across samples.

In addition to resolving complex alleles, long read data creates methylation signals, which we leverage to improve phasing by up to 3-fold in length using MethPhaser. Phasing information is essential to estimate gene dosage and expression consequences.

These innovations will help to identify new gene targets for diseases in *All of Us* and other consortia. In my presentation, I will highlight multiple novel findings enabled by these methodologies and highlight their likely functional and phenotypic consequences.

Session Title: Mendelian Phenotypes Poster Session I

PB4575 17 years old Puerto Rican male with a Laminopathy disorder

Authors:

L. Bou-Padilla[1], S. Carlo[2], E. Albino[3], H. Roman[4], A. S. Cornier[5]; [1]Ponce Hlth.Sci. Univ., Ponce, PR, [2]Ponce Hlth.Sci. Univ., Ponce, PR, [3]Univ. of Puerto Rico - MSC, San Juan, PR, [4]Genetic section - San Jorge Children's Hosp., San Juan, PR, [5]Genetic Section - San Jorge Children s & Women s Hosp., San Juan, PR

Case of a 17-year-old Puerto Rican male was referred to Genetics at the age of 3 ½ with a CPK test of 1,200 mcg/L suggestive of muscular dystrophy. The patient was born to a 27-year-old (G1, P0, C1), and by the age of 5-6 months, motor delay was detected. DNA testing performed at the time was not informative, and a muscle biopsy was obtained, resulting in an unidentified type of muscle dystrophy. Further genetic testing of the LMNA gene demonstrated a de novo dominant negative mutation in the LMNA gene (c.125T>C; p.L42S). A mutation in LMNA results in early onset of Congenital Muscular Dystrophy (CMD) with axial weakness, spinal rigidity, and cardiac and pulmonary involvement, which are the most critical aspects of the condition. Over the years, he had irregular visits to the cardiologist, who recommended atenolol without specific cardiac involvement. At the age of 5 years, he developed respiratory failure for which he required a tracheostomy and assisted mechanical ventilation. At the age of 7 years, left ventricular hypertrophy was noted and has remained stable with medications. Cardiac MRI performed at 11 years of age revealed normal ventricular size and function, but there was mild right atrial enlargement. Holter Monitoring revealed frequent runs of ectopic atrial tachycardia and some episodes of first-degree A-V block, as well as frequent ventricular arrhythmias, including 12 runs of V-tach. By the age of 12 years, the patient developed atrial flutter/fibrillation with rapid ventricular response and requiring admission to the intensive care unit. Over the course of the admission, his electrocardiograms seemed to change from episodes of atrial tachycardia, fibrillation, and flutter with variable conduction. An implantable cardioverter-defibrillator (ICD) was inserted to prevent death. The genetic variant, p.Leu42Ser, involves the replacement of neutral and non-polar leucine with neutral and polar serine at codon 42 of the LMNA protein. This variant is absent in population databases (gnomAD). Similar variants have been observed in individuals with clinical features of LMNA-related conditions (Invitae), and it has been observed as de novo in at least one case. Predictive algorithms (SIFT, PolyPhen-2, Align-GVGD) all suggest that this missense mutation is likely to have a disruptive effect on protein structure and function. Given the patient's fulfillment of clinical criteria for a severely affected individual with laminopathy due to LMNA gene mutations, this variant is considered pathogenic.

Session Title: Mendelian Phenotypes Poster Session II

PB4576 A case of *MBTPS1*-related disorder due to compound heterozygous variants in *MBTPS1* gene: genotype-phenotype expansion and the emergence of a novel syndrome

Authors:

K. Liaqat[1,2,3], K. Treat[1,2,3], L. Mantcheva[1,2,3], A. Nasir[4], E. Conboy[1,2,3], F. Vetrini[1,2,3]; [1]Indiana Univ. Sch. of Med., Indianapolis, IN, [2]Dept. of Med. and Molecular Genetics, Indiana Univ. Sch. of Med., Indianapolis, IN, [3]Undiagnosed Rare Disease Clinic (URDC), Indiana Univ. Sch. of Med., Indianapolis, IN, [4]Dept. of Anesthesiology, Second Affiliated Hosp. of Zhengzhou Univ., Zhengzhou, China

MBTPS1 (NM_003791.4) encodes Site-1 protease (S1P) is a serine protease that functions sequentially with Site-2 protease (S2P) regulating cholesterol homeostasis and endoplasmic reticulum stress response. Bi-allelic loss of function variants in *MBTPS1* are currently associated with Spondyloepiphyseal dysplasia, Kondo-Fu type (MIM:618392). More recently, a few additional syndromic conditions have been associated with the *MBTPS1* disruptions, including cataract, alopecia, oral mucosal disorder, and psoriasis-like (CAOP) syndrome, and Silver-Russell-like syndrome (SRS). In this report, we describe a 14-year-old female with a complex medical history including early-onset cataracts, laryngomalacia, feeding dysfunction, white matter volume loss, inguinal hernia, joint hypermobility, retrognathia, speech delay and dysmorphic features. Additionally, features of ectodermal dysplasia including decreased sweating, heat intolerance, dysplastic nails, chronically dry skin, hair growth issues, and concerns for a mitochondrial disorder as fatigue and hypotonia, were also observed. Previous testing including *MECP2* sequencing, SRS and Angelman and Prader-Willi testing, metabolic screening, CMA karyotype analysis were all negative. To identify the underlying genetic etiology in this patient, whole exome sequencing (WES) analysis was performed, which identified compound heterozygous variants in the *MBTPS1* gene, c.2255G>T: p.(Gly752Val) from mother and a splice site variant c.2831+5G>T from father. The glycine at amino acid position 752 is highly conserved among various species and the 3D modeling predicts a slight local perturbation of the loop region in the mutant protein due to difference in interaction pattern in wild and mutant structure. The effect of the c.2831+5G>T was investigated by RNA-seq analysis and resulting Sashimi plot showed skipping of exon 21, predicted to result in frameshifting p.Ser901fs28* leading to non-sense mediated decay (NMD).To date only few studies have been published that described the *MBPTS1*-related disorders. Interestingly, we observed ectodermal dysplasia in the patient that further expands the phenotypic spectrum of *MBTPS1* gene related disorders. In a recent study, it has already been demonstrated that *MBTPS1* bi-allelic loss of functions causes CAOP syndrome due to mitochondrial dysfunction responsive to riboflavin (Vit.B12) treatment (PMID: 35362222). Of note, we have begun the treatment with Vit.B12 and our patient's hair has begun to grow back. This case expands our current knowledge of this rare syndromic condition and expands the genetic and phenotypic spectrum of the *MBTPS1*-related disorders.

Session Title: Mendelian Phenotypes Poster Session III

PB4577 A case report and review of the literature suggests that Turner syndrome associated with Xp deletions may cause increased autoimmune disease due to aberrant X chromosome inactivation in immune cells.

Authors:

A. Rudrapatna[1], **R. Slaughenhaupt**[1], J. Owens[2], A. Shillington[2], N. Sheanon[2]; [1]Univ. of Cincinnati, Cincinnati, OH, [2]Cincinnati Children's Hosp., Cincinnati, OH

Turner Syndrome (TS), caused by a partial or complete loss of an X chromosome, causes short stature, hypogonadotropic hypogonadism, and characteristic dysmorphic features. There are widely variable rates of autoimmune disease, hearing deficits, lymphedema, skeletal anomalies, congenital heart disease, and renal disease. Despite the relatively high frequency of TS and recognized increased risk of autoimmune disease, inflammatory bowel disease is seen in only 2-7% of TS patients. Here, we describe a 4-year-old girl with short stature, coarctation of the aorta, and early-onset inflammatory bowel disease at 3 months of age. A SNP microarray revealed 78.5% of cells with monosomy X and 22.5% of cells with an Xp22.33p11.22 53.4 Mb terminal deletion, consistent with a diagnosis of mosaic TS.

Small cohorts have demonstrated that, in comparison to monosomy X, patients with TS due to Xp deletions have a higher incidence of autoimmune disease (66.0% vs 31.5%) and inflammatory bowel disease (17.4% vs 7.2%). Individuals with an Xp deletion will generally have preferential inactivation of their partial X chromosome, though a small subset of cells may persist with expression of the partial X chromosome. In most organ systems, this small subset of cells expressing the partial X chromosome is likely not physiologically meaningful. However, immune cells have a special capacity for signal amplification that could allow for only a few cells expressing a partial X chromosome to cause disease. Comparing the Xp deletion of the reported patient to Xp deletions of other TS patients with early-onset inflammatory bowel disease suggested a potential critical region encompassing 400 genes. Of these, *FOXP3* and *POLA1* notably act as immune-supressing genes; loss of function of these genes can lead to increased inflammation via IL-10, NF-κB, and type 1 interferon signaling pathways. Thus, we propose that this paradoxical finding of a smaller deletion causing more severe autoimmune disease is driven by skewed X chromosome inactivation (XCi) in a small subset of immune cells that would occur in partial X chromosome deletions but not monosomy X.

Session Title: Mendelian Phenotypes Poster Session I

PB4578 A case series: phenotypic variations of male MECP2 disorders

Authors:

J. Lee[1], M. F. Barros Perez[1], R. Vela Sosa[1], C. Toribio-Dionicio[1], G. Fradkis[2], M. Banikazemi[3,4]; [1]Dept. of Pediatrics, New York City Hlth.and Hosp. Corp., Metropolitan Hosp. Ctr., NEW YORK, NY, [2]Dept. of Genetics, New York City Hlth.and Hosp. Corp., Metropolitan Hosp. Ctr., NEW YORK, NY, [3]Dept. of Genetics, New York City Hlth.and Hosp. Corp., Metropolitan Hosp. Ctr., New York, NY, [4]Dept. of Pediatrics, New York City Hlth.and Hosp. Corp., Metropolitan Hosp. Ctr., New york, NY

Background: Rett syndrome was previously considered to be exclusive to females and lethal in males. Recently, Rett syndrome with MECP2 variations has been recognized as a distinct entity, and MECP2 disorders are now classified into two separate categories based on gender. Males with MECP2 disorders exhibit three subtypes: severe neonatal encephalopathy, intellectual disability, as well as pyramidal signs, parkinsonism, and macroorchidism (PPM-X) syndrome. The approval of Trofinetide by the FDA in 2023 represents a significant therapeutic breakthrough for Rett syndrome, as it promotes neurological development in individuals with MECP2 mutations regardless of gender. Objective and methods: We identified male patients with MECP2 disorders and characterized their clinical courses. A cohort of 7,790,503 who were screened for male gender and a diagnosis of Rett syndrome with a reported MECP2 mutation. Results: A total of three male patients with reported MECP2 variation were identified. Two of these patients were maternal half-brothers aged 14 and 15 years. The genetic variation was identical between the half-brothers - a novel, frame shift mutation (c.1128_1156del29) in exon 4. Their mother was a carrier of this mutation and had borderline intellectual disability. The elder sibling presented with symptoms of the intellectual disability subtype of male MECP2 disorders. He was initially evaluated for global developmental delay at 2 years of age, which later progressed to profound intellectual disability and spastic cerebral palsy. Interestingly, the younger sibling's presentation was more suggestive of severe neonatal encephalopathy subtype. During infancy, he experienced severe global developmental delay, followed by respiratory insufficiencies after viral infections, and epilepsy at 5 years of age. The most recent case was a full-term neonate who developed a more severe form of neonatal encephalopathy. At birth, he presented with microcephaly and hypotonia. He required a gastrotomy tube insertion for feeding and a tracheostomy for central apnea by the age of 6 months. Genetic analysis identified a variation (c.317 G>A; p.R106Q) in exon 3 of the *MECP2* gene. The same variation has been previously reported in 22 female patients identified from RettBASE, of which 8 patients exhibited classical Rett syndrome. Conclusions: We report three patients of male MECP2 disorders who have not been previously reported in the literature. Recent therapeutic advancements provide hope for changing this devastating disease into a potentially treatable condition, making timely diagnosis even more crucial.

Session Title: Mendelian Phenotypes Poster Session II

PB4579 † A clinical knowledge graph-based machine learning framework to prioritize candidate genes for facilitating diagnosis of Mendelian diseases and rare genetic conditions.

Authors:

R. Gnanaolivu, G. Oliver, G. Jenkinson, N. Chia, E. Klee, C. Wang; Mayo Clinic, Rochester, MN

Background: Diagnosis of mendelian and rare genetic condition requires identification of clinical phenotypes-associated genetics findings and prioritization of likely disease-causing genes. With a large number of genetic variants detected from clinical next-generation sequencing (NGS), effective computational prioritization is desired to integrate with knowledge of patients' phenotypes.
Methods: We seek to develop a machine learning (ML) framework prioritizing candidate diagnostic-relevant genes for genetics conditions, leveraging a large-scale clinical knowledge graph (CKG) consisting of 19,405,058 nodes and 217,341,612 edges as relationships, curated from 24 databases and ten ontology data sources such as the Human Phenotype Ontology (HPO). The entire CKG is stored in a Neo4j graph database for easy querying, visualization, and computations. The developed framework includes two major ML modules: (i) prediction of reliable knowledge relationships using a graph embedding approach FastRP (Fast Random Projection), and (ii) gene-phenotype relevance ranking according to the Cosine similarity of gene and phenotype nodes in CKG, using the predictions and information content for each phenotype as weights. Multiple ML strategies were compared and optimized for both modules. The optimal framework was tested in an institutional rare disease cohort of 250 patient subjects with research consent. PCAN (Phenotype Consensus Analysis), an established gene-phenotype prioritization method without utilizing knowledge relationships, is compared with our proposed framework.
Results: Within the proposed ML framework, we evaluated four graph edge embedding operations (L1, L2, Average, and Hadamard), using three ML algorithms (XGboost, Naïve Bayes, Multilayer Perceptron) to evaluate link predictions. L1 operation with Naïve Bayes performed best with an AUPRC=0.92, followed by L2 with Naïve Bayes with an AUPRC=0.91. When applying the best models to an institutional rare disease cohort with NGS-detected genetic variants, our method ranked the causal gene within the top 40 out of 42,571 genes and 15,872 phenotypes in the CKG network for 91% of the cases, with 97 cases ranking the causal gene within the top 10. With PCAN only 20% of the cohort ranked top 40, and only 18 (7%) cases had the causal gene ranked higher than our model.
Conclusions: These results suggest leveraging knowledge graph methods for facilitating genetic condition diagnosis have value. The proposed ML framework is a scalable solution for integrating multiomics data modalities and identifying disease-causing pathway alternations for other complex diseases.

PB4580 A cohort of Tunisian patients with Netherton syndrome: Molecular signature and Genetic investigations

Authors:

H. CHOUK[1,2], E. Petrova[3], L. Boussofara[4,5], N. Litaiem[6], H. Hammami[7], M. Mokni[8], B. Sriha[9], S. Miskinyte[3], A. Saad[4,2], M. Denguezli[5], A. Hovnanian[10], D. H'mida[4,2]; [1]Higher Inst. of Biotechnology of Monastir, Sousse, Tunisia, [2]Laboratry of Cytogenetics, Molecular Genetics and Reproductive Biology, Sousse, Tunisia, [3]Imagine Inst., Paris, France, [4]Faculty of medicine, Sousse, Tunisia, [5]Service of Dermatology, Farhat Hached, Sousse, Tunisia, [6]Service of Dermatology, Charles Nicolle, Tunis, Tunisia, [7]Service of Dermatology, Habib thameur, Tunis, Tunisia, [8]Service of Dermatology, La Rabta, Tunis, Tunisia, [9]Service of pathology, Farhat Hached, Sousse, Tunisia, [10]Imagine Inst. - INSERM URM 1163, Paris, France

Introduction & Objectives: Netherton syndrome (NS) is a rare autosomal recessive genodermatosis, it is actually defined by the clinical triad characterized by an atopic manifestation, scaly erythroderma (SE) or Ichthyosis Linearis Circunflexa (ILC) and a specific Hair shaft abnormality known as Trichorrhexis invaginata (TI). NS is caused by loss of function mutations in the *SPINK5* gene encoding kazal-type serine protease inhibitors (LEKTI) highly expressed in the stratified epithelium. We aim to analyze NS in Tunisian patients by examining their clinical, biological, histological, and genetic features, and identifying therapeutic targets through analysis of the inflammatory signatures in their skin. **Materials & Methods:** Our study focused on 17 patients from 13 unrelated Tunisian families with NS, who were referred to our department for genetic confirmation of their diagnosis. **Results:** All patients experienced neonatal onset of symptoms, with congenital ichthyosiform erythroderma in 13 cases at birth, and bullous in only one case. The scalp was the site of a diffuse scaly shell. TI, as well as atopic dermatitis, was noted in all patients. Immunostaining of inflammatory cytokines showed massive neutrophil and mast cell infiltrates in the lesion and non-lesion skin in both NS subtypes. A remarkable expression of Th2 cells in the dermis for the two subtypes was noted. Next-generation sequencing and Sanger sequencing of the *SPINK5* gene identified a known homozygous c.1888-1G>A mutation at the splice acceptor site of exon 21 in 7 patients. A homozygous c.2264dupA mutation at exon 24 was present in 2 patients. A homozygous c.2471delAAGA deletion in 2 related patients. A previously described homozygous c.2441+3delCAGT mutation at the splice donor site of exon 25 in one patient. A new nonsense pathogenic variant homozygous c.217G>>T at exon 4 in 2 patients. Furthermore, the last patient was compound heterozygous for a new c.2302G>T mutation, and a deep intronic variant. Haplotype analysis in NS patients by genotyping seven microsatellite markers flanking the *SPINK5* gene indicates that all carriers of the c.1888-1G>A mutation have the same haplotype. **Conclusion:** In conclusion, we present the largest cohort of Tunisian patients with NS, including 7 patients harboring the same mutation, potentially indicating a founder effect. We have also identified 5 pathogenic variants, including 2 novel variants, in a total of 10 patients. Our findings suggest that intra and inter-familial phenotypic variations observed in individuals with the same *SPINK5* mutation may be influenced by other epigenetic and environmental factors, highlighting the complexity of NS expression.

PB4581 A *COL12A1* heterozygous mutation leads to bent bone dysplasia.

Authors:

A. Kot, J. Martin, D. Wachtell, C. Chun, J. Zieba, D. Krakow; UCLA, Los Angeles, CA

Bent bones are described in several skeletal disorders including campomelic dysplasia, bent bone dysplasia FGFR2 type, osteogenesis imperfecta, and hypophosphatasia - the underlying genetic causes of these disorders are well established. Herein, we describe a novel bent bone skeletal dysplasia resulting from a heterozygous missense mutation in *COL12A1*, encoding collagen XII. Collagen XII is expressed in the perichondrium, articular cartilage, and prehypertrophic zone. It interacts with collagen I and other ECM proteins to organize collagen fibrils in dense connective tissue and bone. Collagen XII variants are described in patients with phenotypes including Ehlers-Danlos syndrome and collagen VI related myopathy.

This novel bent bone case was a female at 21 weeks of gestation with nonconsanguineous parents of 2 unaffected children. Radiographic findings included distinctly bent appendicular bones, coronal clefts, underminerlized 12th ribs, and delayed pubis/calcaneus ossification. Trio exome analysis revealed 6 candidate de novo mutations, of which *COL12A1* was prioritized due to its expression in the skeleton. The mutation (NM_004370.5 c.4120A>G, p.Asn1374Asp) occurs 3 residues past a von Willebrand factor domain, which function in cell adhesion and ECM binding.

Histological analysis of the affected femur showed reduced collagen fibril organization with a mildly disorganized hypertrophic zone. Immunofluorescence studies from affected fibroblasts suggest the mutation leads to intracellular retention of collagen XII. As SOX9 expression is critical for chondrocyte differentiation, is expressed in the prehypertrophic zone, and SOX9 mutations cause campomelic dysplasia, we hypothesized SOX9 may be dysregulated in the affected cells and growth plate. Western blot analysis found Increased SOX9 in a primary chondrocytes and fibroblasts. Immunohistochemistry showed increased SOX9 expression throughout the growth plate with strong staining surrounding cartilage canals. This finding adds to the diverse set of molecules that produce bent bone dysplasias, highlights roles of the ECM in skeletogenesis outside of structural support, and implicates SOX9 expression as a novel mechanism in these non-campomelic dysplasia bent bone cases.

PB4582 A comparative analysis of a rare condition with a skeletal phenotype - *FLNB* related spectrum: case series

Authors:

V. Plaiasu, B. Pascu, O. Farkas, V. Comanici, I. Stan; INSMC Alessandrescu-Rusescu, Bucharest, Romania

Background: FLNB-related disorders are a group of disorders characterized by skeletal abnormalities affecting the bones of the hands and feet, the bones of the spine (vertebrae), joint dislocations, and distinctive facial features. The FLNB disorders include a continuum spectrum of phenotypes ranging from mild to severe: spondylocarpotarsal synostosis (SCT) syndrome and Larsen syndrome, boomerang syndrome, atelosteogenesis type I (AOI) and type III (AOIII) and Piepkorn osteochondrodysplasia. While pathogenic variants in FLNB are typically inherited in an autosomal dominant fashion, autosomal recessive inheritance is also possible. Material and methods: Our study makes a comparative analysis among 3 probands with FLNB-mutated autosomal dominant and autosomal recessive spectrum, relating clinical phenotypes to molecular findings. All patients were screened for mutations by Whole Exome Sequencing (WES) technology because they exhibited variability of the clinical findings with a wide and unspecific range of clinical and radiological features involving the skeleton. Results: One patient was diagnosed with Larsen syndrome, an autosomal dominant skeletal dysplasia characterized by large joint dislocations and craniofacial dysmorphism and two patients were described with autosomal recessive spondylocarpotarsal synostosis syndrome, a complex phenotype characterized by disproportionate short stature, spine deformation, carpal and tarsal fusions, mildly dysmorphic features, one of them presented with a rare association between cricopharyngeal achalasia and laryngomalacia with spondylocarpotarsal synostosis syndrome. Our report expands the genetic spectrum of FLNB pathogenic variants with 3 novel mutations. Conclusion: Mutations in FLNB gene lead to various skeletal malformations, involving long bone, joints and vertebra. Clinical, skeletal findings, radiographic examination and molecular results could offer the final diagnosis for the patients. Milder or unusual manifestations of this group of diseases can result in misdiagnosis or no diagnosis at all. But the use of broader genetic testing, such as WES, is important to accurately diagnose individuals with FLNB-related conditions. Recognition of these syndromes also will have implications in genetic counselling for patients.

PB4583 A consanguineous Yemeni Family with 7 sibs affected by either Severe Anterior chamber defects of eyes due to *PXDN* pathogenic variant *exon 17 C/T* and/or Intellectual disability of Unknown Etiology.

Authors:

M. Alwasiyah[1], C. Trujillo[2], R. Lebel[3], S. Scherer[4], M. Zarrei[4]; [1]Jeddah Regional Lab., Jeddah, 21523, Saudi Arabia, [2]Univ. CES, Medellin, Colombia, [3]SUNY Upstate Med Univ, Fayetteville, NY, [4]The Hosp. for Sick Children, Toronto, ON, Canada

A consanguineous Yemeni Family with 7 sibs affected by severe anterior chamber defects of the eyes and/or Intellectual disability. 6 brothers and one sister, parents are 1st cousins. Only one "normal male" 26 years old who came to our clinic for pre-conceptional counseling and testing. The eldest brother is 30 years old affected by severe intellectual disability, ataxic gait, and bilateral microphthalmia with microcornea and diffuse corneal opacities. The second 29 years old "normal" intellect microphthalmia with microcornea bilaterally, in the right eye had a previous surgery 20 years ago, has anterior polar cataract, adhesion with anterior posterior synechia of iris and lens. The third one is 27 years old male, "normal" eyes, severe intellectual disability. The fourth is the proband 26 years old, married, they are not relatives but their families come from the same village in Yemen. The fifth is a 20 years old female with mild myopia and "moderate" intellectual disability. The sixth is 17 years old male, normal intellect has bilateral microphthalmia and microcornea with diffuse corneal opacities, he had in his left eye pupil of slade shape, a corneal graft, and right eye cornea is clear, he can read at very close distance, the retina looks normal. Last one a 7 years old male, normal intellect, left eye, upper corneal opacity, microcornea, microphthalmia, anterior and posterior synechia. Right eye Bupthalmos, Glaucoma, diffuse central opacity and vascularization. We have completed WGS and targeted sequencing experiments, as well as the analysis of the data for this family. Based on the information we have available today, there were no SNVs observed that appear to be contributing to the ID phenotype.We do have a potentially, clinically relevant finding for the eye abnormality. We have detected the following *SNV:PXDN:NM_012293:exon17:c.G3488A:p.R1163Q Chr2: 1652064 C/T*

PB4584 A *Drosophila* Model for MED12-associated Rare Genetic Diseases

Authors:

K. Bussey, N. Nazario-Yepiz, V. Shankar, R. R. H. Anholt, T. F. C. Mackay; Clemson Univ.-Ctr. for Human Genetics, Greenwood, SC

MED12 is a component of the Mediator Complex which regulates gene expression. Mutations in different domains of the MED12 protein are associated with five rare genetic disorders: Lujan Syndrome, FG Syndrome, X-Linked Ohdo Syndrome, Hardikar Syndrome, and Non-Specific Intellectual Disability. The clinical phenotypic spectrum of these disorders is broad, including intellectual disability, behavioral, and congenital defects. Individuals with identical genetic lesions in MED12 can present different severity of symptoms, indicating that genetic modifiers may act on MED12 to alter the manifestation and severity of these rare disorders. Due to the rarity and diversity of these disorders, identifying genetic modifiers is not possible in human populations. *Drosophila melanogaster* has a conserved functional ortholog of MED12, *khotalo* (*kto*). Knocking down *kto* expression using RNA-interference shows that *kto* affects startle response, a proxy for sensorimotor integration, and sleep and activity traits. We can use natural variation among the fully sequenced inbred lines of the *D. melanogaster* Genetic Reference Panel (DGRP) to identify genetic modifiers that alter the effects of *kto* mutations. We crossed a CRISPR/Cas9-generated null mutation of *kto* (kto^{Δ}), and a wild type *kto* allele (kto^{+}) in the same genetic background, to the DGRP lines, and quantified sleep and activity and startle-induced locomotion in the F_1 offspring across 200 different genetic backgrounds. We used analysis of variance to estimate the effects of *kto* genotype (*G*), DGRP line (*L*) and the genotype by line interaction (*G*×*L*) on these phenotypes. A significant *G*×*L* term indicates the presence of modifier loci, (*i.e.*, the effect of *kto* genotype is different across the DGRP lines). Variation in the phenotypic difference between F1 offspring of the wild-type and kto^{Δ} mutant for each DGRP line can be used as a parameter for genome-wide association analysis across the DGRP to identify candidate epistatic modifiers of *kto* with human orthologs. We will report the results of these analyses. Genetic modifiers identified in *Drosophila* will provide insight into how genetic modifiers may influence the manifestation and severity of *MED12*-related disorders that are potential therapeutic targets.

Session Title: Mendelian Phenotypes Poster Session II

PB4585 A Drosophila Model for Mucopolysaccharidosis IIIA

Authors:

R. Bishop, T. F. Mackay, R. R. Anholt, B. Simkhada, P. S. Freymuth, N. O. Nazario-Yapiz, V. Shankar, R. Lyman; Clemson Univ., Greenwood, SC

Sanfilippo syndrome IIIA is a rare lysosomal storage disorder due to a genetic defect within the N- *sulfoglucosamine sulfohydrolase* (*SGSH*) gene, which is a sulfamidase that cleaves a sulfamate bond from heparan sulfate and GM2 gangliosides during catabolic degradation within the lysosome. To assess the effect of genetic background modifiers on disease progression, we used a deletion mutant and nonsynonymous missense mutants of the Drosophila *Sgsh gene* which is orthologous to its human counterpart. Assessment of lysosome integrity in the brains of control and mutant flies for both sexes separately using the Lysotracker Green assay showed an age-dependent progressive increase in fluorescent punctae in the brains of mutants versus controls. Hyperactivity and fragmented sleep patterns of children between ages 5 -10 years-old are prominent hallmarks of the disease phenotype. To assess effects on locomotor behavior and sleep in the Drosophila model, we measured activity at weekly intervals up to 3 weeks of control and mutant flies for sexes separately using Drosophila activity monitors. This system monitors the number of times a single fly housed in a narrow tube crosses the beam of an infrared light. Both the Lysotracker system and the Drosophila activity monitor system can be used to identify genetic modifiers by crossing the *Sgsh* mutants and the control to flies of the Drosophila Genetic Reference Panel, a population of fully sequenced wild derived inbred lines, and analyze variation in differences between control crosses and the corresponding mutants in the resulting heterozygotes. Supported by a Cure Sanfilippo Foundation grant.

Session Title: Mendelian Phenotypes Poster Session III

PB4586 A Drosophila model for Mucopolysaccharidosis type IIIB (MPS IIIB)

Authors:

B. Simkhada, N. O. Nazario-Yepiz, R. R. H. Anholt, T. F. C. Mackay, P. S. Freymuth, R. A. Lyman, V. Shankar; Clemson Univ., Greenwood, SC

Mucopolysaccharidosis type IIIB (MPS IIIB) is a rare human lysosomal storage disorder caused by defects in the lysosomal enzyme alpha-*N*-acetylglucosaminidase (*NAGLU*). Affected individuals appear normal at birth, with clinical symptoms appearing only at around 3-5 years of age. Early symptoms include hyperactivity and lack of sleep, which manifests into neural degeneration by mid-teen years, and death before the age of 30. Mutations in *NAGLU* cause accumulation of partially degraded heparan sulfate in lysosomes, but how this relates to neural degeneration is unknown. We use the functional *Drosophila melanogaster* ortholog of *NAGLU*, *CG13397*, to characterize disease models induced by gene deletion, missense (Drosophila Y160C corresponding to human Y140C), and nonsense (Drosophila W422X corresponding to human W404X) mutations. Fluorescence microscopy on mutant fly brains using Lysotracker dye reveal a significant increase in acidic compartments, characteristic of lysosomal storage diseases. Using the Drosophila Activity Monitor (DAM) system to analyze activity and sleep patterns, we find hyperactivity and sleep defects in mutant flies. RNA sequencing of fly brains can reveal differentially expressed genes to provide mechanistic insights into MPS IIIB pathogenesis.

Session Title: Mendelian Phenotypes Poster Session I

PB4587 A dual diagnosis of Okur-Chung neurodevelopmental syndrome and Becker muscular dystrophy highlights the lower limits of neurodevelopmental functioning attributable to muscular dystrophy

Authors:

V. Liu[1], E. Hanson[1], J. Owens[2], A. Shillington[3]; [1]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [2]Cincinnati Children s Hosp., Cincinnati, OH, [3]Cincinnati Children s Hosp., Cincinnatti, OH

Muscular Dystrophies caused by pathogenic changes in the *DMD* gene present as a spectrum of X-linked recessive disorders. Disease severity correlates to the degree that pathogenic variants disrupt the dystrophin protein, and disruption of specific dystrophin isoforms in the brain can lead to more severe neurodevelopmental delays. Okur-Chung Neurodevelopmental Syndrome (OCNDS) is an autosomal dominant disorder characterized by developmental delay, intellectual disability, dysmorphic facial features, generalized hypotonia, and short stature due to pathogenic *CSNK2A1* variants. We report a 3-year-old male who presented with global developmental delay, postnatal growth failure, feeding difficulties, self-injurious behaviors, and recurrent infections. His facial features are notable for hypertelorism with epicanthic folds, a flat nasal bridge, mild cupid's bow lip, and mild generalized hypotonia. A SNP microarray revealed a maternally inherited 109 kb Xp21.1 interstitial duplication with out-of-frame breakpoints in exon 55 of *DMD*. His *DMD* variant and normal CPK / muscle MRI findings were suggestive of Becker Muscular dystrophy (BMD). Given his dysmorphic features and excessive global delays for BMD, he received whole exome sequencing revealing a de novo *CSNK2A1* c.593A>G (p.Lys198Arg) pathogenic variant consistent with a diagnosis of OCNDS. His clinical history emphasizes the limitations of neurodevelopmental functioning that can be attributed to BMD and Duchenne Muscular Dystrophy (DMD). Large cohorts predict a full scale IQ (FSIQ) of 88.3 ± 13.9 among all patients with BMD and 86.1 ± 15.0 among all patients with DMD, while pathogenic variants impacting the brain dystrophin isoform Dp140 are associated with FSIQ of 77.7 ± 10.8 in BMD and 78.8 ± 18.6 in DMD. We propose that all patients with muscular dystrophy with FSIQ 1 standard deviation below these expected ranges should be assessed for alternative causes for their neurodevelopmental delays, with specific consideration of broad-spectrum genetic testing. All patients with an FSIQ 2 standard deviations below these ranges should receive broad-spectrum genetic testing to screen for an additional genetic diagnosis.

Session Title: Mendelian Phenotypes Poster Session II

PB4588 A genetics-first approach to identify novel variants of the calcium sensing receptor associated with autosomal dominant hypocalcemia type 1

Authors:

J. B. Chang[1], M. M. Soliai[1], C. P. Barnhill[1], L. M. Stapleton Smith[1], A. S. Mathew[1], A. M. Apostolov[2], B. W. Dulken[1,3], A. Petukhov[1], A. V. Sridhar[1], J. Lasky-Su[4], C. Lange[5,4], R. Altman[6], S. H. Adler[1], M. Roberts[1], J. C. Fox[1], S-G. Ji[1]; [1]BridgeBio Pharma, Inc., Palo Alto, CA, [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA, [3]Dept. of Pathology, Stanford Sch. of Med., Stanford, CA, [4]Channing Div. of Network Med., Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [5]Dept. of Biostatistics, Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [6]Dept.s of Bioengineering, Genetics, and Med., Stanford Univ., Stanford, CA

Autosomal dominant hypocalcemia type 1 (ADH1) is a rare genetic disorder caused by gain-of-function (GOF) variants in the calcium sensing receptor, *CASR*, which regulates calcium homeostasis by controlling parathyroid hormone secretion. Diagnosis of ADH1 can be challenging due to variability in clinical presentation and limited knowledge of which *CASR* variants result in GOF. To address these challenges, we integrated biobank and patient data to identify novel *CASR* variants associated with ADH1. We first determined that the prevalence of previously reported *CASR* GOF variants was 2.8-3.8 in 100,000 individuals in gnomAD, TOPMed, and the UK Biobank (UKB), similar to a previous report on the Geisinger cohort. Next, to identify novel GOF variants, we analyzed *CASR* variants in exome sequencing data from 500,000 participants in the UKB. We first confirmed the association of 3 out of 4 previously reported variants found in non-Hispanic White probands with reduced serum calcium level, a hallmark phenotype of ADH1 (Thr151Met: $p = 3.8\times10^{-6}$, Asn124Lys: $p = 2.4\times10^{-3}$, Val104Ile: $p = 8.8\times10^{-3}$, Thr888Met: $p = 0.13$; Bonferroni-adjusted individual significance threshold 1.3×10^{-2}). Val104Ile was also associated with reduced serum calcium level in 4 individuals of Indian ancestry ($p = 2x10^{-6}$). We applied SKAT-O to these 4 variants and 1,518 phenotypes and found that they were associated with hypoparathyroidism, another characteristic ADH1 phenotype ($p = 1\times10^{-56}$, Bonferroni-adjusted significance threshold 3.3×10^{-4}), and five additional phenotypes, suggesting these variants are pleiotropic. Next, we scored all 1,253 variants in the UKB within each ancestry based on regression modeling of ADH1 phenotypes, such as diagnosis code-based phenotypes. Our approach revealed novel associations of multiple variants with ADH1 phenotypes. Notably, one variant (Ser247Phe) scored highly across multiple ancestries. Finally, to search for novel variants beyond public datasets, we evaluated data from 169 patients participating in a sponsored genetic testing program for suspected genetic hypoparathyroidism. We identified a pathogenic/likely pathogenic variant or variant of unknown significance (VUS) of *CASR* in 21% (36/169) of patients. One of the VUS (Ala364Glu) was also found in the UKB and ranked highly by our scoring method. Currently, we are attempting to replicate our findings in two other biobanks (All of Us and Mass General Brigham) and are investigating how these novel ADH1-associated variants impact CASR function *in vitro*. Our study emphasizes the power of large, publicly available genomic datasets to clarify the genotype-phenotype relationship of rare diseases like ADH1.

Session Title: Mendelian Phenotypes Poster Session III

PB4589 A genotype-first approach identifies high incidence of *NF1* pathogenic variants with distinct disease associations

Authors:

T. Drivas[1], A. Safonov[2], T. Nomakuchi[3], E. Chao[4], V. Speare[4], C. Horton[4], J. Dolinksy[4], A. Yussuf[4], H. Laduca[4], Penn Medicine BioBank, Regeneron Genetics Center, Z. Bogus[1], M. Bonanni[1], A. Raper[1], M. Ritchie[1], S. Kallish[1], K. Nathanson[1]; [1]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [2]Mem. Sloan Kettering Hosp., New York, NY, [3]Childrens Hosp. of Philadelphia, Philadelphia, PA, [4]Ambry Genetics, Irvine, CA

Loss of function variants in the *NF1* gene cause neurofibromatosis type 1 (NF1), an autosomal dominant genetic disorder classically characterized by complete penetrance, a prevalence of 1 in 3,000, characteristic physical exam findings, and a substantially increased risk for malignancy. However, our understanding of the disorder is entirely based on patients ascertained through phenotype-first approaches. We have recently been referred four patients with incidentally discovered pathogenic *NF1* variants, but with no features of the syndrome on exam or history. We hypothesized that the true population-level incidence of *NF1* pathogenic variants might be higher than reported, with reduced penetrance or a higher incidence of somatic mosaicism than is currently known.

To investigate this hypothesis, we evaluated two unique large patient cohorts from independent datasets that had undergone comprehensive sequencing of the *NF1* gene: the population-level Penn Medicine Biobank (PMBB, n = 43,731) and a database of patients clinically sequenced for cancer risk evaluation by Ambry Genetics (n = 118,768). We identified an unexpectedly high prevalence (1 in 450-750) of pathogenic variants in *NF1*, more than four times the rate expected given the reported prevalence of NF1. Half of these individuals lacked any evidence of syndromic NF1, and 15-30% of these individuals appeared to be post-zygotic mosaic for the *NF1* variant identified. The discovery of an incidental *NF1* pathogenic variant did not correlate with the presence of classic symptoms of NF1 but was associated with a significantly greater incidence of certain malignancies compared to a matched control population, including ovarian cancer (p=0.01), sarcoma (p=0.04), adrenal cancers (p=1.5e-11), CNS cancers (p=0.04), and hematologic malignancies (p=3.8e-04). Our findings suggest that *NF1* pathogenic variants are substantially more common than previously thought, often characterized by somatic mosaicism and reduced penetrance, and are important contributors to cancer risk in the general population.

Our experience with *NF1* led us to examine the incidence of somatic mosaicism on a larger, population-level scale. Within PMBB, there is clear evidence that nearly all individuals harbor multiple somatic-mosaic variants in various genes, with certain genes being significantly enriched for somatic mosaic variants, at least in peripheral blood. This identification of widespread mosaicism has major implications for future genetic testing and biobanking efforts, and the further investigation of this finding will be critical for accurate counseling of patients and families.

Session Title: Mendelian Phenotypes Poster Session I

PB4590 A heterozygous de novo *FEM1C* variant in a female patient presenting with developmental delay and ataxia.

Authors:

j. verheijen, L. Larson, A. Singla, R. Gavrilova, E. Klee; Mayo Clinic, Rochester, MN

FEM1C (Fem-1 Homolog C) located on chr5q22.3 encodes for a 617 amino-acid substrate recognition protein. FEM1C is involved in protein catabolism through it's role as subunit of the CUL2-RING E3 ubiquitin ligase complex. FEM1C is predicted to selectively interact with substrate proteins by binding to a carboxyl-terminus arginine degradation signal.

We describe a 21-year-old female patient presenting with developmental delay and ataxia. The patient was first evaluated for developmental delay at 13 months of age. The patient was diagnosed with static encephalopathy with hypotonia, ataxia, and global developmental delay at 3 years of age. She subsequently developed quadriplegic cerebral palsy, torsional nystagmus, and esotropia. Whole-genome trio sequencing identified heterozygous *de novo* missense variant c.376G>C p.Asp126His in *FEM1C* in the patient. No additional variants relevant to the patient's phenotype were identified. Previous chromosomal microarray, William's syndrome FISH analysis, and Prader Willi/Angelman analysis returned negative. The variant identified in *FEM1C* is located in residue p.Asp126, which is predicted to be directly involved in substrate binding. This residue is strongly conserved in evolution and present in all three members of the human *FEM1* gene family. Residue p.Asp126 is considered intolerant to substitution, and in-silico tools predict a deleterious effect for variant p.Asp126His. Protein modeling indicates a ΔG Gibbs free-energy change of -1.77.

FEM1C is currently not formally associated with any disorder and categorized as a gene of uncertain significance. However, recent reports have described a neurodevelopmental phenotype in some carriers of *de novo FEM1C* missense variants. Importantly, variant p.Asp126His and alternative substitution p.Asp126Val have recently been reported in pediatric neurodevelopmental disorder patients. In addition, a *de novo* variant in gene *FEM1B* has been recently reported in a pediatric global developmental delay patient, possibly indicating phenotypic overlap for disease variants in the *FEM1* family of genes.

Based on in-silico prediction, absence in healthy cohorts and *de novo* inheritance status, variant p.Asp126His in *FEM1C* is currently curated as VUS with the following criteria assigned: PM2_supporting, PS2_moderate, PS3_supporting. Follow-up analysis will include detailed assessment of variant impact on protein structure and function to further elucidate the pathomechanism for *FEM1C de novo* variants in neurodevelopment.

Session Title: Mendelian Phenotypes Poster Session II

PB4591 A heterozygous mutation in UBE2H in a patient with developmental delay leads to an aberrant brain development in zebrafish

Authors:

Y. Choi[1], U. Shin[1], H. Ko[2], K. Myung[1,2], S. Lee[1], C. Cheon[3], Y. Lee[2,4]; [1]Ulsan Natl. Inst. of Sci. and Technology, Ulsan, Korea, Republic of, [2]Inst. for Basic Sci. (IBS), Ulsan, Korea, Republic of, [3]Pusan Natl. Univ. Children's Hosp., Yangsan-si, Korea, Republic of, [4]Kyung Hee Univ., Seoul, Korea, Republic of

With the advancement of next-generation sequencing, there have been developments in techniques to identify causative variants in patients with rare diseases. However, due to cost and time limitations, panel sequencing is the primary method used. The importance of whole-genome sequencing (WGS) has been emphasized in identifying causative variants in patients who have not been diagnosed using conventional methods such as panel sequencing and microarrays. Additionally, a trio-based approach, in which the parents are also included, can be effective in discovering causative variants more reliably. Therefore, we went beyond conventional methods to identify causative variants in patients using trio-based WGS and experimentally validate them.We carried out trio-based WGS analysis of a patient with clinical phenotypes of developmental delay and intractable convulsion to identify causal mutations that could not be diagnosed using conventional fluorescence in situ hybridization or chromosome microarray tests. Point mutations of all family members (father, mother, and proband) were identified using HaplotypeCaller and only de novo variants, which were defined as those only present in the proband but not in the parents, were selected for further analysis. Rare de novo variants were identified after filtering based on allele frequency (< 0.01) from large-scale variome databases (1KGP, gnomAD, and Korea1K). Notably, the UBE2H (p.Thr150Met) variant was the only rare de novo mutation and was predicted to be deleterious simultaneously by SIFT, PolyPhen, and MutationTaster.Further characterization of the candidate gene, UBE2H, was performed using zebrafish through gene knockdown approaches. We found that Ube2h is required for normal brain development. Transcriptomic analysis using whole embryos of zebrafish knockdown morphants and additional functional studies identified downstream pathways of the Ube2h affecting neurogenesis. Moreover, depletion of ube2h led to the induction of apoptosis, specifically in the differentiated neural cells. Finally, we found that a missense mutation in zebrafish, ube2h (c.449C>T; p.Thr150Met), which mimics a variant identified in a patient with neurodevelopmental defects, causes aberrant Ube2h function in zebrafish embryos. Through our trio-based WGS study, we identified a rare de novo variant present in UBE2H, which may play a role in global developmental delay in pediatric patients. Therefore, we believe that our trio-based approach in analyzing WGS data is effective in discovering causative variants in rare disease patients.

Session Title: Mendelian Phenotypes Poster Session III

PB4592 † A homozygous rare missense variant in *YKT6* results in loss-of-function and is associated with infantile liver failure and developmental delays.

Authors:

M. Ganapathi[1], M. Ma[2], Y. Zheng[2], K-L. Tan[3], O. Kanca[2], N. Quintanilla[4], X. Pan[2], S. Lu[2], J. Rosenfeld[2], C. Thomas[5], C. Leduc[6], A. McPartland[1], J. Hagen[1], Y. Shen[1], P. Hertel[2], W. Chung[1], H. Bellen[2]; [1]Columbia Univ. Med. Ctr., New York, NY, [2]Baylor Coll. of Med., Houston, TX, [3]Baylor Coll. of Med.,, Houston, TX, [4]Texas Children's Hosp., Houston, TX, [5]Carver Coll. of Med., Iowa City, IA, [6]Columbia Univ, New York, NY

Hepatic cirrhosis in the first year of life is most commonly attributed to biliary atresia or genetic/ metabolic disorders, though in up to 15% of cases, the cause remains undetermined. We identified a rare, homozygous, recurrent, predicted likely pathogenic variant in *YKT6* (NM_006555.4:c.554A>G, p.Tyr185Cys) segregating with disease in two unrelated families of South Asian-Indian ancestry. The two affected infants presented with similar clinical features, which included normal prenatal course and birth, poor weight gain and developed micronodular cirrhosis progressing to liver failure. The infant from the first family died of liver failure at 9 months of age. He was also delayed in achieving his gross motor milestones. The second infant was subsequently diagnosed with hepatocellular carcinoma and underwent liver transplant at 1 year of age and is currently 5 years of age but developmentally delayed. These two individuals belong to the Syrian Christian community of Kerala, India, a group currently estimated to be comprised of about 5 million individuals worldwide, and haplotype analysis identified a shared chromosomal region carrying the variant, suggesting a common ancestor. *YKT6* encodes a unique and versatile SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) that plays important roles in intracellular vesicle trafficking events. Currently, *YKT6* is not associated with any known Mendelian disorder. To investigate the impact of the *YKT6* variants, we performed functional assays in Drosophila. The fly ortholog *dYkt6* is an essential gene, and loss-of-function alleles cause lethality. Lethality was less efficiently rescued by the genomic rescue (GR) construct carrying the *dYkt6* p.Y186C variant (corresponding to human *YKT6* p.Y185C) compared to the wild type, and the rescued animals showed significantly reduced lifespan. A $dYkt6^{KG}$ (Kozak-GAL4) allele generated to assess the expression pattern of *dYkt6* detected expression in the fat body (analogous to vertebrate liver) and central nervous system. Loss of *dYkt6* in fat body cells caused autophagy flux defects, and the *dYkt6* p.Y186C GR construct was unable to fully rescue the autophagy phenotypes. Taken together, our findings suggest that the homozygous *YKT6* p.Tyr185Cys variant leads to partial loss-of-function and is associated with infantile liver failure with developmental delays.

Campeau[2,1]; [1]Univ. de Montreal, Montreal, QC, Canada, [2]CHU Sainte-Justine, Montreal, QC, Canada, [3]Univ. de Extremadura, Badajoz, Spain, [4]Aristotle Univ. of Thessaloniki, Thessaloniki, Greece, [5]Inst. for Integrative Biology of the Cell (I2BC), Gif-sur-Yvette, France

Background: TKFC is a bifunctional enzyme involved in fructose metabolism. Triokinase catalyzes the phosphorylation of fructose-derived glyceraldehyde (GA) and exogenous dihydroxyacetone (DHA), while FMN cyclase generates cyclic FMN. Previously reported pathogenic variants in TKFC are associated with either a multisystemic disease including developmental delay, cataracts, cardiomyopathy, liver dysfunction, microcytic anemia, lactic acidosis, and cerebellar hypoplasia or isolated hypotrichosis with loose anagen hairs. Methods: Exome sequencing identified a homozygous novel variant in TKFC (c.1624G>A; p.Gly542Arg) in an individual with complex primary immunodeficiency. The variant was characterized using enzymatic assays and yeast studies. Results: The individual presented with recurrent otitis media, refractory rhinosinusitis, chronic active Epstein-Barr virus disease, chronic Herpes simplex virus gingivostomatitis, Varicella zoster virus infection, folliculitis, eosinophilic esophagitis, and food allergies. Clinical investigations revealed hypogammaglobulinemia, increased immunoglobulins A, near absent NK cells and decreased memory B cells. Enzymatic assays showed that this variant displayed inactive DHA and GA kinase activity while maintaining FMN cyclase activity. Conclusion: Our report suggests an important role of TKFC in immunological function. The pathological features of this variant are possibly linked with DHA/GA kinase inactivation with yet an unknown mechanism.

Session Title: Mendelian Phenotypes Poster Session II

PB4594 A late C-terminal frameshift variant in *GPKOW* is associated with a multisystemic X-linked disorder.

Authors:

K. Machol[1,2], L. Mackay[3], J-W. Mok[1,4], M. Balzo[5], E. Mizerik[1,2], F. Valle Sirias[6], M. Weisz-Hubshman[1,2], S. Ketkar[1], U. Polak[1], A. Tran[1], D. Kearney[7], N. Hanchard[1], O. Kanca[1,4], M. Wangler[1,4], H. Bellen[1,4], B. Lee[1,2], Baylor College of Medicine Center for Precision Medicine Models, S. Yamamoto[1,4]; [1]Baylor Coll. of Med., Houston, TX, [2]Texas Children's Hosp., Houston, TX, [3]UT Southwestern, Dallas, TX, [4]Jan and Dan Duncan Neurological Res. Inst., Houston, TX, [5]Baylor Scott and White, Temple, TX, [6]Rice Univ., Houston, TX, [7]Baylor Collage of Med., Houston, TX

GPKOW is an RNA binding nuclear protein with a role in post-transcriptional mRNA processing as a minor spliceosome subunit. *GPKOW* is located on Xp11.13 and encodes a protein with one G patch domain and two KOW motifs. GPKOW was shown to be important for embryonic development in *C. elegans* but its function has not been investigated in other model organisms. Only one published report associated a pathogenic variant in *GPKOW* to a human phenotype, which is characterized by male perinatal lethal microcephaly and intrauterine growth restriction due to a donor splice-site variant (c.331+5G>A).

We present two maternal half siblings with a maternally inherited hemizygous frameshift variant in *GPKOW* (c.1329dupG: p.S444EfsX28). This variant is expected to cause an exchange of the last 33 amino acids with 28 random amino acids and an early protein termination. Clinical presentation included brain and eye phenotype with microphthalmia, optic nerve hypoplasia, absent septum pellucidum, aqueductal stenosis and ventriculomegaly as well as congenital ichthyosis, skeletal abnormalities, and remote occlusion of portal vein branches. Unfortunately, both siblings died in the first year of life due to respiratory failure. mRNA sequencing in fibroblasts from one sibling confirmed that *GPKOW* mRNA escapes nonsense mediated decay with mRNA levels comparable to male controls. Interestingly, protein levels of GPKOW in patient's fibroblasts were overall reduced which may indicate protein instability.

In vivo studies in *Drosophila* showed that the *GPKOW* ortholog (*CG10324*) is essential and is expressed in a subset of neuronal and glial cells in the eyes and head of developing and adult fly among many other tissues. Knockdown of the fly gene in the developing eye resulted in severe small or no eye/head phenotype, and neuronal or glial knockdown caused lethality or functional defects, demonstrating the importance of this gene in eye development and nervous system function. The c.1329dupG variant human GPKOW is also unstable in flies, consistent with the observations in patient cells, but is unlikely to be a strong loss-of-function allele based on functional studies. Gain-of-function or a dominant-negative allele mechanisms are being evaluated in Drosophila. Of note, trio WES, CMA, and RNAseq studies suggested no other molecular etiology for the congenital ichthyosis phenotype. Our work contributes to the understanding of GPKOW's role in eye and brain development in human and flies and suggests a rare variant in *GPKOW* as a cause for a multisystemic X-linked syndrome with primarily brain and eye involvement with a possibility of congenital ichthyosis as part of the clinical presentation.

Session Title: Mendelian Phenotypes Poster Session III

PB4595 A mouse model of gyrate atrophy shows progressive retinal dysfunction and serves as a tool for investigating novel gene editing and gene replacement therapies.

Authors:

J. Johansson, M. Singh, D. Valle, J. J. Doyle; Johns Hopkins, Baltimore, MD

Gyrate Atrophy (GA) is an autosomal recessive retinal degeneration characterized by early onset high myopia and night blindness, onset of cataracts in the second decade, and progressive chorioretinal degeneration often resulting in vision loss by the fourth to fifth decade of life. GA results from biallelic loss of function mutations in *OAT* which encodes a mitochondrial matrix enzyme, OAT, that catalyzes the interconversion of ornithine and pyrroline-5-carboxylate (P5C), an intermediate in proline and glutamate metabolism. Patients with GA have < 5% fibroblast OAT activity and plasma ornithine levels >10 fold above normal. Treatment with an arginine-restricted diet (ARD) reduces plasma ornithine and slows progression of chorioretinal degeneration in mice and humans with GA, but it is a challenging diet to maintain. Hence, alternate mitigation strategies are needed. *Oat*$^{Rhg/Rhg}$ mice harbor a spontaneous missense mutation in *Oat* (p.G353C)(Bisaillon et al., 2014). We confirmed that *Oat*$^{Rhg/Rhg}$ mice display decreased Oat enzyme activity ($p<0.01$) and increased plasma ornithine levels (>20-fold WT littermates). We newly characterized retinal dysfunction in this mouse model using in-vivo electroretinography (ERG). Compared to WT littermates, *Oat*$^{Rhg/Rhg}$ mice show significantly impaired function of both rod photoreceptors (scotopic a-wave; $p<0.0001$) and downstream bipolar cells (scotopic b-wave amplitude; $p<0.01$) by 6 months of age. Both readouts progressively worsen by 12 months in *Oat*$^{Rhg/Rhg}$ mice ($p<0.01$, $p<0.01$, respectively), while WT responses remained stable. In contrast, we saw no sign of cone photoreceptor dysfunction within this time frame in *Oat*$^{Rhg/Rhg}$ mice. These findings are consistent with the early rod dysfunction and later cone involvement seen in humans with GA in the first few decades of life. Histopathological analysis demonstrates morphological alterations in both the photoreceptors and retinal pigment epithelium (RPE) of *Oat*$^{Rhg/Rhg}$ mice compared to WT controls at 12 months. Amino acid analysis confirmed a selective elevation in plasma ornithine in *Oat*$^{Rhg/Rhg}$ mice compared to WT controls ($p<0.00001$), with all other amino acids being equal between genotypes. Cumulatively these data demonstrate that *Oat*$^{Rhg/Rhg}$ mice recapitulate multiple biochemical, electrophysiological and histopathological features seen in humans with GA. Given the nature of the missense mutation in *Oat*$^{Rhg/Rhg}$ mice, the presence of a progressive retinal phenotype and a robust biochemical readout (plasma ornithine levels), the *Oat*$^{Rhg/Rhg}$ mouse model should serve as a valuable resource to interrogate both gene replacement and novel gene editing strategies.

Background Oculopharyngodistal myopathy (OPDM) is an autosomal dominant disorder characterized by facial and distal limb weakness, ptosis, and external ophthalmoplegia. Patients may have pharyngeal involvement or myopathic changes on skeletal muscle biopsy. Known molecular mechanisms of OPDMs include trinucleotide repeat expansions in LRP12, GIPC1, RILPL1, and NOTCH2NLC. The disease-causing motif is a 5' UTR CGG expansion. Still, roughly 30% of OPDM patients remain genetically undiagnosed.
Case report At the Stanford Center for Undiagnosed Diseases, we evaluated a 68 year old female with significant weakness of facial muscles, bilateral distal upper and lower extremity weakness, respiratory muscle weakness, osteoporosis, dysphagia, dysarthria, double vision, and hypothyroidism. The patient's sister is similarly affected. Clinical genetic workup including targeted testing for muscular dystrophies, exome sequencing, and short read genome sequencing (SR-GS) were nondiagnostic. Suspecting a short tandem repeat expansion, the patient was nominated for evaluation using an ExpansionHunter Denovo (EHDn) pipeline through the Undiagnosed Diseases Network. No expansions were detected in genes associated with OPDM - LRP12, GIPC1, RILPL1, or NOTCH2NLC. EHDn identified a rare, heterozygous CGG expansion in the 5' UTR of the FAM193B gene from SR-GS estimated at 72 [71-121] repeats. The expansion is present in both affected sisters and the unaffected mother, but absent in father and other unrelated controls. To better characterize the true size of the expansion, nanopore long read genome sequencing (LR-GS) was performed. The patient (245 repeats), sister (225 repeats), unaffected mother (185 repeats) were outliers compared to typical <50 repeats at this locus in a cohort of 100 unrelated individuals with LR-GS. Blood RNA sequencing revealed that FAM193B was over-expressed in both affected sisters compared to 282 unrelated controls. The mother's unaffected status despite carrying a smaller expansion may be explained if hers is a premutation allele.
Conclusions The CGG 5' UTR expansion in FAM193B may represent a novel molecular mechanism of OPDM. While SR-GS detected an expansion at this locus, LR-GS was superior in its ability to accurately characterize the expansion size. The integration of LR-GS and transcriptome analyses inform disease-causing potential of the FAM193B 5'UTR CGG repeat expansion. Further work is ongoing to characterize the functional impact of this expansion on RNA and protein and identify additional affected individuals.

Session Title: Mendelian Phenotypes Poster Session II

PB4597 A new gene discovery approach for structural birth defects employing an innovative machine learning algorithm

Authors:

D. Scott[1], T. M. Scott[2], A. Hardcastle[3], R. Belanger Deloge[4], M. R. Sy[1], T. Gordon[1], E. Huth[4], X. Zhao[4], S. Lalani[1], J. Rosenfeld[4], P. Luna[4], C. Shaw[1]; [1]Baylor Coll. Med., Houston, TX, [2]Univ. of Utah, Salt Lake City, UT, [3]Brigham Young Univ., Provo, UT, [4]Baylor Coll. of Med., Houston, TX

A molecular cause is not identified in most children with structural birth defects. This is due, in part, to an incomplete understanding of the genes that contribute to their development. Genes that are associated with low penetrance in humans may go unrecognized even though they play a critical role in development. Identifying these low-penetrance genes is a prerequisite to accurate genetic counseling for families affected by structural birth defects and enhances the ability of physicians to generate individualized medical plans for affected individuals. Deleterious coding variants in low-penetrance genes are also likely to represent very rare variants with modest to intermediate effect sizes, which are difficult to identify in traditional genetic studies. Such variants may represent important genetic modifiers of penetrance and may significantly contribute to the pathogenesis of structural birth defect cases that are associated with polygenic or multifactorial inheritance. To identify low-penetrance genes, we have developed an alternative gene discovery approach in which candidate genes are prioritized based on their similarity to genes already known to cause a phenotype. This prioritization is accomplished using an innovative machine learning algorithm that leverages data from large-scale genomic knowledge sources to generate phenotype-specific pathogenicity scores for all RefSeq genes. Additional evidence in support of a gene's role in the development of the phenotype is then identified from clinical, research, and public databases, expression profiles, animal models, and isolated case reports. Using this approach, we have implicated several human disease genes in the development of a wide variety of structural birth defects including congenital diaphragmatic hernia (*ALG12*, *ARID1A*, *ARID1B*, *ARID2*, *BRCA2*, *CREBBP*, *DPF2*, *EP300*, *FGFRL1*, *FOXP1*, *SMARCA4*, *SMARCA3*, *SMARCB1*, *SMARCC2*, *SMARCE1*, *UBA2*, *USP9X*), anorectal malformations (*ADNP*, *BBS1*, *CREBBP*, *EP300*, *FANCC*, *KDM6A*, *SETD2*, *SMARCA4*), esophageal atresia/tracheoesophageal fistula (*TCF4*, *NRXN1*, *FANCA*, *FANCB*, *FANCC*), orofacial clefting (*EBF3*, *HUWE1*) and anomalous pulmonary venous return (*EFTUD2*, *NAA15*, *NKX2-1*). These phenotype expansions provide compelling evidence that this approach can be used to identify genes for a wide variety of structural birth defects.

Genotypic definition of monogenic inborn errors of immunity (IEIs) continues to accelerate with broader access to next generation sequencing, underscoring this aggregated group of disorders as a major health burden impacting both civilian and military populations. At an estimated prevalence of 1 in 1200 individuals, IEIs affect ~8,000 patients within the Military Health System (MHS). Despite access to targeted gene/exome panels at military treatment facilities, most affected patients never receive a definitive genetic diagnosis that would significantly improve clinical care. To address this gap, we established the first registry of IEI patients within the MHS with the goal of identifying known and novel pathogenic genetic defects to increase diagnosis rates and enhance clinical care. Using the registry, a research protocol was opened in July 2022. Since July we have enrolled 75 IEI patients encompassing a breadth of phenotypes including severe and recurrent infections, bone marrow failure, autoimmunity/autoinflammation, atopic disease, and malignancy. Enrolled patients provide blood and bone marrow samples for whole genome, ultra-deep targeted panel and comprehensive transcriptome sequencing, plus cryopreservation of peripheral blood mononuclear cells for future functional studies. We are also implementing and developing analytical methods for identifying and interrogating non-coding and structural variants. Variants are classified according to the standards and guidelines for sequence variant interpretation of the American College of Medical Genetics and Genomics. These analyses subsequently inform *in vitro* experiments to validate causative mutations using cell reporter systems and primary patient cells. Clinical variant validation and return of genetic results are planned with genetic counseling provided. As a proof of principle, this integrated genetic evaluation pipeline revealed a novel hemizygous*TLR7* nonsense variant that deletes the last 24 amino acids in two adolescent brothers who both endured critical COVID-19 pneumonia, requiring mechanical ventilation and extracorporeal membrane oxygenation. *In vitro* functional studies demonstrate that this nonsense variant affects protein function. Our protocol is therefore poised to greatly enrich clinical genetics resources available in the MHS for IEI patients, contributing to better diagnosis rates, informed family counseling, and targeted treatments that collectively improve the health and readiness of the military community. Moreover, our efforts should yield new mechanistic insights on immune pathogenesis for a broad variety of known and novel IEIs.

Trousseau, Paris, France, [20]Washington Univ. in St. Louis, Saint Louis, MO

Valosin-containing protein (VCP) is an AAA+ ATPase that plays critical roles in multiple ubiquitin-dependent cellular processes. Dominant pathogenic variants in *VCP* are associated with adult-onset multisystem proteinopathy (MSP) that presents with myopathy, bone disease, dementia, and/or motor neuron disease. Through GeneMatcher, we identified 13 unrelated individuals who carry novel heterozygous *VCP* variants (12 *de novo*, 1 inherited) associated with a childhood-onset disorder characterized by developmental delay, intellectual disability, hypotonia, and macrocephaly. Trio exome sequencing or multigene panel identified nine missense variants, two in-frame deletions, one frameshift, and one splicing variant. We performed *in vitro* functional studies and *in silico* modelling to investigate the impact of these variants on protein function. In contrast to MSP variants, most missense variants had decreased ATPase activity, and one caused hyperactivation. Other variants were predicted to cause haploinsufficiency, suggesting a loss-of-function mechanism. This is the first description of *VCP*-related neurodevelopmental disease presenting in childhood.

Session Title: Mendelian Phenotypes Poster Session II

PB4600 A Novel Compound Heterozygous Variant in ATAD3A Associated with Neurodegeneration, Mitochondrial DNA Depletion and Epilepsia Partialis Continua

Authors:

M. Muriello, N. D. Patel, N. Mehta, T. Gonzalez, C. Kielczewski, K. L. Jones; Med. Coll. of Wisconsin, Milwaukee, WI

Progressive neurodegenerative disorders are one of the most urgent situations faced by clinical geneticists. While the optimal diagnostic approach is not always clear, evidence is amassing for exome or genome analysis to become the standard of care. Here we present a 3-year-old girl with a history of congenital cataracts, hypotonia, and global developmental delay with a severe neurologic course. Initial genetic evaluation at age 14 months included exome sequencing with copy-number-variant evaluation that was non-diagnostic, and further evaluation was deferred due to adequate developmental progress. At age 3 years she developed left arm jerking and was found to have epilepsia partialis continua (EPC). Brain MRI showed mild cerebellar encephalomalacia. Due to the new clinical concern, exome reanalysis was ordered. While this was pending, the family noted regression of skills with worsening tone, abnormal movements, and loss of self-care skills. She was admitted and found to have choreoathetosis and ataxia and was in refractory status epilepticus that required multiple attempts at burst-suppression. Brain MRI spectroscopy demonstrated interval volume loss, and a small lactate peak in the putamen. Biochemical testing was non-diagnostic, including global metabolomics of plasma and urine. After preliminary exome reanalysis results were non-diagnostic, both rapid whole genome sequencing (rWGS) and a muscle biopsy were performed due to concern for mitochondrial disease, although the EPC and neurodegenerative course were the only red flags at that point. Muscle biopsy found type 2 atrophy and decreased mitochondrial DNA content (45% of control), with negative mtDNA sequencing. rWGS identified biallelic variants in the *ATAD3A* gene; a 35.56 kb deletion which included exons 1-4 and a missense variant c.412C>T, p.Arg138Trp located in exon 4. *ATAD3A* has been associated with a neurodevelopmental disorder, Harel-Yoon syndrome, mainly characterized by developmental delay, congenital cataracts, hypotonia, cerebellar atrophy, and more recently mitochondrial phenotypes. To date, only one patient with *ATAD3A*-related disease has been reported with EPC in the literature. Additionally, we present this patient as the first case with evidence of mtDNA depletion. This patient's diagnostic course demonstrates the utility of rapid genome sequencing, in a patient with negative exome sequencing results, as an earlier result would have saved healthcare costs and improved patient care.

Session Title: Mendelian Phenotypes Poster Session III

PB4601 A novel deep intronic *PHEX* variant associated with X-linked hypophosphatemia in a two-generation Finnish family

Authors:

L. Koljonen[1,2], M. Pekkinen[3,2,4], M. Muurinen[1,2,4], S. Rusanen[2], S. Hussain[1], P. Nevalainen[5], O. Mäkitie[1,2,4,6]; [1]Univ. of Helsinki, Helsinki, Finland, [2]Folkhälsan Res. Ctr., Helsinki, Finland, [3]Univ. of Helsinki, University of Helsinki, Finland, [4]Children's Hosp., Helsinki, Finland, [5]Tampere Univ. Hosp., Tampere, Finland, [6]Dept. of Molecular Med. and Surgery, Karolinska Inst.t, and Clinical Genetics, Stockholm, Sweden

Hypophosphatemic rickets is a rare bone disease characterized by short stature, bone abnormalities, and dental problems. Several genetic forms have been recognized, presenting with hypophosphatemia and hyperphosphaturia that can be dependent or independent of excessive FGF23. Most commonly, hypophosphatemic rickets is due to pathological variants in the X-chromosomal *PHEX* gene, but also autosomal dominant and autosomal recessive forms exist. We investigated a Finnish family in which the son (index, 29 years) and mother (57 years) had hypophosphatemia since childhood. Both had low plasma phosphate (index: 0.56 mmol/L; reference:0.71-1.53 mmol/L), high FGF23 considering hypophosphatemia (index:107 kRU/L, reference:26-110 kRU/L), and high hemoglobin (index:202 g/L; reference:134-167 g/L). Moreover, both had short stature (162 cm and 145 cm, respectively) and curvature of the legs. The index also had dental abscesses and a pathological femur fracture with delayed healing. Both subjects were treated according to conventional XLH protocols. To determine the genetic cause, a gene panel for hypophosphatemic rickets (*OCRL, ALPL, CLCN5, CYP27B1, CYP2R1, DMP1, ENPP1, FAH, FGF23, KL, PHEX, SLC34A1, SLC34A3*, and *VDR*) was performed in two commercial laboratories (Blueprint Genetics, Finland and Center for Genomics and Transcriptomics, Germany). No pathogenic variants were detected. Molecular karyotyping analysis was also normal. No pathogenic copy number variants were found in known disease genes. Whole exome sequencing identified a rare heterozygous missense variant (NM_002646: c.875G>A, p.Arg292His) in the *PIK3C2B* in both affected individuals. Since the gene had not previously been associated with phosphate metabolism, we next performed whole genome sequencing. It revealed a novel deep intronic *PHEX* variant (NM_000444: c.2147+1197A>G) in both subjects. With the current evidence, the variant is classified as a variant of uncertain significance by ACMG classification. According to predictions by SpliceAI and NetGene2, this intronic *PHEX* variant affects splicing. The variant was also predicted to be disease coding by MutationTaster. The effects of the variant on splicing will be evaluated by RT-PCR and sequencing. Based on the clinical characteristics and genetic findings, it is likely that the patients have *PHEX*-mediated X-linked hypophosphatemia. Our findings emphasize the importance of considering intronic variants in XLH pathogenesis.

PB4602 A novel FAM92A gene variant further confirms its association with non-syndromic postaxial polydactyly type A9

Authors:

M. Umair, M. Alfadhel; KAIMRC, Riyadh, Saudi Arabia

A novel *FAM92A* gene variant further confirms its association with non-syndromic postaxial polydactyly type A9

ABSTRACT Background: Polydactyly is a very common digit anomaly, having extra digits in hands and/or toes. Non-syndromic polydactyly is caused by disease-causing mutations in several genes, including *GLI3*, *ZNF141*, *IQCE*, *GLI1*, *FAM92A*, *STKLD1*, *KIAA0825*, *MIPOL1*, *DACH1*, and *PITX1*. It can be inherited as an autosomal dominant or autosomal recessive disorder. **Methods:** Whole-exome sequencing (WES) was conducted for the single affected member (II-1) to reveal the disease causative variant/gene. Segregation was performed using bi-directional Sanger sequencing. Homology protein modeling was carried out to determine the effect of mutation on the protein structure, and advanced microscopy imaging approaches were used to reveal the localization of the FAM92A protein at the base of primary cilia. **Results:** A novel homozygous missense variant (p.Ala158Pro) was identified in exon 6 of *the FAM92A* gene. The variant segregated perfectly with the disease phenotype using Sanger sequencing. Furthermore, Insilco analysis revealed that the variant significantly changes the protein secondary structure, which might result in improper or loss-of-function of FAM92A protein. Moreover, siRNA-mediated depletion of FAM92 showed a key role of Fam92 in ciliogenesis and cilia function. **Conclusions:** We report the second disease-causing mutation with further phenotypes in the *FAM92A*, causing autosomal recessive non-syndromic PAPA type 9. This confirms the contribution of *FAM92A* in limb development and patterning.

System, Nagoya, Japan

Ectopia lentis (EL) is the dislocation or displacement of the eye lens, and cases with no phenotype in organs other than the eyes are termed isolated EL (IEL). EL can occur after trauma or as part of a systemic manifestation of pseudoexfoliation syndrome or as the result of a genetic disorder. *FBN1* gene mutations, known to cause a variety of EL-related systemic diseases such as Marfan syndrome (MFS) and Weill-Marchesani syndrome, have also been reported as a cause of familial IEL. Mutations in *FBN1* cause a range of clinical phenotypes, but the genotype-phenotype relationships underlying these effects remain unclarified. In this study, we performed a genetic study for a Japanese three-generation family of IEL. A whole-exome sequencing on trio, including an affected mother-daughter pair identified no coding variants of genes previously associated with hereditary lens luxation. By contrast, we found a novel intronic variant within intron 11 of *FBN1* that was shared by the two affected individuals. The SNV, c.1327+3A>C was predicted to have high deleteriousness, with a Combined Annotation-Dependent Depletion (CADD) score of 26.1, and to influence the function of the splicing donor, with a delta score of 0.93 for donor loss in SpliceAI. We next recruited two additional affected relatives and confirmed that they also had the variant. In RT-PCR of mRNAs from peripheral blood mononuclear cells, aberrant transcripts lacking exon 11 of *FBN1* were observed in all four affected individuals. Skipping of exon 11 were also observed in transcripts from *FBN1* minigene models corresponding to either the c.1327+3A>C or c.1327+1G>A, which is a variant previously identified variant in two unrelated EL families without MFS manifestations. The exon 11 encodes 60 amino acids, which correspond to the proline-rich region of FBN1 protein and skipping of this exon may results in an in-frame deletion. These results strongly support to consider c.1327+3A>C of FBN1 as the cause of IEL in this family. Further elucidation of the impact of the deletion of the proline-rich region on FBN1 function is expected to provide insights into the pathogenesis of EL in this family as well as genotype-phenotype correlations of *FBN1*-related diseases.

Hosp. Huddinge, Stockholm, Sweden, [4]Dept. of Neurobiology, Div. for Neurogeriatrics, Ctr. for Alzheimer Res., Care Sci. and Society, Karolinska Inst., Stockholm, Sweden, [5]Dept. of Pediatrics, County Hosp., Kalmar, Sweden, [6]Dept. of Clinical Genetics, Karolinska Univ. Hosp., Stockholm, Sweden, [7]Dept. of Lab. Med., Inst. of Biomedicine, Univ. of Gothenburg, Gothenburg, Sweden, [8]Dept. of Clinical Genetics and Genomics, Sahlgrenska Univ. Hosp., Gothenburg, Sweden

Background: *FLCN*, the disease-causing gene for autosomal dominant Birt-Hogg-Dubé syndrome, encodes a protein with multiple cellular roles, including the regulation of early embryonic development and metabolic modulation through the mTORC1 pathway and transcription factors TFE3/TFEB. Recently, an interactor of FLCN, *FNIP1* has been associated with an autosomal recessive immunodeficiency and cardiomyopathy syndrome, while mosaic variants in *TFE3* lead to a disorder characterized by intellectual disability and growth retardation. Here we present a 14-year-old boy with intellectual disability, short stature, coarse facial features, and immunodeficiency, who developed acute lymphoblastic leukemia at 1 year of age. In the patient, we detected a germline homozygous *FLCN* variant and aimed to characterize the genetic and molecular mechanisms leading to this novel syndrome. **Methods:** We carried out 30X Whole Genome Sequencing (WGS), Sanger sequencing, and flow cytometry from blood samples to confirm the variant's inheritance and evaluate the patient's immunological parameters. Additionally, to investigate the effect of the variant in FLCN-mediated metabolic modulation, we used droplet-digital PCR (ddPCR), western blot (WB) and immunofluorescence (IF) staining on skin fibroblasts. **Results:** WGS analysis in the patient identified a homozygous ultra-rare, and likely damaging missense variant in *FLCN* (p.G15S). The variant was validated by Sanger sequencing, which showed parental inheritance. Flow cytometry results confirmed hypogammaglobinemia (IgM, IgG), and low B- and NK-cells' counts. We did not observe changes in the activation of the mTORC1 pathway in patient's fibroblasts. However, IF staining revealed a significant increase in TFE3 nuclear translocation in the patient, resulting in the transcriptional activation of genes related with mitochondrial biogenesis, glycolysis, lysosomal biogenesis, and nucleic acid metabolism, as previously observed in *FLCN*-deficient animal models. **Conclusion:** Our results suggest that homozygous *FLCN* p.G15S affects TFE3-mediated transcriptional activation of genes involved in cell metabolism. We hypothesize that the variant is hypomorphic, leading to a novel autosomal recessive *FLCN*-related syndrome, characterized by leukemia predisposition, immunodeficiency, and intellectual disability. Interestingly, the phenotype in this syndrome overlaps with *FLCN*-deficient animal models, mosaic *TFE3* intellectual disability syndrome, and autosomal recessive *FNIP1* immunodeficiency.

PB4605 A novel hemizygous variant in *FGD1* in a male patient with X-linked Aarskog-Scott syndrome.

Authors:

I. Showpnil[1], S. Ramadesikan[1], M. Marhabaie[1], A. Daley[1], M. Pastore[2], J. Hunter[1], K. McBride[2,3,4], K. Truxal[2,3], D. Koboldt[1,3], R. Wilson[1,3], R. Stottmann[1,3]; [1]The Steve and Cindy Rasmussen Inst. for Genomic Med., Nationwide Children's Hosp., Columbus, OH, [2]Div. of Genetic and Genomic Med., Nationwide Children's Hosp., Columbus, OH, [3]Dept. of Pediatrics, The Ohio State Univ. Coll. of Med., Columbus, OH, [4]Univ. of Calgary, Calgary, AB, Canada

Craniofacial anomalies are common congenital malformations that can occur as part of a syndromic condition or in isolation. Next-generation sequencing methodologies paired with basic research studies using animal models offer a powerful interdisciplinary approach to identify new genetic causes of craniofacial conditions. In this study, we describe a 6-year-old male who was small for gestational age and presented with short stature (<1 percentile), dysmorphic features that included cleft lip/palate, growth and developmental delays, gastroesophageal reflux disease, chronic otitis media, and eustachian tube dysfunction. Trio whole genome sequencing of the proband and his unaffected parents revealed a maternally inherited hemizygous variant in faciogenital dysplasia 1 (*FGD1*) (c.2581G>T: p.Asp861Tyr).

FGD1 encodes a guanine nucleotide exchange factor that specifically binds and activates the GTPase CDC42 by catalyzing the exchange of inactive GDP for active GTP. This leads to activation of signaling pathways that are critical for development. Pathogenic variants in *FGD1* are associated with Aarskog-Scott syndrome (MIM #305400), an X-linked recessive disorder characterized by short stature, dysmorphic facies, cleft lip/palate, shawl scrotum, and brachydactyly. The disorder exhibits wide phenotypic variability, even within families. The variant identified in our patient is absent from public databases and maps to the first nucleotide of exon 18 causing a missense change at an evolutionarily conserved residue (p.Asp861Tyr). This change is predicted to be damaging by 15 out of 17 in silico pathogenicity prediction tools and has a CADD score of 33.0. Gene constraint metrics show that the *FGD1* transcript is highly intolerant to both missense (Z=3.52) and loss of function (pLI=1.0) variants (gnomAD). In retrospect, our patient exhibits many of the classical features of Aarskog-Scott syndrome, which was considered in the clinical differential.

Pathogenic *FGD1* variants were recently identified in patients with Robinow syndrome (MIM#180700). In fact, the same study showed a high degree of phenotypic similarity between Aarskog-Scott and Robinow Syndromes, suggesting that FGD1 may play a role in the non-canonical WNT/ planar cell polarity signaling pathway, perturbations of which are associated with Robinow syndrome. Our finding therefore provides a long-sought molecular diagnosis for this patient and adds to this expanding phenotypic spectrum of *FGD1* associated anomalies.

PB4606 A novel likely pathogenic *FBN1* variant c.2686T>A, p.(Cys896Ser) associated with Marfan syndrome.

Authors:

M. Ben Amor; CHUDUMONT, Dieppe, NB, Canada

Background. Fibrillin-1 (FBN1) is a major structural component of the extracellular matrix, providing strength and stability to tissues. Pathogenic variants lead to the development of *FBN1*-associated syndromes which comprise a broad host of phenotypes, and more commonly, Marfan syndrome (MFS). MFS is typically diagnosed in patients presenting with ectopia lentis, thoracic or aortic disease, and skeletal features, which may prompt genetic testing. A 21-year-old Caucasian female was evaluated at the New Brunswick medical genetics clinic upon referral from an ophthalmologist regarding ocular anomalies. More specifically, bilateral superior ectopia lentis for which the patient was treated with lensectomy. **Objective**. The objective was to identify the genetic underpinning for the clinical presentation as well as the mode of inheritance. **Methods**. Blood samples were collected from the family with written informed consent. DNA extraction, next generation sequencing, and data analysis were performed in a targeted panel to identify the causal gene and mode of inheritance. **Results**. Herein, we describe the reclassification of a newly identified heterozygous *FBN1* variant, c.2686T>A, p.(Cys896Ser), to likely-pathogenic in a female patient presenting with abnormal superior bilateral ectopia lentis, and mild thoracolumbar scoliosis. Identification of this variant led to cascade testing in the patient's 49-year-old mother. The latter has a history of isolated congenital ectopia lentis and was found to be a carrier of the same *FBN1* variant, thus prompting standard treatment and management as MFS which identified an aortic dilatation. The segregation of the phenotype in both patient and mother, the family member testing, the abnormal aorta in the mother, the variant's absence in control populations, and all in silico tools predicting pathogenicity led to the reclassification of this *FBN1* variant to likely-pathogenic. **Discussion**. The reclassification will contribute to timely actionable interventions earlier in the natural history of MFS and other *FBN1*-associated syndromes.

PB4607 A novel missense variant in *CLPP* gene causing Perrault syndrome in a large Sudanese family

Authors:

A. Babai[1], L. Elsayed[2], I. Mohammed[3], A. Hamed[3], M. Elseed[1]; [1]Univ. of Khartoum, Khartoum, Sudan, [2]Princess Nourah bint Abdulrahman Univ., Riyadh, Saudi Arabia, [3]Faculty of Med., Univ. of Khartoum, Khartoum, Sudan

Perrault syndrome is a rare autosomal recessive condition characterised by sensory neural hearing loss, ovarian dysfunction and neurological features like cerebellar ataxia, sensory motor neuropathy and learning difficulty.
In this study, we report a family with five siblings (four boys and one girl) from a large consanguineous Sudanese family. All of the five siblings presented with sensory neural hearing loss, ataxia, spasticity and learning disability, all within variable stages of severity. The brain MRI showed features of white matter demyelinating changes and brain atrophy. We used whole exome sequencing to investigate the underlying culprit genetic cause of their condition. We were able to identify a novel homozygous missense variant in *CLPP* gene (c.1634C>T) which is predicted to be pathogenic following the ACMG classification and using in silico bioinformatics tools and confirmatory family segregation studies.
This is the first Sudanese family to be diagnosed with Perrault syndrome. We were able to add to the clinical phenotype spectrum of this rare condition and enrich the genetic pool for the involved genetic variants. Our case report also highlights the importance of exploring the African population genomics to reach a better understanding of the rare monogenic neurogenetic diseases.

Session Title: Mendelian Phenotypes Poster Session I

PB4608 A novel SHANK3 missense mutation in a child with autism spectrum disorder, motor delay, and hypotonia.

Authors:

P. Gordon[1], S. R. Katz[2], B. Smith-Packard[1]; [1]Penn State Hlth.Children's Hosp., Hershey, PA, [2]Dept. of Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Deficiency of the neuronal synapse scaffolding protein *SHANK3* has been implicated in neurodevelopmental disorders including autism spectrum disorder and *SHANK3*-related Phelan-McDermid spectrum disorder (OMIM #606232). Although the majority of cases of Phelan-McDermid Syndrome involve deletions of all or part of *SHANK3*, other pathogenic variants within *SHANK3* have been found to cause both Phelan-McDermid Syndrome and autism spectrum disorder. We report the case of a 4.5-year-old phenotypic female with autism spectrum disorder, generalized hypotonia, and motor-specific developmental delay. Genetic testing utilizing the GeneDX Autism/ID Xpanded panel revealed a heterozygous single nucleotide change of c.5170 G>A in the *SHANK3* gene (NM_033517.1). This change causes a missense mutation in the *SHANK3* gene product of an Ala1799Thr substitution in the sterile alpha motif (SAM) domain of the *SHANK3* protein, a region reportedly critical for *SHANK3* polymerization and localization to the postsynaptic density. Thus, in silico analyses of the patient's mutation understandably predict disruption of the protein function and likely pathogenicity. Although the patient shares some features with Phelan-McDermid Syndrome, including autism spectrum disorder, hypotonia, motor delays, and motor planning deficits, she does not have the expected most striking features of absent to severely delayed speech and moderate to profound intellectual disability. She has no signs of intellectual disability and exhibits above-average for age expressive language skills. This case serves to further our understanding of the spectrum of expression of pathogenic *SHANK3* mutations, particularly point mutations not predicted to cause protein truncation, and contributes to our understanding of the range of presentation and phenotypic variability for this rare disorder.

Hosp., the Thai Red Cross Society, Bangkok, Thailand, [8]Hôpital du District de la Commune IV, Bamako, Mali, [9]Yale Univ., Pediatric Genomics Discovery Program, Dept. of Pediatrics, New Haven, CT, [10]Neurogenetics Branch, NINDS, NIH, Bethesda, MD, [11]Natl. Human Genome Res. Inst., NIH, Bethesda, MD

Introduction: Benign adult familial myoclonus epilepsy (BAFME), also known by numerous other names including autosomal dominant cortical myoclonus and epilepsy (ADCME), familial adult myoclonic epilepsy (FAME), and familial cortical myoclonic tremor with epilepsy (FCMTE), is an autosomal dominant disorder characterized by cortical tremors, myoclonus, and infrequent seizures, which progress slowly. Six types of BAFME, all caused by pentanucleotide repeat expansions, have been previously reported. However, their pathomechanism remains unclear. Here, we report a large Malian family with 10 members affected by BAFME with a novel pattern of repeat expansion and insertion.
Aim: To characterize both clinically and genetically a large Malian family with late-onset myoclonic tremor.
Methods: 27 individuals from a large Bambara family were enrolled in our protocol after giving full and informed consent. In addition to a thorough neurological examination, some laboratory works have been performed in available patients including brain imaging, blood chemistry, EEG and Nerve Conduction Study (NCS) in two siblings with neuropathic features. For genetic testing, genomic DNA and RNA were extracted for Long-read sequencing (LRS) and Expression studies. Whole genome sequencing using PacBio's long-read HIFI technique was performed in the 10 affected individuals. In addition, 200 ethnically matched samples were used as controls.
Result: In total,10 individuals were found to have symptoms consistent with BAFME. In addition, two sisters from consanguineous parents also had clinical and electrical features of peripheral Neuropathy. LRS identified TTTTA repeat expansions and TTTCA repeat insertions in intron 4 of the *RAI1* gene that co-segregated with the disease status. The two siblings with neuropathy had a homozygous single nucleotide substitution (c.1A>G) in *PEX10*, leading to initiator codon loss (p.Met1?).
Conclusion: We established a new type of BAFME, BAFME8, in the first African family. Interestingly, this is the only BAFME type where the repeats are in a gene previously associated with a single gene disorder, Smith-Magenis syndrome, which is caused by RAI1 haploinsufficiency. Moreover, Biallelic pathogenic variants in *PEX10* are known to cause the peroxisome biogenesis disorders, suggesting that further studies might be needed in the branch of the family with Neuropathic features.

Session Title: Mendelian Phenotypes Poster Session III

PB4610 A patient with *ATOH7* variants with Delayed Sleep-Wake Phase Disorder and Optic Nerve Hypoplasia.

Authors:

A. Kaden, J. Brzezynski, C. Johnson, A. Goldberg, C. Miller, S. Smieszek, C. Xiao, C. Polymeropoulos, G. Birznieks, M. Polymeropoulos; Vanda Pharmaceuticals Inc., Washington, DC

We are conducting a double-blind, randomized study to evaluate the effects of tasimelteon versus placebo in Delayed Sleep-Wake Phase Disorder (DSWPD) patients with extensive clinical phenotyping. We report our first completed patient from the 11-month Open-Label Extension (OLE), who has a history of Optic Nerve Hypoplasia (ONH). The study consists of screening and treatment phases, followed by an OLE to explore the long-term safety and efficacy of daily dosing with tasimelteon over 11 months. During the OLE, patients answer daily sleep diaries and are instructed to take one dose of tasimelteon 1 hour before their desired bedtime. Patients determine their desired bedtime as the time they would need to go to bed the night before a commitment in order to feel fully rested in the morning. As this study is currently ongoing, conclusions cannot be made about the blinded treatment phase. We present a case of a 24-year-old female diagnosed with DSWPD and ONH, with a confirmed delayed Dim Light Melatonin Onset, who reports the inability to fall asleep at their desired bedtime and the ability to have a full night's sleep when not required to be up at a specific time for societal requirements. After completing the blinded treatment phase of the study, they opted into the OLE. The patient's average sleep onset was 01:27 during screening and 00:42 during the OLE, an improvement of 45 minutes. At screening, the patient reported their symptoms as moderate on the Patient Global Impression of Severity (PGI-S). On average during the OLE, the patient reported their symptoms as mild on the PGI-S and as much improved on the Patient Global Impression of Change. The patient reported a history of ONH, which could indicate lack of proper optic response to light. Abnormal rest-activity rhythmicity patterns are present in 30% of children with ONH. Further research is necessary to characterize the relationship between light response and sleep in this individual. This patient carries two variants in the Atonal BHLH Transcription Factor 7 (*ATOH7*) gene, rs61854782 and rs7916697, known to be associated with ONH. They have a variable number of tandem repeat (VNTR) $PER3^{5/5}$ genotype, associated with normal sleep patterns, and no identified predicted loss-of-function mutations within other circadian genes. This case illustrates the general positive effect of tasimelteon on a patient diagnosed with DSWPD, based on an earlier sleep onset shift and overall improvement in PGI-S responses during OLE compared to screening. It also provides the opportunity for research into ONH and genetics, as well as the relationship with DSWPD and potentially sighted Non-24-Hour Sleep-Wake Disorder.

Session Title: Mendelian Phenotypes Poster Session I

PB4611 † A phenome-wide association study of methylated GC-rich repeats identifies a GCC repeat expansion in *AFF3* as a significant cause of intellectual disability.

Authors:

B. Jadhav[1], P. Garg[1], J. J. F. A. van Vugt[2], K. Ibanez[3], D. Gagliardi[4], W. Lee[1], A. Martin Trujillo[1], M. Barbosa[1], M. Jain[5], H. Houlden[6], B. Paten[5], Genomics England Research Consortium, Project MinE ALS Sequencing Consortium, J. Veldink[2], A. Tucci[3], A. Sharp[1]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY, [2]Utrecht Univ., Utrecht, Netherlands, [3]Queen Mary Univ. of London, London, United Kingdom, [4]Queen Mary Univ. of London, Univ. Coll. London, London, United Kingdom, [5]Univ. of California, Santa Cruz, CA, [6]Univ. Coll. London, London, United Kingdom

GC-rich tandem repeat expansions (TREs) are often associated with DNA hypermethylation, gene silencing and folate-sensitive fragile sites and underlie several congenital and late-onset disorders, including fragile X and ALS. Through a combination of DNA methylation profiling, TR genotyping and long read sequencing, we identified 24 loci where GC-rich TREs cause local DNA hypermethylation. We hypothesized that these TREs represent strong candidates for human disease. To investigate this, we generated TR genotypes and performed phenome-wide association studies in 168,641 individuals from the UK Biobank, identifying 156 significant TRE:trait associations (10% FDR) involving 17 different TREs. In line with its causal role in ALS, all of the traits associated with *C9orf72* expansions were consistent with the known symptoms and treatments of ALS, such as reduced brain volume, increased incidences of dysphagia, neuroticism, brain imaging studies and death attributed to motor neuron disease. However, we also identified 16 other TREs that showed significant associations with diverse phenotypes, including blood cell traits, alcohol consumption, altered microstructure of brain white matter and reductions in cerebellar volume, lung function, height, and overall health. Notably, a GCC repeat expansion in the promoter of *AFF3* was linked with a 2.4-fold reduced probability of completing secondary education ($p=9.4x10^{-11}$), an effect size comparable to several recurrent microdeletion disorders. Given its strong negative influence on educational attainment, we hypothesized that TREs of *AFF3* might represent the pathogenic mutation in some patients with neurodevelopmental disorders. In support of this, in a cohort of 6,371 probands with neurodevelopmental problems of unknown etiology from the 100,000 Genomes Project, we observed a significant enrichment (p=0.002) for expanded *AFF3* alleles compared to controls. With an estimated population prevalence of ~1 per 850, which is 5- to 10-fold higher than the TRE that causes fragile X syndrome and 3- to 8-fold higher than recurrent microdeletions of 1q21.1, 15q13.3 and 16p11.2, *AFF3* expansions therefore represent a common and clinically relevant cause of intellectual disability. Finally, we identified SNVs located within the *AFF3* locus that associate with presence of the TRE and observed that many of these are the same SNVs at the *AFF3* locus that have been reported in prior GWAS for educational attainment. Our observations therefore indicate that a subset of GWAS signals in the genome are likely driven by underlying TREs that preferentially occur on specific founder haplotypes.

Session Title: Mendelian Phenotypes Poster Session II

PB4612 A proposal of mechanism of non-syndromic deafness associated with a novel *BCAP31* variant: mitochondrial dysfunction and high sensitivity to cisplatin

Authors:

B. Kim[1], Y. Kim[2], Y. Kim[3], S-H. Yu[3], J. Han[2], M. Kim[2], L. Seoeun[3], Y. Kang[3], C-H. Kim[3], B. Choi[2]; [1]Chungnam Natl. Univ. Coll. of Med., Sejong, Korea, Republic of, [2]Seoul Natl. Univ. Bundang Hosp., Seongnam, Korea, Republic of, [3]Paean Biotechnology, Seoul, Korea, Republic of

B-cell receptor-associated protein 31 (BAP31 or BCAP31) is an integral ER membrane protein, which involves the transport and quality control of transmembrane proteins. BCAP31 is also important for the cross-talk of apoptotic signals between the ER and mitochondria. Due to its critical role in cellular physiology, the BCAP31 dysfunction has been associated with numerous human diseases including deafness, dystonia, and central hypomyelination (DDCH) syndrome, cancer, metabolic syndrome, cystic fibrosis, and neurodegenerative diseases. Recently, we have found a novel in-frame insertion variant in the *BCAP31* gene from a family segregating only non-syndromic hearing loss in an X-linked, recessive fashion. It is not known how this variant contributes to the hearing loss, which is an important issue to understand the molecular pathogenesis. To address it, we compared the mitochondrial function between the patient-derived lymphoblastoid cell lines (LCLs) and normal LCLs. The patient-derived LCLs showed the elevation in ROS, and the decrease in ATP and membrane potential intracellularly compared to normal LCLs. Surprisingly, the administration of mitochondria (PN-101) isolated from umbilical cord mesenchymal stem cells (UC-MSC) was able to rescue the mitochondrial dysfunction in the patient-derived LCLs. Furthermore, patient-derived LCLs demonstrated more pronounced cisplatin-induced cell death than did normal LCLs by confirming the increase in the expression of pro-apoptotic genes. Taken together, the novel *BCAP31* variant may contribute to the pathogenesis of the impaired hearing due to the mitochondrial dysfunction.

Session Title: Mendelian Phenotypes Poster Session III

PB4613 A rare form of myopathy, with extrapyramidal signs, in a 14-year-old female: case report.

Authors:

S. Ahmed[1], J. Black[2], R. Lebel[2], N. Dosa[2], K. Scott[3]; [1]Dept. of Pediatrics, SUNY Upstate Med. Univ., Syracuse, NY, [2]Ctr. for Dev., Behavior and Genetics, SUNY Upstate Med. Univ., Syracuse, NY, [3]Dept. of Pediatric Hematology/Oncology, SUNY Upstate Med. Univ., Syracuse, NY

Myopathy with extrapyramidal signs (MPXPS) is a disorder characterized by developmental delay (motor and speech) and learning disability, which varies in severity. It is characterized by early childhood onset of non-progressive proximal muscle weakness. Laboratory findings include a significantly elevated CK level, elevated transaminases, and myopathic features on muscle biopsy. Most patients develop extrapyramidal signs which include chorea, tremor, dystonic posturing, and orofacial dyskinesia. These signs are often progressive, and combined with muscle weakness may result in disabling immobility. Other features may include ataxia, ophthalmoplegia, optic atrophy, peripheral axonal neuropathy, ptosis, and seizures. Less frequently reported features include poor growth/short stature, ichthyosis, atopic dermatitis, hepatomegaly, ventricular septal defect, amblyopia, sleep disorder, and hemolytic anemia. This disorder is caused by pathogenic variants in the *MICU1* gene (OMIM #605084), following an autosomal recessive pattern. To our knowledge, there are 30 cases in the literature, many associated with consanguineous parentage.

We report a 14-year-old female born by vaginal delivery at 38 weeks gestation to a 32-year-old primigravid European mother, and father of unknown age. Union is not known to be consanguineous. This patient presented in adolescence with developmental and intellectual disability, speech apraxia, dysmenorrhea, dysphagia, symptomatic erythrocytosis, atopic dermatitis, spasticity, dystonia, and dysmorphic features. She was diagnosed with MPXPS when whole exome sequencing revealed compound heterozygous pathogenic variants in the *MICU1* gene, likely in trans: c.161+1G>A, maternally inherited, and c.386G>C(p.R129P), of uncertain origin (since father did not participate).

The literature reports one other female with this exact genotype, who presented at age 12 with developmental delay, myopathy, ataxia, amblyopia, hyperreflexia, clonus, seizures, and dysmorphic features. Given the rarity of this condition, and the fact that there is another patient with an identical genotype reported, we offer this patient's unique feature (erythrocytosis), as an extension of the phenotypic spectrum.

Session Title: Mendelian Phenotypes Poster Session I

PB4614 A *RING1* contribution to neurogenesis and schizophrenia

Authors:

C. Ryan; Univ. of Michigan, Ann Arbor, MI

Intellectual disability affects 2-3% of the population in industrialized nations, with genetic causes accounting for approximately half of these cases. Whole genome sequencing has led to the discovery of several novel pathogenic variants underlying neurodevelopmental disorders. Among these variants, proteins involved in chromatin post-translational modifications are highly represented. Variants in the polycomb repressive complex 1 (PRC1), the primary catalyst of histone 2A monoubiquitination (H2AUb1), illustrate this trend. RING1 and RNF2 are paralogues that serve as the constituent E3 ubiquitin ligase of PRC1, and missense variants in these genes that blunt H2AUb1 catalysis are associated with a neurodevelopmental disorder characterized by microcephaly, intellectual disability, and early onset schizophrenia. To explore the role of PRC1- dependent H2AUb1 in the context of human corticogenesis, we have generated isogenic human embryonic stem cell (hESC) lines harboring pathogenic variants in *RING1* and subjected them to neural differentiation to generate 3D cerebral organoids. Previous studies suggest that PRC1-dependent H2AUb1 has roles in transcriptional repression and double strand break repair. Consistent with these previous reports, we demonstrate that the $RING1^{G284A/G284A}$ variant diminishes global H2AUb1 levels, leads to increased expression of DNA damage repair genes, and disrupts double strand break repair in neural progenitor cells (NPCs). These defects lead to stalled cell cycle progression due to a prolonged S phase. This work implicates RING1-dependent H2AUb1 in the maintenance of genome integrity during human corticogenesis.

Session Title: Mendelian Phenotypes Poster Session II

PB4615 A study of the natural history of *RARB*-related disorders.

Authors:

V. Chu, A. Tremblay, J. L. Michaud; CHU Sainte-Justine Res. Ctr., Montreal, QC, Canada

Gain-of-function and dominant-negative variants in the Retinoic Acid Receptor Beta (*RARB*) gene cause a syndrome known as MCOPS12 that is characterized by the presence of developmental eye defects, other congenital anomalies, and global developmental delay with dystonia. Although the majority of affected individuals display microphthalmia as well as severe developmental delay and motor impairment, MCOPS12 is variable as cardinal features of the syndrome such as eye anomalies and neurodevelopmental involvement can be absent or minimal in some affected individuals. Moreover, it is not possible to predict at an early stage the clinical course of affected individuals. In order to gain insight into the natural history of MCOPS12, we initiated a prospective study of its course in partnership with patient organizations. Individuals carrying pathogenic or likely pathogenic variants in *RARB* are eligible to participate in the study. In addition to the baseline phenotype of the participants, developmental milestones (Vineland-3, ASQ-3), behavioral profiles (SRS-2, BASC, Sensory Profile 2) and severity of dystonia (Burke-Fahn-Marsden Dystonia Rating Scale, the Hypertonia Assessment Tool scoring chart and the Global Dystonia Severity Rating Scale) are documented on a yearly basis using standardized tools. Caregivers are invited to provide videos of the participants using a standardized protocol for the study of movement disorders. Brain MRI images generated on a clinical basis are also collected. The study framework includes a physician-driven arm and a participant-powered arm, the latter of which involves interviews with the research team to complete some of the assessment tools. For both arms, data are collected via a REDCap-based platform. Consent to participate in the study is also obtained using this platform. We will use *in vitro* transcriptional assays to determine whether novel variants induce gain-of-function or dominant-negative effects. The study is being primed by a series of 43 participants who were previously reported by our group (Srour et al., 2013, Srour et al., 2016, Caron et al., 2023). Patient organisations Cure MCOPS12 and A Cure for Sienna have participated in the development of the study and will provide feedback as it rolls out. As therapeutic options for MCOPS12 are being actively investigated, it is imperative to document the natural history of individuals with this condition. Our study will lead to the establishment of a framework for the development of clinical trials examining MCOPS12.

Session Title: Mendelian Phenotypes Poster Session III

PB4616 A targeted NGS panel with a 20% diagnostic yield in Short Stature reveals the contribution of digenic/oligogenic inheritance in growth disorders disclosing novel potential gene interactions

Authors:

M. Giordano[1], D. Vurchio[1], S. Mellone[2]; [1]Univ. of Eastern Piedmont, Novara, Italy, [2]Ospedale Maggiore della Carità, Novara, Italy

Short stature is one of the most common endocrinological conditions of childhood that occur isolated or in presence of complex phenotypes. To date monogenic causes have been identified in more than 200 mendelian syndromes and skeletal dysplasia. The diagnostic yield of a 106 gene NGS panel was evaluated in a cohort of 302 patients with idiopathic and syndromic short stature. Pathogenic/Likely pathogenic (P/LP) variants were identified in 61 patients representing the 20% of cases. Twenty-nine genes were mutated in at least one patient and 12 genes in more than one, namely *ACAN, KISSIR, GNAS, NF1, SLC26A2, GLI2, PTPN11, GNRHR, SOS, HEXS1, NPR2, COMP*. Interestingly 9 patients carried a VUS in addition to the P/LP variant and three patients carried 2 pathogenic variants suggesting digenic inheritance involving the tested genes. Among these, patient #1006 carried variants in *ACAN* and *FBN1*. From the IPA Ingenuity database, we extracted a predictive indirect gene interaction *ACAN-FBN1* mediated by FN1 a dimeric glycoprotein of the cartilage extracellular matrix. Patient # 2553 carried variants in *SOS1* and *RAF1*, both belonging to the RAS-MAPK pathway. Patient # 1698 carried pathogenic variants in *SHOX* and *COMP* suggestive of interaction between these two chondrogenesis proteins. In conclusion digenic/oligogenic inheritance should be taken into account in deciphering the genetic basis of some forms of short stature, also considering those VUS, that in presence of a P/LP variants are usually underestimated. Besides the relevance for the diagnosis this might lead to highlight novel interactions involved in the complex process of growth.

Session Title: Mendelian Phenotypes Poster Session I

PB4617 A trial of resveratrol therapy in a patient with *CMIP* haploinsufficiency and autism spectrum disorder.

Authors:

C. Hartlage[1], M. K. Diamreyan[1], J. Owens[2], A. Shillington[2]; [1]Univ. of Cincinnati, Cincinnati, OH, [2]Cincinnati Children's Hosp., Cincinnati, OH

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by difficulties with social communication and restricted behaviors. It can be caused by environmental or genetic factors, including the gene *CMIP*. *CMIP* is a scaffolding protein involved in brain development and negative regulation of T cells. Previously reported cases have attributed ASD to *CMIP* loss of function, theorizing a connection to neuroinflammation. Resveratrol, a polyphenol with anti-inflammatory properties, has demonstrated some success as a treatment for ASD symptoms. This report presents a 15-year-old male with ASD and a de-novo *CMIP* variant who showed clinical improvement with resveratrol supplementation.

The patient has a history of ASD, developmental delays, speech and language deficits, generalized anxiety disorder, ADHD, intermittent explosive disorder, constipation, and pancreatitis. He was diagnosed with ASD at age 4. Simultaneous developmental testing assessed his receptive and expressive language to be further delayed than visual perception and fine motor skills. He has a history of recurrent psychiatric admissions due to overactivity and impulsivity with concerns for self-injury. While admitted to inpatient psychiatry at age 12, an ASD-focused gene panel revealed a c.1483G>A (p.Glu495Lys) *CMIP* variant interpreted as contributory. The patient was initiated on resveratrol after his *CMIP* diagnosis at age 13. After 18 months, the patient avoided further admissions and showed improved impulsivity and aggression according to reports from parents. Objective behavioral assessments showed reduced scores compared to before initiation of therapy.

By comparing our patient to reported cases, we demonstrate *CMIP* haploinsufficiency is characterized by ASD, developmental delay, speech and language deficits, hypotonia, gastroesophageal reflux, and feeding intolerance. Our patient’s expressive and receptive language deficits are greater than his gross motor delays; this is supportive of linkage studies that identified *CMIP* SNPs as associated with specific language impairment and general reading ability. Furthermore, the patient responded positively to resveratrol treatment with decreased impulsivity and non-compliant behaviors. While likely multifactorial, we hypothesize that resveratrol's anti-inflammatory properties reduced neuroinflammation, leading to an improvement in ASD and ADHD symptoms. The patient's case helps establish the symptoms associated with *CMIP* haploinsufficiency and demonstrates that resveratrol may help impulsive behaviors in *CMIP*-associated ASD.

Session Title: Mendelian Phenotypes Poster Session II

PB4618 A variant in mitochondrial protein import complex leads to microcephalic osteodysplastic dwarfism with moyamoya disease

Authors:

C. Li[1], P-X. Lin[1], Y-C. Wang[1], L-W. Chen[2], M-H. Shih[3], M-C. Tsai[2], Y-Y. Chou[2], P-C. Chen[1]; [1]Inst. of Clinical Med., Coll. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan, [2]Dept. of Pediatrics, Natl. Cheng Kung Univ. Hosp., Coll. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan, [3]Dept. of Ophthalmology, Natl. Cheng Kung Univ. Hosp., Coll. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan

Mitochondrial diseases caused by impaired mitochondrial import machinery are phenotypically heterogeneous. Through trio-based exome sequencing, we identified a recurrent homozygous missense variant in a small translocase of outer mitochondrial membrane (TOM) in three unrelated probands with microcephaly, short stature, developmental delay, bird-headed faces, atrophic macular scarring, and moyamoya disease. Their parents are all heterozygotes, and the unaffected sibling has the common allele. Translocase of outer mitochondrial membrane that is essential in maintaining proper mitochondrial protein import. We established induced pluripotent cells (iPSCs) with patient-specific variant through CRISPR/Cas9 genome editing and differentiated the iPSCs into endothelial cells to examine the biogenesis of the TOM complex, mitochondrial bioenergetics, quality control, proteomics, and transcriptome. We identified a differential abundance of proteins involved in ATP production, TCA cycle, and gluconeogenesis in homozygous cells. Mitochondrial respiration and ATP production were decreased in homozygous and knock-out cells. Furthermore, transcriptomic studies revealed upregulation of genes involved in glycolysis and hypoxia in homozygous and knockout cells. Finally, CRISPR/Cas9-mediated zebrafish model showed facial dysmorphia, small brain size, and cerebrovascular defects that recapitulated patients' phenotypes. Our results revealed the molecular and cellular mechanisms through which mitochondrial protein import defects lead to a rare autosomal recessive microcephalic osteodysplastic dwarfism with moyamoya disease.

Session Title: Mendelian Phenotypes Poster Session III

PB4619 A Variant in Sperm-Specific Glycolytic Enzyme Enolase 4 *ENO4*Causes Human Male Infertility.

Authors:

S. Nawaz[1], S. Hussain[2], M. Bilal[3], N. Syed[1], W. Ahmad[4], K. Fakhro[5]; [1]Sidra Med., Doha, Qatar, [2]Clinical And Molecular Metabolism Res. Program, Faculty of Med., Univ. of Helsinki, Finland, Helsinki, Finland, [3]Dept. of Pathology and Lab. Med., Agha Khan Univ., Karachi, Pakistan, [4]Dept. of Biochemistry, Doha, Qatar, [5]Sidra Med. and Res. Ctr., Doha, Qatar, Qatar

Though abnormalities in sperm morphology and physiology lead to male infertility, in many instances, the exact disruption of molecular pathways in a given patient is not known. In the present study, we characterize a family with asthenozoospermia and abnormal sperm morphology at clinical and genetic levels. Further, we use computer-assisted semen analysis (CASA), papanicolaou smear staining (Pap smear), and scanning electron microscopy (SEM) to examine sperm motility and morphology. Analysis by whole exome sequencing revealed a homozygous variant [c.293A>G, p.(Lys98Arg)] in the Enolase 4 (*ENO4)* that segregated with infertility in the consanguineous family, shared by affected but not controls. In view of the association of asthenozoospermia and abnormal sperm morphology in *Eno4* knockout mice, we believe this is the first report describing the involvement of *ENO4* gene in human male infertility. We also explore the possible involvement of another variant in explaining other phenotypic features in this family.

Session Title: Mendelian Phenotypes Poster Session I

PB4620 *ABCA1*missense mutations are associated with Lewy body dementia

Authors:

P. Reho[1], A. Ray[1], G. Logroscino[2], S. Barmada[3], O. A. Ross[4], S. W. Scholz[1,5]; [1]Neurodegenerative Diseases Res. Unit, Natl. Inst. of Neurological Disorders and Stroke, Bethesda, MD, [2]Dept. of Basic Med. NeuroSci. and Sense Organs, Univ. of Bari, Bari, Italy, [3]Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI, [4]Dept. of NeuroSci., Mayo Clinic, Jacksonville, FL, [5]Dept. of Neurology, Johns Hopkins Univ. Med. Ctr., Baltimore, MD

Lewy body dementia (LBD) is the second most common dementia after Alzheimer's disease (AD), affecting more than 1.4 million people in the United States. Increasing evidence shows that the genetic architecture of LBD intersects with AD. A recent study identified rare mutations in *ABCA1* and *ATP8B4* genes in Alzheimer's disease patients. Herein, we decided to investigate the association between rare variants in these genes with risk of developing LBD.We studied rare mutations in whole-genome sequence data from a cohort of 2,591 LBD cases and 4,032 controls of European ancestry. All participants have been previously sequenced at 35x coverage on an Illumina 10x platform using PCR-free library preparations. The sequence data were aligned to hg38 and jointly called, followed by stringent sample-level and variant-level quality control checks. We extracted and annotated missense and loss-of-function (LOF) mutations in *ABCA1* (NM_005502.4) and *ATP8B4* (NM_024837.4) genes, setting a minor allele frequency of <0.01 in the reference population. We tested the association of coding mutations with risk for developing LBD by applying the optimized sequence kernel association test (SKAT-O). Single-variant association analysis was performed by Fisher's exact test followed by Bonferroni correction for multiple testing.We identified a significant enrichment of *ABCA1* missense mutations with LBD (SKAT-O p = 2.68E-02), while no associations of *ABCA1* and *ATP8B4* LOF or *ATP8B4* missense mutations were detected. Interestingly, two *ABCA1*missense variants (*c.5398A>C*; p.N1800H and *c.3544G>A*; p.A1182T) showed significant variant-level association with LBD (Fisher p = 1.16E-04, p = 4.29E-02), and the p.N1800H substitution also survived the Bonferroni multiple testing correction (adjusted p = 1.14E-02). Specifically, this substitution was found in twelve LBD patients and one control (odds ratio = 18.48, 95%CI = 2.4-142.8). It is predicted to be pathogenic by the American College of Medical Genetics and has previously been associated with an increased risk for AD. Of note, seven *ABCA1* p.N1800H carriers were pathologically diagnosed cases, among which six patients carried an *APOE* ε4 risk allele and three carried one *GBA* pathogenic mutation (p.N409 or p.S146L). No deleterious mutations in *APP*, *PSEN1*, and *PSEN2* were identified among the *ABCA1* p.N1800H carriers. Our study identifies a significant enrichment of *ABCA1* missense mutations in LBD patients compared to healthy controls, emphasizing the pathogenic role of the p.N1800H substitution and the genomic complexity surrounding LBD.

Session Title: Mendelian Phenotypes Poster Session II

PB4621 ABCC6 three-state structural model enhances functional interpretation of genetic variants.

Authors:

J. Wagenknecht[1], N. Haque[1], S. Jorge[1], B. Ratnasinghe[1], R. Urrutia[1], W. Gahl[2], S. Ziegler[3], M. Zimmermann[1]; [1]Med. Coll. of Wisconsin, Milwaukee, WI, [2]NHGRI (NIH), Bethesda, MD, [3]Johns Hopkins Univ Sch. of Med., Baltimore, MD

Genetic variation within ATP Binding Cassette Subfamily C Member 6 (*ABCC6*) can cause either Pseudoxanthoma Elasticum (PXE) or the more severe condition, Generalized Arterial Calcification of Infancy (GACI). However, the molecular underpinnings are unknown for how variants alter ABCC6 protein function and if those differences contribute to why certain patients develop PXE versus GACI. These two recessive diseases are characterized by calcification of body tissues via hydroxyapatite deposition, yet have drastic differences in phenotype, progression, and prognosis. Furthermore, the same variant in one family can be associated with each condition in different patients. Functional interpretation of genetic variants within the protein is limited without an experimentally solved full-length protein structure. Thus, to better interpret the genetic variation within ABCC6, we used multiple homologous protein structures to generate three structural models that capture the main conformations that ABCC6 takes, i.e., unbound, substrate-bound, and ATP-bound. These models were used in structural calculations of variants from nationwide databases (ClinVar, gnomAD, and HGMD) to analyze 1,215 distinct missense genetic variants. Our use of multiple models is efficient for understanding where each variant acts in the functional mechanism, producing much deeper information than any singular molecular structure. This analysis was performed sequentially and structurally, focusing on the destabilizing effects on each state and the variants' proximity (both sequentially and spatially) to sites of interest (having a motif, post-translational modification, or known functional site). From this, not only were we able to predict a mechanism of damaging effect for 423 of the 991 variants of unknown significance, but we were able to analyze demographic and phenotypic data to look for patterns in inheritance across population groups and biologic sex, along with discovering 3D hotspots for mutations in PXE and GACI, and more. Our results aid in the mechanistic understanding of PXE and GACI and reveal a novel high throughput bioinformatic protein variation analysis method through multi-conformational models informed by functional data.

Session Title: Mendelian Phenotypes Poster Session III

PB4622 Abnormalities of TBX1 result in broad overlapping features of 22q11.2 deletion syndrome

Authors:

D. McDonald-McGinn[1,2,3], V. Giunta[4], T. Crowley[5], D. McGinn[6], B. Emanuel[4], E. Zackai[7], R. Smith[8], E. Moran[9], M. Geremek[10], B. Nowakowska[11]; [1]Children`s Hosp. of Philadelphia, Philadelphia, PA, [2]Perelman Sch. of Med. of the Univ. of Pennsylvania, Philadelphia, PA, [3]Sapienza Univ., Rome, Italy, [4]Children's Hosp. of Philadelphia, Philadelphia, PA, [5]Children s Hosp. of Philadelphia, Philadelphia, PA, [6]Children s Hosp. of Philadelphia and UPenn, Philadelphia, PA, [7]Children S Hosp. of Philadelphia, Philadelphia, PA, [8]Maine Med Partners, Pediatric Specialty Care, Portland, ME, [9]NYU-Hosp Joint Diseases, New York, NY, [10]Inst. of Mother and Child, Warsaw, Poland, [11]Inst Mother & Child, Warsaw, Poland

Background: Tbx1 is a member of the Tbox family of binding domain transcription factors. Mice haploinsufficient for Tbx1 have features associated with 22q11.2 deletion syndrome (22q11.2DS). Tbx1-homozygous null mutant mouse embryos die at birth with cleft palate, absent thymus and parathyroid glands, truncus arteriosus and ventricular septal defects. Despite this association with structural anomalies, and more recently autism, clinicians may be unaware of the importance of considering variants in TBX1, located within the 22q11.2 DiGeorge critical region, as a potential etiology in individuals with overlapping features of 22q11.2DS but without a deletion. Here we report findings in 8 patients with typical features of 22q11.2DS without 22q11.2DS, or another identifiable cause such as diabetic or retinoic acid embryopathy or CHD7 mutations, but with variants in TBX1, providing additional human evidence to support such clinical investigations. **Methods:** We identified 8 patients from 5 families with TBX1 variants under an IRB-approved investigation into 22q11.2DS phenocopies. **Results:** 5 probands, 1 half-sibling, and 2 parents had TBX1 variants (1 nonsense, 1 frameshift, and 1 familial missense mutation, 1 deletion, and 1 familial duplication). 5/8 were female and 5/8 white. Findings included: congenital heart disease (4) including Interrupted Aortic Arch (IAA) (2), tetralogy of Fallot, and vascular ring, significant developmental delay (4), hypocalcemia (2), immunodeficiency (3), FTT (2), lymphedema, and chorioretinal coloboma. The index case with IAA, bicuspid aortic arch, hypocalcemia, thymic hypoplasia, FTT, and GERD, was negative for 22q11.2DS in infancy. She was referred again for 22q11.2 testing at 5 years of age due to her history, as well as velopharyngeal dysfunction, chronic otitis media, obstructive sleep apnea, thrombocytopenia, cervical spine anomalies, winged scapula, hypotonia, developmental and speech delay. This led to investigation of additional patients with 22q11.2DS phenocopies, where the prevalence of associated features in those with TBX1 variants revealed few differences. **Conclusions:** 8 patients with TBX1 variants had overlapping features of 22q11.2DS, adding to a handful of previously reported cases in the literature (Yagi 2003, Zweier 2007, Pan 2015). These findings serve to further confirm the phenotypic overlap between patients with TBX1 variants and 22q11.2DS emphasizing the need to test all patients with 22q11.2DS phenocopies for TBX1 variants immediately when a deletion is not identified in order to provide appropriate medical management, genetic counseling, and to obviate a protracted diagnostic odyssey.

PB4623 Adulthood vs. Childhood Onset MELAS: Clinical insights and prognostic factors explored.

Authors:

H. Bae[1], S. Hwang[1], G-H. Kim[2], J. Yoon[1], D. Kim[1], H. Shin[3], M. Kang[3], I. Choi[4], B. Lee[1,2]; [1]Dept. of Pediatrics, Asan Med. Ctr. Children's Hosp., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, [2]Med. Genetics Ctr., Asan Med. Ctr., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, [3]Asan Inst. for Life Sci., Asan Med. Ctr., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of, [4]Dept. of Genetic Counseling, Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of

Introduction: MELAS (Mitochondrial Encephalopathy, Lactic Acidosis, and Stroke-like episodes) generally presents before age 20. However, MELAS develops in some patients after their twenties. Heteroplasmy, the coexistence of mutated and normal mitochondrial DNA within cells, significantly impacts phenotypic expression. This study aims to explore the clinical and molecular genetic characteristics of MELAS patients. **Method:** The medical records of MELAS patients diagnosed at Asan Medical Center, Seoul, Korea, from January 1998 to May 2023, were reviewed, and compared between childhood-onset and adult-onset MELAS. **Results:** A total of 55 patients from 41 families were enrolled. Fifty-one patients had m.3243 A>G heteroplasmy, 2 patients had m.9957 T>C homoplasmy, 1 patient had m.13513 G>A heteroplasmy, and 1 patient had m.1644 G>A homoplasmy. Eight asymptomatic patients were identified through family testing. Symptomatic patients were divided into two groups based on age of diagnosis: childhood-onset (diagnosed before age 20) and adult-onset. The childhood-onset group exhibited significantly higher mitochondrial heteroplasmy levels compared to the adult-onset group (52.7% [37.4-66.6] vs 29.9% [18.8-36.8], $p<0.001$). The earliest clinical manifestations were different between the two groups: seizures (39.1%), developmental delay (26.1%), and stroke (21.7%) were common in the childhood-onset group, whereas stroke (33.3%), diabetes mellitus (25%), and hearing loss (20.8%) were common in the adult-onset group ($p=0.003$). Median age of death was lower in the childhood-onset group (median, 17.8 [interquartile range, 13.7-27.2] years vs. 41.4 [35.4-53.4] years, $p=0.003$). Poor prognosis was associated with cardiomyopathy, T2/FLAIR hyperintensity on brain MRI, stroke episodes, speech disturbance, gait disturbance, hemiplegia, muscle weakness, short stature at diagnosis, and progression of chronic kidney disease. **Conclusion:** Significant differences were observed in the clinical manifestations and courses between childhood-onset and adult-onset MELAS the young and adult-onset groups of MELAS, associated with heteroplasmy levels. Further study is required to identify other factors contributing to these phenotypic differences.

Session Title: Mendelian Phenotypes Poster Session II

PB4624 † Advancing insights in Xia-Gibbs Syndrome: A universal registry platform for phenotypic analysis and longitudinal patient engagement

Authors:

A. Hansen[1], K. Ward[1], D. Belliston[1], T. R. Greer[1], T. Gerber[2], C. G. Hansen[1], M. Murugan[2], J. Hu[2], R. A. Gibbs[2]; [1]Geneial, Houston, TX, [2]Baylor Coll. of Med., Houston, TX

The pace of discovery of Mendelian disorders and rare diseases has far outweighed the growth of the clinical genetics workforce. Moreover, elucidating the phenotypic spectrum and natural history of these conditions is a labor-intensive process dependent on curation of high-quality phenotypic data. To reduce clinician burden - and to capture a more comprehensive picture including quality of life and social determinants of health - collecting survey data directly from patients or their caregivers is an essential element. Thus, there is a significant need for infrastructure to streamline the process of establishing and managing high-quality registries capable of integrating electronic patient-reported outcomes (ePROs) alongside molecular diagnostic and other clinical data.
To address these needs, we have developed a universal Mendelian disorder registry platform in partnership with the Xia-Gibbs Society that accelerates research and facilitates connectivity with external partners while maintaining data ownership, control, and privacy. We used the platform to rapidly generate an updated variant map for *AHDC1* - the gene underlying Xia-Gibbs Syndrome - and to compare phenotypes of patients joining the registry before 8/9/2021 (publication date of the most recent XGS phenotypic study) (N=94) vs. those joining between 8/9/2021 and 6/7/2023 (N=59). Sixteen HPO-mapped phenotypes were compared against the cohorts, seven of which revealed a statistically significant difference. Notably, all phenotypes with a change in proportion over time were less prevalent in the new cohort, which may suggest more patients are joining the registry with either a milder phenotype or benign *AHDC1* variant over time. For example, delayed speech proportion decreased from 91.49% to 65.52% (p=0.000185, chi-square); motor delay decreased from 90.43% to 63.79% (p=0.000187).
For patients/caregivers, the HIPAA-compliant iOS and Android app currently supports e-Consent and completion of standardized survey data. Through interviews with numerous registry participants and rare disease advocacy group leaders, we have identified an opportunity to return immediate value to participants through expansion of the app to support medical history organization, community connectivity, and dissemination of information. By doing so, we hypothesize that researchers will receive higher quality longitudinal data and an increased ability to reconnect with individuals who opt-in for clinical trial recruitment and other use cases.

Session Title: Mendelian Phenotypes Poster Session III

PB4625 Advancing Tay Sachs Disease Carrier Screening: Insights from Combined Enzyme and Molecular Approaches

Authors:

Q. Sun[1,2], K. V. Schulze[1,2], N. Liu[1,2], L. Meng[1,2], R. Sutton[1,2,3]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Genetics, Houston, TX, [3]Texas Children's Hosp., Houston, TX

Tay Sachs disease carrier screening in a diverse, pan-ethnic population often employs both beta-hexosaminidase A (Hex A) enzyme and *HEXA* gene assays; the DNA assay may be either full-exon or targeted variant sequencing. To assess the efficacy of enzyme carrier testing, we conducted a retrospective analysis of carrier sequencing results from our laboratory database.

A total of 30 cases with positive Hex A enzyme analysis were selected. None of the enzyme activities in these cases were in the indeterminate range. These samples also underwent molecular carrier testing as part of a customizable, comprehensive panel of up to >400 genes, including the *HEXA* gene. While full gene sequencing was performed, the DNA carrier panel reported only selected pathogenic/likely pathogenic or pseudodeficient variants in the *HEXA* gene. Comparative analysis revealed consistent findings in 20 cases, 19 of which were pathogenic/likely pathogenic alleles and 1 pseudodeficient allele in the *HEXA* gene.

Two patients chose a customized carrier panel that initially excluded the HEXA gene. However, on further review in light of the positive enzyme test, both patients were found to carry pathogenic alleles in the *HEXA* gene. Notably, one of these patients was of North European descent. The remaining 8 cases were reported negative for molecular findings in *HEXA.* Nevertheless, further scrutiny of the sequencing results identified several variants of interest. Among these findings, three variants of uncertain significance (VUS) exhibited characteristics suggesting potential pathogenicity: c.1288G>A (p.D430N), c.1061_1063del (p.F354del), and c.590A>C (p.K197T). Another VUS, while likely benign, displayed moderate splicing predictions for an acceptor gain, necessitating further functional studies (c.673-13T>C). No changes were found in the last four cases.

Our results highlight the potential value of including molecular testing for *HEXA* in carrier screening and underscore the impact of novel VUS in Tay Sachs carrier sequencing. Furthermore, we demonstrate that incorporating functional screening of Hex A enzyme facilitates the curation and potential reclassification of VUS, thereby enhancing the sensitivity of Tay Sachs carrier screening. Done in combination, Hex A enzyme and *HEXA* sequencing assays were more effective in identifying true carriers of Tay Sachs disease than either methodology alone.

Session Title: Mendelian Phenotypes Poster Session I

PB4626 Altered lipid storage and metabolism in Smith-Magenis syndrome:*Rai1*haploinsufficiency causes increased storage of cholesterol esters, diacylglycerols, and triacylglycerols in a mouse model of SMS.

Authors:

J. Hauck[1], M. Sun[1,2], S. Hari[1], T. A. Wilson[1], S. H. Elsea[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Rice Univ., Houston, TX

Smith-Magenis syndrome (SMS, OMIM #182290) is a complex neurodevelopmental disorder characterized by a distinct behavioral phenotype, intellectual disability, circadian rhythm disorder, obesity, and craniofacial and skeletal anomalies. Most features of SMS arise due to haploinsufficiency of *RAI1* due to either intragenic variation or 17p11.2 deletion. Previous work has shown potential links between SMS, *RAI1*, obesity, and lipid metabolism abnormalities, including hypercholesterolemia. To better characterize obesity and lipid metabolism alterations observed in SMS, baseline metabolic phenotyping of *Rai1*$^{+/-}$ mice, which display hyperphagia, early onset obesity, and altered adiposity, was performed to include activity, food consumption, growth, and metabolite and lipid analyses. Prior to onset of obesity, 6-week-old singly-housed mice displayed reduced cage activity, lack of wheel running, modestly shifted circadian activity, increased food intake, and rapid weight gain compared to normal littermates ($p<0.01$). Untargeted metabolomic profiling of >1000 metabolites extracted from livers of 5-month-old *Rai1*$^{+/-}$ and wildtype littermates showed altered niacin, biopterin, ascorbate, and glutathione metabolism, as well as decreased levels of plasmalogens and lysoplasmalogens, and evidence of oxidative stress. When compared to wildtype, lipidomic profiling of 883 unique, targeted lipid species in *Rai1*$^{+/-}$livers showed marked elevations of triacylglycerols (4.7-fold), diacylglycerols (1.9-fold), and cholesterol esters (2.9-fold), with decreased monoacylglycerol esters (0.19-fold), and phosphoethanolamine lipid species (0.74-fold) (Welch's two-sample t-test, $P<0.05$). C16, C18, and C20-containing lipids were most consistently altered, with reduction of larger lipid species, suggesting that processing of dietary fats and downstream fatty acid synthesis may be impaired in SMS, supportive of impaired lipid transport and/or processing in the liver. These results support previous claims that haploinsufficiency of *RAI1* contributes to lipid metabolism and autophagy defects in SMS and suggest that individuals with SMS may have an underlying lipid storage disorder. Targeted treatment of lipid metabolism could prove beneficial to persons with SMS, including lifestyle and diet modifications to moderate and manage intake of specific exogenous lipids toward normalizing hepatic lipid metabolism.

Session Title: Mendelian Phenotypes Poster Session II

PB4627 Aminoacylase 1 deficiency: case report on three affected siblings

Authors:

J. Srovnal[1], V. Smolka[2], D. Friedecky[2], O. Tkacik[2], J. Kolarova[2], H. Foltenova[2], V. Bekarek[2], P. Vrtel[2], M. Prochazka[2]; [1]Faculty of Med. and Dentistry, Palacky Univ., Olomouc, Czech Republic, [2]Univ. Hosp. Olomouc, Olomouc, Czech Republic

Background: Aminoacylase 1 (*ACY1*, EC 3.5.1.14) deficiency is a very rare inherited metabolic disease (IMD) with autosomal recessive inheritance (OMIM #609924). It is diagnosed by detecting acetylated amino acids among the patient's urine organic acids by gas chromatography-mass spectrometry. Its clinical manifestations are highly variable, ranging from severe neurological symptoms to being asymptomatic. **Case description:** We present a 14-year-old boy with mild intellectual disability who exhibited increased urinary excretion of acetylated amino acids during testing for inherited metabolic disorders. A suspected *ACY1* deficiency was confirmed by molecular genetic analysis, which revealed the presence of a homozygous pathogenic missense mutation in the *ACY1* gene, c.1057C>T (p.Arg353Cys). The proband underwent speech education with good outcome. The same homozygous mutation was found in the boy's two brothers, who exhibited slightly uneven intellectual ability profile distributions. Follow-up examinations of the siblings revealed no deterioration in their mental skills. **Conclusion:** These results suggest that uneven mental abilities in pediatric patients may be sufficient grounds to warrant metabolic testing for *ACY1* deficiency.**Funding:** The study was supported by Ministry of Education, Youth and Sport of the Czech Republic (NCMG - LM2023067, EATRIS-CZ - LM2018133), Palacky University Olomouc (LF 2023_006) and the project National Institute for Cancer Research (Programme EXCELES, ID Project No. LX22NPO5102) - Funded by the European Union - Next Generation EU.

Session Title: Mendelian Phenotypes Poster Session III

PB4628 An adult male with *UPF1*-related neurodevelopmental disorder

Authors:

M. Chung[1,2], K. Baker[2], M. Wiznitzer[3], J. Chenbhanich[1,2]; [1]Ctr. for Human Genetics, Univ. Hosp. Cleveland Med. Ctr., Cleveland, OH, [2]Dept. of Genetics and Genomic Sci., Case Western Reserve Univ., Cleveland, OH, [3]Dept. of Neurology, Case Western Reserve Univ., Cleveland, OH

The *UPF1* gene encodes for an ATP-driven RNA helicase involved in mRNA nuclear export and mRNA surveillance in the form of initiating mRNA nonsense-mediated decay (NMD). This process is responsible for recognition and destruction of aberrant mRNA containing premature stop codons. To the best of our knowledge, only two patients with *UPF1*-related neurodevelopmental disorder with clinical descriptions have been reported to date.

We describe a 38-year-old male with a history of infantile hypotonia, global developmental delay, intellectual disability, autism, scoliosis, myoclonic epilepsy, bilateral high-frequency hearing loss, and delayed pubertal development. The patient exhibited overgrowth features, as indicated by measurements of head circumference, height, and weight consistently exceeding two standard deviations since birth. Physical exam was remarkable for brachycephaly, tall and narrow face with broad forehead, baldness, midface hypoplasia, coarse facial features, deep-set eyes, downslanting palpebral fissures, high arched palate, large hands and feet, mild camptodacyly, pes planus, hindfoot deformity, and joint laxity. Echocardiogram was unremarkable. Chromosome microarray and fragile X testing were negative. Trio exome sequencing revealed a *de novo* c. 1846 A>G (p.Thr616Ala) variant in exon 14 of the *UPF1* gene. The variant was classified as Likely Pathogenic according to the American College of Medical Genetics and Genomics guidelines.

Further investigation is needed to elucidate the specific molecular mechanisms of *UPF1*-related neurodevelopmental disorder, particularly with respect to the disruption of the NMD pathway. Such knowledge is crucial as it may open up therapeutic possibilities, as evidenced by preclinical studies involving NMD inhibitors in other conditions. Notably, overgrowth has never been described in association with mutations in *UPF1*. Identification of other cases with variants in *UPF1* will allow for a more in-depth characterization of the phenotypic spectrum of this rare disorder.

Session Title: Mendelian Phenotypes Poster Session I

PB4629 An ultra-rare variant of GPX4 reveals the structural basis for lipid membrane attachment

Authors:

A. Wahida; Helmholtz Ctr. Munich, Munich, Germany

Since its coining in 2012, ferroptosis has rapidly evolved into a well-recognized cell death modality with wide implications in various disease entities. Hence, cellular protection mechanisms against ferroptosis constitute critical features of homeostasis. To date, only a few such systems have been characterized, with the enzymatic function of glutathione peroxidase 4 (GPX4) probably being the most important. However, little is known about the structural basis for its anti-ferroptotic function at membranous compartments. Sedaghatian-type Spondylometaphyseal dysplasia (SSMD) is a lethal and ultra-rare inborn disorder affecting newborns and has been linked to genetic lesions in GPX4. Here, we report on a newly discovered missense variant in GPX4 (R152H) which, unlike other truncating mutations, does not lead to loss of protein expression. Surprisingly, although its enzymatic activity remains unaffected by the mutation, the R152H variant invariably failed to rescue from ferroptosis induced by genetic deletion of the wildtype enzyme. A detailed structural analysis of GPX4_R152H using NMR showed that WT and GPX4_R152H were overall well-folded, with some chemical shift perturbations being limited and mapping primarily to a region centered around R152H. This region constitutes a fin-like loop, extruding from the 3D structure in the wildtype enzyme, which partially collapsed in the mutant protein as shown by X-ray structure analysis. Accordingly, NMR spectroscopy analysis of GPX4 wildtype and mutant enzymes with bicelles revealed a marked loss of interaction of the R152H variant with lipid bicelles in contrast to wildtype GPX4. From these studies, we concluded that the R152 is positioned in such a way that it stabilizes a loop essential for GPX4 to be partially immersed into lipid bilayers.

Session Title: Mendelian Phenotypes Poster Session II

PB4630 Analysis of cardiopulmonary function in patients with Gaucher disease

Authors:

G. Lopez[1], J. Lichtenberg[1], R. Seid[1], N. Tayebi[2], A. Steward[3], N. Crooks[1], E. Ryan[4], E. Sidransky[5]; [1]NHGRI (NIH), Bethesda, MD, [2]NIH/NHGRI, Bethesda, MD, [3]NIH, Bethesda, MD, [4]NIH, Bethesda, MD, [5]MGB/NHGRI/NIH, Bethesda, MD

Gaucher disease (GD) is an autosomal recessive lysosomal storage disorder (LSD) characterized by decreased function of the lysosomal enzyme glucocerebrosidase and a subsequent overabundance of the glycosphingolipid glucocerebroside. Glucocerebroside-engorged cells infiltrate various organs, leading to a range of clinical manifestations including enlarged spleen and liver, as well as skeletal and hematological abnormalities. GD is not typically associated with cardiac complications, except for genotype p.D448H/p.D448H, associated with cardiac valvular calcifications. However, few comprehensive studies of cardiac involvement in patients with GD have been reported. This study analyzed the echocardiogram data from 110 patients with either type 1 or type 3 GD, collected between 2006 and 2019. Using normal ranges for echocardiographic measurements established in the 2015 American Society of Echocardiography guidelines, our results show a substantial number of patients with abnormal aortic root and ascending aorta diameter. We also observed individuals in the cohort with parameters indicative of mild to moderate left ventricular hypertrophy. Mixed effects regressions with Subject ID as a random effect suggest a correlation between genotypes except those with an L483P allele and the extent of the enlargement of ascending aorta diameter and the left ventricular posterior wall diastolic thickness. In addition to genotype, regression analysis determined significant correlations between age and sex with different cardiac parameters. This exploratory analysis suggests that mild cardiac abnormalities may be more prevalent in patients with GD and potentially correlated with genotype. Longitudinal evaluation of patients with GD demonstrating abnormal echocardiogram measures is needed to determine whether these patients develop cardiac symptoms, or whether they remain abnormal but stable over time.

PB4631 Anophthalmia/ Microphthalmia Spectrum: Clinical, cytogenetics and molecular results of 45 Egyptian Patients

Authors:

G. El-Makkawy[1], A. Nabil[1], F. Harms[2], D. Schorderet[3], V. Ruiz-Perez[4], M. Ali[5], D. Maskill[6], N. Elshakankiri[7], E. Abdalla[1]; [1]Dept. of Human Genetics, Med. Res. Inst., Alexandria Univ., Egypt, Alexandria, Egypt, [2]Inst. of Human Genetics, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany, Hamburg, Germany, [3]Faculty of Biology and Med. - Jules Gonin Eye Hosp. (HOP) -, Lausanne, France, [4]Inst. de Investigaciones Biomedicas de Madrid, madrid, Spain, [5]Leeds Inst. of Med. Res., Univ. of Leeds, Leeds, United Kingdom, [6]Leeds Inst. of Med. Res., Univ. of Leeds, leeds, United Kingdom, [7]Dept. of Ophthalmology, Univ. of Alexandria, Egypt, Alexandria, Egypt

Anophthalmia and microphthalmia (A/M) constitutes a spectrum of developmental ocular disorders that can be caused by chromosomal aberrations, copy number variations, and single gene mutations, besides environmental factors. A/M may present as an isolated anomaly or associated with other extraocular anomalies. Syndromic A/M represents the greater proportion of cases and is also known to have higher identifiable genetic causes and higher diagnostic rates. Identifying the underlying genetic cause is the key to provide patients with appropriate care by a multidisciplinary team and to offer their families a proper genetic counseling. The wide genetic heterogeneity of A/M, together with variation in expression, incomplete penetrance, and overlapping phenotypes, make diagnosis and genetic counseling very challenging. Aiming to gain insight into genetic etiologies of A/M in the Egyptian population, we studied a cohort of 45 patients derived from 39 unrelated Egyptian families with A/M spectrum. All patients were subjected to full clinical examination and ophthalmological assessment. Environmental factors were identified in 3 patients who were, thus, excluded from further genetic testing, and 4 patients were diagnosed as trisomy 13 and confirmed by karyotyping. For the remaining patients, molecular testing was conducted in 23 families; either in the form of direct sequencing of candidate genes or whole exome sequencing. The causative mutations were identified in 11 families by WES; 7 pathogenic, 2 likely pathogenic variants, and 2 variants of unknown significance in *OTX2, CHD7, HMX1, PRR12, ATOH7, STRA6, ZBTB11, B3GALNT2, GCNT2*, 8 of which are novel mutations, in addition to a pathogenic variant in *DPH1* gene in a female patient with bilateral severe microphthalmia and this is a novel phenotype associated with mutations in this gene. However, 9 families remained unsolved. Furthermore, *SOX2* Sanger sequencing was performed to 3 patients with features suggestive for anophthalmia-esophageal-genital syndrome and all of them turned out negative. We also clinically diagnosed other A/M syndromes as Oculo-dento-digital syndrome, Fryns syndrome, and Oculo-auriculo-vertebral spectrum. Collectively, the diagnostic yield was higher in the syndromic group than in the isolated A/M as potentially causal mutation was identified in the majority of the cohort with syndromic A/M 60% versus 40% in isolated A/M. Our data confirm that genetic factors constitute a predominant cause of both syndromic and non-syndromic A/M and, expand the mutational spectrum of A/M by reporting novel mutations in our population, also expand the phenotypic spectrum of specific syndromes.

Session Title: Mendelian Phenotypes Poster Session I

PB4632 Apert Syndrome: A New Variant With Uncertain Significance

Authors:

M. Arteaga Pichardo, F. Bernate, L. C. Rosas, A. V. Mora, M. C. Vega, D. D. Mora, A. Vargas, V. A. Peña, M. Ramirez, M. Saenz, S. Atuesta Escobar, L. G. Celis Regalado; Univ. de la Sabana, Cundinamarca, Colombia

Introduction: Apert syndrome is an autosomal disorder of low prevalence is a genetic disorder caused by the mutation of the gene that encodes the Fibroblast Growth Factor Receptor 2 *(FGFR2)* and is characterized by the presence of craniosynostosis accompanied in most cases by symmetric syndactyly. Its diagnosis is generally made prenatally during the first trimester of pregnancy, given that most craniofacial anomalies can manifest and be visible at week 19 of pregnancy.
Methods: The case of a 31 year old female G2P0A1,with normal prenatal controls displayed an ultrasound at 30.5 weeks gestation reporting cerebral ventricular asymmetry with ventriculomegaly of the left fetal ventricle. The patient is born at 39.2 weeks of gestation, XX genotype with adequate neonatal adaptation, weight and length. During the first months of life, the patient develops relevant phenotypic features: strabismus and proptosis of the right eye, hyperostosis of the right coronal suture with craniofacial deformity due to reduced diameter of the right orbit, right frontal planning with left frontal compensation and bilateral increase in hallux size. At 5 months of age the patient is intervened surgically for orbital correction and remodeling. A conventional cytogenetics and molecular panel of 38 genes for craniosynostosis is done.
Results: The study identifies a pathogenic heterozygous variant of the FGFR2 gene, consistent with a change of cytosine for guanine at position 755 of DNAc, in exon 7; level in which the protein produces a missense mutation of a serine for a tryptophan in the 252 amino acid. This variant is reported in databases as pathogenic for Apert Syndrome with an allelic frequency in the control population of 0.000004 and the responsible of 70% of cases in Apert syndrome. Another variant of important clinical significance in the same gene generated a change in cytosine for thymine in the 532 position in the DNAc, exon 5, at which the protein produces a missense mutation of arginine for a cysteine in the 178 amino acid moderately conserved. This variant has not been reported in gene databases and has an allelic frequency of 0.00001, classified as a deleterious allelic variant of uncertain significance.
Conclusions: A new variant was identified not yet reported in gen databases and it is classified as a deleterious allelic variant of uncertain significance for which further investigation in impact is merited. Additionally, there is a necessity to find a consensus with clearer, more specific clinical criteria to help diagnose this syndrome, as well as to determine the age of surgical intervention, personalized treatment and genetic counseling for each case.

Session Title: Mendelian Phenotypes Poster Session II

PB4633 Argininosuccinate lyase deficiency is associated with blood-brain barrier disruption via nitric oxide-mediated dysregulation of claudin expression.

Authors:

J. Kho[1], U. Polak[1], M-M. Jiang[1], J. Odom[1], J. Hunter[1], S. Ali[1], L. Burrage[1], S. Nagamani[1], R. Pautler[1], H. P. Thompson[2], A. Urayama[2], Z. Jin[1], B. Lee[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Univ. of Texas Hlth.Sci. Ctr., Houston, TX

Argininosuccinic aciduria is the second most common urea cycle disorder (UCD) caused by deficiency of argininosuccinate lyase (ASL), a metabolic enzyme that catalyzes the fourth reaction in the urea cycle. Humans with argininosuccinate lyase deficiency (ASLD) are at increased risk for developing hyperammonemia due to a block in ureagenesis. However, natural history studies have shown that individuals with ASLD can present with more complex clinical phenotypes including neurocognitive deficits that can be independent of hyperammonemia. Thus, there's a significant gap in understanding the pathogenesis of neurocognitive deficits in ASLD. Blood-brain barrier (BBB) breakdown has recently been shown as an early biomarker of cognitive impairment in humans. We have previously discovered that beyond its role in ureagenesis in the liver, ASL is also required for the systemic synthesis of nitric oxide (NO), a critical signaling molecule that regulates BBB permeability and has been linked to pathogenesis of many neurocognitive diseases. Here, using ASLD as a model of cell-autonomous, nitric oxide synthase (NOS)-dependent NO deficiency, we investigated the effects of NO on brain endothelial cells *in vitro* and the BBB *in vivo*. *ASL* knockdown in human brain microvascular endothelial cells (HBMECs) led to decreased NO production and transendothelial electrical resistance (TEER), indicative of increased cell permeability. Loss of ASL also caused dysregulation of BBB-associated genes, marked by a decreased expression of CLDN5, a key regulator of BBB, and an increased expression of CLDN1, which is normally present in low concentration in the BBB. We found that treatment with an external source of NO or inhibition of *Claudin-1* improved barrier integrity in ASL-deficient HBMECs. To further evaluate the effects of NO deficiency on BBB *in vivo*, we independently assessed BBB leakage in a hypomorphic mouse model of ASLD by performing DCE-MRI (after injection with a gadolinium based-contrast agent) and Evans blue assay. We found a significant increase of both gadolinium enhancement and Evans blue dye extravasation in mutant mice, suggesting an evidence of BBB breakdown. Consistent with our *in vitro* data, we also discovered that BBB leakage could be partially rescued by NO supplementation. In conclusion, our results suggest that ASL-mediated NO synthesis is required for proper maintenance of brain microvascular endothelial cell functions as well as BBB integrity.

Session Title: Mendelian Phenotypes Poster Session III

PB4634 *ARHGAP1* identified as a candidate gene for a novel autosomal dominant syndromic neurodevelopmental disorder.

Authors:

H. Mendez[1,2], Y. Huang[3,4], D. Bonner[1,2], O. Kanca[3,4], R. Levy[5,2], E. Kravets[1,2], J. Kohler[1,2], C. Reuter[1,2], S. Marwaha[1,2], M. Wangler[3,4], S. Yamamoto[3,4], J. A. Bernstein[1,2], H. Bellen[3,4], M. T. Wheeler[1,2], The Undiagnosed Diseases Network; [1]Stanford Ctr. for Undiagnosed Diseases, Stanford, CA, [2]Stanford Univ., Stanford, CA, [3]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [4]Jan and Dan Duncan Neurological Res. Inst., Houston, TX, [5]Stanford Hlth.Care, Stanford, CA

Background: GTPase-activating proteins play a crucial role in a wide spectrum of signal transduction pathways regulated by GTP-binding proteins. In this study, we provide initial clinical and functional evidence supporting a role for a Rho GAP gene, *ARHGAP1*, in a patient presenting with a syndromic neurodevelopmental disorder. **Case report:** We report a 6-year-old female presenting with microcephaly, global developmental delay, and dysmorphic features. She is the first child of a non-consanguineous couple with no relevant family history. Prenatal history of controlled gestational diabetes and decreased fetal movement was reported. She was born at full term but required admission to the NICU due to inadequate feeding. She started sitting at 7 months, walking at over 23 months and spoke her first words at 23 months. Physical examination revealed a depressed nasal root, broad bridge, and bilateral short fifth fingers. X-ray of the hands revealed short fifth metacarpals, angel-shaped fifth middle phalanges, and small distal phalanges. Additionally, a brain MRI displayed a few small cystic changes in the posterior periventricular white matter. Trio genome sequencing identified a de novo heterozygous missense variant in *ARHGAP1* (NM_004308.5): c.309G>T (p.Lys103Asn). In silico prediction tools support a deleterious effect (CAAD Score: 23.3, PolyPhen and SIFT: damaging), and the variant is absent in population databases (gnomAD and Bravo TopMED). **Model organism:** To investigate the functional consequences of the *ARHGAP1* variant, we performed experiments in Drosophila. First, we generated a versatile T2-GAL4 gene trap line in the fly *ARHGAP1* (RhoGAP68F) and found that this is not an essential gene. Second, we found that RhoGAP68F is expressed in a subset of neurons and glia in the nervous system. Third, while overexpression of the variant human *ARHGAP1* causes semi-lethality accompanied by shortened lifespan and developmental defects in appendages such as the wing and legs, the reference protein expressed under the same condition causes much milder or no phenotype. Since similar defects are found when the fly RhoGAP68F is overexpressed, the human *ARHGAP1* p.Lys103Asn variant is likely to be a gain-of-function allele. **Conclusions:** These data provide initial evidence that *ARHGAP1* gain-of-function variants might be the cause of a novel syndromic neurological disease involving severe neurological impairment with distal limb anomalies and dysmorphism. This association would be strengthened by the identification of other patients with *ARHGAP1* variants.

Session Title: Mendelian Phenotypes Poster Session I

PB4635 Assessing the genetic and phenotypic spectrum of *DNM1*-related disorders in the landscape of neurodevelopmental disorders

Authors:

S. Parthasarathy[1], A. Harrison[1], K. Thalwitzer[1], M. Pendziwiat[2], Y. Weber[2], S. Ruggiero[1], I. Helbig[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ.sklinikum Schleswig Holstein Campus, Kiel, Germany

Disease-causing variants in *DNM1* are an established cause of a severe neurodevelopmental disorder (NDD) including hypotonia, severe to profound developmental delay, and West syndrome, a severe epilepsy characterized by infantile spasms and hypsarrhythmia. Known pathogenic variants are predominantly missense variants causing dominant-negative impairment of vesicle fission by dynamin-1 homooligomers. Since the initial descriptions of *DNM1*-related disorder, a more complex genetic landscape has begun to emerge, including alternative exons, splicing variants, and biallelic loss-of-function; moreover, several clinical reports in the literature are expanding the known phenotypic spectrum. Accordingly, we harmonized clinical data across 73 individuals with *DNM1*-related disorder, including 62 previously reported and 11 unreported individuals. We used the Human Phenotype Ontology to capture 3,508 phenotypic annotations and compared this cohort to data from previous studies on two other severe genetic epilepsies, *SCN2A*-related (n = 413) and *STXBP1*-related (n = 534) disorders. Using an HPO-based semantic similarity approach, we show that *DNM1*-related disorder represents a homogeneous disease entity within the context of other neurodevelopmental disorders ($p < 0.01$). Furthermore, individuals with variants in the alternatively spliced exon 10a, including the recurrent p.I398_R399insCR variant, had a highly similar phenotypic picture within the *DNM1* spectrum (n = 13, $p < 0.01$); this similarity was driven by higher frequency of cortical visual impairment (HP:0100704, $p < 0.001$, OR = 22.8 [95% CI = 4.55-144]) and more profound developmental delay (HP:0012736, OR = 112 [95% CI = 11.6-5,600]), as well as lower frequency of speech impairment (HP:0002167, $p = 0.02$, OR = 0.211 [95% CI = 0.0419-0.872]). By using a new semantic similarity method for comparison between subgroups, we demonstrate that both this exon 10a-related phenotype ($p < 0.01$) and that of individuals with biallelic loss-of-function variants (n=3, $p < 0.01$) fall in the overall *DNM1* spectrum within a larger NDD context, illustrating that this phenotype is caused by reduction of a majority of dynamin-1 protein function. In summary, through a computational phenotyping approach, we define the *DNM1*-related phenotype as a homogeneous disease entity, establishing a more comprehensive baseline for granular anticipatory guidance and development of therapies targeted towards largely recurrent dominant-negative variants.

Session Title: Mendelian Phenotypes Poster Session II

PB4636 Assessment of potential loss of function variants in children with DS-associated congenital heart defects as possible modifying factors.

Authors:

E. Feldman[1], D. Cutler[1], T. Rosser[1], S. Wechsler[1], L. Sanclemente[2], A. Rachubinski[3], K. Rabin[2], M. Wagner[4], B. Gelb[5], J. Espinosa[3], P. Lupo[2], S. Sherman[1], E. Leslie[1]; [1]Emory Univ., Atlanta, GA, [2]Baylor Coll. of Med., Houston, TX, [3]Univ. of Colorado, Aurora, CO, [4]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, [5]Icahn Sch. of Med. at Mount Sinai, New York, NY

Congenital heart defects (CHDs) are the most common structural birth defect and are present in 40-50% of children with Down syndrome (DS). In DS, the most common types of CHD are atrial septal defects (ASD), ventricular septal defects (VSD), and atrioventricular septal defects (AVSD). While increased dosage of genes on chromosome 21 contributes to this risk, about 50% of infants with DS have structurally normal hearts. Thus, additional modifying genetic or environmental factors may exist. In order to characterize the genetic architecture of various DS-associated CHDs, we sequenced genomes of a multiethnic group of children with DS and a CHD (DS+CHD, n=886: AVSD, n=438; ASD, n=122; VSD, n=170; Other CHD, n = 156) or DS and a structurally normal heart (DS+NH, n=572) as part of the Gabriella Miller Kids First Pediatric Research Program and the INCLUDE (INvestigation of Co-occurring conditions across the Lifespan to Understand Down syndromE) Project. We analyzed rare variants (allele frequency < 0.0001 in gnomAD) that are predicted to be loss of function (pLoF). Exome-wide, rare pLoF variants were not enriched in DS+CHD vs. DS+NH ($p = 0.96$) nor were they enriched when restricting to genes constrained to loss-of-function variation. We then prioritized rare pLoF variants in 611 genes included on clinical genetic testing panels for CHD. We found 105 such variants in 78 genes but these were also not enriched among individuals with DS+CHD ($p = 1$). A total of 64 DS+CHD cases and 38 DS+NH controls carried at least one rare pLOF variant in the gene list. The majority of individuals carried a single pLoF allele in a gene associated with autosomal recessive (AR) disease. Interestingly, two individuals, both with NH+DS, had two heterozygous variants (and are suspected to be compound heterozygous) in *IFT172* and *DNAAF1*, both associated with autosomal recessive syndromes that typically include CHD. 9 individuals with DS+CHD were heterozygous for variants in genes associated with autosomal dominant CHD or heart dysfunction including *EP300* (DS+VSD), *EVC2* (DS+ASD), *KCNA5* (DS+AVSD), *LAMA4* (DS+AVSD), *MIB1* (DS+AVSD), *SCN2B* (DS+AVSD, DS+ASD+VSD), *SMC3* (DS+ASD+VSD), and *ZMIZ1* (DS+AVSD). Overall, we find that approximately 7% of individuals with DS+CHD and those with DS+NH harbor rare, potentially diagnostic pLoF variants in CHD-associated genes. Most of the observed variants were in genes unconstrained to LoF variation and associated with recessive disease. Here, the absence of an enrichment in DS+CHD cases suggests that being a carrier for AR-associated CHD genes does not interact with trisomy 21 to lead to CHD.

Session Title: Mendelian Phenotypes Poster Session III

PB4637 Association between rs1045642, rs2032582 and rs1128503 polymorphism of ABCB1 gene in Asian population and resistance to AEDs, a meta-analysis.

Authors:

Z. Agha, m. salman, i. shaheen; COMSATS Univ. ISLAMABAD, Islamabad, Pakistan

Epilepsy is a neurological disorder characterized by prolonged and recurrent seizures. It is considered the most common intellectual disorder relate to the nervous system. Despite the increased use of anti-epileptic drugs (AEDs) for treatment, 30% of patients remain unresponsive to them. Drug-resistant epilepsy may cause by pharmacokinetic and pharmacogenetic factors and cause severe disability. Several studies reported the association of ATP-binding cassette superfamily members such as ABCB1 gene polymorphisms C3435T, G2677T, and C1236T with drug resistance to AEDs. In the present study, we performed a meta-analysis to assess the association between common polymorphism in *ABCB1* and the risk of drug resistance in epileptic patients. We collected data from multiple online libraries before November 2021, and 12 studies were included selected for our meta-analysis. To assess the strength of association, we calculated pooled odds ratios with 95% confidence intervals. The Fisher's Z test suggests there is no publication bias in selected studies and results of statistical analysis showed that common SNPs rs1045642 (C3435T), rs1128503 (C1236T), and rs2032582 (G2677T) of ABCB1 are associated with drug resistance in an Asian population with (OR= 2.0606, CI95% [1.5827; 2.6828]; P= 7.85e-08). A sub-group analysis showed C3435T and C1236T variants are associated with drug resistance in Caucasians while G2677T is presented in the Arab ethnic group. Conclusion: We conclude that the polymorphisms of *ABCB1* (rs2032582, rs1045642, rs1128503) are associated with the risk of drug-resistant epilepsy in general epileptic patients. Meta-analysis indicates the association of *ABCB1* polymorphism with drug-resistant epilepsy is approximately independent of the ethnic group.

PB4638 *ASXL3*: Connecting chromatin biology to neurodevelopmental disorders.

Authors:

E. Peirent, Y-C. Tsan, S. Regan, C. Ryan, S. Bielas; Univ. of Michigan, Ann Arbor, MI

Human genetics studies of neurodevelopmental disorders highlight chromatin's importance in corticogenesis, with pathogenic variants enriched in networks linked to chromatin regulation. Dynamic regulation of histone modifications is especially critical for the transcriptional plasticity required during this cellular differentiation. One such modification is mono-ubiquitination of histone H2A (H2AUb1), a conserved, traditionally repressive histone mark that is reversed by the polycomb repressive deubiquitinase (PR-DUB) complex. We identified *de novo* dominant truncating variants in *ASXL3*, a key component of PR-DUB, as the genetic basis of both Bainbridge Ropers Syndrome (BRS) and autism spectrum disorder (ASD), characterized by failure to thrive, global developmental delay, feeding problems, hypotonia, profound speech deficits, and intellectual disability. We identified dysregulation of H2AUb1 as a key molecular pathology in primary cells derived from individuals with BRS. To investigate this *ASXL3*-dependent neuropathology in early corticogenesis, we generated human neural progenitor cells and 3D cerebral organoids that recapitulate context-dependent features of *in vivo* cortical development in a reproducible manner. In CRISPR-edited and patient-derived iPSC lines, we observe *ASXL3*-dependent defects in the differentiation of pluripotent cells to the full spectrum of mature cortical neuron subtypes. We then utilized transcriptomic and epigenomic techniques including RNA-sequencing and CUT&RUN to probe the role of *ASXL3*-dependent H2AUb1 deubiquitination in regulating transcriptional profiles critical to NPC fate decisions during corticogenesis. Finally, we examined how such changes in dynamic H2AUb1 exchange impact DNA damage repair. Together, our functional investigation of BRS- and ASD-associated genetic variants provides molecular insights towards uncovering the elusive role of H2AUb1 in neural development.

PB4639 Atypical clinical spectrum in *NDUFS2*-related mitochondrial complex I deficiency.

Authors:

P. Jacob[1], A. Vasanth[2], S. J. Patil[3]; [1]Dept. of Med. Genetics, JSS Med. Coll. and JSS Hosp., Mysuru, India, [2]Pediatric Nephrology, Dept. of Pediatrics, Mazumdar Shaw Med. Ctr., Narayana Hrudayalaya Hosp., Bangalore, India, [3]Dept. of Med. Genetics, Mazumdar Shaw Med. Ctr., Narayana Hrudayalaya Hosp., Bangalore, India

IntroductionMitochondrial complex I deficiency, nuclear type 6 (MIM#618228) is a rare subtype of oxidative phosphorylation (OXPHOS) disease caused by biallelic variants in *NDUFS2*. This early-onset, multi-systemic disorder is characterized by respiratory abnormalities, neurologic regression, muscular atrophy, cardiac anomalies, and lactic acidosis, often leading to a lethal outcome before the age of ten years.
MethodsOne affected individual born of a consanguineously married couple was ascertained for this study. Detailed clinical features, family history, along with radiological, and biochemical findings were recorded. Systemic investigations including MRI, USG (abdomen), ECHO, GCMS (urine), and TMS (blood) were performed. Exome sequencing (ES) was performed for the proband, data analysis, and interpretation were performed using standard procedures.
ResultsThe proband initially presented with failure to thrive, developmental delay, polyuria, and polydipsia at the age of one year. At 1 year 8 months of age, he had subtle facial dysmorphism, distal renal tubular acidosis, and increased serum lactate levels (3.8 mmol/L). Other systemic examinations were unremarkable. ES helped in the identification of a likely pathogenic variant, c.685C>A p.(Pro229Thr) in homozygous state in *NDUFS2* which causes Mitochondrial complex I deficiency, nuclear type 6. A novel missense change at the same amino acid residue p.(Pro229Gln) has been reported previously.
ConclusionOur study provides the first evidence of a patient with mild clinical spectrum of *NDUFS2*-related mitochondrial complex I deficiency. Early molecular diagnosis helped us to initiate the clinical management of the patient with Riboflavin. Interestingly, the reported patient with the variant at the same amino acid codon has severe clinical manifestations of the disease. Further functional studies would help to determine the rationale for the clinical heterogeneity of this rare mitochondrial disease.

PB4640 Atypical plantar hyperkeratosis, multiple pigmented nevi, facial dymorphism, skeletal abnormalities, and mental retardation.

Authors:

A. Rincón[1], S. A. Ramírez-García[2], R. Hernández-Ramírez[3], V. C. Ledezma-Rodríguez[4], V. Y. Jimenez-Rodríguez[3], N. O. Dávalos-Rodríguez[5,6]; [1]IBMMTG, Depto. Molecular Biology and Genomic, Univ. of Guadalajara,, Guadalajara, Jalisco., Mexico, [2]MePiel Dermatological Ctr., Guadalajara, Jalisco., Mexico, [3]Med. degree, CUCS Univ. of Guadalajara,, Guadalajara, Jalisco, Mexico, [4]Dept. of Plastic and Reconstructive Surgery of the Hosp. de Especialidades, CMNO IMSS, Guadalajara, Mexico, [5]Inst. of Human Genetics, Dept. of Molecular Biology and Genomics, CUCS Univ. of Guadalajara,, Guadalajara, Jalisco,, Mexico, [6]Genetics, Regional Hosp. "Dr. Valentín Gómez Farías" ISSSTE., Zapopán, Jalisco, Mexico

Pigmentary lesions and palmoplantar hyperkeratosis may be related to different syndromes. However, the combination of facial dysmorphia, skeletal abnormalities, and palmoplantar keratoderma does not fit into any known syndromes. **Case report.** A 24-year-old female with facial dysmorphism, multiple nevi, plantar hyperkeratosis, mental retardation, and skeletal abnormalities is described. The proposita was the 3rd pregnancy of non-consanguineous parents, with normal karyotype and irrelevant hereditary family history. The arm span was 171 cm revealing a disproportion in upper limbs. She had facial dysmorphism, brachycephaly, arched and sparse eyebrows, down-slanting palpebral fissures, deep-set eyes, epicanthal folds, a bulbous nasal tip, and smooth philtrum, thick upper lip, malpositioned teeth, and mandibular prognathism. Bilateral cubitus valgus and thoracic scoliosis. Large hands according to the body, bilateral clinodactyly of the fifth fingers, and distal camptodactyly of the 2nd and 3rd fingers bilaterally. The nails were convex, and she had deep creases on the palms. Feet revealed hallux valgus bilateral, partial proximal cutaneous syndactyly between the 1st and 2nd toe and overlapping of the second over the first toe. The skin showed multiple pigmented nevi over the body. Radiological studies revealed temporomandibular sclerosis, wide sella turcica, and hypertrophic nasal conchae. Thorax with wide ribs, thoracolumbar scoliosis, and lumbar hyperlordosis; irregular vertebral bodies with a big right apophysis transverse on C7, intervertebral collapse at the dorsal level, sclerosis, and osteophytes grade II-IV at the lumbar level and interphase arthrosis; L5 has incomplete dysraphism and big apophyses transverses. Extremities upper: the radius bone showed a not a well-defined limit in the middle's union with the proximal third segment. Lower: *genu valgus* with medial arthrosis and *pes valgus* secondary to a tarsal coalition. Large bones still present growth nucleus rest. **Discussion**: Multiple nevi can occur in families (MIM#162900), punctate hereditary palmoplantar keratoderma (MIM#148600), and one case was described by Öktenli et al., 2003 with facial dysmorphism, multiple pigmented nevi, osteoporosis, brachydactyly, and skeletal anomalies. Although the present case showed clinical findings similar to those previously mentioned, our patient differs in facial dysmorphism, skeletal abnormalities, multiple pigmented nevus, plantar hyperkeratosis, and mental retardation. We conclude that the patient presented several findings not included in any known syndrome reported that could represent a new entity.

Session Title: Mendelian Phenotypes Poster Session I

PB4641 Autonomic nervous symptom may be a novel clinical manifestation of stress-induced childhood-onset neurodegeneration with variable ataxia and seizures syndrome caused by compound heterozygous variants in *ADPRHL2*.

Authors:

E. Sato[1], M. Fujimoto[1], T. Iwaki[1], Y. Nakamura[1], D. Ieda[1], Y. Negishi[1], A. Hattori[1], Y. Kubota[2], M. Asai[2], S. Saitoh[1]; [1]Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan, [2]Daido Hosp., Nagoya, Japan

[Background]*ADPRHL2* encodes ADP-ribosylhydrolase3(ARH3), which removes poly(ADP-ribose) polymers after ADP-ribosylation process under the cellular stress. Stress-induced childhood-onset neurodegeneration with variable ataxia and seizures (CONDSIAS) is an autosomal recessive disease and caused by loss of function in *ADPRHL2*. Other clinical features are developmental delay or regression and axonal sensorimotor neuropathy. Although all previous cases had been homozygous variants in *ADPRHL2* since first reported in 2018, we describe an additional patient with a novel compound heterozygous variant in *ADPRHL2* following two patients of compound heterozygous variants reported last year.[Case report]The patient is a 7-year-old male born with a weight of 2870g at 41 weeks of an uneventful pregnancy. His early development was normal. At 1 year 2 months of age, he was able to walk independently. Since 1 year 6 months of age, he had had recurrent episodes of ataxia and walking difficulty with fever. After those episodes he had recovered gradually in several weeks. At the age of 7 years, he showed walking difficulty, limb weakness and urinary retention in association with fever. The amplitude and conduction velocity of the motor nerve decreased. His head and spinal cords MRI did not show obvious pathological findings. We performed whole exome sequencing analysis and identified compound heterozygous variants in *ADPRHL2* gene (NM_017825:c.580C>T:p.Gln194Ter, NM_017825:c.712G>T:p.Glu238Ter). Sanger sequencing was applied to validate the patient and his parents. Those variants c.580C>T and c.712G>T inherited from his father and mother, respectively. c.712G>T was a novel variant while c.580C>T was reported previously in a patient with CONDSIAS. According to the ACMG guideline, both of the variants were classified as pathogenic.[Conclusion]As a previous report of a patient with compound heterozygous variants in *ADPRHL2*, he showed autonomic nervous dysfunction such as urinary retention, which was not mentioned in patients with homozygous variants. We consider that autonomic nervous dysfunction could be added to classical manifestations of CONDSIAS.

AUTS2 syndrome is a fairly newly identified condition characterized by autism spectrum disorder, developmental delay and intellectual disability, hyperactivity, short stature, distinctive facial features, feeding difficulties, seizures. AUTS2 gene transcribes a distinct long and short isoforms from alternative promoters. In the context of a European collaborative research study, using array CGH combined with next generation sequencing techniques, we collected a large cohort of 37 patients harboring genomic rearrangements in the AUTS2 region (13/37) and point mutations (24/37). The identified pathogenic variants were mostly loss of function and some of them, like the p. R316* in exon 7 or the p.His535_Thr542del in exon 9, were recurrently found in patients from different countries suggesting the existence of mutational hotspots. The genomic rearrangements consisted mostly of interstitial deletions (6/13) spanning from exon 3 to exon 6 with two deletions in the 5' part of the gene (2/13),one of which affecting neighboring genes and one C terminal part deletion (1/13). A duplication of the 5' region was detected in three patients and a duplication extended from exon 7 to the 3'UTR was detected in one patient. A common clinical phenotype was observed independently from the underlying molecular mechanisms; it consists of autistic behavior, hyperactivity, learning difficulties and speech delay. A statistically significant more recognizable phenotype, with a typical facial gestalt consisting of microcephaly, stereotypic movements, hypertelorism, short and downslanting palpebral fissures, broad nasal bridge, anteverted nares and prominent nasal tip, was mostly observed in patients harboring loss of function variants compared to genomic rearrangements Neurological signs such as arthrogryposis and joint contractures were only noticed in patients harboring point mutations in the first exons (2-5) suggesting a role of the longer isoform in these aspects.Our data broaden the clinical and molecular spectrum associated with AUTS2-related disorder. They allow concluding that while AUTS2 rearrangements are mostly characterized by behavioral features and intellectual disability, point mutations are distinguished by a recognizable facial gestalt which can resemble Rubinstein-Taybi syndrome.

PB4643 BCM-GREGoR: A rare disease program to solve the unsolved with novel methods and analytical approaches.

Authors:

S. Jhangiani[1], F. Sedlazeck[1,2], H. Du[1], R. Duan[1], D. Calame[1], V. R. Sutton[1,3], M. Dawood[1], M. Mahmoud[1], S. Behera[1], A. K. Saad[1], A. Rivera[1], A. Jolly[1], A. Rai[4], C. Munderloh[1], C. M. Grochowski[1], D. Marafi[1], D. Pehlivan[1], I. K. Chinn[1,3], J. Fatih[1], N. Gogate[1], P. Kaur[1], P. Liu[1], R. M. Belanger Deloge[1], R. Lewis[1,3], S. Barish[1], S. T. Beheshti[1], S. Morris[1,3], T. Bozkurt[4], Z. Dardas[1], Z. Coban Akdemir[4], Z. Khan[1], K. Walker[1], H. Doddapaneni[1], J. R. Lupski[1,3], D. M. Muzny[1], R. A. Gibbs[1], J. E. Posey[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Rice Univ., Houston, TX, [3]Texas Children's Hosp., Houston, TX, [4]Univ. of Texas Hlth.and Sci. Ctr., Houston, TX

Nearly 30 million people in the United States are affected by rare diseases, although many families lack a molecular diagnosis. Since its inception in 2021, the GREGoR Consortium (Genomics Research to Elucidate the Genetics of Rare diseases) continues to optimize benchside methods, utilize diverse sequencing approaches, and develop novel analytical tools toward the aim of 'solving the unsolved'. BCM-GREGoR has enrolled more than 1,400 individuals (340 families), and the Human Genome Sequencing Center has generated sequence data for 1,065 study participants and performed reanalysis of extant data for more than 200 samples utilizing a stepwise approach to apply exomes, short and long read genome sequencing technologies, and RNA sequencing. Additionally, we are investigating the diagnostic utility of short and long read RNA sequencing in 8 families. For a cost-effective long read approach, we developed a custom panel and a sequencing protocol that covers 389 genes inaccessible with short reads alone and yields on average, 94% of targeted bases at 8x coverage or greater. Application of this panel to several families is in progress. Novel analytical approaches leverage this rare disease dataset, and we are currently investigating the role of reference/pangenomes in identifying molecular diagnoses. One study utilizes a modified GRCh38 version that accounts for reference errors involving 33 protein coding genes, of which 12 are medically relevant, and will assess the difference between the diagnostic yield of short read data to those data from long reads with this improved reference. Analyses of these approaches is challenging but is aided by tools such as VizCNV, an in-house developed analytical tool for detection, visualization, and interpretation of copy number variations and other products of structural variation mutagenesis. Major phenotypes studied include neurodevelopmental disorders, structural brain abnormalities, and intellectual disability. Thirty-five percent of this dataset includes a unique cohort from the Middle East and Northern Africa with a molecular diagnostic rate of at least 41%, including both novel and known genes. Cumulative analysis of the BCM-GREGoR dataset has yielded 22 manuscripts detailing discoveries in 230 genes of which 38% are novel. Data and methods are rapidly disseminated through AnVIL, GeneMatcher, VariantMatcher, ClinVar, and GitHub. Each discovery provides insight into the genomics of rare diseases and insights into human disease biology - bringing us a step closer to equitable personalized medicine.

Session Title: Mendelian Phenotypes Poster Session I

PB4644 Bi-allelic *ACBD6* variants lead to a neurodevelopmental syndrome with progressive complex movement disorders

Authors:

S-J. Lin[1], R. Kaiyrzhanov[2], A. Rad[3,4], A. Bertoli-Avella[5], W. W. Kallemeijn[6,7], A. Godwin[8], ACBD6 International Study Group, M. Guille[9], E. W. Tate[6,7], H. Houlden[2], R. Maroofian[2], G. K. Varshney[1]; [1]Oklahoma Med. Res. Fndn., Oklahoma City, OK, [2]UCL Inst. of Neurology, London, United Kingdom, [3]Eberhard Karls Univ., Tübingen, Germany, [4]Sabzevar Univ. of Med. Sci., Sabzevar, Iran, Islamic Republic of, [5]Centogene AG, Rostock, Germany, [6]Imperial Coll. London, Molecular Sci. Res. Hub, London, United Kingdom, [7]The Francis Crick Inst., London, United Kingdom, [8]Univ. of Portsmouth, European Xenopus Resource Ctr., Portsmouth, United Kingdom, [9]Univ. of Portsmouth, Portsmouth, United Kingdom

The acyl-CoA-binding domain-containing protein 6 (ACBD6) is involved in lipid and protein acylation and regulates protein *N*-myristoylation through *N*-myristoyltransferase enzymes (NMTs). However, the precise function of ACBD6 in cells and its impact on human pathophysiology remain unclear. To shed light on this, we studied 43 affected individuals from 27 families with bi-allelic pathogenic variants in *ACBD6*, using exome sequencing and international collaborations. Most variants were loss-of-function mutations (18/20). We generated acbd6 knockouts in zebrafish and Xenopus using CRISPR/Cas9 and investigated ACBD6's role in protein *N*-myristoylation in these models and human cells. We also examined ACBD6's peroxisomal localization in human cells. The affected individuals (21 males, 22 females) exhibited a complex and progressive disease with global developmental delay/intellectual disability (100%), expressive language impairment (97%), facial dysmorphism (94%), movement disorders (94%), mild cerebellar ataxia (85%), gait impairment (94%), limb spasticity/hypertonia (74%), oculomotor abnormalities (68%), behavioral abnormalities (63%), weight gain (59%), microcephaly (38%), and epilepsy (38%). Dystonia was the predominant movement disorder (90%), causing early-onset postural deformities (93%), limb dystonia (40%), and cervical dystonia (25%). Other common movement disorders included jerky tremors in upper limbs (61%), mild head tremor (56%), parkinsonism/hypokinesia with age (31%), and simple motor/vocal tics. Neuroimaging revealed midline brain malformations: corpus callosum abnormalities (67%), anterior commissure hypoplasia/agenesis (63%), short midbrain and small inferior cerebellar vermis (41% each), and clava hypertrophy (19%). Acbd6-deficient zebrafish and Xenopus models recapitulated patient phenotypes, including movement disorders, progressive neuromotor impairment, seizures, microcephaly, craniofacial dysmorphism, and midbrain defects with developmental delay and increased mortality. Unlike ACBD5, ACBD6 deficiency did not affect peroxisomal parameters in patient fibroblasts. Patient fibroblasts showed significant differences in labeling of 68 co- and 18 post-translationally *N*-myristoylated proteins using YnMyr-labelling. *N*-myristoylation was similarly affected in Acbd6-deficient zebrafish and Xenopus models, involving proteins linked to neurological diseases (FUS, MARCKS, CHCHD). This study establishes that bi-allelic pathogenic variants in *ACBD6* cause a distinct neurodevelopmental syndrome characterized by complex and progressive cognitive and movement disorders.

Session Title: Mendelian Phenotypes Poster Session II

PB4645 Biallelic *FLVCR1* variants cause a disease spectrum from adult neurodegeneration to severe neurodevelopmental disorders through disrupted choline transport

Authors:

Maroofian[12], F. Alkuraya[9], J. R. Lupski[1], L. N. Nguyen[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Natl. Univ. of Singapore, Singapore, Singapore, [3]BCM, Houston, TX, [4]UTHlth.Sch. of Publ. Hlth., Houston, TX, [5]Univ. of Nebraska Med. Ctr., Omaha, NE, [6]Boys Town Natl. Res. Hosp., Boys Town, NE, [7]Near NIMHANS, Bengaluru, India, [8]Boston Children's Hosp., Bostn, MA, [9]King Faisal Specialist Hosp. & Res. Ctr., Riyadh, Saudi Arabia, [10]Univ. of Gaziantep, Gaziantep, Turkey, [11]Baylor Coll. Med., Houston, TX, [12]Univ. Coll. London, London, United Kingdom

Background: FLVCR1 is a solute transporter implicated in cellular heme export and detoxification. *Flvcr1* knockout mice resemble Diamond-Blackfan anemia (DBA) with macrocytic anemia, craniofacial and digital deformities, and embryonic lethality. *FLVCR1* encodes mitochondrial and plasma membrane isoforms; both are required for murine viability. In contrast, biallelic *FLVCR1* variants cause autosomal recessive neurodegenerative phenotypes in humans: posterior column ataxia with retinitis pigmentosa and hereditary sensory and autonomic neuropathy (PCARP-HSAN). Recent evidence implicates FLVCR1 in the Kennedy pathway - a pathway responsible for *de novo* synthesis of the most abundant phospholipids in mammalian cells: phosphatidylcholine and phosphatidylethanolamine. The physiological significance of FLVCR1 in heme detoxification has been questioned.
Methods: To investigate apparent discrepancies between human and mouse *FLVCR1* phenotypes, we analyzed genomic data from >30,000 individuals with rare diseases for biallelic rare damaging *FLVCR1* variants. We performed molecular modeling of *FLVCR1* variants and developed a transport assay using FLVCR1-transfected HEK293 cells incubated with radiolabeled Kennedy pathway substrates. We examined the impact of *FLVCR1* missense variants on choline transport using the transport assay.
Results: We identified 20 individuals from 14 unrelated families with biallelic *FLVCR1* variants and severe developmental disorders (DD) distinct from PCARP-HSAN. Common findings included microcephaly, brain atrophy, profound developmental delay, epilepsy, and premature death. 8 individuals including 2 human knockouts exhibited additional findings seen in *Flvcr1* knockout mice and DBA [megaloblastic anemia, craniofacial malformations, and digital anomalies]. Severe DD associated missense alleles cluster in the protein transmembrane domains 9-11 and impact mitochondrial and plasma membrane isoforms. PCARP-HSAN associated missense variants are widely distributed and often only impact the plasma membrane isoform. We confirm FLVCR1 is a selective and highly conserved choline transporter through overexpression and knockdown studies. Furthermore, we show nearly all disease associated *FLVCR1* missense variants reduce choline transport.
Conclusions: The *FLVCR1* allelic series i) reconciles observed differences between mouse and human phenotypes, ii) demonstrates a broad human disease spectrum from adult-onset neurodegeneration to severe DD, and iii) suggests genotype-phenotype correlations. Ongoing research efforts will explore disease mechanisms and possible treatments for this disease.

Ctr., Riyadh, Saudi Arabia

Background: The homologous *GTPBP1* and *GTPBP2* genes encode GTP-binding proteins 1 and 2 that are involved in ribosomal homeostasis. Pathogenic variants in *GTPBP2* were recently shown to be an ultra-rare cause of neurodegenerative or neurodevelopmental disorders (NDDs). Until now, no human phenotype has been linked to *GTPBP1*. Here, we describe the first patients carrying biallelic *GTPBP1* variants, that display an identical phenotype with *GTPBP2,* and characterize the overall spectrum of GTP-binding protein (1/2)-related disorders. **Methods:** Twenty patients from 16 families with distinct NDDs and syndromic facial features were investigated by whole exome (WES) or genome (WGS) sequencing. To assess the functional impact of the identified genetic variants, semi-quantitative PCR, western blot and ribosome profiling assays were performed in patient-derived fibroblasts. *Drosophila melanogaster* lines harbouring hypomorphic mutations in *cg2017*, the fruit fly homolog of human *GTPBP1/2*, were also investigated. **Results:** Patients with biallelic *GTPBP1* or *GTPBP2* variants presented with microcephaly, pathognomonic craniofacial features and ectodermal defects. Neurodevelopmental impairment was profound in all cases. Abnormal vision and/or hearing, progressive spasticity, choreoathetoid movements, refractory epilepsy, and brain and cerebellar atrophy were part of the core phenotype of this syndrome. Cell lines studies identified a loss-of-function (LoF) impact of the disease-associated variants on both mRNA and protein levels, but no significant abnormalities on ribosome profiling assays. Reduced expression of *cg2017* isoforms was associated with locomotor impairment in *Drosophila*. **Conclusions**: Biallelic *GTPBP1* and *GTPBP2* LoF variants cause an identical, distinct and severe neurodevelopmental syndrome. Based on our observations, we propose to define this condition as **G**tpbp1/2 **R**elated **E**ctodermal **N**euro**D**evelopmental (GREND) syndrome. Our findings add insights into the consequences of biallelic LoF genetic defects in both GTPBP1 and GTPBP2, highlighting that 'GREND syndrome' can result from the loss of either homologous translational GTPase in humans. Neurological impairment of mutant flies highlight the conserved role for GTP-binding proteins in nervous system development across species.

DNA Methyltransferase 1 Associated Protein 1 (*DMAP1*) encodes a versatile protein involved in different complexes responsible for maintenance of DNA methylation, DNA damage repair, regulation of histone acetylation and catalysis of exchange of histone H2A and H2A.Z. Despite DMAP1's essential roles in multiple transcriptional processes, it has not been implicated in human disease. Through exome sequencing and subsequent reach out to the international matchmaking community, we identified ten individuals from nine families with a syndromic neurodevelopmental disorder carrying homozygous or compound heterozygous variants in *DMAP1*. Among these variants were three splice-altering or frameshift variants and seven missense variants residing in or around the SANT domain, suggesting they may affect interactions with DNA and/or histones. All ten individuals have global developmental delay, intellectual disability, hypotonia, and craniofacial dysmorphisms, although the reported findings varied. Detailed clinical assessment demonstrated that additional features, such as microcephaly, short stature, seizures, and brain malformation, were concomitant in at least three individuals. Utilizing the Gal4-UAS system to perform neural-specific knockdown of the *Drosophila* ortholog *Dmap1*, we observed pupal lethality and structural defects in the mushroom body (MB), highlighting an underappreciated role of Dmap1 in MB development. These phenotypes can be rescued by the wild-type (WT) and the two missense variants of human *DMAP1*, allowed us to conduct the social space assay to further query the high order effect in social behavior. We found that WT DMAP1 restored proper fly distribution, whereas the two missense variants caused clustering and reduced inter fly distance, reflecting impaired social avoidance and conforming the pathogenicity of these missense variants. Additionally, WT DAMP1 but not the two missense variants partially rescued the seizures induced by mechanical stimulation in a sex dependent manner. Transcriptome analyses from *Drosophila* RNAi brains identified dysregulation of hundreds of genes implicated in transcription processing, neuronal function, and brain development. In light of its involvement in DNA methylation, we performed an episignature analysis using blood-derived genomic DNA and identified a specific DNA methylation episignature. Further inversigations on DNA damage repair, histone H2A.Z deposition and histone acetylation are currently underway and will be presented. Taken together, we demonstrate that biallelic variants in *DMAP1* are associated with a novel neurodevelopmental disorder.

Introduction: CHARGE syndrome (Coloboma, Heart anomalies, Atresia of choanae, Retarded growth and mental development, Genital anomalies, and Ear malformations and hearing loss) is a well-established disorder. Diagnostic criteria now mandate the presence of the 3C triad: coloboma, choanal atresia, and abnormal semicircular canals. Only one gene, *CDH7*, has an established association with autosomal dominant CHARGE syndrome. *CDK9* was proposed to cause an autosomal recessive CHARGE-like syndrome after four Arabian families with a homozygous *CDK9* variant [c.673C>T:p. (Arg225Cys)] were identified. One more family has been described since; yet, this disease-gene association remains unestablished. **Methods:** We used GeneMatcher and access to different clinical and research laboratories to identify subjects with biallelic *CDK9* variant alleles and systemically evaluate their phenotype. All subjects had exome sequencing followed by a segregation study. **Results:** We ascertained 13 individuals from 11 families with biallelic *CDK9* deleterious variants including two families with novel variants [c.1118_*18del and c.26A>G; p.(Glu9Gly)] and 9 families (5 new and 4 previously-published) from a large Arabian tribe with the previously described founder variant [c.673C>T:p. (Arg225Cys)]. All subjects had profound global developmental delay/intellectual disability; half had neonatal hypotonia, epilepsy and/or peripheral hypertonia. Dysmorphic features included webbed neck (100%), micrognathia and palatal abnormalities (91%), prominent nasal bridge (81%), curved eyebrows (75%), microcephaly (69%) and midfacial hypoplasia and choanal atresia (55%). Eye abnormalities (83%) included congenital cataract (58%), visual impairment (57%), microphthalmia (56%), and microcornea (33%). Macrotia was observed in 33% and hearing loss in 30%. A third of the subjects had cardiac anomalies and half had genitourinary anomalies including cryptorchidism in all 3 males and absent ovaries with uterine abnormalities in 33% of the female. Abnormal kidneys, hydronephrosis and ectopic ureter were observed in a third each. Neuroimaging findings included vermian hypoplasia (62%), delayed myelination (58%), and dysmorphic large ventricles (55%). None had the 3C triad with coloboma observed in only 17% and external ear abnormalities in 31%. **Conclusion:** Our data upgrade the link between *CDK9* and CHARGE-like syndrome from limited to moderate (GenCC), which allows clinical molecular reporting of this disease. This study underscores the importance of studying diverse populations to aid in disease gene discovery and enhance our understanding of human biology and disease.

Introduction: DNA replication is vital for cell division and repair, and its precise regulation is critical for maintaining genomic integrity. Errors in DNA replication contribute to the pathogenesis of several Mendelian DNA repair and replication disorders, as well as more common diseases such as cancer. The Replication Factor C (RFC) complex consists of five subunits and loads proliferating cell nuclear antigen (PCNA) onto DNA, facilitating the recruitment of replication and repair proteins and enhancing DNA polymerase processivity. While RFC1 dysfunction has been associated with Cerebellar Ataxia, Neuropathy, and Vestibular Areflexia Syndrome (CANVAS), the role of RFC2-5 in human disease remains unclear. In this study, we identified *RFC4*, which encodes one of the subunits of the RFC complex, as a candidate gene in five individuals with an undiagnosed neurological disorder.

Methods: Each proband underwent extensive clinical evaluation. To identify potential disease-causing genetic loci, we performed a combination of exome/genome sequencing, RNA sequencing, and family-based genomics. Collaborative variant re-analysis was conducted to refine the candidate variants, which were validated by genomic DNA Sanger sequencing. Splicing variants were confirmed by cDNA Sanger sequencing. *RFC4* gene expression and RFC4 protein levels were assessed by quantitative PCR and immunoblot analysis, respectively. Functional studies on protein stability and RFC complex formation were performed using a mutant RFC4 overexpression system.

Results: The affected individuals exhibited ataxia, muscular weakness, hearing impairment, and/or short stature, varying in severity and age at onset. Rare, conserved, likely pathogenic, bi-allelic variants in *RFC4* were identified in all affected individuals and segregated with disease. RNA sequencing and cDNA Sanger sequencing analyses confirmed that the splice site variants lead to exon skipping. All variants were predicted to alter or remove the C-terminal domain, which is indispensable for RFC complex formation. Further, RFC4 protein levels were significantly decreased in cultured patient fibroblasts compared to unaffected controls, and overexpression studies of each RFC4 variant demonstrated decreased protein stability and/or RFC complex formation.

Conclusion: Our findings from in silico analysis and functional assays, together with the overlapping clinical phenotypes observed in CANVAS due to bi-allelic *RFC1* repeat expansions or protein-truncating variants, provide compelling evidence that bi-allelic loss-of-function *RFC4* variants contribute to the pathogenesis of this new neurological disorder.

PB4650 † Biallelic loss-of-function variants in *SLC13A1* are associated with skeletal dysplasia phenotypes in humans

Authors:

C. Tise[1], K. Ashton[2], L. De Hayr[3], E. Krzesinski[4], J. Bassetti[5], A. Zankl[6], A. Khanshour[7], J. Rios[7], C. Wise[7], T. Roscioli[2], M. Buckley[2], R. Harvey[3], P. Dawson[8]; [1]Stanford Univ., Palo Alto, CA, [2]NSW Hlth.Pathology, Sydney, Australia, [3]Univ. of the Sunshine Coast, Queensland, Australia, [4]Monash Hlth., Melbourne, Australia, [5]Weill Cornell Med., New York, NY, [6]The Children's Hosp. at Westmead, New South Wales, Australia, [7]Texas Scottish Rite Hosp. for Children, Dallas, TX, [8]Mater Res. Inst., Brisbane, Australia

Sulfate (SO_4^{2-}) is necessary for a variety of physiological processes, including structural and functional maintenance of macromolecules and the formation of sulfur-containing compounds. The key role of sulfate in skeletal growth and development is exemplified by the abnormal bone and cartilage phenotypes of individuals with certain forms of skeletal dysplasias, including diastrophic dysplasia caused by biallelic pathogenic variants in the sulfate transporter gene *SLC26A2*. In this study, we explored a novel association between variants in *SLC13A1* and skeletal phenotypes. SLC13A1 is a sodium-sulfate cotransporter primarily expressed in the kidney where it mediates sulfate reabsorption and maintenance of circulating sulfate levels to meet demands of other tissues. Previous reports described two rare, unlinked nonsense variants in *SLC13A1*, NM_022444.3:c.34C>T[p.R12*] and NM_022444.3:c.144G>A[p.W48*], associated with a ~30% reduction in serum sulfate level in heterozygotes (0.25 mM vs. 0.36 mM in controls) without any obvious physical phenotype. Given the hyposulfatemia and osteochondrodysplasia observed in animals with biallelic loss-of-function (LOF) variants in *Slc13a1*, a skeletal phenotype in humans with biallelic LOF variants has been suspected. Through use of trio exome sequencing and GeneMatcher (https://genematcher.org), a compilation of six children from four families with biallelic variants in *SLC13A1* and a skeletal dysplasia phenotype has emerged. All presented with short stature and were found to have abnormal radiological features, including scoliosis and/or a (spondylo)epimetaphyseal dysplasia. Identified *SLC13A1* variants include the aforementioned nonsense variants and three additional missense variants, NM_022444.3:c.1343G>A[p.G448D], NM_022444.3:c.1547T>C[p.L516P], and NM_022444.4:c.1744T>C[p.Y582H]. Genotypes include homozygous nonsense (n=1), homozygous missense (n=1), and compound heterozygosity for nonsense/missense variants (n=4). The serum sulfate level in the individual with a homozygous missense variant was proportionately reduced compared to individuals with heterozygous *SLC13A1* nonsense variants (0.11 mM vs. 0.25 mM), consistent with these representing LOF alleles of similar effect size. This work defines biallelic LOF variants in *SLC13A1* as a novel cause of skeletal dysplasia phenotypes in humans. Functional studies are underway to characterize the impact of these *SLC13A1* variants on sulfate transport. These findings also highlight the importance of considering sulfate measurements in cases of unsolved short stature with or without obvious skeletal dysplasia features.

Session Title: Mendelian Phenotypes Poster Session II

PB4651 Biallelic *PSTK* variants disrupt selenoprotein synthesis and cause a multisystemic disorder.

Sch., Boston, MA, [4]Office of the Clinical Director, Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [5]Pediatric Neurology and Neuromuscular Med., Johns Hopkins Sch. of Med., Baltimore, MD, [6]Neurology & Dev.al Med., Kennedy Krieger Inst., Baltimore, MA, [7]Bioinformatics and Computational BioSci.s Branch, Natl. Inst. of Allergy and Infectious Diseases, NIH, Bethesda, MD, [8]Broad Inst., Cambridge, MA, [9]Human Biochemical Genetics Section, Med. Genetics Branch, Natl. Human Genome Res. Inst., NIH, Bethesda, MD

Background: Selenoproteins are a distinct class of proteins that contain selenocysteine as a unique amino acid and are involved in a wide range of biological functions, including antioxidant defense, redox regulation, and thyroid hormone metabolism. The highly regulated selenoprotein biosynthesis pathway plays a vital role in the incorporation of the essential micronutrient selenium as selenocysteine (Sec). One critical enzyme in this pathway is phosphoseryl-tRNA$^{[Ser]Sec}$ kinase (PSTK), which phosphorylates seryl-tRNA$^{[Ser]Sec}$. This phosphorylated tRNA facilitates the delivery of selenium to the ribosome for the incorporation of selenocysteine into selenoproteins. Although human diseases have been associated with other key genes in the selenoprotein biosynthesis pathway, including *SECISBP2*, *TRU-TCA-1*, and *SEPSECS*, no human condition has been associated with *PSTK*. Here, we report compound heterozygous variants in *PSTK* in a 2 y/o proband with severe refractory epileptic encephalopathy.
Methods: The proband underwent comprehensive clinical and biochemical evaluation, including research reanalysis of genome sequencing data. Functional validation of the identified variants was performed on patient's biological samples and primary cell lines. Oxidative stress assays were conducted, and selenium and antioxidant therapy were also initiated.
Results: The proband had hypotonia, global developmental delay with regression, sensorineural hearing loss, acquired microcephaly, and seizures, which became refractory and led to encephalopathy and multisystem compromise. Genome sequencing reanalysis identified compound heterozygous variants in *PSTK*. Biochemical studies revealed abnormal thyroid hormone levels, low circulating selenium, and undetectable glutathione peroxidase activity and selenoprotein P levels, consistent with a defect in selenoprotein biosynthesis. The patient's fibroblasts showed poor survival in the absence of high-dose vitamin E supplementation. High levels of reactive oxygen species were detected, suggesting the presence of significant oxidative stress and the potential involvement of ferroptosis.
Conclusion: Collectively, these findings suggest that biallelic *PSTK* variants result in selenoprotein deficiency, contributing to the pleiotropic phenotype observed in this individual. This case highlights the critical role of PSTK in maintaining selenium homeostasis and underscores the importance of selenoproteins in neurological function.

Session Title: Mendelian Phenotypes Poster Session III

PB4652 Biallelic structural variations within *FGF12* detected by long-read sequencing in epilepsy

Authors:

N. Matsumoto, A. Fujita, S. Ohori; Yokohama City Univ. Graduate Sch. of Med., Yokohama, Japan

We discovered biallelic intragenic structural variations (SVs) in *FGF12* by applying long-read whole genome sequencing (LRWGS) to an exome-negative patient with development and epileptic encephalopathy (DEE). We also found another DEE patient carrying a biallelic (homozygous) single nucleotide variant (SNV) in FGF12 that was detected by exome sequencing. *FGF12* heterozygous recurrent missense variants with gain-of-function or heterozygous entire duplication of *FGF12* are known causes of epilepsy, but biallelic SNVs/SVs have never been described. *FGF12* encodes intracellular proteins interacting with the C-terminal domain of the alpha-subunit of voltage-gated sodium channels 1.2, 1.5, and 1.6, promoting excitability by delaying fast inactivation of the channels. To validate the molecular pathomechanisms of these biallelic *FGF12* SVs/SNV, highly sensitive gene expression analyses using lymphoblastoid cells from the patient with biallelic SVs, structural considerations, and Drosophila in vivo functional analysis of the SNV were performed, confirming loss-of-function. Our study highlights the importance of small SVs in Mendelian disorders, which may be overlooked by exome sequencing but can be detected efficiently by LRWGS, providing new insights into the pathomechanisms of human diseases.**Acknowledgments**Akihiko Miyauchi, Hitoshi Osaka, Charles Marques Lourenco, Naohiro Arakaki, Toru Sengoku, Kazuhiro Ogata, Rachel Sayuri Honjo, Chong Ae Kim, Satomi Mitsuhashi, Martin C. Session Title: Mendelian Phenotypes Poster Session I

PB4653 Biallelic variant in *TGFBR3* is implicated in human craniosynostosis.

Authors:

R. M. Elshafie[1], D. J. Bernard[2], Y-F. Lin[2], I. Pecora[2], E. R. Buddle[2], D. Marafi[1,3], A. Elshafey[1], A. Alshammari[1], H. Alsharhan[1,3], D. Ibrahim[1], L. Bastaki[1]; [1]Kuwait Med. Genetics Ctr., Ministry of Hlth., Sulaibikhat 80901, Kuwait, [2]Dept. of Pharmacology and Therapeutics, McGill Univ., Montreal, QC, Canada, [3]Dept. of Paediatrics, Faculty of Med., Kuwait Univ., Jabriya, P.O. Box 24923, 13110 Safat, Kuwait

Background: Fusion of cranial sutures is a pre-programmed orchestrated process. Disruption of this process in the underlying signaling pathways results in premature fusion and ossification of sutures (craniosynostosis). Knowledge of the molecular mechanisms underlying craniosynostosis remains limited. The transforming growth factor ß (TGF-ß) superfamily is signaling molecules regulating various biological functions in connective and other tissues. Until now, no clear association between the TGF-ß family and a known form of craniosynostosis was established; however, previous studies demonstrated high expression of TGF-ß1, 2, and 3 in cranial sutures and dura matter. The TGF-ß type III receptor (TGFBR3) is a transmembrane proteoglycan that binds TGF-ß isoforms. Half of *Tgfbr3* knockout mouse embryos revealed a generalized reduction in the size and ossification of the craniofacial and appendicular skeletons. No definitive human phenotypes have been associated with *TGFBR3* mutations. Here, we report two Kuwaiti brothers with craniosynostosis and a homozygous variant in *TGFBR3*.Material-Methods: We performed exome sequencing reanalysis on two brothers with craniosynostosis followed by a family segregation study of the identified *TGFBR3* variant. The variant was then introduced into a human *TGFBR3* expression vector using site-directed mutagenesis to study its effect in vitro. Results: We identified a novel homozygous nonsense variant in *TGFBR3* [NM_003243.4: c.2418G>A :p. (Trp806Ter)] in the two brothers. A segregation study for the family confirmed Mendelian autosomal recessive inheritance. Both brothers had posterior sagittal and lambdoid synostosis, undescended testes, hypospadias, and congenital hip dislocation. Mutant *TGFBR3* was expressed at the plasma membrane of heterologous HEK293T cells but was notably smaller due to the loss of its intracellular C-terminus. Mutant TGFBR3 was capable of potentiating responses to TGF-ß1, 2, and 3 in cell-based reporter assays. Collectively, the data show that premature stop codon leads to truncation of TGFBR3 but does not appear to affect its production, subcellular localization, or ability to mediate canonical signaling via the three TGF-ß isoforms. Additional in vitro studies are undergoing to evaluate the potential deleterious effects on non-canonical signaling mediated via the C-terminus of the protein. Conclusion: In conclusion, our study demonstrates the potential association of TGFBR3 signaling dysregulation with syndromic craniosynostosis and is the first report to elucidate such an observation. Identification of additional cases is important to further consolidate our findings.

Session Title: Mendelian Phenotypes Poster Session II

PB4654 † Biallelic variants in *ANKRD6* are a candidate cause for a rare multisystemic congenital anomaly disorder

Authors:

S. Khan[1,2], T. Arbogast[3], L. Ellen[4], H. Cope[4], B. Brita[5], E. Davis[1,6]; [1]Ann & Robert H. Lurie Children's Hosp. of Chicago, Chicago, IL, [2]Human Molecular Genetics Lab., Hlth.Biotechnology Div., Natl. Inst. for Biotechnology and Genetic Engineering (NIBGE), Pakistan., Fasialabad, Pakistan, [3]Ann & Robert H. Lurie children s Hosp. of Chicago, Chicago, IL, [4]Ctr. for Human Disease Modeling, Duke Univ., Durham, NC, [5]Fetal Diagnostic Ctr., Duke Univ. Med. Ctr., Durham, NC, [6]Dept. of Pediatrics and Cell and Dev.al Biology, Fienberg Shchool of Med., Northwestren Univ., Chicago, IL

Wnt signaling regulates crucial aspects of cell fate determination, cell migration, cell polarity, neural patterning, and organogenesis during embryonic development. Diversin, encoded by *ANKRD6* (ankyrin repeat domain-containing 6), acts as a molecular switch between canonical and non-canonical Wnt signaling (planar cell polarity, PCP). As part of our ongoing efforts to identify the genetic basis of congenital anomalies in neonates and children, we performed trio exome sequencing (ES) in healthy parents and a prenatally referred female with multiple congenital anomalies, consistent with VACTERL. Specifically, she has laterality defects, renal agenesis, esophageal atresia, tracheoesophageal fistula, and complex cardiovascular phenotypes, and was enrolled in our research study at 5 days of age. We identified rare compound heterozygous nonsynonymous variants (NM_014942: c.38G>A, p.Arg13His and c.1880G>A, p.Arg627His) in *ANKRD6* that segregate with disease. To establish the physiological relevance of disease phenotypes, we generated CRISPR-Cas9 mutant and transient suppression zebrafish models. The F0 mosaic mutants recapitulate phenotypes observed in the proband, including laterality phenotypes and renal hypoplasia. We validated further the phenotypes observed in our F0 mutants by transient suppression with a splice-blocking morpholino. We evaluated convergent extension and left-right asymmetry defects and observed that morphants displayed shortened body axes, broadening, and thinning of somites, undulating notochords, and a decreased size of anterior structures with concomitant left-right asymmetric defects when compared to controls. Furthermore, *in vivo* complementation assays suggest that p.Arg13His and p.Arg627His variants confer hypomorphic and functional null effects on protein function, respectively. Together, our genetic and functional data implicate *ANKRD6* as an ultra-rare candidate gene for a VACTERL-like syndrome, which highlights a critical role of Wnt/PCP in human development and disease.

Session Title: Mendelian Phenotypes Poster Session III

PB4655 Biallelic variants in ARHGAP19 cause a motor-predominant neuropathy with conduction slowing

Authors:

S. Efthymiou[1], N. Dominik[1], C. Record[1], X. Miao[2], ARHGAP19 Clinical Consortium, D. Osborn[3], J. Jepson[1], N. Lamarche-Vane[2], M. Hanna[1], M. Reilly[1], H. Houlden[1]; [1]UCL Inst. of Neurology, London, United Kingdom, [2]Dept. of Anatomy and Cell Biology, McGill Univ.,, Montréal, QC, Canada, [3]St George Univ. of London, London, United Kingdom

Rho GTPases are members of the large superfamily of small GTPase proteins considered as molecular switches in various cellular events. One of the major regulators of Rho GTPases are Rho GTPase-activating proteins (GAPs). RhoGAPs stimulate intrinsic GTPase activity of Rho GTPases therefore acting as negative regulators of Rho pathway. One of the Rho effectors, the serine/threonine protein kinase ROCK, has important role in actin organisation, cell migration regulation, cell cycle control, and cell adhesion. By using next generation sequencing we identified 17 individuals from 16 unrelated families with biallelic variants in Rho GTPase-activating protein 19 (ARHGAP19) presenting with young age of onset, mild to moderate motor predominant, length-dependent neuropathy with sensory symptoms. Nerve conduction studies reveal chronic denervation and a predominantly axonal neuropathy. We are using various approaches to model these variants; *in-vitro* GAP assays to assess if the GAP activity is affected by expression of proteins carrying ARHGAP19 mutations, complemented by an *in-vivo Drosophila melanogaster* and *Danio rerio* models to test for movement, lifespan and neuromuscular junction integrity; in silico approach to gain an understanding of protein structure changes and its implications. Ongoing studies such as the *in-vitro* GAP assays show that ARHGAP19 has GAP activity towards RhoA but not Rac1 or Cdc42. Three of the mutations found in patients are being tested for their GAP activity and preliminary data suggest a loss of the GAP activity in a frameshift mutations. Visualisation of the endogenous expression pattern of ARHGAP19 ortholog in fly, RhoGAP54D, suggest the protein is expressed in perineural or subperineural glia in the fly brain. Preliminary results indicate that RNAi knockdown of RhoGAP54D in flies reduces both overall movement and startle responses to light-dark transitions. This is a first association of ARHGAP19 with neurological disease and deep phenotyping analysis in conjunction with the in-vivo animal model and the *in-vitro* GAP assay will help highlight he importance of the gene in early human brain development and function.

Session Title: Mendelian Phenotypes Poster Session I

PB4656 Biallelic variants in *BECN1*, an autophagy effector, are associated with a rare neurodevelopmental syndrome

Authors:

F. Ullah[1,2], V. Salpietro[3], M. Coghlan[4], A. M. Sharma[4], A. Mercier[5], A. McRae[5], H. Houlden[6], E. Davis[7]; [1]Lurie Children's Hosp. of Chicago, Chicago, IL, [2]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL, USA., Chicago, IL, [3]UCL, London, United Kingdom, [4]Div. of Neonatology, Dept. of Pediatrics, Ann & Robert H. Autophagy is a hallmark cellular process involved in the elimination of cytoplasmic materials and degradation of macromolecules via lysosomal machinery. Although impaired autophagy has garnered longstanding attention for involvement in neurodegenerative disorders, pathogenic variants in pathway effectors such as *VPS15* and *ATG7* have more recently emerged as rare contributors to neurodevelopmental disease. As part of our ongoing efforts to identify new causes for rare fetal and pediatric onset central nervous system anomalies, we performed parent-proband exome sequencing and chromosomal microarray in affected individuals from three unrelated families and found rare variants in *BECN1*, encoding Beclin 1. Beclin 1 is a key component of the PI3K-III complex involved in the initiation, recruitment, and activation of autophagosome formation. Ablation of *Becn1* in mice leads to preweaning lethality, but the locus has not been implicated previously in human phenotypes. In family 1, two affected sisters presented with prenatal findings of severe ventriculomegaly, macrocephaly, callosal anomalies, dysplastic cerebellum, and hypoplasia of the vermis, associated postnatally with hypoventilation/apnea ultimately leading to death at <3 months of age. We detected rare, compound heterozygous variants in *BECN1* (p.Cys375Arg and p.Gln326*) co-segregating with the disease. The family 2 proband, harboring a homozygous p.Gly107Ser variant, has macrocephaly, intellectual disability, dysgenesis of the corpus callosum and cortical malformation. The family 3 proband, who has a biallelic p.Gly355Arg change, displays developmental delay and intellectual disability. To assess the functional consequences of *BECN1* biallelic variants, we generated stable mutant and transient suppression zebrafish models. Zebrafish larvae with *becn1* loss of function show a significantly increased head size and a reduced number of commissural axons as proxies for macrocephaly and corpus callosum defects, respectively. We also observe a concomitant increase in cell death in anterior structures in the context of *becn1* loss, and larval lethality in homozygous mutants carrying a frameshifting variant. *In vivo* complementation assays confirm that the missense variants are either loss of function or hypomorphic. Finally, we accompanied our *in vivo* studies with biochemical assays in patient-derived fibroblasts to show that *BECN1* variants induce aberrant AKT-mTOR signaling. Taken together, these data suggest a critical role for Beclin 1 and autophagy-related functions in brain development across different species.

Coll., Manipal, MAHE, Manipal, Manipal, Udupi, India

In neuronal tissues, the protein encoded by the *EPB41L3* gene, commonly referred to as 4.1B, has been found to play important roles in neuronal development, myelination, and cytoskeletal organization. The close relationship between neurons and oligodendrocytes is essential for neuronal function. Cell-type specificity in expression of 4.1B isoforms is important for both neurons as well as oligodendrocytes during development, which challenges current models of 4.1B function restricted to nodes of Ranvier. Here, we describe six individuals with novel biallelic *EPB41L3* variants (two nonsense and three frameshift) who present with global developmental delay, intellectual disability, epilepsy, hypotonia, and delayed myelination. This represents the first clinical description of an autosomal recessive disorder associated with variants in *EPB41L3*, which we refer to as *EPB41L3*-associated developmental disorder (EADD). The clinical features of EADD do not phenocopy the *Epb41l3* knockout mouse models. To investigate pathogenic mechanisms, we utilize patient-derived fibroblasts and neural progenitor cell lines from human embryonic stem cells harboring patient variants. Our findings indicate greater involvement of oligodendrocyte 4.1B in human EADD neuropathology than has been implicated in *Epb41l3* mouse models. Together, our findings identify *EPB41L3* variants as the basis of a newly described neurodevelopmental disorder.

Session Title: Mendelian Phenotypes Poster Session III

PB4658 Biallelic variants in GET4 cause developmental disabilities with a variable degree of phenotypic spectrum

Authors:

A. Fatima[1], G. Banneau[2], S. Hashami[1], J. Iwaszkiewicz[3], R. Ibrahim[1], M. Jameel[1], A. Khan[4], S. Baig[5], M. Toft[6], Z. Iqbal[7]; [1]Aga Khan Univ., Karachi, Karachi, Pakistan, [2]CHU Toulouse, France, Toulouse, France, [3]SIB Swiss Inst. of Bioinformatics, Lausanne, Switzerland, [4]Natl. Inst. for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, Pakistan, [5]Aga Khan Univ., karachi, Pakistan, [6]Oslo Univ. Hosp, Oslo, Norway, [7]Oslo Univ. Hosp., RH, Oslo, Norway

GET4 is one of the six components of the transmembrane domain recognition complex (TRC) pathway. TRC directs the tail-anchored proteins to the appropriate cellular membranes. A single patient with compound heterozygous variant in the gene GET4 has been reported with global developmental delay, intellectual disability (ID) and seizures. We studied a five-generation Pakistani consanguineous family having four affected members presenting with variable degree of developmental disability including ID, seizures and developmental delay. Through whole exome sequencing, we identified a rare homozygous missense variant c.803G>A; p.R268Q (NM_015949.3) in GET4 gene which segregated with the phenotype. By GeneMatcher, we found another homozygous missense variant c.326C>G; p.A109G in GET4 in a patient of a consanguineous family. The patient presented with global developmental delay, and aspecific dysmorphia. In silico molecular modelling of the identified variants revealed that R268 residue's side chain is forming a hydrogen bond with the Q1035 of BAG6 gene and p.R268Q variant in GET4 possibly influences this interaction. It was predicted that this variant could lead to destabilization of the local protein structure. The p.A109G variant was predicted to decrease the stability of GET4 protein by destabilizing the alpha-helix structure, as Gly is known as a helix breaker. Moreover, we have initiated some functional experiments to study possible defects in TRC pathway and to prove the pathogenicity of these variants.In conclusion, we found two homozygous missense variants, p.R268Q and p.A109G in GET4 causing variable degree of developmental disability by plausibly influencing the stability and the structure of the GET4 protein.

Session Title: Mendelian Phenotypes Poster Session I

PB4659 Biallelic variants in *IFT57* may cause Bardet-Biedl Syndrome.

Authors:

A. Nitoiu[1], Q. Zhang[2], M. Rashid[1], E. Tavares[1], K. Ahmed[1], V. Sheffield[2], A. Vincent[1], E. Heon[1]; [1]The Hosp. for Sick Children (SickKids), Toronto, ON, Canada, [2]Univ. of Iowa, Iowa City, IA

Primary cilia are critical components of most cells, and are involved in many cell signalling pathways that regulate cellular and organ development. When this process goes wrong, patients develop ciliopathies; a genetically and clinically heterogenous group of diseases with a wide range of morbidities. Bardet Biedl syndrome (BBS) is a genetically heterogeneous ciliopathy with retinal degeneration, among other morbidities. The connecting cilium of the photoreceptor is a modified primary cilium sharing proteins and pathways with primary cilia. Approximately 20% of BBS cases remain genetically unsolved. We studied an unsolved case using whole genome sequencing (WGS). Results: A 29-year old male with clinical features suggestive of BBS had negative clinical genetic testing. WGS and comprehensive filtering identified biallelic *IFT57* variants in *trans* (NM_018010.4). The variants included c.675delA; p.(Lys225Asnfs*17), a frameshift deletion in exon 6 of chromosome 3 causing loss of function, and a c.1190T>A:p.(Val397Glu) missense variant in exon 11 of chromosome 3, a variant of unknown significance (VUS). Using patient-derived skin fibroblasts, immunofluorescence revealed a lower cilia count and abnormal cilia appearance. Using IMCD3 *IFT57* knockout cells showed that either a human or mouse Val397Glu variant can rescue ciliogenesis defects, but not in RPE1 knockout *IFT57* cells, suggesting a cell autonomous process. Conclusions: These results suggest that the missense variant Val397Glu acts as a hypomorph and together with the knockout variant likely causes our patient's observed ciliopathy phenotype. This adds complexity to the BBS genetic heterogeneity and demonstrates the value of further exploring VUSs.

Session Title: Mendelian Phenotypes Poster Session II

PB4660 Biallelic variants in SLC4A10 encoding the sodium-dependent chloride-bicarbonate exchanger NCBE lead to neurodevelopmental disorder

Authors:

R. Kaiyrzhanov[1], R. Maroofian[2], M. Zamani[3], L. Liebmann[4], SLC4A10 study group, H. Houlden[5], C. A. Hübner[4]; [1]South Kazakhstan Med. Academy, Shymkent, Kazakhstan, [2]UCL, London, United Kingdom, [3]Shahid Chamran Univ., Faradonbeh, Iran, Islamic Republic of, [4]Inst. of Human Genetics, Jena Univ. Hosp., Friedrich Schiller Univ., Jena, Germany, [5]Inst Neurology, London, United Kingdom

Background: *SLC4A10* encodes a plasma membrane-bound ion transport protein, which mediates Na^+-dependent HCO_3^- import thus mediating acid extrusion. *Slc4a10* knockout (KO) mice show collapsed brain ventricles, an increased seizure threshold, mild behavioral abnormalities, impaired vision, and deafness. Pathogenic variants in *SLC4A10* have hitherto not been associated with monogenic human disease traits. **Methods:** Utilizing proband-only or trio-exome/genome sequencing in families with undiagnosed neurodevelopmental disorders (NDD) and extensive international data sharing, 11 patients from 6 independent families with biallelic predicted-damaging variants in *SLC4A10* were identified. Clinical features, neuroimaging data, and facial images were reviewed by a group of clinical geneticists, neurologists, and a pediatric neuroradiologist. A minigene assay, intracellular pH recordings, and protein modelling were performed to study the possible functional consequences of the variant alleles. **Results**: The worldwide cohort harbours 8 rare/ultra-rare biallelic *SLC4A10* variants (7 missense and 1 splicing), which segregate with the disease within the families. Patients present with a clinical spectrum of global developmental delay/intellectual disability and central hypotonia associated with variable speech delay, microcephaly, cerebellar ataxia, epilepsy, and facial dysmorphism. Neuroimaging features are ranging from some non-specific to distinct neuroradiological findings, including slit ventricles and a peculiar form of bilateral curvilinear nodular heterotopia. All missense variants affect evolutionary highly conserved residues and are predicted to be damaging according to various *in silico* analyses. Intracellular pH recordings supported the disease-causing effect for 4/7 missense variants. **Conclusion**: We provide evidence that pathogenic biallelic *SLC4A10* variants can lead to NDD, which is characterized by variable abnormalities of the central nervous system including altered brain ventricles thus resembling several features observed in KO mice. Our study further highlights the challenges of assessing sequence variants identified in patients and distinguishing pathogenic variants from other potentially functional variants.

Session Title: Mendelian Phenotypes Poster Session III

PB4661 Biochemical Screening of Intellectually Disabled Patients A Stepping Stone to Initiate a Newborn Screening Program in Pakistan

Authors:

M. Wasim[1,2], H. Khan[1,2], H. Ayesha[3], S. Goorden[4], F. Vaz[4], C. Karnebeek[4], F. Arain[1], F. Awan[2]; [1]The Aga Khan Univ., Karachi, Pakistan, [2]Natl. Inst. for Biotechnology and Genetic Engineering, Faisalabad, Pakistan, [3]Faisalabad Med. Univ., Faisalabad, Pakistan, [4]Univ. of Amsterdam, Amsterdam, Netherlands

Inborn errors of metabolism (IEMs) are rare group of genetic disorders comprising of more than 1,000 different types. Around 200 of IEMs are potentially treatable through diet, pharmacological and other therapies, if diagnosed earlier in life. IEMs can be diagnosed early through newborn screening (NBS) programs, which are in place in most of the developed countries. However, establishing a NBS in a developing country is a challenging task due to scarcity of disease related data, large population size, poor economy, and burden of other common disorders. Since, not enough data is available for the prevalence of IEMs in Pakistan; therefore, in this study, we set out to find the prevalence of various treatable IEMs in a cohort of intellectually disabled patients suspected for IEMs, which will help us to initiate a NBS program for the most frequent IEMs in Pakistan. Therefore, a total of 429 intellectually disabled (IQ < 70) patient samples were collected from Pakistan. A subset of 113 patient samples was selected based on the clinical information for the detailed biochemical screening. Advance analytical techniques like, Amino Acid Analyzer, GC-MS, UHPLC-MS, and MS/MS were used to screen for different treatable IEMs like aminoacidopathies, fatty acid b-oxidation disorders and mucopolysaccharidoses (MPS) etc. A total of 14 patients were diagnosed with an IEM i.e., 9 with homocystinuria, 2 with MPS, 2 with Guanidinoacetate methyltransferase (GAMT) deficiency and 1 with sitosterolemia. These IEMs are found frequent in the collected patient samples from Pakistan. Thus, present study can help to take an initiative step to start a NBS program in Pakistan, especially for the homocystinuria having highest incidence among aminoacidopathies in the studied patients, and which is amenable to treatment. This endeavor will pave the way for a healthier life of affected patients and will lessen the burden on their families and society.

Session Title: Mendelian Phenotypes Poster Session I

PB4662 † Breeding scheme affects mouse model for atypical type VI osteogenesis imperfecta with*Ifitm5*/BRIL p.S42L

Authors:

E. Evans[1], M. Jovanovic[1], T. Hefferan[2], C. Locke[3], A. Barnes[1], K. Kozloff[3], J. Marini[1]; [1]Natl. Inst. of Child Hlth.and Human Dev., Bethesda, MD, [2]Mayo Clinic, Rochester, MN, [3]Univ. of Michigan, Dept.s of Orthopedic Surgery and BioMed. Engineering, Ann Arbor, MI

Background: Osteogenesis Imperfecta (OI) or brittle bone disease, is a genetic connective tissue disorder with major findings of bone fractures and deformities, and short stature. OI is a collagen-related disorder, with classical OI types caused by defects in type I collagen structure or quantity, while most rare types are caused by defects in molecules that interact with collagen. Type V, caused by recurrent dominant mutation in *IFITM5*/BRIL, and type VI OI, caused by recessive null mutations in *SERPINF1*/PEDF, have distinct phenotype and biochemistry. Atypical type VI OI (aVI) is caused by an *IFITM5* p.S40L substitution but is similar to type VI in terms of having progressive bone dysplasia, a fish-scale appearance to bone lamellae under polarized light and decreased cellular PEDF secretion. We generated a conditional KI *Ifitm5*/BRIL p.S42L murine model. Female heterozygous (HET) bone has increased BMDD, disordered collagen fibers on SHG, and increased osteocyte lacunar density but decreased osteocyte canalicular networks. However, bone tissue and osteoblasts of mutant mice from HET S42L x HET S42L matings do not replicate aVI OI lamellar organization and PEDF under-secretion.
Methods: Offspring of HET S42L x WT matings were examined as murine models of human aVI OI. Our approach encompasses comparison of male S42L and *Serpinf1* KO mice by RNAseq, X-Ray, and histology, and western blotting analysis of differentiating osteoblasts from newborn pups. Bone mechanics and histomorphometry of *Serpinf1* WT and KO mice were evaluated.
Results: HET S42L mice have decreased static histology parameters Tb. Th, OV/BV, OS/BS, and Ct.W. The dynamic histology parameters analyzed after calcein injections were generally decreased including MAR, BFR/BS, and BFR/BV. Whole-body, spine, and femur BMD were significantly decreased in S42L by DXA. Differentiating calvarial osteoblasts of HET S42L mice from a WT x HET mating exhibited significantly decreased PEDF secretion on days 0 and 10, while BRIL production was significantly increased at day 0. HBM osteoblast collagen secretion was normal except a1(1) secretion was significantly increased while pC/pN a1(1) and proa1(1) were decreased on day 0.
Conclusions: Our findings support an uncharacterized link between PEDF and BRIL revealed by aVI type OI. The HET S42L mice from a HET x WT mating had decreased PEDF secretion, similar to this parameter in aVI OI patients. Collagen produced by cells with BRIL or PEDF defects has normal primary structure and post-translational modification, suggesting these defects cause OI by affecting matrix formation and late osteoblast differentiation; future studies will characterize this mechanism.

Session Title: Mendelian Phenotypes Poster Session II

PB4663 Bringing genetic diagnosis to patients with hereditary sensory neuropathy through a comprehensive analysis of molecular and proteomic data.

Authors:

P. Lassuthova[1], R. Mazanec[2], D. Brožková[1], P. Seeman[3], A. Majcher[4], A. Museer[4], I. Kurth[5], T. Hornemann[4]; [1]Charles Univ., Dept. of Paediatric Neurology, 2nd Faculty of Med., Prague, Czech Republic, [2]Charles Univ., Dept. of Neurology, Faculty of Med., Prague, Czech Republic, [3]Charles Univ., Dept. of Paediatric Neurology, 2nd Faculty of Med., Praha 5, Czech Republic, [4]Univ. Hosp. Zurich, Dept. of Clinical Chemistry, Zurich, Switzerland, [5]Uniklinik RWTH Aachen, Aachen, Germany

Introduction: Hereditary sensory and autonomic neuropathies (HSAN) and congenital insensitivity to pain (CIP) are rare genetic disorders characterised by a lack of pain sensation. **Aim of the study:** To determine the genetic causes of HSAN/CIP. **Patients and methods:** At our centre, we have assembled a cohort of 82 Czech patients with HSAN. Of these, *SPTLC1* variants were found in two families, *SPTLC2* in two families and *RAB7* in three families. Afterwards, most unresolved patients had their exomes sequenced (ES). **Results:** Using ES, additional causal variants were found (always 1 family) in these genes: *NTRK1, SCN11A, SCN10A, MME, DST, and SPTLC2*. A likely pathogenic variant in *SCN11A* in one family was also detected. In addition, a biallelic pathogenic *RCF1* expansion was found in 6 patients. After ES and these analyses, a total of 50 patients remained unresolved. We approached the analysis of ES data based on proteomic data in an attempt to further identify the cause in this group - as the biosynthesis of sphingolipids is crucial in HSAN, genes involved in this pathway were analysed. In one patient we found a variant in the *PHGDH* gene, which is the rate-limiting enzyme in the serine synthesis. The patient is a sporadic case in the family. The first symptoms appeared at the age of 22 after an injury, before which he was an active boxer. Afterwards, he developed complications that led to the amputation of the second digit of the right foot. Currently, at the age of 37, he has undergone amputation of both lower limbs below the knee. A variant in the *PHGDH* gene (NM_006623.4): c.682G>T, p.(Gly228Trp) in the homozygous state was detected in the patient. Both parents are heterozygous carriers. The patient's plasma showed a reduced serine concentration and an increased alanine to serine ratio, which was associated with an increased deoxysphingolipid formation. Biallelic loss-of-function mutations in *PHGDH* have been described to cause Neu-Laxova syndrome and are also associated with macular telangiectasia. The phenotype of our patient is different as he presented with axonal sensory neuropathy. The p.(Gly228Trp) variant is also expected to be loss-of-function, however the residual activity of the enzyme has to be determined. **Conclusions:** Our study presents molecular genetic data from a relatively large cohort of patients with HSAN. The combination of genomic and proteomic data analysis may be helpful in identifying potential targets. All authors declare no conflict of interest. The research follows the criteria of Declaration of Helsinki. Supported by: LX22NPO5107.

Session Title: Mendelian Phenotypes Poster Session III

PB4664 Burden of GM2 gangliosidosis in Kuwait is driven by founder mutations.

Authors:

N. Almoosawy[1,2], F. Mohammed[3], A. Elshafey[3], M. Pavlovic[4], A. Alaqeel[5], I. H. Almashmoom[5], A. Al-Ahmad[6], B. Albash[3], L. Bastaki[3], D. Marafi[7]; [1]Kuwait Univ., Faculty of Med., Kuwait, Hawalli, Jabriya, Kuwait, [2]Dept. of Pediatrics, Mubarak Alkabeer Hosp., Ministry of Hlth., Kuwait, Hawalli, Jabriya, Kuwait, Kuwait, [3]Kuwait Med. Genetics Ctr., Ministry of Hlth., Sulaibikhat, Kuwait, Kuwait, [4]Dept. of Pediatrics, Pediatric Neurology Unit, Alsabah Hosp., Alsabah, Kuwait, Kuwait, [5]Ahmadi Hosp., Kuwait Oil Company, Ahmadi, Kuwait, Kuwait, [6]Kuwait Med. Genetic Ctr., Sulaibikhat, Kuwait, [7]Kuwait Univ., Jabriya, Kuwait

Introduction: GM2 gangliosidoses are a group of rare lysosomal storage disorders resulting from deficiency of the beta-hexosaminidase enzyme including Tay-sachs disease (TD), causing hexosaminidase A (Hex A) deficiency due to biallelic HEXA pathogenic variants; Sandhoff disease (SD), causing hexosaminidase A and B (Hex A and B) deficiency due to biallelic HEXB pathogenic variants; and the AB variant, caused by biallelic GM2A pathogenic variants. In Kuwait, data about GM2 gangliosidoses are lacking. We provide a summary of phenotypic-genotypic features of such disorders in Kuwait showing that their burden is driven by founder mutations. **Methods:** A retrospective review of all cases at Kuwait Medical Genetic Center with a molecular diagnosis of TD, SD or AB variant either by next generation sequencing or targeted testing.**Results:** We identified 12 subjects with genetically-confirmed GM2 gangliosidoses, including seven TD cases, four SD cases, and one AB variant case. All seven subjects with TD were born to five families from the same ancestral background and were homozygous for a single start codon variant c.2T>C;p.(Met1Thr), confirmed pathogenic by enzyme testing, with all having the juvenile form and typical TD features. The four subjects with SD were born to three unrelated families from the same tribe all of which had the same intronic variant c.1169+3_1169+10del, previously reported pathogenic in three SD cases from Saudi Arabia, either in homozygous state, or in compound heterozygous state with another intronic variant c.771+5G>C in trans. The c.1169+3_1169+10del variant was confirmed a tribal founder variant by genealogical analysis and confirmed pathogenic by enzymatic testing. All subjects had the infantile form with typical SD features and abnormal brain MRI imaging. All subjects but one had retinal cherry red spot, macrocephaly and epilepsy. A single subject had absence of cherry red spot at 16 months and microcephaly with no reported seizures. One subject with AB variant had a homozygous 691 kb deletion at 5q33.1 encompassing GM2A and presenting with global developmental delay, immunodeficiency, and failure to thrive. **Conclusion:** Our data expand the phenotypic spectrum of GM2 gangliosidoses and suggest that the burden in Kuwait is driven by tribal and ancestral founder mutations, guiding clinical practice and prevention policies. Clinicians should have high index of suspicion for these disorders in at-risk children, based on ancestral origin, presenting with regression or ataxia. Inclusion of aforementioned founder mutations in the premarital carrier screening may lead to significant reduction in burden of such disorders in Kuwait.

Session Title: Mendelian Phenotypes Poster Session I

PB4665 C2S2: Phenotype-driven clustering for discovery of disease subgroups.

Authors:

D. Danis[1], A. J. M. Dingemans[2], M. Pekar[3,4], P. N. Robinson[1]; [1]The Jackson Lab. for Genomic Med., Farmington, CT, [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [3]Dept. of Physiology, Med. Faculty, Masaryk Univ., Brno, Czech Republic, [4]Vascular and Miniinvasive Surgery Ctr., AGEL Trinec-Podlesi, Trinec, Czech Republic

Deep phenotyping is an increasingly valuable source of information for understanding the genetic and environmental factors that contribute to human health and disease. One key question for precision genetic medicine involves the balance between lumping and splitting. Over 1000 genes are associated with two or more disease entities in the Online Mendelian Inheritance in Man (OMIM) knowledge base. The "splitting" of diseases associated with any given gene into multiple entities has been largely driven by expert opinion. Here, our goal was to use a data-driven approach to assess the optimal number of subgroups (clusters) in cohorts of genetic syndromes. We developed Consensus Clustering with Semantic Similarity (C2S2), a novel algorithm and a software library for unsupervised phenotype-driven clustering of individuals to discover groups with similar phenotypic characteristics and to support expert analysis. Starting from a cohort of individuals encoded as GA4GH Phenopackets and annotated with terms from Human Phenotype Ontology, C2S2 clusters the cohort using a novel semantic distance measure that takes into account both present and excluded phenotypic features. Next, the algorithm determines if the data are best described by one or multiple clusters and in the latter case leverages consensus clustering to determine the best number of clusters. To enhance the interpretability of the results, C2S2 identifies phenotypic features characteristic for individual clusterings and generates figures to visualize the inter-cluster differences. We demonstrate the performance on 10 cohorts of individuals harboring disease-causing variants in genes associated with two or more Mendelian diseases. The interpretable clustering results provided by C2S2 algorithm will aid in the stratification of patients into disease subgroups for tailored clinical management and to deliver on the promise of precision genomic medicine.

Session Title: Mendelian Phenotypes Poster Session II

PB4666 *CACNA1B* gene mutation associated with typical Rett Syndrome patients from India

Authors:

G. Mohan[1], V. Balachandar[2], S. Nachimuthu[3]; [1]Karpagam Academy of Higher Ed., Coimbatore, India, [2]Central Univ. of Punjab, Bathinda, Punjab, India, [3]Mizoram Univ., Aizawl, India

Background/Objectives: *CACNA1B* encodes the alpha-1-subunit of a voltage-dependent N-type calcium channel Cav2.2 expressed in brain. The heterozygous variants of *CACNA1B* have been previously reported in association with ASD and other neurodevelopmental disorders. Here, we report the rare familial case series of three Rett Syndrome siblings with intellectual disability (ID).**Methods:** After signing informed consent from the patients/parents this study was conducted in accordance with the principles of the World Medical Declaration of Helsinki. The phenotypic characteristics were recorded and for the genotypic analysis whole blood of 3 ml was collected and the DNA was extracted and purified using Qiagen kit. Genomic DNA with high integrity, as checked by nanodrop-based spectrophotometric and Qubit based fluorometric method, were used as the input material for exome sequencing library preparation using TruSeq DNA Exome Library Prep Kit (illumina). HaplotypeCaller of Genome Analysis Toolkit (GATK v4.1.4.1) was used for the germline variant calling.**Results:** In three profound patients showed the phenotypic characteristics of microcephaly, short stature, loss of communication, gait abnormalities, apraxia, hypoalgesia, and repetitive movements. We had found the pathogenic heterozygous variant of rs4422842 (*CACNA1B*) associated with Rett Syndrome in three ID patients. There was a correlation of microcephaly and short stature with the *CACNA1B* variants found in 3 siblings.**Conclusion:** The phenotype of rare neurological disorders often overlaps. For proper genetic counselling and treatment, both phenotype and genotype information should be used to make the diagnosis. Whole exome sequencing studies showed that the genetic varients in *CACNA1B*, increase the risk of intellectual disability. Screening of calcium voltage dependent genes are inevitable for the ID patients.

Session Title: Mendelian Phenotypes Poster Session I

PB4668 *CAMK2*, from mice to men and back: insights in the CAMK2 expertise center where clinicians and scientists work side-by-side.

Authors:

G. van Woerden, D. C. M. Veenma; Erasmus Med. Ctr., Rotterdam, Netherlands

With the advancing technological developments in the field of DNA diagnostics for rare congenital neurocognitive developmental disorders (NDD), the number of newly identified disorders has greatly increased in the past 10 years. For a large portion of these rare NDDs, very little is known about the underlying mechanism, which severely hampers the development of a possible treatment, or optimal care. The ENCORE Expertise Center in Rotterdam, The Netherlands, is an international expertise center for various rare NDDs, where a multidiciplinary team of clinicians and fundamental scientists, closely collaborate to gain more insights into these NDDs and strive to achieve optimal care and identify optimal treatment.
One of the relatively novel rare NDDs for which ENCORE is the only expertise center worldwide, is the CAMK2 syndrome. CAMK2 is a highly abundant protein kinase in the brain, known to play a critical role in synaptic plasticity, and learning and memory. Despite extensive fundamental research on CAMK2 from ourself and others, not much is known about disease etiologie, prognosis or potential treatments. For this reason we have initiated a natural history study in the clinic, and functional genomic studies in the lab to understand the pathogenicity of CAMK2 variants identified in patients. Additionally, in the lab we focus on potential therapeutic options, which we then can bring to the clinic to initiate Phase I clinical trials. Based on this joint effort of the multidisciplinary team of the expertise center, we will be able to identify genotype - phenotype correlations and aim to have in place optimal care and potential treatment options in the near future. During the presentation, I will use the CAMK2 expertise center as an example, sharing preliminary data, for what we believe is the best way forward from diagnosis of rare NDDs towards treatment options for these patients.

BACKGROUND

Thoracic Aortic Aneurysm & Dissection (TAAD) can arise at any time without previous warning and with fatal consequences. About 20% of non-syndromic TAAD is inherited with variable penetrance and severity. It has been crucial to make collaborations with TAAD networks around the world to facilitate novel gene discovery like LMOD1 gene. Our database has collected (over >30 years) 91 probands (53 with a family history and 38 sporadic cases). The proband of one of these TAAD families had an emergency aortic root replacement for Type A dissection (age 52); 2/3 of his sons (at age 25 [4cm] and 28 [4.3cm], both of them on losartan medication), and his cousin (at age 37 [4.2cm]) have an aortic aneurysm. Full features suggesting Marfan, Loeys-Dietz and Ehlers-Danlos were not met upon examination and were excluded by subsequent testing of *ACTA2*, *FBN1*, *PRKG1*, *SMAD3*, and *TGFBR1/2* genes. Negative results from an "aortopathy gene panel" were recorded in 2014. Proband has a deletion picked up by microarray-CGH: 12p12.23 (DNA size deletion [455 kb], which did not segregate with disease in the family. There is no family history of joint dislocations, slipped disc, knee problems or ocular disease.

METHODS

From the family pedigree, the 2 most distantly related affected individuals were processed for WES. Sequence alignment to the GRCh38, variant calling and annotation were performed. The complete variant list was filtered using our in-house pipeline that included the removal of all intronic and intergenic polymorphisms (except splice-site disrupting variants), heterozygous variants with MAF of >0.001 (gnomAD & ExAC), CAD score <20, those that did not segregate with the disease, and all homozygous variants. Then, the list was further filtered based on the frequency of the most common causative variant in *ACTA2* (R258C, MAF=0.00032).

RESULTS

The final list contains 5 candidate genes (3 non-synonymous [*GRIFIN*, *RMND1*, *SYNE1*], 1 frameshift insertion [*LAPTM4B*], and 1 stop-gain [*TSPAN10*] variants). Two promising candidate genes (*SYNE1* and *LAPTM4B*) were found to have a high expression in the ascending aorta tissue (Bgee), and in-silico analysis classified them as being disease-causing variants. *SYNE1* stands out in Phenolyzer with a 0.017 score, while *LAPTM4B* & *TSPAN10* have a 0 score. Exomiser prioritised *SYNE1*, *MANF* (filtered out after exclusion of 5'UTR variants), and *MUC12*, *MUC16* & *MAN2C1* (filtered out after CADD exclusion step).

CONCLUSIONS

This study is still in progress, but the variant in candidate gene *SYNE1* has maximum priority. Family segregation analyses are being performed for these 5 candidate genes to confirm their association with the TAAD phenotype in this family.

BACKGROUND

Hypermobile Ehlers-Danlos syndrome (hEDS) seems to be an autosomal dominant type of connective tissue disorder within the family of EDS. The molecular basis of this disease is still unmapped. Because of this the diagnosis of the disease is based solely on family history discussion and its clinical manifestations. These features include joint hypermobility, proneness to muscle weakness and general musculoskeletal involvement, abnormal skin hyperextensibility and tissue fragility. Some EDS phenotypic features have been linked with altered collagen producing genes like the *COL5A1* gene; however, hEDS is most likely not correlated to collagen and appears to be non-fatal. From a large family with hEDS (recruited - Rheumatology Clinic), a female member, age 54, was presented to the Chest Pain Clinic with chest pain diagnosed as costochondritis, which resolved spontaneously. On examination she is mildly myopic, but with no lens or retinal problems, with normal palate and teeth. She has no scoliosis, pectus deformity or arachnodactyly. Her Beighton Score is 4/9 and she has 90˚little fingers and thumb touching forearm bilaterally. Her echocardiogram was normal, with no aortic root aneurysm. Her sister was known to experience hypermobile joint pain, as is the proband's maternal aunt; a second maternal aunt, her daughter and her granddaughters were also affected. A specific marker of this family is a hypermobile 90˚interphalangeal thumb joint as also demonstrated in 1 male and 2 female family members in the last generation of the pedigree.

METHODOLOGY

From a cohort of hEDS probands, 1 family was entered in this study and 2 related family members were screened by whole genome sequencing; known EDS genes were ruled out. The variants were filtered according to an in-house protocol, which includes removal of all intronic and intergenic polymorphism (except splice site related), heterozygous with MAF>0.001 (gnomAD, ExAC), CADD<20, non-segregating with the disease, and all homozygous variants. Candidate genes were reviewed using databases like OMIM, GeneCards, GTex and Bgee.

RESULTS

Out of 15 variants, 9 are non-synonymous, 2 stop-gain, 2 frameshift insertion, 1 non-frameshift insertion and 1 splicing. Candidate genes: high expression scores in cartilage tissue (Bgee) (*PABPC3*, *SRA1*, *IL32*, *ITGAE*). Phenolyzer top genes: *DGKA* and *HLA-DRB1*. Genomiser prioritized *HLA-DRB1*, *GAB2* (filtered out after MAF) and *FOXD4L4* (filtered out after CADD) as top genes.

CONCLUSION

Priority lies on 6/14 genes based on expression levels in relevant tissues (Bgee). Family segregation studies are being performed to confirm the association of the candidate genes with hEDS phenotype.

Hosp., Turin, Italy

Cell cycle-associated protein 1 (*CAPRIN1*; OMIM* 601178) is a ubiquitous protein involved in cell proliferation and migration. In neurons, it likely regulates the transport and translation of mRNAs involved in synaptic plasticity. We have recently associated *CAPRIN1* loss-of-function variants with an autosomal dominant neurodevelopmental disorder characterized by language impairment/speech delay (n:12; 100%), intellectual disability (83%), ADHD (82%), and ASD (67%). In this study, we have generated CRISPR/Cas9-engineered *CAPRIN1*$^{+/-}$ hiPSCs-lines and differentiated them into neuronal cells, observing several defects including decreased processes length, overall disruption of the neuronal structure, enhanced neuronal death, impaired calcium signalling, increase protein translation and oxidative stress (PMID:35979925).To further define the mechanisms behind those neuronal defects, we performed transcriptomics analysis in early and late differentiated hiPSCs-derived neurons. The obtained data explained the physiological defects we previously observed, highlighting impaired oxidative phosphorylation, neuronal outgrowth, and translation. We also found a significant increase in genes involved in cell cycle control, DNA replication, proliferation, and dopaminergic neurogenesis and a decrease in GABA pathway-related genes. Preliminary data on *CAPRIN1*$^{+/-}$ neuronal progenitor cells, showed an increased proliferative rate and expression of PAX6, NESTIN and SOX2, further suggesting a possible loss of balance in neuronal proliferation/differentiation. To explore these features, we are generating forebrain cortical organoids (fBOs) from *CAPRIN1* patient-derived hiPSCs lines, to analyse their cellular architecture, neuronal activity and the cellular composition combining immunofluorescence analysis and a multicolor immunophenotyping panel (NeurOMIP assay, PMID:33852833). First results show an important impact of *CAPRIN1* loss on the development of neuronal rosettes and fBOs structure. In addition, we previously reported defective translation in *CAPRIN1*$^{+/-}$ neurons; these defects are detectable also in fBOs models at day 30-50 of differentiation, and preliminary data show an effect on some specific neuronal populations, including MAP2B and GFAP positive cells. Further experiments are ongoing to assess the impact of *CAPRIN1* loss on certain neuronal populations, and to establish the specific role of the defective protein translation. In conclusion, our study will unravel the impact of *CAPRIN1* loss in neurodevelopment, shedding light on its role in neuronal differentiation, neurogenesis and proliferation.

PB4673 Cardiomyopathy, an uncommon phenotype of congenital disorders of glycosylation: Characterization of the spectrum and recommendations for follow-up.

Authors:

R. Zemet Lazar[1], A. Edmondson[2], R. Shah[3], M. Patino[2], K. D. Hope[1], A. M. Yesso[1], K. Sarafoglou[4], A. Larson[5], C. Lam[6], E. Morava[3], F. Scaglia[7]; [1]Baylor Coll. of Med., Houston, TX, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Mayo Clinic, Rochester, MN, [4]Univ. of Minnesota Med. Sch., Minneapolis, MN, [5]Univ. of Colorado, Denver, CO, [6]Univ. of Washington, Seattle, WA, [7]Baylor Col Med, Houston, TX

Background Congenital disorders of glycosylation (CDGs) are a continuously expanding group of monogenic disorders of glycoprotein and glycolipid biosynthesis that cause multi-system diseases. Cardiac involvement in CDGs can vary significantly, not only based on the specific disorder, but also between patients with the same disorder. In this study, we aimed to identify common cardiomyopathy patterns among patients with a broad spectrum of CDGs, and to propose follow up recommendations for implementation in clinical practice. **Methods** Patients were enrolled in the Frontiers in Congenital Disorders of Glycosylation Consortium (FCDGC) natural history study. We analyzed clinical and molecular history, imaging characteristics of cardiac involvement, type of cardiomyopathy, and clinical outcomes of individuals with CDG also found to have cardiomyopathy. **Results** Out of 282 patients with CDG enrolled in the FCDGC study, we identified 16 individuals, 9 females and 7 males, diagnosed with CDG confirmed by molecular testing, who also exhibit cardiomyopathy. The majority of these patients are diagnosed with PMM2-CDG (n=10), however, cardiomyopathy was seen in other diagnoses including PGM1-CDG (n=3), ALG3-CDG (n=1), DPM1-CDG (n=1), and DPAGT1-CDG (n=1). Most patients (ten with PMM2-CDG) presented with hypertrophic cardiomyopathy, three with dilated cardiomyopathy (two with PGM1-CDG and one with ALG3-CDG), two with left ventricular non-compaction cardiomyopathy (one with PGM1-CDG and one with DPAGT1-CDG), and one patient with DPM1-CDG presented with an unspecified cardiomyopathy type. The estimated median age of cardiomyopathy onset was 5 months (range: prenatal-23 years). Seven patients were deceased, including five with PMM2-CDG, one with DPAGT1-CDG, and one with ALG3-CDG, though cardiomyopathy was not necessarily the primary cause of death. Cardiac improvement was observed in three patients with PMM2-CDG and one patient with DPM1-CDG, four patients demonstrated a progressive course of cardiomyopathy, while the condition remained static in eight individuals. One patient with PGM1-CDG underwent cardiac transplantation. **Conclusion** Cardiomyopathy can manifest in patients with CDG. Interestingly, some of these cases do not appear to exhibit progression. We advocate that clinicians caring for patients with CDGs should be aware of the risk of cardiomyopathy, especially in PMM2 and PGM1-CDG, and obtain baseline and periodic cardiac evaluation, especially if clinical concerns arise. Furthermore, patients diagnosed with cardiomyopathy should be under periodic cardiological supervision for optimal management and monitoring of their condition

Session Title: Mendelian Phenotypes Poster Session I

PB4674 Carriers of pathogenic variants in causal cardiomyopathy genes show incomplete disease penetrance in UK Biobank

Authors:

S. Klasfeld, H. Kim, R. Moccia, J. Berghout; Pfizer, Cambridge, MA

Identifiable rare, pathogenic mutations explain a significant proportion of intrinsic cardiomyopathy risk. More than twenty genes have been curated by the ClinGen cardiomyopathy working group as having a strong or definitive causal relationship to cardiomyopathies. However, individual carriers of the same or similar rare variants can exhibit variable penetrance and expressivity of disease. We designed a computational filtering strategy to classify UK biobank (UKBB) observed variants as known or predicted pathogenic by using a combination of frequency, literature/ClinVar assertions, and functional consequence prediction (VEP/LOFTEE, Mutpred2, etc). We applied this pipeline to UKBB (data release 450K participants) which yielded genetically defined case (n=10,896 carriers of risk variants for dilated cardiomyopathy (DCM), 6,248 hypertrophic cardiomyopathy (HCM), 3,245 arrhythmogenic right ventricular cardiomyopathy (ARVC)) and control cohorts. Using electronic health records data to identify cardiomyopathy-relevant phenotypes, we determined that the overall rate of phenotype positivity in carriers of DCM risk variants was 22.02%, HCM risk variants was 21.91% and ARVC risk variants carriers was 21.79%. In ongoing work, we will use this genotype-first strategy together with UKBB genetic and clinical information to explain a proportion of gene and gene-set penetrance variability.

Session Title: Mendelian Phenotypes Poster Session II

PB4675 Case report of a novel *FGFR2* gene mutation resulting in mild clinical manifestations of Crouzon syndrome.

Authors:

N. Cruz-Perez[1], E. Albino[2], N. Arciniegas[3], A. Cornier[4], S. Carlo[1,3,5]; [1]Ponce Hlth.Sci. Univ., Ponce, PR, [2]Univ. of Puerto Rico - Sch. of Hlth.Professions, San Juan, PR, [3]Mayaguez Med. Ctr., Mayaguez, PR, [4]San Jorge Children s & Women s Hosp., San Juan, PR, [5]Ponce Res. Inst., Ponce, PR

Craniosynostosis refers to the early closure of cranial sutures during infancy and can be classified as syndromic or non-syndromic based on its clinical presentation. Syndromic craniosynostosis consists of autosomal dominant genetic syndromes and has been linked to specific mutations in the fibroblast growth factor receptor (*FGFR*) genes. Crouzon syndrome (CS) is one of the most common forms of syndromic craniosynostosis, presenting with a flattened forehead, proptosis, hypertelorism, a beaked nose, and midface hypoplasia. It is known that CS is caused by mutations in the *FGFR2* gene, and many variants have been found to be characteristic of this syndrome. Here, we present a 5-year-old Puerto Rican male with craniosynostosis, bilateral exophthalmos, inattention, and episodes of non-responsiveness who is suspected of having attention deficit/hyperactivity disorder. A Blueprint Genetics Whole Exome Plus test revealed a heterozygous missense variant in the *FGFR2* gene (Leu357Ser). This mutation is predicted to be likely pathogenic and possibly caused by a de novo variant. Moreover, head computer tomography revealed the closure of the sagittal, coronal, and lambdoid sutures, which is congruent with craniosynostosis. This case report describes a patient with a novel *FGFR2* mutation resulting in mild phenotypical characteristics quite similar to those of CS, the mildness of which prevents an accurate diagnosis. Genetic testing is vital to correctly diagnose syndromic craniosynostosis, particularly when its variable expressivity results in minimal clinical manifestations.

Session Title: Mendelian Phenotypes Poster Session III

PB4676 Case Report: CAMK2B variant with tetralogy of Fallot, developmental delay, and growth retardation.

Authors:

Y. Kuroda, Y. Saito, Y. Enomoto, T. Naruto, K. Kurosawa; Kanagawa Children's Med. Ctr., Yokohama, Japan

CAMK2B encodes the beta-subunit of calcium/calmodulin-dependent protein kinase II (CAMK2). CAMK2B is associated with intellectual disability and developmental delay, and more than 19 patients have been reported. Here, we described a novel de novo CAMK2B variant in a patient with tetralogy of Fallot (TOF), developmental delay, and growth retardation. The patient was a 2-year-old female and the second child of healthy nonconsanguineous parents. She was delivered at 36 weeks 6 days gestational age by caesarean section due to non-reassuring fetal status, with birth weight of 1,680 g (-2.0 SD), birth length of 43.5 cm (-1.5 SD), and occipital-frontal head circumference (OFC) of 29.4 cm (-1.7 SD). She was diagnosed with Tetralogy of Fallot (TOF) by her fetal echocardiogram. Blalock-Taussig shunt was performed at 9 months of age. Head MRI revealed no other anomaly than slightly white matter volume loss and hypoplastic corpus callosum at 13 months of age. She was referred to our department at the age of 18 months for assessment of developmental delay, microcephaly, and growth retardation. At referral, her height was 68.8 cm (-3.9 SD), weight was 5.7 kg (-4.2 SD), and OFC was 40 cm (-4.3 SD). She controlled her head position at four months, rolled at six months, sat at 13 months, crawled at 18 months, and walked with support at 21 months. She began speaking words at 2 years old. Her karyotype and chromosomal microarray were normal. Her dysmorphic features included puffy eyelids, puffy cheeks, and cup ears.In the patient's exome sequencing, the mean depth of coverage was 103.13 per base, and 96.3 % of the coding region was covered by at least 20 reads. A de novo missense CAMK2B variant (NM_172079.2:c.895A>G (p.Lys299Glu) NC_000007.14:g.44241708T>C (hg38)) was identified by proband exome sequencing. The de novo variant was confirmed by Sanger sequencing. According to ACMG 2015 variant interpretation guidelines, this variant was classified as "Likely pathogenic (PS2+PM2_supporting+PP2+PP3+PP4)". No other candidate variants have been detected.CAMK2A and 2B-related neurodevelopmental disorders (NDDs) are characterized by various degrees of developmental delay and intellectual disability, autistic behavior, epilepsy, and dysmorphic features. More than 36 patients have been reported as CAMK2A and 2B-related NDDs. Congenital heart defect was an atypical phenotype in these NDDs, and only one patient had ventricular septal defect with CAMK2A variant. TOF has never described in previously reported patients. As a de novo CAMK2B (p.Leu443Val) variant have been found in a cohort of TOF, CAMK2B may be associated with TOF.

Session Title: Mendelian Phenotypes Poster Session I

PB4677 Cell type specific network analysis in Diversity Outbred mice identifies genes potentially responsible for human bone mineral density GWAS associations.

Authors:

L. Dillard, G. Calabrese, L. Mesner, B. Al-Barghouthi, A. Abood, C. Farber; Univ. of Virginia, Charlottesville, VA

BACKGROUND: Genome-wide association studies (GWAS) have identified over 1,100 statistically independent associations for bone mineral density (BMD), the most significant clinical predictor of osteoporotic fracture. We previously performed network analyses based on bulk transcriptomic data from bone tissues and heterogenous primary bone cells to predict candidate causal genes for BMD GWAS associations. Here, we applied the same network approaches to transcriptomic profiles of specific osteogenic cell types with the goal of identifying additional candidate causal GWAS genes. This approach also provides information regarding the cellular context for putative causal genes which is essential for future functional studies.
METHODS: Using the Diversity Outbred (DO) mouse population (N=80, 32 females, 48 males), we performed scRNA-seq on bone marrow-derived stromal cells cultured under osteogenic differentiation. After stringent processing and quality control, the dataset consisted of 139,392 total cells from 15 cell clusters ranging from cell types of the osteogenic lineage to various immune cells (e.g., macrophages and lymphocytes). To prioritize cell types, we used CELLECT with the largest BMD GWAS performed to date to identify cell types enriched for BMD heritability. For each prioritized cell type, we generated co-expression networks. Next, Bayesian networks were generated for each co-expression network whose module eigengene was correlated with at least one of 55 bone strength-related traits collected in the same DO mice. Key driver analysis was performed to identify critical network genes. Mouse key drivers with a corresponding human homolog were prioritized based on proximity to BMD GWAS associations, colocalizing expression quantitative trait loci (eQTL) or splicing QTL (sQTL) from the Genotype-Tissue Expression (GTEx) Project, and evidence of impacting BMD based on mouse knockout data from the International Mouse Knockout Consortium (IMPC).
RESULTS: We identified 148 cell type-specific modules that were correlated with at least one bone strength trait in the DO mice. Key driver analysis identified 834 network “key driver” genes on average per cell type. Of the key driver genes across all cell types, 394 had a colocalizing eQTL and/or sQTL. Of these, 61 demonstrated a statistically significant effect on BMD in IMPC knockout mice.
SUMMARY: Using our network-based approach and prioritization scheme leveraging multiple data modalities, we discovered many genes, including novel targets such as, *Prpf40a*, *Tmem97*, *Atf7*, *Creld2*, *Zzef1*, and *Eif5b*, that are putatively implicated in variation in BMD, bone strength, and risk of osteoporosis.

Session Title: Mendelian Phenotypes Poster Session II

PB4678 Cerebral vasculopathy in Rubinstein-Taybi syndrome

Authors:

K. Kurosawa, Y. Saito, Y. Kuroda; Kanagawa Children's Med. Ctr., Yokohama, Japan

Rubinstein-Taybi syndrome (RSTS) is a rare malformation syndrome characterized by broad thumbs and toes, intellectual disability, developmental delay, and distinctive facial appearance. The causative genes comprise CREBBP and EP300 through loss of function for the disorder. Mice with homozygous mutation of CREBBP show defects of vasculo-angiogenesis and hematopoiesis, leading to severe hemorrhage in telencephalon and mesencephalon, resulting in embryonic lethality. However, the defects of vasculo-angiogenesis, shown by the previous studies in mice, have been reported in a few cases. We report Moyamoya disease in the patient with RSTS associated with t(2;16), reported by Imaizumi and Kuroki [1991]. At age 34, brain magnetic resonance angiography (MRA) revealed moyamoya vessels in the right hemisphere. The neurological investigation was within normal ranges, including deep tendon reflex, diadochokinetic signs, and muscle tonus. Sequence analysis of RNF213 identified the most common susceptibility variant p.(R4810K) in East Asian. After that, we continued conservative follow-up for her. At age 37, she underwent neurosurgery for subarachnoid hemorrhage with no apparent origin of bleeding. Prior information about moyamoya disease enabled prompt neurosurgery, and she recovered without paralysis. At 48, she still has cerebrovascular abnormalities as moyamoya disease but has not had any stroke or other ischemic symptoms. The previous reports of a cerebrovascular anomaly in RSTS are so limited. The cerebrovascular anomaly or strokes were not noted in the study of adult individuals with RSTS. Park et al. [2021] suggested that having the pathogenic variants both in the EP300 gene and the PLAU gene, which is involved in angiogenesis, predisposed to abnormal angiogenesis in their patient. Combined with studies of CREBBP/EP300-deficient mice and limited case reports, RSTS individuals may develop cerebral vascular hemorrhage and abnormal angiogenesis when another genetic background related to the vasculopathy is added. Therefore, cerebrovascular disease should also be included in the medical management of RSTS in adulthood.

Session Title: Mendelian Phenotypes Poster Session III

PB4679 Characteristics of *JAG1* and *NOTCH2* variants in patients with Alagille syndrome in Japan.

Authors:

T. Tanimura[1], T. Togawa[1], S. Ito[1], K. Ohashi[1], K. Imagawa[2], H. Hayashi[3], K. Ito[1], T. Endo[1], T. Sugiura[1], S. Saitoh[1]; [1]Nagoya City Univ., Nagoya, Japan, [2]Univ. of Tsukuba, Tsukuba, Japan, [3]The Univ. of Tokyo, Tokyo, Japan

Alagille syndrome (ALGS; OMIM 118450) is an autosomal dominant multisystem disorder that affects the liver, heart, face, eyes, skeleton, and other organs. Its prevalence is estimated to be 1 in 30,000 live births. ALGS is caused by pathogenic variants in one of two genes in the Notch signaling pathway, *JAG1* or, rarely, *NOTCH2*. Pathogenic variants in *JAG1* are most commonly protein-truncating, such as frameshift, nonsense, exon level deletions, and splice site. *NOTCH2* variants are predominantly missense. Pathogenic variants in *JAG1* have been identified in approximately 90% of clinically diagnosed ALGS patients. To date, *JAG1* and *NOTCH2* variants, over 800 and 100, respectively, have been reported in Western countries and East Asia, while *JAG1* and *NOTCH2* variants in patients with ALGS have not been reported in a large series in Japan, except in our previous report (n = 28, Ohashi et al., Acta Paediatr. 2017). We aimed to elucidate the diversity of *JAG1* and *NOTCH2* variants in Japanese patients with ALGS. We carried out molecular genetic analyses with targeted next-generation sequencing of *JAG1* and *NOTCH2* and/or multiplex ligation probe amplification covering the entire exons of *JAG1*. We detected 81 *JAG1* pathogenic variants in unrelated patients who were diagnosed or highly suspected as ALGS, and 73 of those variants were unique. Regarding the *JAG1* variant types, 22 frameshift variants (32%), 17 nonsense variants (28%), 11 splice site variants (14%), 8 gross deletions (10%), and 10 missense variants (16%) were detected. We observed fewer frameshift variants and more nonsense variants than those in the largest previous study (Gilbert MA et al., Hum Mutat. 2019). Forty-nine (60%) of all the variants were presented in 8 exons of *JAG1*; exon 2, 4, 6, 10, 12, 17, 23, and 24. In contrast, there was no variant in 8 exons; exon 1, 7, 8, 9, 14, 19, 20, and 25. The distribution of variants in *JAG1* was more similar to that reported in Western countries (Warthen DM et al., Hum Mutat, 2006) than that from China (Li L et al., PLoS One. 2015). Three pathogenic variants in *NOTCH2* were detected: one frameshift, one nonsense, and one missense variant. These findings could provide the characteristics of *JAG1* and *NOTCH2* variants in the patients with ALGS in Japan.

Session Title: Mendelian Phenotypes Poster Session I

PB4680 † Characterization of a chromosome 5q35 Alzheimer disease risk locus in African Ancestry families using short and long read whole genome sequencing

Authors:

D. Van Booven[1], S. Fazal[1], A. Griswold[1], K. Nuytemans[1], F. Rajabli[1], M. Jean-Francois[1], L. Adams[1], T. D. Starks[2], P. Whitehead[1], B. Kunkle[1], M. Cuccaro[1], J. Vance[1], J. Haines[3], C. Reitz[4], G. S. Byrd[2], G. Beecham[1], M. Pericak-Vance[1]; [1]Univ. of Miami, Miami, FL, [2]Wake Forest Univ., Winston-Salem, NC, [3]Case Western Reserve Univ., Cleveland, OH, [4]Columbia Univ., New York, NY

Background: Genetic risk for Alzheimer's disease (AD) can vary between genetic ancestral populations, with the best example being the significantly lower risk conferred by *APOEe4* in African relative to European or East Asian ancestries. Thus, identification of other ancestry specific risk or protective factors is critical to understand the etiology of AD in diverse populations.
Method: Multipoint linkage was performed across 51 African American (AA) multiplex AD families, consisting of 160 AD and 318 cognitively unimpaired (CU) individuals, as part of the Research in African American Alzheimer Disease Initiative (REAAADI) and Late-Onset AD Family Study (LOAD) initiatives. Fine mapping of linked loci was performed using short-read whole genome sequencing (WGS) followed by variant annotation for putative function including protein changes for coding variants and evidence for regulatory activity (ENCODE, RoadMap Epigenome) and chromatin interactions (publicly available HiC and promoter capture C) for noncoding variants followed by co-segregation analysis. To identify potential structural variants (SV) underlying signals we also performed long-read WGS (LRS) using the Oxford Nanopore PromethION followed by alignment with minimap2 and variant calling with Sniffles2.
Result: Linkage analyses identified a peak LOD score (HLOD=3.20) on chr5q35. Co-segregation analysis of the short-read WGS identified a 3'UTR and synonymous variant in *INSYN2B* as well as a promoter variant in *WWC1* (all MAF<0.01) segregating with disease in the AD individuals of the family with the highest LOD score contributing to the linkage peak. Interestingly, four other AA families contributing to the chr5 linkage signal harbor different within-family shared variants located in *INSYN2B*'s promoter or in enhancer regions with evidence for interaction with *INSYN2B*'s promoter. Co-segregation analysis of the LRS SVs in the highest LOD score family revealed further potential candidate genes with all AD individuals sharing eight SVs (six deletions, 2 insertions). These include a deletion of an exon in *KCNMB1*. Combining ongoing functional validation in this region will help us better understand the contribution of these genes to AD development.
Discussion: Our analyses provide evidence for candidate genes *INSYN2B*, encoding an inhibitory synaptic factor active in oligodendrocytes and neurons, and *KCNMB1,* encoding a potassium calcium-activated channel, to play a role in AD genetics in the AA population. This finding highlights the importance of diversifying population-level genetic data to better understand the genetic contributions to AD on a global scale.

PB4681 Characterization of lower limb differences in individuals with Cornelia de Lange syndrome.

Authors:

K. Arnold[1], S. Raible[2], L. Conway[1], I. Krantz[2,3]; [1]Master of Sci. in Genetic Counseling Program, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [2]Roberts Individualized Med. Genetics Ctr., Div. of Human Genetics, Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Dept. of Pediatrics, Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

Cornelia de Lange syndrome (CdLS) is a genetic, multisystem diagnosis that has been associated with morphologic differences of the upper limbs such as small hands, proximally placed thumbs, fifth finger clinodactyly, radioulnar synostosis and variable limb reductions. Lower limb involvement commonly includes small feet and 2-3 toe syndactyly with structural/reduction difference being much less frequently reported. Recent observations suggest that lower limb involvement in individuals with CdLS can be more severe, and is not fully represented in the literature. This study aims to: 1) review the existing literature on lower limb involvement in CdLS, 2) characterize lower limb anomalies in CdLS individuals seen at the Children's Hospital of Philadelphia (CHOP), and 3) identify additional CdLS individuals with lower extremity structural differences via an IRB-exempt, RedCap administered survey sent to the National CdLS Foundation. A PubMed search to identify previously reported individuals with a diagnosis of CdLS and lower limb differences yielded 82 articles. Of these, 10 articles contained sufficient information on 13 cases identified to have CdLS and unique lower limb differences. Anomalies were often associated with the fibulae and tibulae, variants in the *NIPBL* gene (when tested for), and significant upper limb involvement. For the CHOP cohort, information for 2,006 probands was obtained through an existing cohort of individuals previously enrolled under an IRB approved protocol of informed consent. Of the 2,006 affected individuals, 137 (6.8%) had photos of the lower extremities available for review and at least one lower limb difference. Minor lower limb differences such as small feet (76%), 2-3 toe syndactyly (40%), brachydactyly (38%), and lateral deviation of the first toe (18%) were commonly seen in CdLS while 6 (0.3%) individuals had more involved lower limb differences such as oligodactyly with clubfoot or 1-2 syndactyly. For the CdLS survey, 32 survey responses were received; however, only 7 individuals were identified as having less common lower limb features including limb length discrepancies (6/7) often occurring below the knee and one individual with bilateral in-toeing, bent tibiae and fibulae, and a left clubfoot. A majority (6/7) of individuals had an intervention for their lower limb involvement including occupational (3/7) or physical therapy (4/7), surgery (2/7) or shoe modification (3/7). These results provide a more complete phenotype of CdLS limb anomalies, guide management options, and improve clinical diagnostics and targeted genetic testing for patients and families prenatally and postnatally.

PB4682 Characterization of the impact of NSD2 loss on the transcriptional and epigenetic landscape in the brain

Authors:

S. Kinoshita[1,2], K. Kojima[1], E. Ohnishi[1], Y. Takayama[1], H. Kikuchi[1], S. Takada[1], K. Nakabayashi[1], T. Kawai[1], K. Hata[1,3]; [1]Natl. Res. Inst. for Child Hlth.and Dev., Tokyo, Japan, [2]Tokyo Med. and Dental Univ. Graduate Sch. of Med. and Dental Sci., Tokyo, Japan, [3]Gunma Univ. Graduate Sch. of Med., Gunma, Japan

Epigenetic disruptions have been implicated in neurodevelopmental disorders. Recent studies have shown that *NSD2* is associated with developmental delay/intellectual disability; however, its role in brain development and function remains unclear. To better understand the role of NSD2 in the brain, we performed transcriptomic and epigenetic analyses using *Nsd2* knockout mice. We found that the loss of NSD2 caused dysregulation of genes related to synaptic transmission and formation in the brain. Genome-wide analysis showed that NSD2-mediated H3 lysine 36 dimethylation (H3K36me2) marked quiescent regions in the embryonic brain. Finally, changes in H3K36me2 were partially associated with changes in gene expression in *Nsd2* knockout brains. These results suggest that NSD2 is involved in the regulation of genes that are important for neural function via H3K36me2. Our findings provide insights into the role of NSD2 in the brain and provide a better understanding of the pathogenesis of NSD2-associated neurodevelopmental disorders.

Session Title: Mendelian Phenotypes Poster Session I

PB4683 Characterizing the phenotypic abnormalities of a mouse model of Snyder Robinson-syndrome: a valuable tool for therapeutic development

Authors:

O. Akinyele[1], A. Munir[2], M. Johnson[1], M. Perez[2], Y. Gao[1], J. Foley[3], Y. Wu[1], T. Murray-Stewart[3], B. Casero[3], H. Bayir[1], D. Kemaladewi[4]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of Pittsburgh, PITTSBURGH, PA, [3]Johns Hopkins Sch. of Med., Baltimore, MD, [4]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

The polyamines (putrescine, spermidine, and spermine) are essential for normal cellular functions and are subject to strict metabolic regulation. Mutations in the gene encoding spermine synthase (SMS) lead to the accumulation of spermidine in an X-linked recessive disorder known as Snyder-Robinson syndrome (SRS), which manifests with a spectrum of symptoms including intellectual disability, developmental delay, thin habitus, and low muscle tone with no available treatment. Development of therapeutic interventions for SRS would require a suitable disease-specific animal model that recapitulates many of the abnormalities observed in affected individuals. Here, we study the molecular, behavioral, and neuroanatomical features of a mouse model with a missense mutation in the *Sms* gene that results in a glycine-to-serine substitution at position 56 (G56S) of the SMS protein. The G56S mice exhibit a complete loss of SMS protein and elevated spermidine/spermine ratio in the skeletal muscles and the brain, as well as increased anxiety, impaired learning, and decreased explorative behavior. Furthermore, these mice fail to gain weight over time and exhibit abnormalities in brain structure and bone density. Transcriptomic analysis of the cerebral cortex revealed the downregulation of genes associated with ribosomal protein synthesis and mitochondrial oxidative phosphorylation, which were functionally recapitulated in fibroblasts. Collectively, our findings establish the first in-depth characterization of an SRS preclinical mouse model that identifies cellular processes that could be targeted for future therapeutic development. Current experiments focus on developing an effective gene therapy approach for SRS via viral-mediated expression of WT *Sms* transgene. We anticipate that the successful completion of this study will open the door to a gene therapy approach for SRS and other polyamine-related genetic diseases

Session Title: Mendelian Phenotypes Poster Session II

PB4684 Chimeric *TNXB/TNXA* gene mutations in hypermobile Ehlers Danlos Syndrome.

Authors:

M. Galindo[1], R. E. Handsaker[2,3], J. G. Andrews[1], C. M. Laukaitis[4]; [1]Univ. of Arizona, Tucson, AZ, [2]Broad Inst., Cambridge, MA, [3]Harvard Med. Sch., Dept. of Genetics, Boston, MA, [4]Carle Illinois Coll. of Med., Urbana, IL

Introduction: Biallelic pathogenic mutations in *TNXB* are known to cause classic-like Ehlers Danlos Syndrome (EDS), but less described heterozygous mutations in *TNXB* can cause hypermobile EDS (hEDS). *TNXA* is a pseudogene of *TNXB* that is non-functional due to two mutations: a 120 base pair deletion that removes a splice junction for exon 35 and an amino acid substitution in exon 40. The paralogy of *TNXB* and *TNXA* precludes use of next generation sequencing to investigate the region, as short-reads do not unambiguously map to either the gene or pseudogene. The similarities also predispose to misalignment of DNA, which can produce a chimeric dysfunctional *TNXB/A* chimera that deletes material from *TNXB* (copy number loss) and incorporates *TNXA* mutations. There are two *TNXB/A* chimeric configurations that have been described in individuals with hEDS, but these mutations have not been explored in a cohort of individuals with hEDS to determine frequency in a population.
Methods: The hEDS Gene Study enrolled and obtained biosamples from 100 people diagnosed with hEDS using the 2017 diagnostic criteria. A validated TaqMan assay was used to identify wild type *TNXB* copies in genomic DNA by targeting two sites that distinguish it from *TNXA*: the deletion (exon 35) and single nucleotide variant (exon 40; C4060W). This assay was run in triplicate on DNA from study participants using *HBB* as an endogenous control. The cycle threshold mean was calculated per individual to determine *TNXB* copy number.
Results: Of the 100 participants, 91.0% are female and the average age is 44.5 years (s.d. 14.9). 71/100 individuals had the expected two copies of *TNXB* exon 40 and 35, representing the wild type allele. More than two *TNXB* exon 40 alleles were seen in conjunction with only two *TNXB* exon 35 sequences in 23/100 individuals. Finally, 6/100 had three or more alleles reflecting wild type *TNXB*. There were no people with copy number losses causing chimeric *TNXB/A*.
Conclusion: Chimeric *TNXB/A* genes with a loss of expressed *TNXB* are seen in individuals with hEDS, but were not observed in our study, suggesting this may not be a frequent cause of hEDS. Observed copy number discrepancies between *TNXB* exons 35 and 40 suggest there may be chimeric genes creating a copy number gain, but this assay is not able to determine if the chimeric gene is expressed or could contribute to the hEDS phenotype. Since copy number variation in this region is observed in the general population, further analysis is needed to determine whether the variation seen in this population with hEDS differs from the general population.

PB4685 Cleidocranial Dysplasia Family Case Report and identification of *RUNX2* and *SULF1* variants

Authors:

A. Rivera-Cameras[1], A. V. Ruiz-Ramírez[2], M. A. Aceves-Aceves[3], M. C. Morán-Moguel[4], M. Salazar-Paramo[5], I. P. Dávalos-Rodríguez[1]; [1]División de Genética, Centro de Investigación Biomédica de Occidente, IMSS, Guadalajara, México, Doctorado en Genética Humana, CUCS, Univ. de Guadalajara, México., Guadalajara, México, Mexico, [2]Univ. Autónoma de Guadalajara, Departamento de Neurociencias, Programa Internacional de la Facultad de Med., Guadalajara, Mexico, Mexico, [3]Unidad Medica Alta Especialidad, HGO, CMNO, IMSS, Guadalajara, México, Mexico, [4]Departamento de Biología Molecular y Genómica, CUCS, Univ. de Guadalajara, México., Guadalajara, México, Mexico, [5]Departamento de Fisiología, CUCS, Univ. de Guadalajara, Guadalajara, México, Mexico

INTRODUCTION: Cleidocranial dysplasia (CCD), OMIM #119600, is a rare autosomal dominant disorder characterized principally by delayed fusion of cranial sutures, hypoplastic or aplastic clavicles, and dental abnormalities. CCD is caused by pathogenic variants in the RUNX2 (Runt-related transcription factor 2) gene (6p21.1) involved in the differentiation of osteoblasts and bone formation. OBJECTIVE: To describe a family with clinical and radiological data of CDD and molecular diagnosis. RESULTS: Heterozygous pathogenic variant was identified in the RUNX2 gene c.852del (p.Ile285Leufs*23) in three family members, and additionally, in one of them, a heterozygous uncertain variant was identified in the SULF1 gene c.643G>C (p.Val215Leu). We performed a bioinformatic analysis and predicted that the SULF1 variant is in an important functional domain, and it could probably affect the activity of the protein. Since SULF1 is implicated in the Wnt and BMP signaling pathways as RUNX2, it will ultimately increase the affectation in developing tissues such as chondrogenesis and skeletal bone formation. CONCLUSIONS: We propose that the SULF1 gene could act as a modulator gene of the CDD phenotype by intervening in the same signaling pathways, which would affect the development of tissues such as chondrogenesis and skeletal bone formation. We suggest a more detailed analysis of variants in potential modifiers genes that could contribute to clinical variable expression in CDD patients.

PB4686 Clinical and genetic characteristics of 78 Chinese subjects with *POU3F4*-related hearing loss.

Authors:

H. Yuan; Inst. of Rare Diseases, West China Hosp. of Sichuan Univ., Chengdu, China

This study aims to enhance our understanding of X-linked hearing loss (DFNX2) associated with the *POU3F4* gene by investigating its clinical and genetic spectrum, as well as the underlying pathophysiological mechanisms. While previous reports have described DFNX2 in numerous male patients, most of the identified *POU3F4* variants have been documented in case reports with limited sample sizes. We identified 75 pathogenic variants, including single nucleotide variants, insertions/deletions, and copy number variants, within the *POU3F4* gene in a cohort of 78 male patients. The clinical manifestations and severity of the hearing loss displayed significant variability among male patients and female carriers. Missense variants were found to cluster in the POU-specific and POU homeodomain regions, demonstrating an association with highly and moderately conserved residues among POU family proteins (paralog-conservation). Stop-loss variants primarily disrupt the normal function of *POU3F4* by impairing its DNA-binding ability and exhibiting additional effects such as mislocalization. This study expands the clinical and genetic spectrum of the *POU3F4* gene.

PB4687 Clinical and genetic spectrum in a cohort of Lithuanian patients with limb girdle muscular dystrophy

Authors:

B. Burnyte[1], G. Asadauskaite[2], A. Morkuniene[1], A. Matuleviciene[1], L. Cimbalistiene[1], A. Utkus[1]; [1]Inst. Of BioMed. Sci., Faculty Of Med., Vilnius Univ., Vilnius, Lithuania, [2]Faculty Of Med., Vilnius Univ., Vilnius, Lithuania

Introduction Limb-girdle muscular dystrophies (LGMDs) encompass a group of genetic disorders characterized by predominant proximal muscle weakness and wasting. LGMD type R1, resulting from pathogenic variants in the *CAPN3* gene, is the most common subtype worldwide. This study aims to investigate the clinical and genetic spectrum of LGMD in a cohort of Lithuanian patients. Methods In this retrospective cohort study, we collected data from 45 patients with LGMD who were genetically diagnosed between 2012 and 2021. We analyzed clinical, demographic and molecular genetic data. Results The study cohort included 19 (42%) males and 26 (58%) females with a mean age of 31.27 years. Proximal muscle weakness of the upper and lower limbs was the most common presenting symptom. The most frequently identified causative genes were *CAPN3* (n=32), *DYSF* (n = 4), *FKRP* (n = 4), *ANO5* (n = 2), and *SGCB* (n = 1). Additionally, we identified a c.598_612del variant in the *CAPN3* associated with dominant inheritance in one family. The *CAPN3* c.550del, p.(Thr184fs) variant was the most commonly observed, and two new *CAPN3* variants (c.1342C>T and c.1746-3C>A) were identified. Conclusion Our study suggests that a significant proportion of LGMD cases in the Lithuanian cohort are associated with *CAPN3* variants.

Session Title: Mendelian Phenotypes Poster Session III

PB4688 Frequency of genetic disorders associated with pseudoanodontia, revisiting classification, and suggestive management.

Authors:

M. Mostafa[1], M. Mehrez[2], I. Sayed[3], N. Hassib[4]; [1]Natl. Res. Ctr., Dokki, Egypt, [2]Natl. Res. Ctr., Cairo, Egypt, [3]Natl. Res. Ctr., Dokki, Cairo, Egypt, [4]Natl. research centre, Cairo, Egypt

Absence of teeth in the oral cavity is one of the most common dental abnormalities. Anodontia is a term used to describe congenitally missing teeth.This condition can be either true, due to tooth agenesis or false (pseudo) due to impaction, or failure of eruption. In this single-center seven-year retrospective study, we report and describe the frequency of genetic disorders associated with pseudoanodontia in patients who presented to the outpatient clinic of Oro-dental Genetics Department at the National Research Center, Cairo, Egypt.The recorded patients were classified into; primary pseudoanodontia (failure of teeth eruption) and secondary pseudoanodontia (early loss of teeth). Cleidocranial dysplasia was the most frequent disorder in the primary pseudoanodontia followed by GAPO syndrome, while Papillon-Lefèvre syndrome was the most frequent disorder in the secondary pseudoanodontia followed by congenital insensitivity to pain with anhydrosis and hypophosphatasia. Dental mangement of primary pseudoanodontia is challenging, in this study we reported The dental management of 19-year old male suffered from Cleidocranial dysplasia depended on preservation of the unerupted teeth by orthodontic traction after their surgical exposure and 11-year old male suffered from GAPO syndrome by conventional complete denture.

Session Title: Mendelian Phenotypes Poster Session I

PB4689 Clinical exome sequencing efficacy and phenotypic expansions involving anomalous pulmonary venous return.

Authors:

E. Huth[1], X. Zhao[1], P. N. Luna[1], I. Vogel[2], I. L. H. Dorf[3], S. Joss[4], J. Clayton-Smith[5], M. J. Parker[6], J. J. Louw[7], M. Gewillig[8], J. Breckpot[9], A. Kraus[10], E. Sasaki[11], U. Kini[12], T. Burgess[13], T. Y. Tan[13], R. Armstrong[14], K. Neas[15], G. B. Ferrero[16], A. Brusco[16], W. S. Kerstjens-Frederikse[17], J. Rankin[18], L. R. Helvaty[19], B. J. Landis[19], G. C. Geddes[19], K. L. McBride[20], S. M. Ware[21], C. A. Shaw[1], S. R. Lalani[1], J. A. Rosenfeld[1], D. A. Scott[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Aarhus Univ., Aarhus, Denmark, [3]Aarhus Univ. Hosp., Aarhus, Denmark, [4]Queen Elizabeth Univ. Hosp., Glasgow, United Kingdom, [5]Manchester Univ. Hosp., Manchester, United Kingdom, [6]Sheffield Children's Hosp., Sheffield, United Kingdom, [7]Pediatric Cardiology Maastricht Univ. Med. Ctr., Maastricht, Netherlands, [8]Dept. of Cardiovascular Sci. KU Leuven, Leuven, Belgium, [9]Catholic Univ. Leuven, Leuven, Belgium, [10]Chapel Allerton Hosp., Leeds, United Kingdom, [11]Oxford Ctr. for Genomic Med., Oxford, United Kingdom, [12]Oxford Univ. Hosp. NHS FT, Oxford, United Kingdom, [13]Murdoch Children's Res. Inst., Melbourne, Australia, [14]Addenbrooke's Hosp., Cambridge, United Kingdom, [15]Genetic Hlth.Service NZ, Wellington, New Zealand, [16]Univ. of Torino, Torino, Italy, [17]Univ. Med. Ctr. Groningen, Groningen, Netherlands, [18]Peninsula Clinical Genetics Service, Exeter, United Kingdom, [19]Indiana Univ. Sch. of Med., Indianapolis, IN, [20]Univ. of Calgary, Calgary, AB, Canada, [21]Indiana Univ., Indianapolis, IN

Anomalous pulmonary venous return (APVR) frequently occurs with other congenital heart defects (CHDs) or extra-cardiac anomalies. While some genetic causes have been identified, the optimal approach to genetic testing in individuals with APVR remains uncertain, and the etiology of most cases of APVR is unclear. Here, we analyzed molecular data from 49 individuals who received clinical exome sequencing from Baylor Genetics to determine the diagnostic yield of clinical exome sequencing (ES) for non-isolated APVR. A definitive or probable diagnosis was made for 8 of those individuals yielding a diagnostic efficacy rate of 16.3%. We then analyzed molecular data from 62 individuals with APVR accrued from three databases (Baylor Genetics clinical exome, Cytogenetics of Cardiovascular Malformations Consortium Registry, and DECIPHER) to identify novel APVR genes. Based on data from this analysis, published case reports, mouse models, and/or similarity to known APVR genes as revealed by a machine learning algorithm, we identified 3 genes—*EFTUD2*, *NAA15*, and *NKX2-1*—for which there is sufficient evidence to support phenotypic expansion to include APVR. We also provide evidence that 3 recurrent copy number variants contribute to the development of APVR: proximal 1q21.1 microdeletions involving *RBM8A* and *PDZK1*, recurrent BP1-BP2 15q11.2 deletions, and central 22q11.2 deletions involving *CRKL*. Our results suggest that ES and chromosomal microarray analysis (or genome sequencing) should be considered for individuals with non-isolated APVR for whom a genetic etiology has not been identified, and that genetic testing to identify an independent genetic etiology of APVR is not warranted in individuals with *EFTUD2*-, *NAA15*-, and *NKX2-1*-related disorders.

Session Title: Mendelian Phenotypes Poster Session II

PB4690 Clinical features of 110 patients with Angelman syndrome.

Authors:

M. Fujimoto[1], Y. Nakamura[1], T. Iwaki[1], E. Sato[2], D. Ieda[1], Y. Negishi[1], A. Hattori[1], S. Saitoh[1]; [1]Nagoya City Univ., Nagoya, Japan, [2]Nagoya city Univ., Nagoya, Japan

Background: Angelman syndrome (AS) is a severe neurodevelopmental disorder caused by loss of function of maternal *UBE3A*. The clinical features of AS include severe neurodevelopmental delay, easily provoked laughter, and seizures. Williams (Am J Med Genet 2006) reported that all AS patients exhibited developmental delay, movement or balance disorder, behavioral uniqueness and speech impairment. Additionally, over 80% of AS patients displayed seizures, abnormal electroencephalogram (EEG) and microcephaly. Sleep disorders and hypopigmentation were observed in 20-80% of AS. However, occasionally we experienced AS patients who did not match these features and might miss the opportunities to examine appropriate genetic tests. Here, we investigated clinical features of substantially large number of AS patients. **Methods**: We investigated the clinical features and genetic causes of AS patients through surveys from physicians treating AS patients. **Results**: We investigated 110 AS patients, of whom 28 were caused by a maternal deletion in 15q11-q13, 35 by uniparental disomy (UPD) or imprinting disorder (ID) and 47 by a *UBE3A* mutation. Developmental delay was present in all AS patients. But movement or balance disorders were observed in 91% of patients. Behavioral uniqueness was observed in 97% of patients, and language impairment was present in 80% of patients. Notably, some AS patients caused by UPD or ID tended to exhibit loss of these features. All AS patients with a deletion showed seizures and abnormal EEG. However, approximately 30% of AS patients with UPD/ID or a *UBE3A* mutation did not experience seizures. Microcephaly was observed in less than 50% of AS patients. Sleep disorders were present in over 80% of all AS patients, and more than 50% did not exhibit hypopigmentation. **Conclusion**: Our study demonstrated clinical features of 110 AS patients. Although developmental delay was present in 100%, movement or balance disorder and behavioral uniqueness were not present in all patients. Patients with UPD/ID or a *UBE3A* mutation tended to show less specific phenotypes as reported in previous literature. Therefore, genetic test should not be limited to patients with typical clinical features of AS.

Session Title: Mendelian Phenotypes Poster Session III

PB4691 Clinical features of eight cases of neuronal intranuclear inclusion disease (NIID) in Kochi prefecture, Japan

Authors:

H. Furuya[1,2], D. Yoshimoto[1], S. Ohturu[1], T. Shogase[1], Y. Nishikawa[1], Y. Hashimoto[1], Y. Morita[1], Y. Osaki[1], H. Nakazawa[2], T. Matsushita[1]; [1]Kochi Med. Sch., Kochi Univ., Kochi, Japan, [2]Dept. of Neurology, Nankoku Hosp., Kochi, Japan

Background : Neuronal intranuclear inclusion disease (NIID) (MIM 603472), caused by an expansion of GGC repeats in the 5'-untranslated region of *NOTCH2NLC*, is a neurodegenerative disorder characterized by eosinophilic intranuclear inclusions in neuronal cells and other tissues. Such inclusions are also found in non-neuronal cells. The clinical features and pathological findings in patients with NIID are highly varied, except for progressive dementia.**Objective**: In this study, we present eight cases of NIID in Kochi Prefecture, Japan. Three of the cases deceased after an average clinical course of 11.6 years.**Results**: All cases underwent skin biopsy, MRI imaging, and genetic analysis. Eosinophilic inclusion bodies and increased signals in the corticomedullary junction curvilinear lesions on diffusion-weighted imaging (DWI) were observed in all cases. Expanded GGC repeats were found in all patients. The median age at symptom onset was 61.8 years (range, 57-72 years), and the initial clinical symptoms included dementia (50%), syncope or loss of consciousness (25%), dizziness (25%), parkinsonism (gait disturbance, resting tremor, rigidity) (50%), depression (25%), and character change (25%). All patients exhibited dementia, and six patients (75%) showed parkinsonism during the clinical course. Five patients underwent MIBG cardiac scintigraphy and DAT scans, which showed no abnormalities. Levodopa treatment was administered to all patients with parkinsonism, and some patients showed positive drug effects. In neurological examinations, six NIID patients (75%) showed laterality or severely increased Pulmomental Reflex.**Conclusion:** NIID is considered a clinically heterogeneous disease entity with various clinical features. Dementia is a common symptom, but parkinsonism also commonly occurs during the course of the disease.**Achknowledgement:** We also thank to Prof. Sone J (Department of Neurology, Aichi Medical University, Japan) and Prof. Toda T (Department of Neurology, Tokyo University, Japan) for immune staining of biopsy specimen and genetic analysis.

Session Title: Mendelian Phenotypes Poster Session I

PB4692 Clinical Features of Individuals with Rauch-Steindl Syndrome due to *NSD2* pathogenic variant.

Authors:

E. Nishi[1], K. Yanagi[2], N. Okamoto[1], T. Kaname[3]; [1]Osaka Women s and Children s Hosp., Osaka, Japan, [2]Natl. Ctr. for Child Hlth.and Dev. (NCCHD), Tokyo, Japan, [3]Natl Ctr Child Hlth Dev (NCCHD), Tokyo, Japan

Rauch-Steindl syndrome (RAUST) (MIM#619695) is a rare genetic syndrome characterized by prenatal and postnatal growth retardation, distinctive facial features, and psychomotor delay caused by heterozygous pathogenic variants in *NSD2*. RAUST is similar to Wolff-Hirschhorn syndrome (WHS), caused by a deletion of the chromosome 4p16.3 region where *NSD2* is located. *NSD2*, also known as *WHSC1*, has been recognized as important for the WHS phenotype. While both RAUST and WHS share growth failure and psychomotor delay, there are differences between the two syndromes. RAUST presents with a milder phenotype compared to WHS, and characteristic symptoms such as seizures, cleft palate, and heart disease commonly observed in WHS are less frequent in RAUST. Moreover, facial features of individuals with RAUST have been reported to have sufficient specificity to distinguish it as a distinct syndrome (Zanoni et al., 2021). Here, we present the clinical details of two individuals with *de novo* heterozygous pathogenic variants in *NSD2*. Individual 1: A 7-year-old boy, born at 41 weeks and 3 days via normal delivery. He did not experience respiratory or feeding difficulties in the neonatal period but had feeding problems as an infant. He exhibited moderate psychomotor delay (began walking independently at 28 months, first speech at 4 years; DQ 35). Short stature and delayed bone age were also present. We identified a novel nonsense variant in *NSD2*. Individual 2: A 5-year-old boy, delivered by cesarean section at 36 weeks and 1 day due to umbilical cord torsion. He required ventilator support for 1 day due to respiratory failure. He also showed moderate psychomotor developmental delay (began walking independently at 24 months, first speech at 2 years; DQ 37). Short stature and delayed bone age were evident. We identified a reccurent frameshift variant in *NSD2*. Both individuals exhibited craniofacial features consistent with previously reported RAUST cases, including relative macrocephaly, triangular face, broad arches, and sparse horizontal eyebrows. Neither individual had a history of epilepsy, although individual 1 had abnormal EEG findings. Chiari malformation type I was detected in individual 2 through brain MRI. Cleft lip and palate or congenital heart disease were not present in either individuals. The ages of gait and speech acquisition also suggest that the psychomotor delay seen in RAUST is milder than that in WHS.These findings support previous reports. The accumulation of more RAUST individuals is expected to contribute to the establishment of medical management for RAUST.

PB4693 Clinical findings of the developmental disorder by *KDM5C* variants

Authors:

H. Futagawa[1], K. Fukuda[1], H. Yamanaka[1], M. Kuroda[1], S. Ito[1], M. Honda[1], M. Yamada[2], H. Suzuki[2], T. Takenouchi[3], K. Kosaki[4]; [1]Tokyo Metropolitan Children's Med. Ctr., Tokyo, Japan, [2]Ctr. for Med. Genetics, Keio Univ., Shinjuku-ku, Tokyo, Japan, [3]Keio Univ, Tokyo, Japan, [4]Keio Univ. Sch. of Med., Tokyo, Japan

<Introduction> Loss-of-function variants in *KDM5C* (Xp11.22) is known to cause Intellectual developmental disorder, X-linked syndromic, Claes-Jensen type (MIM#300534: MRXSCJ) in which one of the most common causative gene of X-linked intellectual disability. Here, we report additionally two Japanese patients of MRXSCJ.<Patient 1> He was a 5-year-old male born to non-consanguineous healthy Japanese parents. Other than a dilated renal pelvis noted in the second trimester, the perinatal history was normal. The age of two, delayed speech emerged. At five years of age, he had moderate developmental delay. His anthropometry values were within normal range. Dysmorphic features included, short and down slanted palpebral fissure, long philtrum and micrognathia. He suffered recurrent epilepsy and had overfriendly. Trio exome analysis revealed de novo hemizygous missense *KDM5C* variant which was categorized as “Likely Pathogenic” according to ACMG/AMP guideline: NM_004187.5:c.1354G>A p.(Gly452Ser).<Patient 2> He was a 5-years-old male born to non-consanguineous healthy Japanese parents. He was born after an uneventful pregnancy. The age of two, delayed developmental milestone was noted. At five years of age, he had moderate developmental delay. His height was 92.2cm (-3.5SD) which indicated short stature. Dysmorphic features included down slanted palpebral fissure, prominent nasal tip, micrognathia, short neck. Trio exome analysis revealed de novo hemizygous nonsense *KDM5C* variant which was categorized as “Pathogenic” according to ACMG/AMP guideline: NM_004187.5:c.1153C>T p.(Arg385Ter).<Discussion>The patients reported here had facial gestalt similar to Rubinstein-Taybi syndrome (RTS), especially Patient 1 had a happy demeanor compatible to RTS. However, common features suggestive of RTS, a downward nasal septum and broad thumb, were not present. In male patients with atypical RTS, careful physical evaluation may lead to a clinical diagnosis of MRXSCJ. MRXSCJ may require genetic counseling regarding X-linked inheritance and is important as one of the differential diagnosis for RTS, which is generally autosomal dominant inheritance.*KDM5C* is the epigenetic regulator which removes methylation of H3K4me2/3 through the JmjC domain. The pathogenic variant of the Patient 1 was located at JmjC domain and presumed to affect the KDM5C demethylase activity. This variant was novel variant and would expand genotypic knowledge of the *KDM5C*.<Conclusion>In male patients with intellectual disability, distinctive facial dysmorphism and happy demeanor, the X-linked disorder MRXSCJ would be considered.

PB4694 Closing the gap: overcoming the challenges of *RPGR* ORF15 sequencing, a target for gene therapy of X-linked retinitis pigmentosa.

Authors:

S. Van De Sompele[1], M. De Bruyne[1], M. Van Heetvelde[1], B. P. Leroy[2], J. De Zaeytijd[3], B. Guillemyn[1], K. Claes[1], T. Rosseel[1], K. De Leeneer[1], M. Bauwens[1], E. De Baere[1]; [1]Dept. of Biomolecular Med. & Ctr. for Med. Genetics Ghent, Ghent Univ. and Ghent Univ. Hosp., Ghent, Belgium, [2]Dept. of Ophthalmology & Ctr. for Med. Genetics Ghent, Ghent Univ. and Ghent Univ. Hosp., Ghent, Belgium, [3]Dept. of Ophthalmology, Ghent Univ. and Ghent Univ. Hosp., Ghent, Belgium

Retinitis pigmentosa (RP) is a group of inherited retinal diseases (IRD) leading to vision impairment in 2 million people worldwide. Representing approximately 10% of all cases, X-linked RP (XLRP) is the most severe form, being generally associated with an earlier disease onset and more rapid progression up to legal blindness by the third-fourth decade. The major gene responsible for XLRP is *RPGR*, encoding a protein involved in the regulation of ciliary transport, harboring up to 80% of pathogenic variants underlying XLRP. Interestingly, the majority of pathogenic *RPGR* variants are located in ORF15, an exon unique to a retina-specific *RPGR* isoform that is expressed in the cilium and basal bodies of the photoreceptor cells.

During recent years, several gene therapy clinical trials have been conducted, aimed at halting the degenerative processes in *RPGR*-IRD. To be eligible for such innovative therapeutic interventions, an accurate and fast molecular diagnosis is required. Due to its highly repetitive and purine-rich nature, ORF15 does however pose substantial technical challenges for genetic testing, including PCR amplification artifacts, insufficient coverage, sequence misalignments, and inaccurate variant calling. Here, we evaluated the performance of different sequencing technologies to overcome these challenges.

We observed that whole exome (WES) and short-read whole genome sequencing (SR-WGS) (Illumina) provide a minimum coverage of <20X for the purine-rich ORF15 subregion (amino acid 700-1030), resulting in inaccurate capture of genetic information within this region. Variants in ORF15 generally need to be confirmed, which requires unique reagents, multiple pairs of overlapping primers, and specific PCR conditions, thus hampering its application in routine diagnostics. Long-read WGS (LR-WGS) using Oxford Nanopore Technologies (ONT) on the other hand demonstrated drastic improvements in the coverage uniformity of the entire ORF15 region, albeit at a ten times higher cost. To overcome these limitations, we designed a KAPA HyperCap probe set (Roche) for the targeted enrichment of ~400 kb clinically relevant regions, including *RPGR*. Sequencing on a NovaSeq 6000 platform (Illumina) resulted in an overall higher coverage, with ORF15 demonstrating a minimum coverage of >120X. Moreover, this strategy allowed us to accurately detect variants in both the purine-rich ORF15 subregion and a broad selection of other IRD genes, for almost half the cost of WES.

Overall, these findings accelerate the molecular diagnosis of *RPGR*-IRD in a robust and cost-effective way, improving patients' eligibility for therapeutic interventions.

Session Title: Mendelian Phenotypes Poster Session I

PB4695 Clusters of rare skeletal dysplasias in Brazil

Authors:

D. Cavalcanti[1], L. Bonadia[1], C. A. Moreno[1], I. Monlléo[2], M. Santos[2], S. Oliveira[3], K. Nunes[4], F. Gameleira[5]; [1]Univ. of Campinas (UNICAMP), Campinas, SP, Brazil, [2]Federal Univ. of Alagoas, Maceió, AL, Brazil, [3]Univ. of Brasilia, Brasília, DF, Brazil, [4]Univ. of São Paulo, São Paulo, SP, Brazil, [5]Prefeitura de Ouro Preto, Ouro Preto, MG, Brazil

In the last 13 years, the Skeletal Dysplasia Group at UNICAMP found evidence of clusters for at least four different osteochondrodysplasias (OCD). Three proven clusters are summarized here. The first was recently found in a small community with less than 300 inhabitants in the South of Minas Gerais, a State of the Brazilian Southeast. In an inbred family in this village, three affected individuals with typical Omodysplasia were found, all of them carriers of a homozygous variant in *GPC6* (c.878-2A>G). The other two clusters were found in Northeastern Brazil, both involving increased bone density. Pycnodysostosis was the 1st one reported by our group (DOI 10.1186/s40001-016-0228-7*)*, and the 2nd cluster is here reported and involves a lethal phenotype - Blomstrand Dysplasia (BD). This OCD is associated with biallelic mutations in the *PTHR1* gene, and fewer than 20 patients have been reported. All available members of three nuclear families were studied using Sanger sequencing, microsatellite analysis, and a high-density SNP array (~600K). The kinship analyses were performed by the method of the moment SNPRelate. The mutation age was inferred using the Gamma method. Finally, genetic ancestry was carried out through the genomic ancestry average (Admixture) and ancestry observed in the genomic mutation region (RFMIX). The same variant (c.639-2 A>G) in *PTHR1* identified in HMZ in two fetuses with BD from two families was found in HTZ in the parents and one unaffected sib of a fetus with BD previously reported (Pediatr Radiol 1999 29:842-845). Microsatellite analysis confirmed the founder effect. Analysis of the SNP array confirmed a second cousin's kinship between the three genealogies and a minimum haplotype shared of ~13 Kb between carriers' individuals. The time since the most recent common ancestor between them was inferred in 5.9 generations (CI=2.3-15.4), meaning the mutation has been segregated in this family for approximately 150 years (CI = 50-375 years). The average genomic ancestry was 72% European, 19% African, and 9% Native American. All carriers have the mutation in a segment of European ancestry. In conclusion, these results confirm our 3rd cluster of OCD due to a founder effect of the c.639-2A>G variant in *PTHR1* that probably emerged in Brazil over 150 years ago or was brought by a European colonizer. Session Title: Mendelian Phenotypes Poster Session II

PB4696 *CNP* variants cause non-syndromic high myopia in humans

Authors:

T. Qi[1], K. Rizwan[1], T. Runyi[1], Z. Liyu[1], M. Sigurbjörn[2], R. Arne[2], F. Chaolan[1], T. Ping[1], K. Petri[2], X. Kun[1], H. Zhengmao[1]; [1]Central South Univ., Changsha, China, [2]Univ. of Bergen, Bergen, Norway

High myopia (HM) is a common form of refractive error with high heritability and one of the leading causes of blindness worldwide. Only a few genes have been implicated in HM, while the genetic basis for most cases remains elusive. This study identified a heterozygous missense variant (c.59A>C, p.K20T) on the *CNP* gene (which encodes the 2',3'-cyclic nucleotide 3'-phosphodiesterase, CNPase) co-segregated with HM in a three-generation family from China. Subsequent screening of *CNP* in the HM cohort led to the discovery of three additional variants; two were recurrent with low frequency (c.59A>G, p.K20R; c.1015G>A, p.V339I), and the remaining one was novel (c.1034G>A, p.G345D). Single-cell RNA sequencing and qPCR demonstrated that *Cnp* was abundantly expressed in the progenitor cells of developing mouse retina, indicating the importance of CNPase in retinal development. Under transmission electron microscopy, the mitochondria size was increased, and the cristae number per mitochondria was decreased in the *CNP* knockout Hela cell lines, implicating the swelling of the mitochondria and disturbed oxidative phosphorylation. After overexpression of CNP wild type and mutants in the knockout cell lines, we detected an increased mitochondrial permeability transition pore opening using the mPTP assay in the mutant groups, indicating that the mitochondria's swelling may attribute to the mPTP opening in knockout cell lines. Then we analyzed the interactomes of CNP wild type and K20T mutant using label-free mass spectrometry. We found that interactive PMPCB (a catalytic subunit of the essential mitochondrial processing protease) was increased, and NFDUFB4 (a subunit of the complex I in the mitochondrial electron transport chain) was decreased in the K20T mutant group. Moreover, in the overexpression experiment, the mitochondrial targeting sequence (MTS) cleavage of K20T was reduced, indicating that K20T's MTS cannot be cleaved normally and play its role subsequently, such as regulating oxidative phosphorylation. We hypothesize that CNP mutations may disturb its pre-peptide processing or its function in the oxidative phosphorylation regulating, thus affecting retina development through impaired mitochondria function and causing high myopia ultimately. To conclude, we found that *CNP* is a novel causal gene in the monogenic form of HM. Its defects may cause HM through impaired mitochondrial function during eye development.

PB4697 Comparative RNAseq analysis for the study of motoneuron diseases in multi-omics approaches

Authors:

S. Chen[1], U. Ulmer[2], M. Synofzik[3], R. Schule[4], S. Zuchner[1], M. Danzi[1]; [1]Univ. of Miami, Miami, FL, [2]Univ. of Tübingen, Tübingen, Germany, [3]Hertie Inst. for Clinical Brain Res., Tuebingen, Baden Wã¼rttemberg, Germany, [4]Ctr. for Neurology and Hertie Inst. for Clinical Brain Res., Tübingen, Germany

Nearly half of patients with suspected monogenic Mendelian diseases still remain undiagnosed. Deep intronic non-coding variation contributes to mis-splicing, thereby constituting pathogenic changes that are difficult to discern when analyzing whole genome data alone. The integration of genome sequencing and RNA sequencing can reveal the functional significance of rare changes. However, this approach is challenged when studying neurological and motoneuron diseases. Obtaining affected tissue samples from living patients is typically not feasible. Therefore, it is important to compromise on the availability of type of tissue and its reflection of the target tissue expression patterns. Here we explore the utility of typically available sources of material for RNAseq studies that can empower genome analysis. We found that fibroblasts detectably express 76.8%,81.2%, and 73.6% of genes known to cause the monogenic diseases CMT, HSP, and ataxia, respectively. This outperformed other peripheral tissues such as whole blood and lymphocytes, thereby making fibroblasts a valuable tissue for studying motoneuron diseases. making them a valuable tool for studying HSP. Furthermore, we analyzed RNA-seq data from fibroblasts of two HSP patients carrying a POLR3A splicing variant to evaluate the sensitivity and specificity of several alternative splicing detection tools for diagnostic purposes. Our results highlight the potential of fibroblast RNA-seq data for diagnosing and studying HSP and other motoneuron diseases using peripheral tissue.

PB4698 Complex genetic architecture underlies craniofacial microsomia.

Authors:

N. Gogate[1], A. Jolly[1], J. Punetha[1], H. Streff[2], A. Ayaz[3], E. Macnamara[4], M. Racobaldo[5], H. Du[6], H. Du[1], S. Jhangiani[7], D. Muzny[7], R. Gibbs[7], D. Pehlivan[1], S. Antonarakis[8], R. Lewis[9], J. Lupski[1], J. Posey[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Texas Children s Hosp., Houston, TX, [3]Dept. of Med. Genetics, Adana City Training and Res. Hosp., Dept.s of Med. Genetics, Sch. of Med., Istanbul Medipol Univ.,, Adana and Istanbul, Turkey, [4]NIH, Bethesda, MD, [5]Univ. of South Florida, Tampa, FL, [6]BCM, Houston, TX, [7]Baylor Coll. Med., Houston, TX, [8]Univ. of Geneva, Geneva, Switzerland, [9]Baylor Col Med, T-803 Taub Building, Houston, TX

Craniofacial microsomia (CFM, also known as Goldenhar syndrome), is the second most frequent congenital malformation of craniofacial development with an incidence of 1 in 3500 to 5600 births. CFM has variable expressivity with a recognizable clinical set of abnormalities, such as asymmetric development of the ear (with preauricular tags), nose, soft palate, lip, and mandible. CFM has been suggested to be a genetically heterogeneous condition from studies of candidate genes and variant alleles, but only a handful of these alterations seem to be recurrent in unrelated patients with CFM. Most CFM cases are sporadic and largely the molecular basis remains elusive. Through the Baylor Hopkins Center for Mendelian Genomics (BHCMG) and Baylor College of Medicine Genomic Research to Elucidate the Genetics of Rare (BCM-GREGoR) databases, we investigated a cohort of 18 unrelated families with 20 affected individuals diagnosed with CFM using exome sequencing and rare variant, family-based, genomic analyses. Previously, we had identified *FOXI3* as a candidate gene associated with CFM, and affected individuals presented with types II and III microtia or with ear deformity and preauricular tags. Additionally, we identified a homozygous *MACF1* variant (c.4084G>A, (p.E1362K)) in a case with hemifacial microsomia along with cortical dysplasia and focal epileptic findings. Three more individuals with biallelic variants (c.5569C>T, p.(R1857W); c.485C>T, p.(T162I), c.5557T>C, p.(S1853P)) were ascertained through GeneMatcher and provide supplementary evidence for phenotypic expansion of CFM with neurological features. These biallelic *MACF1* variant alleles occur closer to the N-terminus of the encoded protein and present a partially overlapping but unique disease trait from that caused by monoallelic variants within the GAR domain of *MACF1*. Furthermore, through retrospective cohort-wide analysis, we identified putatively damaging variants in candidate genes *SF3B2* and *SIX5*. *SF3B2* haploinsufficiency has been ascertained recently as one cause of CFM, while *SIX5* has been associated with craniofacial microsomia phenotypes in Branchio-Oto-Renal Syndrome 2. These results provide insight into the complex genetic architectures underlying CFM and highlight an evolving picture of genetic heterogeneity contributing to the CFM trait. Furthermore, comprehensive genotype-phenotype studies may better delineate the phenotypic spectrum of CFM or help to identify syndromic presentations driven by unique molecular etiologies.

Session Title: Mendelian Phenotypes Poster Session II

PB4699 Compound Heterozygous Variants in *PRDM5* Causing Brittle Cornea Syndrome Type 2 - A Case Report.

Authors:

C. Lyon[1], J. Black[1], R. Lebel[2]; [1]SUNY Upstate Med. Univ., Syracuse, NY, [2]SUNY Upstate Med Univ, Fayetteville, NY

Background: Brittle cornea syndrome type 2 (OMIM #614170) is an autosomal recessive condition caused by variants in the *PRDM5* gene (OMIM #614161). Typical manifestations are blue sclera, corneal rupture after minor trauma, keratoconus, hyper-elasticity of the skin, and hypermobility of the joints. The *PRDM5* gene plays a role in regulating the development and thickness of the cornea.
Case presentation: A 26-year-old female, born in a non-consanguineous union, had typical neurodevelopment and was in good general health when she presented with progressive sensorineural hearing loss, keratoconus, joint laxity, patellofemoral instability, dystrophic scarring, easy bruising, *pes planus*, blue sclerae, and heterochromia. Whole exome sequencing revealed heterozygous pathogenic variant in *PRDM5* (c. 1513dup) and heterozygous likely pathogenic variant in (c.301-5T>G) in trans. Ophthalmological exam revealed thinning of the central cornea, superficial punctate keratitis that is mild but more in the left than in the right eye, chorioretinal scar right eye, keratoconus, left eye myopia, right eye hypermetropia, bilateral astigmatism, and normal vitreo-retinal imaging, scanning laser ophthalmoscopy, and field studies.
Conclusion: Brittle cornea syndrome type 2 is usually associated with consanguinity, which are not present in this patient. In addition, this patient does not present with a history of corneal perforation, typically a hallmark of this disease. This atypical phenotypic presentation for brittle cornea syndrome type 2 is likely due to the compound heterozygous nature (rather than homozygosity by common descent) of its inheritance. Due to the novel genetic mutations and phenotypic characteristics, this case offers an expansion of the genotype-phenotype correlations in this rare condition.

Faculty, Dept. of Neurology, Istanbul, Turkey

Multiple sclerosis (MS) is a chronic, immune-mediated neurological disease with a complex inheritance pattern. In this study, we conducted exome sequencing to explore genetic variants in 45 multiply affected MS families (101 patients and 53 unaffected family members). In 33 families (73 patients and 53 unaffected family members), the pVAAST burden test and Exomiser gene prioritization were performed using 206 MS-related Human Phenotype Ontology terms, and variants with a minor allele frequency (MAF) < 0.01 were selected for both dominant and recessive segregation patterns. This resulted in 527 genes, which then underwent functional enrichment analysis through g:Profiler in multiple databases. These genes were associated with several immunological and cell signaling adhesion pathways, among which the Laminin Subunit Alpha 5 (*LAMA5*) gene, involved in blood-brain barrier (BBB) processes such as cell adhesion, differentiation, migration, and signaling, was highlighted. Variations in *LAMA5* were found as well as in other laminin genes essential for BBB function, such as *LAMA1, LAMC5, LAMA2, LAMB1,* and *LAMA3*. This co-occurrence pattern was identified in patients exhibiting protein-changing variants with a MAF < 0.05 in the gnomAD exome database. Among 40 variants identified in the *LAMA5* gene in the patients (all with a MAF < 0.05 in gnomAD and causing amino acid changes), rs79319629 (p.Lys812Thr; c.2435A>C; ENST00000252999.7; CADD score: 17.18) was found in nine patients across families. This variant was detected in an affected mother-son duo, a nephew and aunt, a sibling pair, and three patients in different families. Other significant rare variants with a global MAF of 0.003 (*LILRA1*) and 0.0006 (*LILRB1*) were identified. *LILRA1* and *LILRB1* are associated with immunoregulatory interactions, including response pathways to natalizumab, which is used in MS treatment. The *LILRA1* variant rs75416770 (p.His164Tyr; c.490C>T; ENST00000251372.8) was detected in one family exhibiting an autosomal dominant inheritance. Selected variants are currently being studied to assess their functionality in co-culture models using genome-edited BBB cells together with peripheral blood mononuclear cells. Acknowledgement: We thank Clifton L. Dalgard and Uniformed Services University, Laboratory Core of the Collaborative Health Initiative Research Program, and Yale Center for Genome Analysis, for sequencing services.

Session Title: Mendelian Phenotypes Poster Session I

PB4701 Comprehensive compendium of Joubert syndrome gene variants and associated phenotypes highlights genetic and phenotypic overlap in ciliopathies.

Authors:

B. Henning[1], H. Loucks[1], A. K. Christman[1], P. Panchal[1], J. Du[1], V. Bowman[1], J. Dempsey[2], D. Doherty[2]; [1]Univ. of Washington, Seattle, WA, [2]Univ of Washington, Seattle, WA

Joubert syndrome (JS) is a largely recessive neurodevelopmental condition that overlaps clinically and genetically with Meckel syndrome (MKS), Nephronophthisis (NPH) and other ciliopathies. >40 genes have been associated with JS, while ~20 have been associated with MKS, and ~40 with NPH. Understanding the genotype-phenotype associations within ciliopathies is essential for interpreting genetic testing. Here, we compile a comprehensive dataset of variants in JS-genes linked to individual phenotypes extracted from the literature. We aim to identify gene-diagnostic category associations and variant-phenotype associations; and create a comprehensive database of JS-genes variants. We searched PubMed for papers reporting known and candidate JS-associated gene variants in patients with ciliopathy or neurodevelopmental phenotypes between 05/2004-07/2021. We extracted variant information, and used the Ensembl Variant Effect Predictor to determine pathogenicity based on predicted functional effect, Genome Aggregation Database (gnomAD) allele frequencies, and Combined Annotation Dependent Depletion (CADD) scores. We also extracted individual phenotypic features, which we mapped to Human Phenotype Ontology (HPO) terms using an in-house algorithm. We computed the percentage of individuals with variants in each phenotypic category and functional category. Data curation is partially done. So far, we have compiled 902 unique variants in 1437 individuals assigned to 12 diagnostic groups: JS (38%), retinal dystrophy (21%), NPH (18%), MKS (12%), and oral-facial-digital syndrome (7%). Other diagnostic groups each represented ~1%. Of the 43 JS-associated genes, 15 were only associated with JS, while 19 were associated with JS and MKS, and 7 with JS-NPH. *CEP290* variants were associated with the largest number of conditions (NPH, SLS, JS, MKS, RD, OCRS, NDC-NOS). About 60% of the variants had allele frequencies <= 0.001 in gnomAD. The top 25% most common variants had allele frequencies between 0.01-0.04. ~98% of the variants had CADD scores >15, 94% >20, 80% >25, 49% >30. 67% of individuals with JS had frameshift variants only, 17% truncating variants only, 4% missense variants only; 1% CNV variants only. In summary, we assembled a comprehensive and highly curated database of JS-gene variants and the associated phenotypes, which will aid in determining the pathogenicity of future variants. Going forward, we will analyze genotype-phenotype correlations, identify all variants that might be amenable to antisense oligonucleotide treatment, and contribute the curated variants to publicly accessible databases.

Session Title: Mendelian Phenotypes Poster Session II

PB4702 Comprehensive Genetic Evaluation of Witteveen-Kolk Syndrome in a 6-Year-Old Puerto Rican Girl: Identification of a Novel *SIN3A* Variant

Authors:

C. Rodriguez[1], E. Albino[2], F. Velez-Bartolomei[1], S. Carlo[3], A. Cornier[4]; [1]San Jorge Children & Women's Hosp., San Juan, PR, [2]Univ. of Puerto Rico - MSC, San Juan, PR, [3]Ponce Hlth.Sci. Univ., Cabo Rojo, PR, [4]San Jorge Children s & Women s Hosp., San Juan, PR

Witteveen-Kolk syndrome is a rare neurodevelopmental disorder characterized by developmental delay and intellectual disability. With less than 50 reported cases worldwide, the syndrome occurs in approximately 1 in 10,000 individuals. We present the case of a 6-year-old Puerto Rican girl referred for genetic evaluation due to speech and developmental delay since the age of four, accompanied by mild hypotonia. A comprehensive genetic assessment was performed on the patient, starting with a metabolic newborn screening panel that revealed a heterozygous pathogenic mutation in the *MMACHC* gene (c.481C>T; p.Arg161), associated with autosomal recessive methylmalonic aciduria with homocystinuria due to cobalamin deficiency. Further evaluation using a neurodevelopmental disorders gene panel identified a novel variant in the *SIN3A gene* (c.269C>T; p.Ala90Val) located on chromosome 15. This variant, replacing alanine with valine, has not been reported in the literature for individuals affected with *SIN3A*-related conditions but is present in population databases (gnomAD 0.0009%). The patient exhibits clinical features overlapping with Witteveen-Kolk syndrome, including characteristic facial features such as a broad and tall forehead, thin upper lids, and a pointed chin. Despite the variant's classification as uncertain significance, the patient's clinical manifestations, including facial features, hypotonia, developmental delay, and intellectual disabilities, strongly suggest pathogenicity. Further neurological and hearing evaluations are recommended to assess potential seizures and hearing impairment commonly associated with this syndrome. The identification of this variant expands our understanding of the syndrome's genetic landscape and emphasizes the need for further clinical assessments to manage potential complications. Enhancing our knowledge of this rare disorder will facilitate improved diagnosis, prognosis, and potential therapeutic interventions for affected individuals within the Puerto Rican population.

PB4703 Comprehensive genomic analysis of a trios family study with an index child diagnosed with autism spectrum disorders

Authors:

D. Manjegowda[1], U. Radhakrishna[2], S. Chettiar[3]; [1]Dayananda Sagar Univ., Bangalore, India, [2]Green Cross Pathology & Molecular Lab., Ahmedabad, India, [3]Genexplore Diagnostics and Res. Ctr., Ahmedabad, India

Autism Spectrum Disorder (ASD) is a complex neurodevelopmental disorder characterized by impaired social interaction, communication difficulties, and restricted repetitive behaviors. ASD is a complex and heterogeneous disorder, and it is likely that multiple genes, as well as environmental factors, contribute to its development, however, the underlying genomic landscape and the specific genetic variants associated with the disorder remain largely unknown. We performed a comprehensive genomic analysis to identify potential genetic factors contributing to the disorder. A total of 27 Indian trios between the ages of 8 and 12 with clinically diagnosed ASD index children were recruited and their blood genomic DNAs were prepared. Microarray analysis and Next-Generation Sequencing (NGS) were used to analyze the samples. The data was integrated using programmatic series of analyses (bioinformatics, statistical, computational biology, and pathway analyses), to explore the relation of genomic variants to ASD to lead to identification pathophysiology of disease and new therapeutic targets for preventing ASD. Microarray analysis revealed copy number variations (CNVs) less than 1MB duplications among chromosomal critical region 6p21.32, 7p21.2, 8p23.3, 14q12.14, Xp22.11. Whole-exome sequencing (WES) revealed single nucleotide variants (SNVs) in *CDK5RAP2, CC2D1A, AP4M1, SYNGAP1, STXBP1, ACSL4, ASTN1, MBD5, CDK5RAP2, CNTNAP2, SCN8A, SATB1, CREBBP, SHANK3, SHANK2, GNG13 and PPP3CB.* While most of these variants are novel and may contribute to the development of ASD, a few were previously reported in ways related to synaptic function, neuronal connectivity, and neurodevelopmental processes. Analyses of pathways and functional enrichment revealed dysregulation of glutamatergic synaptic transmission. Glutamate is the most abundant excitatory neurotransmitter in the brain and plays a crucial role in synaptic transmission and abnormalities in glutamatergic neurotransmission may contribute to the pathophysiology of ASD.Through the integration of clinical data with comprehensive genomic analysis in trios, genetic variations associated with ASD can be more precisely identified. As a result of these findings, genetic counseling may be able to develop targeted therapeutic interventions and personalized treatment strategies for individuals with ASD.

Session Title: Mendelian Phenotypes Poster Session II

PB4705 Consistent long-term clinical benefit with govorestat treatment: results of the ACTION-Galactosemia Kids trial

Authors:

R. Perfetti, E. Bailey, S. Wang, S. Shendelman; Applied Therapeutics Inc., New York, NY

Classic Galactosemia (CG) is an autosomal recessive disease caused by deficiency in the GALT enzyme, which is required for galactose metabolism. At abnormally high levels, galactose becomes an aberrant substrate for the enzyme aldose reductase, resulting in conversion to a toxic metabolite, galactitol. Newborn screening and implementation of a galactose-restricted diet has reduced newborn fatalities. However, despite early dietary intervention, children continue to develop progressive long-term complications. Govorestat (AT-007) is an oral, CNS penetrant aldose reductase inhibitor, which prevents conversion of galactose to the toxic metabolite galactitol.The ACTION-Galactosemia Kids Ph 3 study was designed to evaluate the impact of govorestat vs. placebo on clinical outcomes in 47 children age 2-17 with CG.The primary endpoint was a composite sum of change across four endpoints: OWLS-2 Oral Expression and Listening Comprehension, BASC-3 Behavior Symptoms Index and Activities of Daily Living. Cognition was included as a pre-specified sensitivity analysis to the primary endpoint. Additional secondary endpoints included adaptive skills and tremor. Data was assessed every 6 months by a firewalled independent DMC.Treatment with govorestat provided sustained clinical benefit on activities of daily living, behavioral symptoms, cognition, adaptive behavior and tremor over 18 months of treatment. While statistical significance ($p<0.05$) was not met on the primary endpoint, systematic improvement over time was demonstrated for the overall primary endpoint ($p=0.1030$) and for the sensitivity analyses including cognition ($p=0.0698$). Speech components were not impacted, which is suspected to be due to lack of progression in the placebo group and concomitant speech therapy received by almost all children in the trial. A post-hoc analysis of the primary endpoint excluding speech components demonstrated a highly statistically significant benefit of govorestat vs. placebo ($p=0.0205$). Govorestat provided significant benefit on tremor ($p=0.0428$), and adaptive skills (BASC-3 Adaptive Skills Index) ($p=0.0265$). Improvement in galactitol level was sustained throughout the trial with no impact on Gal-1p or galactose. Govorestat was generally safe and well tolerated, with no treatment-related SAEs.

Session Title: Mendelian Phenotypes Poster Session III

PB4706 Contribution of rare genetic variants to aortic valve stenosis in Quebec French-Canadians.

Authors:

E. MacKenzie[1], U. Houessou[2], K. Desbiens[3], L. Dufresne[3], K. Trajanoska[1], V. Mooser[4], S. Thériault[2], G. Thanassoulis[3], J. Engert[1]; [1]McGill, Montréal, QC, Canada, [2]Université Laval, Québec, QC, Canada, [3]McGill Univ. Hlth.Ctr. and Res. Inst., Montreal, QC, Canada, [4]McGill Genome Ctr., Westmount, QC, Canada

Background

Aortic valve stenosis (AS) is a severe disease affecting 2 to 5% of the North American population over age 65. Typically viewed as a polygenic condition, several common variants have been associated with AS through GWAS, yet monogenic contributors to AS have not been studied in the general population. Here, we aimed to identify rare genetic variations with a strong impact on AS in the Quebec French-Canadian population, which is genetically unique due to a limited number of original French colonisers, creating a founder effect.

Methods

Whole exome sequencing data from 310 AS patients of French-Canadian ancestry were analyzed. Rare variants (MAF < 0.001) were scored based on their predicted pathogenicity, minor allele frequency, and involvement in other diseases with similar phenotypes using Exomiser. Two independent datasets were then queried for the presence of high-scoring variants: UK Biobank (415,346 participants including 4,762 cases, imputed array and exome sequencing data) and the Quebec-based CARTaGENE cohort (11,587 participants including 263 cases, imputed array data). The association with AS of variants available in these datasets was assessed using logistic regression.

Results

A total of 722 variants found in the AS patients passed our score thresholds. Of these, 369 and 541 were present in CARTaGENE and UK Biobank respectively. 13 and 29 variants in the respective datasets were also nominally associated with AS ($p < 0.05$). One missense variant (rs368711105) in the elastin gene (*ELN*) was associated with AS in both CARTaGENE (p=0.023, OR=11.95) and UK Biobank (p=0.014, OR=10.80), and two additional genes each contained at least one associating variant in each cohort (myosin heavy chain (*MYH7*) rs149193520: p=0.0065, OR=5.23 in UK Biobank, rs200939753: p=0.0064, OR=50.53 in CARTaGENE; titin (*TTN*) rs190041566: p=0.016, OR=15.46 in UK Biobank, rs200843338: p=0.022, OR=33.65 in CARTaGENE). Of note, the *ELN* variant was observed at a higher frequency in CARTaGENE than in any other cohort listed in the dbSNP database.

Conclusion

These results support a potential role for elastin, myosin heavy chain and titin in the development of AS, as well as point to possible monogenic contributors to AS in a subset of patients. Variants in *ELN* have previously been associated with supravalvular aortic stenosis and play a role in valve pathogenesis in mice; variants in *MYH7* and *TTN* are involved in dilated and hypertrophic cardiomyopathy. Future work will attempt to identify the mechanism underlying these novel genetic associations, and seek to identify additional rare variants associated with AS, both Quebec-specific and those shared with other populations.

Session Title: Mendelian Phenotypes Poster Session I

PB4707 Copy number and non-coding variants leading to *NMNAT1*-related retinopathy

Authors:

E. Place; Mass Eye & Ear, Boston, MA

Purpose: Mutations in *NMNAT1* are associated with autosomal recessive retinal dystrophy. The most recognized retinal phenotype is Leber congenital amaurosis (LCA), which is characterized by poor visual acuity in the first year of life with characteristic colobomatous macular atrophy. Variants in this gene have also been associated with milder and later onset pan-retinal disease as well as cone and cone-rod dystrophy. Over 90 variants have been reported to be disease causing with the vast majority single nucleotide variants (SNV) and small insertions/deletions. For inherited retinal disorders, it has been shown that structural variation including copy number as well as non-coding variants contribute to disease causality. The purpose of this study was to assess the role and contribution of copy number variants (CNV) and non-coding variants in *NMNAT1*-related retinopathy.
Methods: Over 3000 subjects with retinal dystrophy were screened for *NMNAT1* variants through Next-generation sequencing (NGS) targeted gene sequencing, whole exome sequencing, or whole genome sequencing. NGS data was used to detect CNVs with gCNV. Likely causal CNVs were validated by quantitative polymerase chain reaction (qPCR). Likely causal non-coding variants were assessed with in silico predictions as well as in vitro studies. Individuals were eligible for inclusion if they had either one CNV or non-coding variant, or, if they had a less typical phenotype.
Results: 7 individuals with biallelic *NMNAT1* variants were identified. Three unrelated subjects had at least one structural variant. Two individuals both had a tandem duplication spanning exon 2 to 3'UTR , and a single exon deletion was identified in the third. Two of these individuals had clinical diagnoses of LCA while the third had a diagnosis of macular dystrophy. Non-coding likely causal variants were identified in 2 subjects: one with a clinical diagnosis of LCA and the other with macular dystrophy. Additionally, analysis identified two unrelated subjects with cone-rod dystrophy and compound heterozygous causal missense coding variants.
Conclusions: Inherited retinal diseases (IRDs) are phenotypically heterogenous and it is well established that a single IRD gene can be associated with a spectrum of retinal phenotypes. The phenotypic and molecular findings from this study adds to the growing evidence supporting the phenotype spectrum associated with *NMNAT1* and highlights the contribution copy number and non-coding variants in *NMNAT1*-related retinopathy.

Session Title: Mendelian Phenotypes Poster Session II

PB4708 CRISPR/Cas9 gene-edited zebrafish model for Noonan syndrome.

Authors:

P-X. Lin, C-Y. Li, Y-C. Wang, P-C. Chen; Inst. of Clinical Med., Coll. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan

Noonan syndrome (NS) is an autosomal dominant genetic disease characterized by short stature, facial dysmorphia, congenital heart disease, and developmental delay. In our previous study of identifying disease-causing genes for Noonan syndrome, we identified variants in *RASIP1*, which encodes RAS interacting protein 1, in familial and sporadic NS cases. RASIP1 plays an important role in maintaining endothelial cell functions that is essential throughout vasculogenesis. Patients with *RASIP1* variants developed atypical cardiovascular phenotypes of NS, such as aortic coarctation and aortic aneurysm. To prove the causality of RASIP1, a zebrafish model was generated through CRISPR/Cas9. Early morphogenesis at different embryonic developmental stages and craniofacial features in the mutant zebrafish were monitored. Additionally, double transgenic zebrafish *Tg(fli1:EGFP; gata1a:dsRed)*, which expresses the fluorescent protein in endothelial and blood cells, was used to investigate vascular development. Our results suggested that the deficiency of *rasip1* in the zebrafish leads to developmental delay, abnormal craniofacial features, and impaired vasculogenesis that recapitulate NS patients' phenotypes.

Session Title: Mendelian Phenotypes Poster Session III

PB4709 CRISPR-Cas9 knock-out model of NGLY1 Deficiency in *Danio rerio* (zebrafish) harbors mild phenotypic changes detectable with automated phenotyping

Authors:

M. Mooney, B. Figueroa, A. Bartkowiak; Univ. of North Florida, Jacksonville, FL

Background: Loss-of-Function variants in NGLY1 result in NGLY1 Deficiency, a rare recessive disorder with variable phenotypes. Human symptoms can include developmental delay, visual impairment, and deficits in neurological function. Animal models of NGLY1 Deficiency from invertebrates to mice are often lethal or infertile, though different genetic backgrounds can ameliorate these phenotypes. In contrast, zebrafish models of NGLY1 Deficiency are viable and fecund and display milder phenotypes. **Methods:** We created *ngly1-/-* knock-out zebrafish using CRISPR-Cas9 targeted to exon 2 to generate a premature stop codon just outside the conserved PUB domain. These fish have been maintained past generation F5 and produce stable homozygotes from Het x Het crosses in the expected 1:2:1 genotypic ratio. Using these crosses and automated microscopy produced large image sets from single clutches with randomized genotypes. Phenotypes assessed included body length, eye size, and brain metrics (cortical area, ventricular area, optic tectal area, neuronal cell density), using measures made both manually and via automated processing with ImageJ macros. **Results:** Automated microscopy and image processing revealed significant phenotypes with small effect between wild-type and *ngly1-/-* genotypes from the same clutch. Body length displayed dose-dependent reduction in *ngly1-/-* fish: the Kruskal-Wallis H test/post-Hoc Dunn's test, α=0.05, indicated the mean rank between *ngly1+/+* vs *ngly1-/-* is significantly different (p=0.013). There is also significant reduction in eye area, with mean ranks 43.13 for *ngly1+/+*, 26.93 for *ngly1+/-*, 28.85 for *ngly1-/-* (p=.008). The eye radius measure returned significant reduction in *ngly1-/-* fish without a detectible phenotype in heterozygotes (*ngly1+/+* vs *ngly1-/-*, p=0.019; *ngly1+/-* vs *ngly1-/-*, p=0.002). Likewise, *ngly1-/-* fish also had reduced cortical area (p=0.002), but no difference in neuronal density, or in ventricular and optic tectal area. **Conclusion:** This *ngly1-/-* zebrafish model reveals new, mild morphological phenotypes detectable through automated microscopy. The reduced body length of *ngly1-/-* fish suggests developmental delay, as in humans. Differences in the alignment of heterozygous fish with either wild-type or *ngly1-/-* eye phenotypes and the small effect size suggest correlation with developmental delay. Likewise, cortical area reduction in *ngly1-/-* fish may correlate with delay, however neuronal density appears unaffected at 3dpf. Comparative studies with other models of NGLY1 Deficiency that express extreme phenotypes might suggest key compensatory mechanisms at work in *ngly1-/-* zebrafish.

Session Title: Mendelian Phenotypes Poster Session I

PB4710 *CTSA* variants c.430del (p.Leu144Trpfs*49) and c.587G>C (p.Ser196Thr) as a cause of late infantile Galactosialidosis in a Hispanic American patient: a case report

Authors:

C. Hollas[1], Z. Yu[1], J. Gamblin[1], S. Palle[1], Y. Enchautegui-Colon[2]; [1]OUHSC, Oklahoma City, OK, [2]Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK

We present a 3-year-old girl who was referred to genetics evaluation due to elevated liver enzymes, hepatomegaly, and abnormal liver biopsy with foamy hepatocytes and Kupffer cells concerning for glycogen storage disease (GSD). At birth, the patient had a 2-week NICU stay due to direct hyperbilirubinemia, elevated TSH, withdrawal from intrauterine exposure to illicit drugs, and feeding problems. The patient's bilirubin normalized. Then at 19 months of age, her liver enzymes were found to be elevated. A cholestasis molecular panel was negative. Workup for infectious and autoimmune causes of hepatobiliary disease was negative. Physical examination was remarkable for coarse facial features, thick eyebrows, flat nasal bridge, hepatomegaly, and extensive Mongolian spots, raising high concern for a lysosomal storage disorder (LSD). A skeletal survey revealed "oar shape ribs" and vertebral body beaking. She was identified to have macular cherry spots by ophthalmology evaluation. She also has a history of global developmental delays. Molecular testing for GSDs and LSDs was performed. Two variants in the *CTSA* gene were identified: c.430del (p.Leu144Trpfs*49) classified as pathogenic, and c.587G>C (p.Ser196Thr) classified as a variant of uncertain significance (VUS). Given the high suspicion for Galactosialidosis, urine oligosaccharides were obtained and were abnormal. Neu5Ac1Hex3HexNAc2 was significantly elevated and Hex3HexNAc2 was mildly elevated. No variants were identified in the *NEU1* gene. The patient is adopted and biological parents are not available. The clinical features, presence of these two variants in the *CTSA* gene, the liver biopsy with foamy hepatocytes and Kupffer cells, and abnormal urine oligosaccharides support the diagnosis of Galactosialidosis in this patient. Galactosialidosis is an extremely rare disorder. This patient is unique because her combination of variants has not been reported before and the majority of patients have the juvenile/adult form. Additionally, the pathogenic variant in this patient is novel. The VUS found in this patient has been reported in trans with a pathogenic variant in at least one individual affected with Galactosialidosis. This, along with our patient's clinical findings, supports the pathogenicity of the *CTSA* c.587G>C (p.Ser196Thr) variant. Given that this disorder has been found to have genetic heterogeneity and a spectrum of severity, knowledge of the variants in this patient will help to further classify the spectrum and natural history of disease for future patients with this disorder or similar molecular findings.

PB4711 Data sharing in the GREGoR Consortium to support rare genetic disease research.

Authors:

B. Heavner[1], S. I. Berger[2], J. X. Chong[1], S. N. Jhangiani[3], A. O'Donnell-Luria[4], C. Austin-Tse[5], S. Baxter[4], M. Conomos[1], Z. Coban-Akdemir[6,7], E. C. Délot[8], P. C. Goddard[9], S. M. Gogarten[1], A. Jolly[7], M. Mahmoud[7], S. Marwaha[10], D. E. Miller[1], J. E. Posey[7], A. Sanchis-Juan[11], A. M. Stilp[1], R. A. Ungar[12], Genomics Research to Elucidate the Genetics of Rare Diseases (GREGoR) Consortium; [1]Univ. of Washington, Seattle, WA, [2]Children's Natl. Hosp., Washington, DC, [3]Baylor Coll. Med., Houston, TX, [4]Broad Inst. of MIT and Harvard, Cambridge, MA, [5]Broad Inst. of MIT and Harvard Cambridge, Cambridge, MA, [6]Univ. of Texas Sch. of Publ. Hlth., Houston, TX, [7]Baylor Coll. of Med., Houston, TX, [8]George Washington Univ., Washington, DC, [9]Stanford Univ., Menlo Park, CA, [10]Stanford Univ., Palo Alto, CA, [11]Ctr. for Genomic Med., Massachusetts Gen. Hosp., Boston, MA, [12]Stanford, Stanford, CA

The members of the Genomics Research to Elucidate the Genetics of Rare Diseases (GREGoR) Consortium are working collaboratively to advance rare genetic disease research. To succeed, this effort requires rapid Consortium-wide sharing of data generated by participating Research Centers and controlled-access release of a coherent Consortium data set to the broader scientific community. The GREGoR Consortium has developed a flexible, expandable, and publicly available data model that serves as a robust and scalable metadata framework, which can be extended to support data from a wide range of experiment types.

The GREGoR Consortium leverages NHGRI's AnVIL platform for a secure and scalable cloud environment for Consortium data sharing and analysis. Since each participating Research Center uses the Consortium metadata standards defined by the Consortium Data Model for data they upload to AnVIL, the Consortium is able to quickly share and update data on a regular quarterly cycle. In this cycle, each Research Center uploads data to an AnVIL workspace, where it can be validated for conformance to the data model using a workflow-based validation process. Once the data is validated and uploaded into AnVIL workspaces, the Data Coordinating Center can merge the data submitted by the Research Centers into a single, shared workspace for Consortium-wide sharing, collaborative analysis, and regular, periodic release for controlled access by the broader scientific community.

Through this process, the GREGoR Consortium has produced a comprehensive and growing data set that is available to the broader scientific community. The Consortium Data Set currently includes short-read and long-read genome sequencing data, RNA-seq data, family structure, phenotype information, and genetic findings from our collaborating Research Centers. We anticipate that the data set will expand to include additional data types produced by participating Research Centers. The GREGoR Consortium Data Set is broadly consented and allows researchers worldwide to access a wealth of information, accelerating their own investigations into rare diseases or other areas of research. Researchers may obtain access to the GREGoR Consortium Data Set by submitting a Data Access Request via dbGaP.

Session Title: Mendelian Phenotypes Poster Session III

PB4712 De novo and inherited variants in *DDX39B* cause a novel syndrome characterized by neurodevelopmental delay, congenital hypotonia, and short stature.

Authors:

M. Chui[1], K. T. A. Booth[2], S. V. Jangam[3], K. Treat[2], K. White[2], C. K. Christensen[4], T. Lynnes[2], S. Yamamoto[3], O. Kanca[3], M. H. Y. Tsang[1], S. A. Lynch[5], S. V. Mullegama[6], Y. Yuen[7], D. Iancu[8], S. K. Joss[5], J. Baptista[9], C. C. Y. Mak[1], A. K. Y. Kwong[1], H. J. Bellen[3], M. F. Wangler[3], BCM Center for Precision Medicine Models, E. Conboy[2], B. H. Y. Chung[1], F. Vetrini[2]; [1]The Univ. of Hong Kong, Hong Kong, China, [2]Indiana Univ. Sch. of Med., Indianapolis, IN, [3]Baylor Coll. of Med., Houston, TX, [4]Riley Dev.al Pediatrics, Indianapolis, IN, [5]Queen Elizabeth Univ. Hosp., Glasgow, United Kingdom, [6]GeneDx, Gaithersburg, MD, [7]Hong Kong Children's Hosp., Hong Kong, China, [8]Univ. Coll. of London, London, United Kingdom, [9]Univ. of Plymouth, Plymouth, United Kingdom

DDX39B is a member of the DEAD-box family of ATP-dependent RNA helicases. DEAD-box proteins are ubiquitously expressed from yeast to humans and perform essential functions associated with mRNA metabolism. *DDX39B* is also a crucial component of the TRanscription-EXport (TREX) super protein complex, which recent studies have highlighted the important role of its subunits in neurodevelopmental disorders. Here, we describe six individuals from five families, four with novel de novo missense variants in *DDX39B*, and one carrying an inherited splicing variant, all presenting with mild to severe global developmental delay, congenital hypotonia, epilepsy, short stature, skeletal abnormalities and variable dysmorphic features. 3D molecular modeling predicts these variants would alter protein structure. *DDX39B* is a conserved gene and Drosophila melanogaster (fruit flies) studies were conducted. We generated a new Hel25E Kozak-GAL4 allele which disrupts the fly gene and allows expression of transgenes. We also generated transgenic *DDX39B*-reference and variant flies. Human transgenic *DDX39B* was unable to rescue *Hel25E* loss in the fly. However, human reference *DDX39B* when overexpressed ubiquitously leads to lethality but the variants found in the patients do not recapitulate the lethality suggesting that the mutants are loss of function alleles. Blood transcriptomics of the patients revealed an excess of aberrant splicing events, indicating a disrupted mRNA processing as anticipated from the role of *DDX39B* in mRNA metabolism. Our human genetic data, coupled with *in silico* and *in vivo* data supports that *DDX39B* is a novel candidate gene in a potential group of disorders named TREX-complex related neurodevelopmental syndrome.

Session Title: Mendelian Phenotypes Poster Session I

PB4713 *De novo* dominant negative variants of *IKZF2* cause ICHAD syndrome, a new disorder characterized by Immunodysregulation, Craniofacial Anomalies, Hearing Impairment, Athelia, and Developmental Delay.

Authors:

A. Mohajeri[1], M. Vaseghi-Shanjani[1], J. A. Rosenfeld[2], G. X. Yang[1], H. Lu[1], M. Sharma[1], S. Lin[1], A. Salman[1], M. Waqas[1], M. Sababi Azamian[2], K. C. Worley[2], K. L. Del Bel[1], F. K. Kozak[1], R. Rahmanian[1], M. Biggs, Catherine[1], K. J. Hildebrand[1], S. R. Lalani[2], S. K. Nicholas[3], D. A. Scott[2], S. Mostafavi[1], C. van Karnebeek[1], E. Henkelman[1], J. Halparin[1], C. L. Yang[1], L. Armstrong[1], Undiagnosed Diseases Network, Care4Rare Canada Consortium, S. Turvey[1], A. Lehman[1]; [1]The Univ. of British Columbia, Vancouver, BC, Canada, [2]Baylor Coll. of Med., Houston, TX, [3]Texas Children's Hosp., Houston, TX

Background: *IKZF2* encodes Helios, a transcription factor and chromatin remodeler that plays roles in the development and regulation of immune function. Germline and somatic variants in this gene have been implicated in an inborn disorder of immunity and in hematopoietic malignancies, respectively. The present study reports two *de novo* dominant negative variants of *IKZF2* causing a novel syndrome in two probands with T cell lymphopenia, recurrent respiratory infections, craniofacial differences, cleft palate, sensorineural hearing impairment, athelia, and developmental delay. **Methods:** Proband 1 was enrolled in the C4R-SOLVE project, and Proband 2 was identified via GeneMatcher. Genome sequencing and exome sequencing was conducted for Proband 1 and 2, respectively. To investigate the functional impact of *IKZF2* variants, RT-PCR, Sanger sequencing, Western blot analysis and Luciferase assays were undertaken. **Results:** Our analysis revealed a *de novo* tandem duplication and a *de novo* missense variant in exon 5 of *IKZF2*, which encodes the critical Zinc fingers 2 and 3 that are responsible for the DNA binding activity of Helios. Tandem duplications of exon 5 have been previously reported in cases of T-cell lymphoma, and a similar missense variant affecting a homologous residue in family member Aiolos has been associated with a disorder of immunity. RT-PCR and Sanger confirmed an in-frame duplication of exon 5. Western blot analysis demonstrated expression of both altered proteins. Luciferase assay verified that co-expression of the altered proteins with the wild-type protein significantly reduced the suppressor ability of the wild-type on *IL2* promoter, indicating a dominant negative effect of these variants. **Conclusion:** Previous studies have reported germline variants in *IKZF2* and other Ikaros family members resulting in immunodeficiency. The present study is the first to report two *de novo* dominant negative *IKZF2* variants that cause ICHAD syndrome, a multiorgan disorder Characterized by Immunodysregulation, Craniofacial Anomalies, Hearing Impairment, Athelia, and Developmental Delay.

Session Title: Mendelian Phenotypes Poster Session II

PB4714 De novo variant in TLK2: clinical evaluation & genotype-phenotype of a neurodevelopmental disorder

Authors:

T. Carrion[1,2]; [1]Hosp. universitario son espases, palma, Spain, [2]Centro medico Teknon, Barcelona, Spain

We report the case of a 22- year -old woman, followed for genetics, psychiatry and neurologist due to intellectual disability, dysmorphic symptoms and attention deficit hyperactivity disorder. She was born of non-consanguineous parents. No history of intellectual disability or neurological diseases. Two healthy male brothers aged 29 and 26. She was delivery at 38 weeks without complications. Weight 2.400 gr, T: 44 cm and PC 31 cm. Delay in acquiring developmental milestones. Examination at 22-yo showed peculiar fascies, microcephaly, broad forehead, hypertelorism. Palpebral fissures short, oblique upwards. Bilateral epicanthal folds, ears of low implantation. Large nose with bulbous tip, small mouth, with thin lips, macroglossia, broad lower jaw, short and flat philtrum, prognathism and high palate. Throughout years, extensive investigations were performed, metabolic studies and skeletal series were normal. CT, MRI and MR angio 2002 it has a ventricular size in high limits. 2nd MRI and MR angio 2005 moderate dilation of the ventricular system, in the same, which may be significant for some subcortical atrophy. Karyotype 46 XX - X-fragile: negative. Most common microdeletion syndromes (MLPA) : normal.Molecular study to detect microdeletion in region 22q11.2 : normal.Smith-Magenis SD and congenital central hypoventilation syndrome: negative FISH: no deletion of subtelomeric regions. Array-CGH 60 Kb : Normal High resolution karyotype 46XX Microarray CGH 1000K arr 8p23.3 1,504-084-1,509,519 x1 female karyotype with microdeletion in 8p23.3 de novo. Study of family segregation: negative. Whole exome sequencing detected LP heterozygous variant p**.** Arg546Gly in the TLK2 gene. The variant found p.Arg546Gly is not found in the databases of general population consulted. It has not been described in the scientific literature or classified in databases of genetic variants of clinical relevance. Predictors indicate a deleterious effect on the protein encoded by this gene. This variant is located in a functionally relevant domain of the protein involving a hot spot. TLK2 is a protein-coding gene. It encodes a nuclear serine/threonine kinase. The encoded protein functions in regulating chromatin assembly in the S phase of the cell cycle by regulating the levels of a histone H3-H4 chaperone. Associated with repairing double-stranded breaks of DNA damage caused by radiation. Associated diseases include autosomal dominant intellectual developmental disorder 57. Among its related pathways are the regulation of miRNA, the response to DNA damage and the regulation of Chks at checkpoints.

FRYL belongs to a Furry protein family which is evolutionarily conserved from yeast to human. The functions of FRYL in mammals are largely unknown, and variants in *FRYL* have not previously been associated with a Mendelian disease. Here, we report fourteen individuals with heterozygous variants in *FRYL* who present with developmental delay, intellectual disability, dysmorphic features, and other congenital anomalies. The variants are confirmed *de novo* in all individuals except one whose mother has not been tested. Among the variants, nine are likely gene disrupting variants (stop gain, frameshift, or splicing variants) and five are missense variants. Human genetic data suggest that *FRYL* is intolerant to loss of function (LoF). We found that the fly *FRYL* ortholog, *furry* (*fry*), is expressed in multiple tissues including the central nervous system where it is present in neurons but not in glia. We demonstrated that *fry* LoF mutant flies are lethal at early developmental stages and loss of *fry* in mutant clones causes defects in the wings and compound eyes. We next modeled four out of the five missense variants using gene knock-in alleles. The knock-in alleles were generated using prime editing and a novel Recombinase-Mediated Cassette Exchange (RMCE)-based strategy, which introduce amino acid changes analogous to the human variants into the endogenous *fry* locus in flies. One variant allele (*fry* p.Phe2746Ser, analogous to *FRYL* p.Phe2295Ser) fails to complement *fry* severe LoF alleles and phenocopies a severe LoF allele in homozygous clones, suggesting that it causes a severe LoF. Two variants (*fry* p.Phe2024Leu and p.Tyr3410Cys, analogous to *FRYL* p.Phe1628Leu and p.Tyr2951Cys, respectively) complement severe LoF alleles. However, both cause developmental delay in compound heterozygous animals when crossed to a severe LoF allele, whereas one allele (*fry* p.Phe2024Leu) causes defects in the response to light in compound eyes. These data suggest that the two variants behave as partial LoF variants. One variant (*fry* p.Ser2910Ile) does not cause any observable defect in flies and the corresponding human variant (*FRYL* p.Ser2397Ile) is not confirmed *de novo*, suggesting the variant is benign and may not be the cause of the clinical features of the affected individual. In summary, our findings support that *fry* is required for proper fly development, and that the LoF variants in *FRYL* may cause a disorder with developmental and neurological symptoms.

Sci., Charotar Univ. of Sci. and Technology, Changa, India

Autism spectrum disorder (ASD) is a heterogeneous group of neurodevelopmental disorders (NDD) and is characterized by impaired social communication along with repetitive behavior or restricted interests which can persist throughout lifetime. Guidelines put forth a decade ago by the American College of Medical Genetics suggests using chromosomal microarray (CMA) as a first line test for genetic diagnosis of ASD. However, latest results from whole exome sequencing (WES) studies suggests higher diagnostic yield compared to CMA due to detection of *de novo* SNVs; a significant cause for NDD. No study has been performed to delineate the genetic architecture of ASD in the Indian population which can help in selection of first-tier test. We present results of the first systematic study to assess the genetic architecture and diagnostic yields of karyotype, Fragile-X testing, CMA and WES in a cohort of 101 patient-parent trios with ASD from India. No positive genetic diagnosis was obtained from karyotyping and Fragile-X testing. Of 101 trios, 3 (2.9%) and 30 (29.7%) trios received a confirmed genetic diagnosis from CMA and WES, respectively. Amongst diagnosis from WES, SNVs were detected in 27 cases (90%) and CNVs in 3 cases (10%), including the 3 CNVs detected from CMA. Segregation analysis showed 66.6% (n=3 for CNVs and n=17 for SNVs) and 16.6% (n=5) cases had *de novo* and recessive variants, respectively, which is in concordance with the distribution of variant types and mode of inheritance observed in ASD patients of non-Hispanic white/ European ethnicity. *De novo* SNVs were found primarily in previously known ASD genes- *MECP2, SCN2A, KCNQ2, TBL1XR1, CNTNAP2, TCF4, CAMK2A, NF1, AUTS2, FOXP2* and *NLGN3.* Of 17 *de novo* SNVs, 6 were predicted to be loss of function (35.2%) whereas the remaining were missense variants. *MECP2* gene was the most recurrently mutated gene (n=6; 20%). Additionally, WES identified 22 variants of uncertain significance in 21 patients (n=21/101; 20.8%). These were identified in genes that have previously been associated with or implicated in ASD etiology. Of these, majority of the probands were detected with heterozygous variants (66.6%) which were inherited from either of the unaffected parents with equal distribution. Lastly, 4 genes (*NEUROG1*, *LRFN1*, *UNC13A* and *UNC79*) were identified as potential novel candidates for ASD. Majority of the detected genes are involved in synaptic formation, transcription and its regulation, ubiquitination and chromatin remodeling. Ours is the first study to suggest *de novo* variants as a major cause of ASD and provide evidence for implementation of WES as a first-tier test for genetic diagnosis of ASD in the Indian population.

Disease-causing variant in genes involved in synaptic function are common causes of severe neurodevelopmental disorders and epilepsy. However, in contrast to other genetic causes of neurodevelopmental disorders, milder presentations have largely not been observed so far. Here, we report on 9 individuals identified through Genematcher with *de novo* disruptive variants in *BSN*, encoding the presynaptic protein bassoon. All individuals presented with mild developmental differences and variable types of epilepsy. In order to aggregate available information on the trajectory of *BSN*-related disorders, we screened clinical and genetic information from the Penn Medicine Biobank (PMBB), a large biorepository with over 60,000 individuals and retrieved clinical information on 8 individuals that carry protein-truncating *BSN* variants. Only 1 individual had a neurological diagnosis code, suggesting a generally mild presentation in adulthood. Reconstruction of phenotypic presentations were completed using the Human Phenotype Ontology (HPO), a standardized phenotypic dictionary, which allows us to map heterogeneous clinical data to a common framework. We identified seizure disorders present in 7 individuals, with the majority having febrile seizures (n=5) followed by bilateral tonic-clonic seizures (n=3). Most cases presented with behavioral abnormalities, such as autistic (n=4) and hyperactive (n=4) behavior. We applied a previously reported phenotypic similarity algorithm to derive a similarity score (sim score) based on pairwise phenotypic similarities between individuals through various combinations of the most specific terms shard by both individuals. When comparing sim scores of different genetic conditions, *BSN* altogether is more significant than expected by chance through phenotypic terms alone. In summary, we identify *de novo BSN* variants as the cause for a new class of synapse disorders with an unusually mild clinical presentation. In addition, we demonstrate how existing data repositories can be leveraged to maximize available information on rare neurodevelopmental conditions that would otherwise remain unexplored.

Zurich, Zurich, Switzerland

Zinc RING finger 3 (ZNRF3) is a negative-feedback regulator of the Wnt/β-catenin signaling, which plays an important role in the development of the human brain. Although somatic mutations are frequently observed in cancer, germline variants in ZNRF3 for neurodevelopmental disorders have not been reported so far. Here, we describe mirror brain phenotypes in a total of seven patients harboring de novo deleterious missense ZNRF3 variants and demonstrate that these variants led to distinct domain-specific opposing effects on the Wnt/β-catenin signaling. Using in vitro transcriptional reporter assays and structural modelling we found that one missense variant located in the protease-associated (PA)-domain in a patient with microcephaly attenuated the Wnt/β-catenin signaling through loss of the binding affinity to R-spondin, a positive regulator of the Wnt/β-catenin signaling. Two of six other missense variants located in the RING domain found in patients with macrocephaly were studied by the same assays. They showed enhanced Wnt/β-catenin signaling in a dominant negative manner by disrupting the ubiquitin ligase function and presumably compromising the Wnt receptor turnover. Taken together, we provide evidence for mirror brain size phenotypes caused by distinct mechanism of action on the Wnt/β-catenin signaling through protein domain-specific deleterious germline gene variants in ZNRF3.

PB4720 Delineation of*AMMECR1*as a candidate gene for idiopathic short stature

Authors:

C. Thiel, A. Schulz, A. Fink, C. Kraus, S. Uebe, E. Arif, M. Krumbiegel, A. Reis; Inst. of Human Genetics, FAU Erlangen-Nürnberg, Erlangen, Germany

Short stature is a common medical concern in childhood and affects 3 % of the general population. It is thought to be controlled by a multitude of genetic variants with a broad range of effect sizes. We recently demonstrated that rare variants play significant role in the etiology of idiopathic short stature by confirming variants in known short stature associated genes in more than 16 % of these patients. In addition, we identified 63 candidate genes for short stature. In a study group of 605 patients with idiopathic short stature we identified an affected male with an *de novo* InDel-Variant in the X-linked *AMMECR1* gene, leading to a frameshift p.(Arg152Aspfs*11). The variant was detected in the patient's transcriptome by reverse transcriptase RT-PCR. Using quantitative real-time qPCR, we observed significantly decreased expression of the *AMMECR1* gene in lymphocytes of this individual. Immunofluorescence showed that the protein was expressed at a lower level in patient-derived lymphoblastoid cells (LCLs) and resided in the nucleus. These results implicate mRNA decay and loss-of function as the underlying disease mechanism.Disease causing variants in *AMMECR1* have been recently described in three independent reports to be associated with growth deficit, hearing impairment, elliptocytosis, and nephrocalcinosis. Even though, no additional symptoms beside short stature were observed in the case reported here, we provide supporting evidence for *AMMECR1* as a novel candidate gene for idiopathic short stature.

Pulmonary arterial hypertension (PAH) is an infrequent and progressive disorder characterized by high blood pressure in the pulmonary arteries. It may lead to premature death of the patient or the requirement for lung and/or heart transplantation. PAH can be classified into different groups, with the most common form being idiopathic PAH (IPAH). Other forms of PAH can be associated with primary conditions such as connective tissue diseases (PAH-CTD), congenital heart defects (PAH-CHD), or drug and toxin exposure (PAH-TX). Genetics plays an important role in this early diagnosis and targeted therapy of PAH. The increased use of NGS has led to an increased frequency of reporting new potential risk genes. In this work, we will focus on the relationship between *SOX17* variants and the development of PAH. SOX17 plays a critical role in embryonic development, is involved in the regulation of various developmental processes and plays a crucial role in the development of the cardiovascular system and the remodeling of blood vessels after birth. Thereby, dysregulation in *SOX17* expression or activity can contribute to endothelial dysfunction, which may contribute to the development or progression of PAH. Here, we report six additional patients with variants in *SOX17* and a review of previously described patients in the literature. In general, all patients described in this study suffered for other comorbidities including large septal defects as described by other groups. Collectively, 25 candidate variants were reported, including missense and predicted loss-of-function variants, in patients with H/IPAH. We add four new IPAH cases, two of them showing the same variant previously detected in multiple patients. In total, seven PAH patients have been detected as having the same variant, suggesting a possible hot spot. In addition, two of them were diagnosed with PAH-CHD and the rest as IPAH. Moreover, research conducted on a group of PAH patients with congenital heart disease indicated that *SOX17* variations are particularly prevalent in this subgroup, which experiences an early onset of the disease. Here we report a pediatric patient carrying a pathogenic variant not described previously and in which the same corkscrew tortuous arteries, confirming it relationship.The majority of nonsense and frameshift mutations found in PAH cases occur in the last exon, which encoded for the conserved β-catenin-binding domain. Meanwhile, the majority of missense variants are located in exon 1, in the HMG Box domain. Further research is still needed to clarify the precise mechanisms and extent of the association between SOX17 and the development of PAH

Session Title: Mendelian Phenotypes Poster Session I

PB4722 Detection of intronic variants as the genetic causes of inherited retinal degenerations.

Authors:

Y-S. Huang[1,2], J. Hsu[3], C-H. Yang[2,4], T-C. Chen[2,5], P-L. Chen[1,3,6]; [1]Graduate Inst. of Clinical Med., Coll. of Med., Natl. Taiwan Univ., Taipei City, Taiwan, [2]Dept. of Ophthalmology, Natl. Taiwan Univ. Hosp., Taipei City, Taiwan, [3]Graduate Inst. of Med. Genomics and Proteomics, Coll. of Med., Natl. Taiwan Univ., Taipei City, Taiwan, [4]Dept. of Ophthalmology, Coll. of Med., Natl. Taiwan Univ., Taipei City, Taiwan, [5]Ctr. of Frontier Med., Natl. Taiwan Univ. Hosp., Taipei City, Taiwan, [6]Dept. of Med. Genetics, Natl. Taiwan Univ. Hosp., Taipei City, Taiwan

Inherited retinal degenerations (IRDs) encompass a group of monogenic disorders that lead to the death of retinal cells and eventual vision loss in patients. There have been nearly 270 genes associated with IRDs. In a previous study, we conducted panel sequencing on 556 Taiwanese families and successfully diagnosed approximately 58% of the patients. However, more than forty percent of the patients remain undiagnosed. We hypothesized that disease-causing variants might reside within the intronic regions, which are typically overlooked during routine analysis. To predict variants that affect splicing, we utilized the spliceAI and dbscSNV_ADA tools. We excluded variants with a gnomAD East Asian allele frequency higher than 0.05 and those identified as benign or likely benign according to ACMG guidelines. The remaining variants were filtered based on the following criteria: a spliceAI score of > 0.2 or a dbscSNV_ADA score of > 0.6. As a result, we identified a total of 265 variants as splice-affected variants, with 90 of them located in introns. By evaluating the patients' family history and clinical symptoms, we further identified 18 potential disease-causing variants. Among these, 8 variants were found in deep intronic regions, and 10 variants were located in non-canonical splice sites. The variants *CNGB1*:c.1122-3344G>A, *USH2A*:c.5573-276G>A, *EYS*:c.5644+5G>A, and *TULP1*:c.499+5G>C were the most frequently observed intronic variants in our cohort. The use of splice prediction tools is crucial in the analysis of IRDs as it helps to narrow down the list of candidate variants, which can then be confirmed through minigene assays. Intronic variants should not be overlooked when definitive genetic etiology has not been identified, particularly in cases where only one variant is found in an autosomal recessive inheritance pattern. Furthermore, understanding the expected outcomes of intronic variants contributes to the development of potential therapies for IRDs.

Session Title: Mendelian Phenotypes Poster Session II

PB4723 Developing a morbidity gene panel for evaluation of kidney transplant recipients.

Authors:

B. Ma, N. T. Elefant, M. Tedesco, K. Bogyo, N. Vena, S. A. Bheda, S. K. Murthy, H. Milo Rasouly, A. G. Gharavi; Columbia Univ. Med. Ctr., New York, NY

Background: Significant resources are invested in kidney transplantation because it offers better survival than dialysis for patients with end stage kidney disease. However, morbidity and mortality in kidney transplantation remains high, mostly due to cardiovascular disease, infection and malignancy. Identification of monogenic conditions that contribute to these common complications can enable personalized management plans for kidney transplant recipients (KTRs) starting from the peri-operative period.
Methods: We developed a transplant morbidity panel of 355 genes associated with four common complications of transplantation: 1) cardiovascular diseases and risk factors such as hypertension, diabetes mellitus, dyslipidemia, 2) adult onset immunodeficiency, 3) post-transplant malignancy and hereditary cancer syndromes, 4) thrombophilia. We also incorporated the ACMG recommended genes for secondary findings. The gene list was evaluated in 1590 KTRs who had undergone whole exome sequencing. Diagnostic analysis was performed for genes in the panel per ACMG/AMP and ClinGen guidelines. Reverse phenotyping was performed to look for compatible clinical features and family history. Clinical implications of diagnostic variants were studied case-by-case.
Results: Among the 1590 KTRs, 257 individuals (16.2%) had a monogenic form of kidney disease. The transplant morbidity panel detected 58 different monogenic disorders in 146 individuals (9.2% diagnostic rate). 83 KTRs (5.2%) have diagnostic variants in cardiovascular disease category, 34 (2.1%) in malignancy category, 29 (1.8%) in immunodeficiency category and 3 (0.2%) in thrombophilia category. 8 patients (0.5%) have dual genetic diagnoses. 74 patients (50.7%) had supporting clinical features or family history of the monogenic disorders, while the rest have either absence or no documentation of any supporting features. Among KTRs with diagnostic variants, identification of these monogenic disorders and risk factors would allow physicians to set specific risk factor targets in 11 individuals (7.5%), arrange intensive surveillance in 142 (97.3%), utilize preventive measures in 19 (13.0%), guide disease-specific therapy in 94 (64.4%), initiate specialty referral in 132 (90.4%) and alter immunosuppressive regimens in 84 (57.5%).
Conclusion: Clinically important monogenic disorders, unrelated to the primary cause of kidney disease, were identified in 9.2% of KTRs, with multiple implications for clinical management. Incorporating genetic diagnostics into the transplant evaluation protocol would enable personalized management plans and help reduce complications.

Session Title: Mendelian Phenotypes Poster Session III

PB4724 Development and characterization of a novel TAFAZZIN-deficient iPSC derived skeletal muscle model of Barth Syndrome: a new tool to study muscle phenotypes in BTHS.

Authors:

K. Lee, O. Sniezek, H. Vernon; Johns Hopkins Sch. of Med., Baltimore, MD

Barth syndrome (BTHS) is a rare, X-linked disorder caused by pathogenic variants in the gene *TAFFAZIN* (TAZ), which results in abnormal remodeling of cardiolipin (CL) in mitochondria and a clinical phenotype including cardiomyopathy, skeletal myopathy, and neutropenia. Cardiolipin is responsible for key mitochondrial functions, and the failure to fulfill these roles properly leads to not only mitochondrial dysfunction, but also to broader cellular dysfunction. We generated wild type and TAZ knockout (TAZ-KO) cardiomyocytes (CM) and neural progenitor cells (NPCs) from induced pluripotent stem cells (iPSCs) to compare the mitochondrial and cellular pathology in cell types affected and unaffected, respectively, in BTHS. Interestingly, we observed abnormal cell maturation in TAZ-KO CMs but not NPCs, and dysregulated WNT signaling in the TAZ-KO undifferentiated iPSCs. As BTHS patients often have left ventricular noncompaction, a developmental phenotype, we hypothesized that differentiation defects in cardiomyocytes may underlie the early cardiac phenotype. We further hypothesized that skeletal myopathy in BTHS may also be due to a developmental muscle defect. To characterize the muscle mitochondrial and developmental phenotype in BTHS, we developed WT and TAZ-KO iPSC-derived skeletal muscle cells (SKM). Both WT and TAZ-KO SKMs achieved the appropriate intermediate and terminal stages of differentiation: mesoderm, SKM precursors, myoblasts, myotubes, and mature/fused myotubes. We validated these stages with qRT PCR markers appropriate for each stage and performed immunofluorescence staining with the antibodies for terminally differentiated myoblasts and myotubes. Since CMs and SKMs have similar initial stages of differentiation, and then diverge, we are currently detailing at which stage TAZ-deficiency has the largest impact. By investigating both muscle cell types simultaneously, we will ascertain how TAZ-KO CM and SKM cells differ in their differentiation timeline, progression, and efficacy of reaching each stage of differentiation and gain an understanding of how TAZ-deficiency contributes to the developmental tissue pathology in BTHS.

PB4725 Diagnostic whole exome sequencing in presumably autosomal recessively inherited retinal dystrophies in an Iranian population

Authors:

L. Hoefsloot[1], P. Heutinck[2,3], M. van Tienhoven[1], S. Kheradmand Kia[4], C. Klaver[5,3,6,7], D. D. Farhud[8,9], M. Meester-Smoor[2,3], A. A. H. Thiadens[2], V. J. M. Verhoeven[1,2]; [1]Dept Clinical Genetics, Erasmus MC, Rotterdam, Netherlands, [2]Dept Opththalmology, Erasmus MC, Rotterdam, Netherlands, [3]Dept. of Epidemiology, Erasmus MC, Rotterdam, Netherlands, [4]. Lab. for Red Blood Cell Diagnostics, Sanquin, Amsterdam, Netherlands, [5]Dept Opththalmology, Erasmus MC, R0tterdam, Netherlands, [6]Dept Ophthalmology, Radboud UMC, Nijmegen, Netherlands, [7]Inst. of Molecular and Clinical Ophthalmology, Basel, Switzerland, [8]Farhud Genetics Clinic, Tehran, Iran, Islamic Republic of, [9]Sch. of Publ. Hlth., Tehran Univ. of Med. Sci.,, Tehran, Iran, Islamic Republic of

Purpose: Genetic testing in inherited retinal dystrophies (IRD) allows for accurate identification of inheritance pattern, thereby improving genetic counselling and potential (gene) therapy options for affected individuals and their families. IRDs can show various inheritance patters, e.g. autosomal dominant, autosomal-recessive, and X-linked inheritance. In this study, we aimed to uncover the genetic cause of presumably autosomal recessively inherited IRDs in a cohort of patients from Iranian descent. **Methods:** IRD patients were recruited by ophthalmologists of the Tehran University of Medical Sciences. Whole exome sequencing (WES) was performed using a gene panel including ~500 genes involved in inherited eye disorders. Variants were classified according the ACMG guidelines using Alamut Visual, the CADD scoring website and the online Franklin tool. Unsolved cases are currently being taken forward for analyses of relevant homozygous or other variants outside of the gene panel. **Results:** 111 patients (58 females, 53 males) with inherited retinal dystrophies [VV1] were recruited and successfully underwent WES. Mean age at recruitment was 37.2 years old (+/- 11.2 yrs SDS; age range 15-68). ⋯% of the cohort originated from a consanguineous background, mostly due to first cousin marriages. [VV2] In 59% of the cases, we found a causative (homozygous) variant; in another 31% of the cases, we found a potentially causative (homozygous) variant. The most frequently involved genes were CERKL (15%), EYS (11%), and RPE65 (9%). **Conclusion:** Using WES with a filter for known IRD genes as a first-tier genetic test in this consanguineous IRD Iranian cohort, we were able to identify a (potential) causative (homozygous) variant in almost 90% of the cases. Expanding the WES analyses outside of the panel will probably even increase the diagnostic yield.

Session Title: Mendelian Phenotypes Poster Session II

PB4726 Differences in cardiac mechanics among genetically at-risk first-degree relatives of probands with dilated cardiomyopathy indicate that variants of uncertain significance are clinically relevant: The DCM Precision Medicine Study.

Authors:

D. D. Kinnamon[1], J. E. Wilcox[2], L. Beussink-Nelson[2], J. Cao[1], R. Kumar[2], E. Jordan[1], H. Ni[1], S. J. Shah[2], R. E. Hershberger[1]; [1]The Ohio State Univ., Columbus, OH, [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Among genetically at-risk first-degree relatives (FDRs) of probands with dilated cardiomyopathy (DCM), the ability to detect early changes in left ventricular (LV) mechanics with normal LV size and ejection fraction (LVEF) remains incompletely explored, particularly among FDRs harboring only their proband's variants of uncertain significance (VUSs). We sought to define a pre-DCM phenotype among at-risk FDRs, including those with only VUSs, using LV global longitudinal strain (GLS), an early measure of abnormal cardiac mechanics. LV structure and function, including speckle-tracking analysis for LV GLS, were evaluated in 124 FDRs (65% female; median age 44.9 [IQR: 30.6-60.3] years) of 66 DCM probands of European ancestry sequenced for rare variants in 35 DCM genes. All FDRs had normal LV size and LVEF. Probands' variants were adjudicated using published American College of Medical Genetics (ACMG) and ClinGen-based criteria tailored to DCM and assigned to an ACMG category. Pathogenic (P), likely pathogenic (LP), and VUS variants were confirmed in the proband and cascade-tested in FDRs by Sanger sequencing. Negative FDRs of probands with P/LP variants (n=28) were a reference group to which negative FDRs of probands without P/LP variants (n=30), FDRs with only VUSs (n=27), and FDRs with P/LP variants (n=39) were compared. In an analysis accounting for sex, height, weight, image quality, and the age-dependent penetrance of DCM, FDRs below the sample median age showed minimal differences in LV GLS across groups, consistent with reduced penetrance at younger ages. However, those above the sample median age with P/LP variants or only VUSs had lower absolute LV GLS values than the reference group (-3.9 [95% CI: -5.7, -2.1] or -3.1 [-4.8, -1.4] %-units) and negative FDRs of probands without P/LP variants (-2.6 [-4.0, -1.2] or -1.8 [-3.1, -0.6]). As lower absolute LV GLS values are indicative of worse cardiac mechanics, these findings indicate that both P/LP and some DCM-related VUSs are clinically relevant. In particular, the finding that FDRs harboring only VUSs had lower absolute LV GLS values than another group also considered to have uncertain genetic risk, negative FDRs of probands without P/LP variants, suggests that FDRs currently classified as having uncertain genetic risk could be further stratified by whether they harbor a DCM-relevant VUS. Taken together, these findings suggest that LV GLS may have utility for defining a pre-DCM phenotype in FDRs across the genetic risk spectrum.

PB4727 Different variants of cardiac remodeling and genetic variant spectrum in patients with left ventricular noncompaction.

Authors:

M. Polyak[1], S. L. Dzemeshkevich[1], O. V. Blagova[2], Y. A. Lutokhina[2], E. V. Zaklyazminskaya[1]; [1]Petrovsky Natl. Res. Ctr. of Surgery, Moscow, Russian Federation, [2]Sechenov First Moscow State Med. Univ., Moscow, Russian Federation

Abstract. Left ventricular noncompaction (LVNC) is a well-described phenomenon of two-layer myocardium. The genetic findings in LVNC patients overlap with cardiomyopathies, but genetic landscape remains debatable. It is unclear if LVNC represents a distinct entity or is a common sign or stage of cardiomyopathy. We deeply investigated cardiac remodeling in LVNC patients and the diagnostics yield of screening of the 13 genes with the most proven causative role in cardiomyopathies. Methods. We performed clinical and genetic testing for 67 probands diagnosed with LVNC according to Jenni criteria (2001). Custom-designed target genes panel (*MYH7*, *MYBPC3*, *TPM1*, *TNNT2*, *TNNI3*, *TAZ*, *MYL2*, *MYL3*, *ACTC1*, *LDB3*, *LMNA*, *DTNA*, *DES*) was sequenced by IonTorrent PGM. For statistical analysis, we used the SciPy and StatsModels software; for all tests, the differences were considered significant at $p<0.05$.Results. Complete pedigrees were available in 44 families. Sporadic origin of LVNC was predominant (26/44) in probands with reliable family history. Isolated LVNC was observed in 15 out of 67 probands (22%). In 78% of probands, the LVNC was accompanied by another cardiomyopathy. The most common variant of cardiac remodeling was dilated cardiomyopathy (35 out of 67 probands). Hypertrophy was found in 15 probands (22%), and 10 out of these 15 probands had also chambers dilatation. This subgroup of patients might represent dilation phase as an advanced stage of HCM. Two LVNC probands met the Marcus criteria (2010) for ARVC. Thirteen pathogenic (P) and likely pathogenic (LP) variants were found in 15 probands; none of them was detected in patients with an isolated LVNC. Diagnostic yield was the highest in patients with LVNC and cardiac hypertrophy. Patients carrying P/LP variants had an earlier age of manifestation and a higher rate of SCD in the family ($p < 0.05$). We identified 20 genetic variants of uncertain significance (VUS) in 17 unrelated probands. Most of the variants were detected in *MYH7* and *MYPBC3* genes. Other findings included variants in *TNNT2*, *LMNA*, and *DES*. Remarkably, non-carriers of P/LP variants had a higher ratio of non-compact to compact myocardial layers ($p < 0.05$).Conclusion. Diagnostic yield for the 13 genes panel was 22% in the whole group, and 33% in patients with LVNC and HCM]. Young patients with a combination of LVNC and cardiac hypertrophy had the highest benefit from the testing. Genotype-positive patients had earlier manifestation and higher risk of SCD. We hypothesize that lone LVNC phenomena might represent developmental failure, and the spectrum of causative genes differs from primary cardiomyopathies and might be close to one for congenital heart defects.

Orofaciodigital (OFD) syndromes represent a group of rare genetically heterogeneous developmental disorders. OFDs are due to pathogenic variants in genes that are involved in primary cilia formation and/or function. We identified the same germline variant c.1207_1208del (p.Arg403Glyfs*24) in the last exon of ZRSR2, either occurring de novo or inherited in an X-linked recessive pattern, in 6 affected males from 4 unrelated families with OFD syndrome in association with structural brain abnormalities, ranging from alobar holoprosencephaly to pituitary abnormalities. ZRSR2, located on the X chromosome, is part of the minor spliceosome complex which recognizes minor (U12-type) introns, representing 0.35% of human introns. Although somatic pathogenic variants in ZRSR2 were associated with the development of myelodysplastic syndrome (MDS), this is the first association of germline variation in ZRSR2 with a human developmental disorder. Alternative splicing analysis of minor spliceosome gene targets in lymphoblastoid and fibroblast cell lines from an affected patient harboring the ZRSR2 variant and from unrelated controls, showed significant enrichment of minor intron retention. Among the differentially spliced targets are ciliopathy-related genes, such as TMEM107 and CIBAR1. Primary fibroblasts containing this ZRSR2 variant had abnormally elongated cilia, confirming an association between defective U12-type intron splicing and abnormal primary cilia morphogenesis.

PB4729 Disease causing variants in several genes causing Bardet Biedl Syndrome

Authors:

F. RATHER[1], M. Umair[2]; [1]KING SAUD BIN ABDUL AZIZ Univ. FRO HEALTH Sci.S, RIYADH, Saudi Arabia, [2]KAIMRC, Riyadh, Saudi Arabia

Background Bardet Biedl syndrome is a rare heterogeneous autosomal recessive multi systemic condition with twenty two identified genes. Six distinct clinical and diagnostic features include rod cone dystrophy, learning difficulties, renal abnormalities, male hypogonadism, postaxial polydactyly, and obesity. Methods Here, we provide data from nine consanguineous families and one nonconsanguineous family, in which multiple members were affected and displayed characteristic BBS clinical symptoms. Ten BBS Pakistani families were involved in the current investigation, and whole exome sequencing identified novel and recurrent gene variations. Results WES revealed four novel biallelic nonsense variants in four families, *IFT27, BBIP1, WDPCP, LZTFL1* genes, likewise six previously reported variants in five different genes *BBS5, BBS1, BBS1, MKKS, BBS5.* Conclusion Our findings confirm the significance of these genes in the emergence of multi systemic human genetic illness and broaden the mutational and phenotypic spectrum of four distinct forms of ciliopathies that cause BBS.

Inherited photosensitivity syndromes are a heterogeneous group of genetic skin disorders with tremendous phenotypic variability, characterized by photosensitivity and defective DNA repair, especially nucleotide excision repair. A cohort of 17 Iranian families with heritable photosensitivity syndromes was evaluated to identify their genetic defect. The patients' DNA was analyzed with whole-exome sequencing. The interpretations of the genomic results were guided by genome-wide homozygosity mapping. Haplotype analysis was performed for cases with recurrent mutations. RNA sequencing (RNA-Seq) was also utilized to determine germline and somatic variants for exploring the pathogenicity and cancer mutational signature analysis, respectively. Thirteen sequence variants, including six previously unreported pathogenic variants, were disclosed in 17 Iranian cohort, with *XPC* as the most common mutated gene in 10 families (59%). In one patient, RNA-Seq, as a first-tier diagnostic approach, revealed a non-canonical homozygous germline variant: *XPC*:c.413-9T>A. The Sashimi plot showed skipping of exon 4 with dramatic XPC down-expression. RNA-Seq-based somatic variant analysis including the somatic variant annotation and mutation signature profiling disclosed driver mutations in cancer-related genes such as *PTCH1*. This mutational signature was deconvoluted into component signatures of 1, 5, 12, and 20 of the COSMIC signatures. Haplotype analysis of *XPC*:c.2251-1G>C and *XPC*:1243C>T in four families showed common haplotypes of 1.7 Mb and 2.6 Mb, respectively, denoting a founder effect. Lastly, two extremely rare cases were presented in this report: a homozygous *UVSSA*:c.1990C>T was disclosed in a family in which homozygous and heterozygous patients had severe and minimal presentations, respectively. A family with *ERCC2*-related COFS with an early childhood death was reported. A direct comparison of our data with the results of previously reported cohorts demonstrates the international mutation landscape of DNA repair-related photosensitivity disorders; although, population-specific differences were observed.

PB4731 Dominant *OGDH* mutations cause peripheral neuropathy with ataxia and optical atrophy

Authors:

L. Van de Vondel[1], J. De Winter[1], A. Sandoval[2], J. F. Ramirez[2], R. Horvath[3], J. De Bleecker[4], S. Zuchner[5], W. Yoon[2], J. Baets[6]; [1]Univ. of Antwerp, Wilrijk, Antwerpen, Belgium, [2]Oklahoma Med. Res. Fndn., Oklahoma City, OK, [3]Univ. of Cambridge, Cambridge, United Kingdom, [4]Univ. of Ghent, Ghent, Belgium, [5]Univ. of Miami Miller Sch. of Med., Miami, FL, [6]Univ. of Antwerp, Wilrijk, Antwerp, Belgium

2-oxyglutrate dehydrogenase (OGDH) is an E1 component of α-ketoglutarate dehydrogenase complex (α-KGDH) that plays a crucial role in the Krebs cycle metabolism. Biallelic variants in *OGDH* have been reported to cause OGDH deficiency (OGDHD; OMIM: # 203740), a condition that leads to an early-onset neurodevelopmental and mitochondrial disorder. However, whether monoallelic *OGDH* variants could also exhibit dominant effects in humans had not been known. In this study, we identified a *de novo OGDH* c. 1909C>T (p.Arg637Trp) variant by whole-exome sequencing (WES) in a patient manifesting late-onset neurological phenotypes, including peripheral neuropathy, cerebellar ataxia and bilateral optic atrophy. Blood analysis revealed ketogenosis. In patient lymphoblasts, *OGDH* levels do not seem altered in the whole cell lysate nor specifically in the mitochondrial fraction compared to familial controls. In contrast, these cells displayed decreased α-KGDH activity. These findings strongly suggest that the p.Arg673Trp variant acts as a dominant-negative mutation. To test this hypothesis, we generated *Drosophila* model carrying *UAS-dOgdh (p.Arg639Trp)* transgene, harboring the homologous mutation to the human variant. Using this transgenic fly, we will determine whether neuronal expression of the mutant dOgdh (p.Arg639Trp) leads to developmental and degenerative defects in neurons, as well as impairment of Krebs cycle metabolism.Additionally, through genetic matchmaking, we identified two additional families with patients harboring heterozygous *OGDH*variants, all presenting late-onset neurological phenotypes. Collectively, our data suggest that the monoallelic *OGDH* variants disrupt α-KGDH function, thereby leading to late-onset neurological diseases in humans.

Session Title: Mendelian Phenotypes Poster Session II

PB4732 *Drosophila* model of *de novo PHACTR1* variant highlights the role of exon 5 duplication in novel neurodevelopmental disorder

Authors:

J. Andrews[1,2], S. Jangam[1,2], L. Briere[3], R. Townsley[1,2], Undiagnosed Disease Network, S. Yamamoto[1,2], D. Sweetser[3], M. Wangler[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Houston, TX, [3]Massachusetts Gen Hosp, Boston, MA

Phosphatase and Actin Regulator 1 (PHACTR1) is a member of a family of Protein Phosphatase 1 (PP1) binding proteins which defines the substrate specificity of the Phactr1/PP1 holoenzyme. PHACTR1 is broadly expressed within the central nervous system and is believed to play an important role in the regulation of actin cytoskeletal dynamics, actin stress fiber formation, cell motility, and cell survival. Multiple *PHACTR1* variants have been previously associated with different pathologies, including developmental and epileptic encephalopathy, West syndrome, myocardial infarction, melanoma growth, coronary artery disease, and cervical artery dissection. Here we report a proband with a *de novo* duplication of exon 5 and parts of the surrounding introns who presented with global developmental delay, hypotonia, absent speech, seizures, behavioral problems, mild prominence of ventricles and sulci, and slight dysmorphism of the left hippocampus. We have generated a *Drosophila* model utilizing the UAS/GAL4 system to drive the expression of *PHACTR1* human cDNA within the fly. Overexpression of either the reference or variant human cDNA via a Nubbin-Gal4 driver produced no changes within the wing tissues, and overexpression within the eye by GMR-Gal4 produced only minor changes in eye morphology. However, the ubiquitous overexpression of the putatively pathogenic variant using either an Actin or Tubulin-Gal4 driver was sufficient to induce forking or abnormal bends in bristles within the head, notum, and sternopleurum. These changes within the actin-rich bristle structures were not observed in animals overexpressing the reference human cDNA. Likewise, the ubiquitous overexpression of *CG32264*, the *Drosophila* ortholog to *PHACTR1*, showed no alterations in bristle morphology. Conversely, ubiquitous depletion of *CG32264* via two different RNAi lines ($CG32264^{JF02975}$ and $CG32264^{HMC05840}$) failed to cause any changes in bristle morphology. However, the expression of $CG32264^{JF02975}$, but not $CG32264^{HMC05840}$, in eye tissues via GMR-Gal4 produced a rough-eye phenotype. Our initial assessment demonstrates that *Drosophila* is a suitable model for further exploration of *PHACTR1* variants and identifies that duplications of the 5th exon are putatively deleterious and may underly a novel disorder separate from those previously associated with *PHACTR1*.

Widespread use of clinical exome and genome sequencing in pediatric cohorts with suspected ciliopathies has led to an accelerated improvement of diagnostic rate. Yet, a subset of individuals who display hallmark ciliopathy features harbor hitherto unknown causal loci offering an opportunity for disease gene discovery. Here, we report the identification of *CEP76*, encoding centrosomal protein 76, as a causal ciliopathy locus. Data sharing platforms connected five independent groups who had performed either targeted sequencing or proband-parent trio whole exome/genome sequencing on unrelated pedigrees with suspected genetic disorders. Five unrelated affected children with partially overlapping phenotypes harbor rare biallelic variants in *CEP76* that segregate with disease and are predicted to impact protein function. One male proband with biallelic nonsense variants was diagnosed with Bardet-Biedl syndrome; a second affected male with an mRNA splice altering variant in trans with a rare missense change fulfilled diagnostic criteria of Joubert syndrome; a third male with a rare homozygous missense change displayed syndromic intellectual disability; a fourth affected female harboring biallelic missense variants exhibited Joubert syndrome-like features; and a fifth affected female carrying homozygous missense variant presented with retinitis pigmentosa. CEP76 has been shown previously to associate with CP110, a CDK2 substrate, and CEP97, a calcium-binding protein, which localize to the basal body and daughter centriole of primary cilia. Importantly, our zebrafish stable mutants with a homozygous intragenic deletion of *cep76* display photoreceptor deficits as evidenced by significantly altered response to light-dark stimuli and histological phenotypes including rhodopsin mislocalization and significantly reduced ciliary length compared to controls. Furthermore, RNA silencing of endogenous *CEP76* and/or chemical perturbation induced centriolar proliferation phenotypes *in vitro* in U2OS cell lines. These phenotypes were rescued by introduction of wild type *CEP76*, however, introduction of a subset of patient variants did not rescue the aberrant centriolar phenotypes. Together, our human genetic and functional data provide evidence to support causality of *CEP76* in a clinically heterogenous human disorder. Our ongoing studies aim to explain phenotypic differences among affected individuals and pursue hypotheses of differing *CEP76* variant strength and physical interactions with other centrosomal and ciliary loci.

Session Title: Mendelian Phenotypes Poster Session I

PB4734 Dysmyelination or demyelination: Investigating the role of *SLC17A5* in myelination in a murine model of Free Sialic Acid Storage Disorder.

Authors:

M. Hossain[1], M. Sabir[1,2], M. Hackbarth[3,1], P. Leoyklang[1], H. Dorward[1], M. Huizing[1], W. Gahl[1], M. C. V. Malicdan[1]; [1]NIH, Bethesda, MD, [2]Univ. of Oxford, Oxford, United Kingdom, [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Background: Free Sialic Acid Storage Disorder (FSASD) is a rare lysosomal storage disorder resulting from bi-allelic variants in *SLC17A5*. It is characterized by a multisystemic phenotype, including progressive neurodegeneration and significant hypomyelination. Although SLC17A5, a lysosomal membrane protein, is known to transport sialic acid from lysosomes to the cytosol, the pathophysiology of myelination defects and neurodegeneration in FSASD and the relationship between lysosomal SLC17A5 function and myelin production, composition, and maintenance remain enigmatic. To investigate SLC17A5 function, we generated an $Slc17a5^{R39C}$ knock-in mouse model with the prevalent p.Arg39Cys (R39C) mutation. These mice exhibit features of FSASD, including progressive ataxia, neurodegeneration, and hypomyelination.
Methods: To understand the extent by which SLC17A5 dysfunction leads to myelination problems and neurodegeneration, we further characterized $Slc17a5^{R39C}$ mice. Using histopathological techniques, we examined expression of proteins related to myelin or CNS regulation in the cortex, cerebellum, and cervical spinal cord of $Slc17a5^{R39C}$ mice and control littermates at various stages of postnatal development. Immunofluorescence staining was performed using antibodies specific for myelin basic protein (MBP), Purkinje cells (PCP4) and astrocytes (GFAP).
Results: $Slc17a5^{R39C}$ mice had decreased MBP expression, significant white matter astrogliosis, and decreased PCP4 expression over time, indicating progressive Purkinje cell loss throughout development. Luxol Fast Blue staining, which highlights myelinated regions, revealed prominent hypomyelination in the corpus callosum, cerebellar white matter, and all major spinal white matter tracts as early as P14 in $Slc17a5^{R39C}$ mice. Surprisingly, Nissl staining did not show differences in neuronal body numbers, suggesting myelin density changes are independent of neuronal loss.
Conclusion: Our findings suggest dysmyelination or hypomyelination has occurred as early as P14, within the biological window for myelination, resulting in myelination deficits in the $Slc17a5^{R39C}$ mouse model. Progressive neurodegeneration occurs alongside myelination abnormalities. These results align with clinical presentation in FSASD patients and provide insights into the pathophysiology of FSASD and the impact of SLC17A5 on myelin production, composition, and maintenance. The findings could have implications for the development of personalized therapies for patients with FSASD or other disorders characterized by myelin defects or neurodegeneration.

PB4735 E-cadherin gene deletion and complete anodontia: A case report.

Authors:

S. Beiraghi[1], O. Klein[2], C. Billington, Jr.[1]; [1]Univ Minnesota, Minneapolis, MN, [2]Cedars-Sinai, Los Angeles, CA

The CDH1 gene codes for the Cadherin-1, or E-Cadherin, protein which is important for the epithelial tissue growth and function. In-frame gene deletions of *CDH1* have been linked to tooth anomalies such as complete anodontia. This case report presents the first incidence of a female toddler with in-frame deletion of the *CDH1* gene and complete anodontia. Dental x-rays revealed no primary teeth and no evidence of tooth buds. Exome sequencing was performed and it revealed heterozygous change in *CDH1*. This patient has an in-frame deletion of Asn458 (NM_004360 c.1371_1371del). It is *de novo* and rare in the population. This case report reveals that the *CDH1* gene might impact tooth development and the first case of a patient with complete anodontia and *CDH1* gene deletion.

Session Title: Mendelian Phenotypes Poster Session III

PB4736 Effect of Polymorphisms in *BCL11A, APOL1* genes and Expression of Foetal Haemoglobin on Sickle Cell Disease Phenotypes

Authors:

M-L. Sakyi[1,2,3], N. A. Karikari Agyemang[4,2], M. E. Gakpey[4,2,3], D. Adu[2,3], L. N. Amenga-Etego[5]; [1]Univ. of Ghana, Accra, Ghana, [2]Human Hereditary Hlth.Africa Kidney Disease Res. Network, Genomics Lab., Accra, Ghana, [3]West Africa Genetic Med. Ctr., Accra, Ghana, [4]Noguchi Mem. Inst. For Med. Res., Accra, Ghana, [5]West Africa Ctr. for Cell Biology of Infectious Pathogens, Accra, Ghana

Renal complication is a leading cause of early mortality in sickle cell disease (SCD). Foetal haemoglobin (HbF), a major genetic modulator in SCD ameliorates related complications. Mutations in BCL11A gene also induce increased expression of Hb F transcription. However, APOL1 genetic variants (G1 and G2) are linked with development of chronic kidney disease (CKD). This study sought to understand the interplay of APOL1 mutations in SCD patients with CKD. Cross-sectional random sampling was used to recruit 384 SCD patients visiting Komfo Anokye and Korle Bu Teaching Hospitals in Ghana after ethical approval. Hematological and biochemical tests were conducted to determine SCD phenotypes followed by haemoglobin fractionation. Genomic DNA was isolated from whole blood followed by PCR-Ligase detection reaction and TaqMan SNP genotyping assay to genotype APOL1 and BCL11A SNPs. Pearson's correlation was used to test for correlation of two variables (r). Chi Square test and logistic regression was used to test for association of genotype and phenotypes. In all participants, age had a negative correlation (p=0.014) with HbF. Age was significantly (p=0.014) associated with CKD. No significant correlation was observed between HbF and CKD (r=0.02, p<0.71), whereas weak negative correlation was seen between age and HbF in participants without CKD (r= -0.25, P<0.001). HbS and F showed a significant increased risk of developing CKD for having either one or both variants (HbS (OR=1.02-1.07, p=0.001), HbF (OR = 0.95; 95%CI [0.90-0.94], p<0.001). APOL1 showed significant difference between disease status using the combined risk alleles (p=0.021). No significant association was observed between APOL1 risk alleles and SCD-CKD. HbF may modulate SCD complication such as CKD for an extended life expectancy by persisting in adult SCD patients. Risk and development of SCD associated CKD may not be solely attributed to presence of the APOL1 risk variants. However, BCL11A may be used as genetic modulators for SCD clinical management. More research using a larger study population is required to confirm these significant findings.

Session Title: Mendelian Phenotypes Poster Session I

PB4737 Elucidating the genetic etiology underlying septo optic dysplasia (SOD).

Authors:

S. T. Beheshti[1], A. Jolly[1], J. R. Lupski[1,2,3,4], R. A. Lewis[1,5,3,4], J. E. Posey[6]; [1]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [2]Human Genome Sequencing Ctr., Baylor Coll. of Med., Houston, TX, [3]Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, [4]Texas Children's Hosp., Houston, TX, [5]Dept. of Ophthalmology, Baylor Coll. of Med., Houston, TX, [6]Baylor Coll. of Med., Houston, TX

Septo-optic dysplasia (SOD) is a rare congenital disorder with an estimated incidence of 1 in 10,000 newborns. SOD is a cerebral midline anomaly, and its classic triad of features includes optic nerve hypoplasia (ONH), agenesis of the septum pellucidum and corpus callosum, and hypoplasia of the hypothalamo-pituitary axis. The presence of two or more components of the classic triad is "diagnostic" for SOD. Despite this narrowly defined clinical definition, only 40-47% of individuals who receive a diagnosis of SOD will have the full triad of SOD features. Moreover, additional brain abnormalities have been observed in SOD individuals, including hydrocephalus, polymicrogyria, and grey matter heterotopia, among others. The full molecular etiology of SOD is not yet known; however, it is widely believed that a combination of genetic predisposition and prenatal environmental factors contribute substantially to its development. Several genes, such as *HESX1, SOX2/SOX3*, *OTX2*, *GLI2*, *PAX6*, *PROP1*, and *TAX1BP3* have been identified to play crucial roles in the embryonic development of the eyes, optic nerves, and pituitary gland, thereby influencing the expression of SOD. Despite these advancements in the underlying molecular mechanisms of SOD, a substantial number of SOD families still lack a molecular diagnosis. Through the Baylor Hopkins Center for Mendelian Genomics (BHCMG) and Baylor College of Medicine Genomic Research to Elucidate the Genetics of Rare (BCM-GREGoR) databases, we have identified 12 unrelated SOD probands and their families for exome sequencing (ES) data. Using a rare variant, family-based analysis approach leveraging existing genomic knowledge sources, we have identified putative candidate, rare variants (MAF ≤ 0.1%) predicted to impact protein function in four candidate disease genes that demonstrate biological roles relevant to the SOD phenotype (*KIF26A*, *NFIA*, *TUBB2B*, and *SLCO1A2*). These molecular findings in rare disease may inform septo-optic dysplasia molecular diagnosis and clinical presentation(s).

Session Title: Mendelian Phenotypes Poster Session II

PB4738 Engineering and analysis of new mouse mutants carrying the novel triplications of human chromosome 21 syntenic regions to reveal the unique genotype/phenotype relationship.

Authors:

A. Douglas, X. Jiang, C. Liu, Z. Xing, A. Pao, Y. Yu; Roswell Park Comprehensive Cancer Ctr., Buffalo, NY

Down syndrome (DS), associated with trisomy 21, is one of the most important chromosomal alterations because it is both common and connected with a constellation of medically important co-occurring conditions. DS occurs in approximately 1 in 691 live births and is present in approximately 1 in 1,499 inhabitants in the US; notably, DS is a leading genetic cause of developmental delays and intellectual disabilities, which currently lack effective treatments. The mouse has been used extensively to study DS based on the evolutionary conservation between mouse genomic regions and human chromosome 21. Mouse mutants carrying three copies of human chromosome 21 syntenic regions have been generated and analyzed to understand the impacts of gene dosage increase on DS-associated phenotypes. In this project, we have engineered three new duplication mutants spanning three human chromosome 21 syntenic regions on mouse chromosome 16 by using Cre/loxP-mediated chromosome engineering. These duplications were first engineered in mouse embryonic stem (ES) cells, and these mutant ES cells were then used to generate chimeric mice. Germ-line transmissions led to the establishment of the duplication mutant mouse lines constitutionally. These duplications span the regions between *Setd4* and *Kcnj6* as well as between *Kcnj15* and *Mx2*. A duplication mouse mutant line was also engineered for Dyrk1a and Kcnj6 alone. The behavioral tests were performed for these mutants, including open field test, T maze test, novel objective recognition test, and fear conditioning test. These efforts identified a novel genomic region associated with cognitive deficits and revealed the unexpected effects of simultaneous triplications of *Dyrk1a* and *Kcnj6*. These results will have significant implications for understanding of disease mechanisms of DS and for development of novel and effective treatments for this genetic condition.

Session Title: Mendelian Phenotypes Poster Session III

PB4739 Establishment the transgenic pig model and exploration the molecularmechanisms of rare disease white sponge nevus

Authors:

W. Cai[1,2]; [1]Tongji Univ. Sch. of Med., Shanghai, China, [2]Tenth People's Hosp. Affiliated of Tongji Univesity, Shanghai, China

White sponge nevus (WSN) is an autosomal dominant inherited rare disease and associated with the mutation of Keratin 4 (KRT4) and Keratin 13 (KRT13) gene. Till now, almost all WSN study are focus on case report or mutation report. The mechanism of WSN is still unclear. In this project, we recruited WSN Chinese family, and oral lesions biopsy with hematoxylin and eosin staining showed that patients had significantly pathological characteristics. The mutations of KRT4 and KRT13 gene were detected by PCR and direct sequencing. Sequencing analysis shows that the mutation of KRT13 was T332C, and amino acid change was Leu111Pro. Preliminary molecular research showed that the abnormal degradation of KRT13 protein of WSN probably associate with abnormal ubiquitination process. However, the molecular mechanism of this process in vivo is not comprehensive. In this project, using the CRISPR/Cas9 to build the KRT13 T332C WSN transgenic mini pig model and phenotyping, RNA-seq sequencing expression profiles provide important signaling pathways important to focus on gene transgenic mini pig cell transcriptome and genome comparative analysis to explore the pathogenesis of WSN. The platform of phenotype reversal comprehensive treatment and drug screening to interpretation and validation of molecular pathogenesis mechanism WSN in vivo. It provides an important reference for further explore the molecular mechanism of WSN, clinical treatment and drug screening to interpretation and validation of molecular pathogenesis mechanism WSN in vivo. It provides an important reference for further explore the molecular mechanism of WSN, clinical treatment and drug screening.

Session Title: Mendelian Phenotypes Poster Session I

PB4740 Estimation of carrier frequencies in Finnish population: utilizing the gnomAD database for ACMG recommended carrier screening genes and Finnish disease heritage disorders

Authors:

E. Salminen, M. Kandolin, M. Pöyhönen; Univ. of Helsinki, Helsinki, Finland

Background: ACMG recently published practice resource proposing that Tier 3 carrier screening for conditions with a combined carrier frequency ≥1/200 should be offered for all pregnant patients and those planning a pregnancy. Altogether 96 genes causing autosomal recessive disorders and 18 X-chromosomal genes were considered as appropriate for pan-ethnic carrier screening. In Finland, a relatively small number of founder individuals and strong genetic isolation over centuries have shaped the genetic landscape leading to certain disorders (referred as Finnish disease heritage) being more common than elsewhere. In these disorders, a single founder variant explains majority of the Finnish cases. **Objective:** To study the carrier frequencies in Finnish population for the ACMG suggested carrier screening genes and estimate the carrier frequencies in Finnish disease heritage disorders utilizing gnomAD v2.1 database. **Methods**: gnomAD v.2.1.1 sequence variant data was extracted for the genes causing autosomal recessive and X-linked Finnish disease heritage disorders and for the genes suggested for carrier screening by ACMG. Variants reported as pathogenic or likely pathogenic (P/LP) in ClinVar, loss-of-function (lof) variants in gnomAD (stop_gain, frameshift_variant, splice_acceptor_variant, splice_donor_variant), as well as Finnish founder variants were included. Gene carrier rate (GCR), cumulative carrier rate (CCR) and at-risk carrier couple rate (ACR) were estimated. In addition, estimated number of affected children born annually was estimated for the autosomal recessive disorders. Analysis was performed for Finnish (FIN), non-Finnish European (NFE) and Ashkenazi Jewish (ASJ) subpopulations in gnomAD. Some of the suggested genes were not able to be analyzed due to known variant type (eg single exon deletion, repeat expansion). **Results:** The cumulative carrier rate (CCR) for the Finnish founder variants for Finnish disease heritage disorders was 28,0 % and the Finnish founder variants covered 93,4 % of the CCR for Finnish disease heritage disorders in Finnish population. There were 47 genes having GCR over 0,5 % in Finnish population. The CCRs in the FIN, non-Finnish European, and Ashkenazi Jewish populations were 51,3 %, 46,7 % and 56,9 %, respectively. The CCR of Finnish heritage diseases in each population was 30,0 %, 9,1 %, and 5,8 %, respectively. At-risk couple rates in AR conditions for the Finnish, non-Finnish European and Ashkenazi Jewish populations were 1,6 %, 1,3 % and 2,6 %, respectively. In Finland, 133 children affected with an AR condition studied are estimated to be born annually.

Session Title: Mendelian Phenotypes Poster Session II

PB4741 Existing and novel tumor associations in NF1: the DiscovEHR cohort experience.

Authors:

A. Pemov[1], J. Kim[2], J. S. Haley[3], U. Mirshahi[4], H. Rao[5], DiscovEHR Collaboration, D. J. Carey[4], D. R. Stewart[2]; [1]NIH, NCI, Rockville, MD, [2]Natl. Cancer Inst., Rockville, MD, [3]Geisinger, Danville, PA, [4]Geisinger Clinic, Danville, PA, [5]Geisinger Hlth.System, Danville, PA

Background. Large-scale exome sequencing linked to electronic health records (EHR) and broad ascertainment of participants' clinical phenotypes provides a unique opportunity to investigate genotype-phenotype correlations, improve the estimates of prevalence and penetrance of Mendelian disorders, and ultimately, advance disease prognosis, risk stratification and care for patients. **Methods**. First, we identified persons with heterozygous pathogenic (P) or likely pathogenic (LP) variants as well as large deletions (CNV) in *NF1*, the causative gene in neurofibromatosis type 1 (NF1). We then examined EHR (C, D an Z icd10 codes for neoplasms) and tumor registry records for the participants carrying these variants, combined similar neoplasms in 20 larger groups, and performed a series of association analyses of carriers (participants with P/LP or CNV in *NF1*, n=130) vs. non-carriers (participants without any rare (<1% population frequency in gnomAD) *NF1* variants, n=55,000) for these 20 tumor phenotypes. Age, sex, BMI, and smoking status were used as co-variates. **Results.** Out of 170,053 participants, we identified 123 with P/LP variants, and 7 with *NF1* CNV (prevalence 1:1,308). The association analysis identified the following significant (p-value<0.0025, after the Bonferroni correction) tumor phenotypes that were previously shown to be involved in NF1: adrenal/neuroendocrine, GIST, peripheral nervous system, central nervous system, and soft and connective tissue tumors. In addition, we identified several novel significant associations such as bone, head/face/neck, leukemia/lymphoma, ovary, and thorax/mediastinum tumors. There were several suggestively significant associations as well (nominal p-value<0.05), including breast (p-value=0.0046), melanocytic nevi/melanoma (p-value=0.0034), salivary (p-value=0.0092), and uterine (p-value=0.023) tumors. **Conclusions.** By utilizing a genome-first approach in the DiscovEHR cohort, we confirmed existing tumor associations with NF1 and identified potential novel neoplasm risks in NF1 patients. One important distinction between this and previous association studies is that deleterious *NF1* variant carriers rather than clinically affected NF1 individuals were the focus of the present investigation. Given the wide range of expressivity of the NF1 phenotype, previous studies might have underestimated prevalence of some tumors in the NF1 population. A validation of these findings in an independent cohort is underway.

Session Title: Mendelian Phenotypes Poster Session III

PB4742 † *EXOC6B* associated with spondyloepimetaphysealdysplasia with joint laxity type 3 plays an essential role in primary ciliogenesis and chondrogenic differentiation *in vitro*

Authors:

V. Guleria, N. Quadri, P. Upadhyai; Kasturba Med. Coll., Manipal, Manipal, India

Spondyloepimetaphyseal dysplasia with joint laxity type 3 (SEMDJL3) is a rare skeletal dysplasia characterized by profound skeletal abnormalities and joint laxity. It is associated with *EXOC6B*, a component of the exocyst complex, involved in vesicle tethering and exocytosis at the plasma membrane. So far, the underlying molecular mechanisms driving the pathogenesis of SEMD-JL3 remain largely unknown. In ATDC5 prechondrocytes, intracellular localization of Exoc6b was determined by immunofluorescence. It appeared predominantly perinuclear and localized at the base of primary cilia. Immunofluorescence and western blot analysis revealed that *Exoc6b* shRNA lentiviral knockdown (KD) in prechondrocytes significantly impaired primary ciliogenesis and expression of Ift88, an essential ciliary protein. Chondrogenic differentiation was evaluated by extracellular matrix (ECM) mineralization and estimation of transcript levels of chondrogenic markers using Alizarin Red staining and reverse transcription quantitative real-time PCR. In *Exoc6b* KD prechondrocytes *Col2a1* and *Ihh*, markers of proliferative chondrocytes, were upregulated following 7 and 14 days of differentiation. At 14 days of differentiation, the chondrocyte hypertrophy marker, *Col10a1* mRNA levels were increased. Congruently, at day 14 of differentiation, *Axin2*, a canonical Wnt pathway modulator that inhibits chondrocyte hypertrophy, was suppressed. The expression of *Mmp13* and *Adamts4* that are terminal chondrocyte hypertrophy markers involved in ECM remodeling were downregulated at 7 and 14 days of chondrogenesis. Finally, at 14 days of chondrocyte differentiation, *Bglap*, which encodes for the most prevalent non-collagenous bone matrix component and ECM calcification, was suppressed. This study provides initial molecular insights into the pathogenesis of SEMD-JL3 by elucidating the cellular distribution and role of Exoc6b in primary ciliogenesis and effects on chondrogenic differentiation.

Session Title: Mendelian Phenotypes Poster Session I

PB4743 Exome sequencing for children with encephalopathy and severe COVID-19 infection

Authors:

N-C. Lee, T-Y. Yen, H-H. Yu, Y-H. Chien, W-L. Hwu, W-T. Lee, L-Y. Chang, COVID study group; Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Background Host genetic factors are one of major factors in the consequence after COVID-19 infection. A variety of genes related to immunodeficiency or immune dysregulation, such as TLR3 pathway and RNA metabolism, innate RNA POL III signaling had been to this condition. In Taiwan, a subgroup of children was noted to have rapidly progress encephalopathy during COVID-19 pandemic. Therefore, we would like to decipher relationship between host genetic susceptibility and COVID infection in our cohort. **Materials and Methods** During May 2022 to May 2023, children with encephalopathy and severe COVID-19 infection were enrolled. Genomic DNA from peripheral blood was collected. Exome sequencing was performed with KAPA HyperExome kit (Roche) and Illumina NovaSeq 6000 system. Sequencing result was aligned to human reference genome (GRCh38) using Burrow-Wheeler Aligner for short-read alignment (BWA-MEM2) and variant calling will be performed using Genome Analysis Tool Kit (GATK V3.5, Broad institute) and further annotated using ANNOVAR. Monogenic disorders or susceptible genes were filtered with maximum minor allele frequency less than 0.01 and ACMG interpretation criteria. **Results** A total 33 children with 21 boys and 12 girls were enrolled. The median age was 6.5 y (range 0.2-18 y). Among them, 10 were noted to have rare variants related to single gene disorders, including DNM1_related mitochondrial disease, mandibulofacial dysostosis, Guion-Almeida type (EFTUD2), intellectual developmental disorder with macrocephaly, seizures, and speech delay (PAK1), Brugada syndrome (SCN5A), Dent disease 2 (OCRL), POLG_related mitochondrial disorders, GDF1_related heart disorders, LIG4 syndrome, chr4 duplication, and DiGeorge syndrome. For inborn error of immunity, 23 susceptible variants on 19 genes were also identified. Among them, PLB1, TYK2, RANBP2, and TNFSF12 were recurrent. **Conclusion** Children with single gene condition tended to have encephalopathy or severe conditions after COVID-19 infection. A promptly early identification of these conditions may prevent further decline or perceive these at-risk groups earlier.

Session Title: Mendelian Phenotypes Poster Session II

PB4744 Exome sequencing leads, in a consanguineous family, to the identification of a novel gene, SLC22A24, for an autosomal-recessive non-syndromic hearing disorder

Authors:

R. Birkenhager, S. Weis, S. Hollander, S. Arndt, A. Aschendorff, A. Knopf; Univ. Med. Ctr., Dept. of Otorhinolaryngologie, Freiburg, Germany

Hearing impairment is the most common sensorineural disorder in humans. Approximately one of every 1000 newborns is born profoundly deaf and one of every 300 newborns has a permanent mild-to-profound congenital hearing impairment. Hearing disorders can be caused by environmental factors or viral infections, strong sources of noise, ototoxic substances and genetic causes. About ~ 60% of all prelingual hearing disorders are genetic. Inherited hearing disorders are divided into syndromal (SHL) or nonsyndromal (NSHL). Almost 70% of cases of inherited hearing disorders are non-syndromic and mainly due to sensorineural causes. About 80% of this cases follow an autosomal recessive (DFNB) and 18% an autosomal dominant (DFNA) inheritance, about 2% are x-chromosomal (DFNX) or mitochondrial (MT) linked. A total of 196 gene loci have been described to date, from which 131 genes have so far been identified, 65 genes at least are still unknown.Autosomal recessive non-syndromic hearing loss (ARNSHL) is a genetically hetero-geneous sensorineural disorder, with prelingual hearing loss and absence of other clinical manifestations. Based on the clinical diagnosis it is not possible to recognize in which gene mutations are present. This is only feasible in exceptional cases (7/131). The aim of this study is to identify the pathogenic gene in different families. Hearing test BERA/Electrocochleography and a radiological high-resolution CT scan was performed. Mutational analysis of two affected family members, using direct sequencing of the coding exon and intron transitions of the genes GJB2 and GJB6, including deletion analysis, was performed. For investigation of autosomal recessive nonsyndromic hearing loss genes, whole exome sequencing was performed, with the “INVIEW HUMAN EXOME” platform; array Agilent Genomics SureSelectXT All Exon V5. In the DNFB1 gene locus, containing the genes GJB2 and GJB6, no mutations could be identified. A further targeted analysis of other genes was not possible; therefore complete exome sequencing took place. All known genes for hearing impairment were analyzed, in different families. A homozygous splice site mutation IVS1+1G>A was identified in the gene SLC22A24 in a consanguineous family. Sanger sequencing confirmed this mutation. This mutation prevents the expression of the gene SLC22A24, detected by quantitative real-time PCR. SLC22A24 belongs to a large family of transmembrane proteins that function as transport of organic ions across cell membranes. Here, for the first time, the gene SLC22A24 (MIM 611698, Gene ID: 283238) is described that leads to an autosomal recessive hearing disorder.

Session Title: Mendelian Phenotypes Poster Session III

PB4745 Exome Sequencing Links the SUMO Protease SENP7 with Fatal Arthrogryposis Multiplex Congenita, Early Respiratory Failure, and Neutropenia.

Authors:

K. Weiss[1], N. Samra[2], N. S. Jansen[3], I. Morani[2], T. Paperna[1], R. Wevers[4], H. Mandel[5], A. C. Vertegaal[6]; [1]Genetics Inst. Rambam Hlth.Care Campus, Haifa, Israel, [2]Dept. of Genetics Ziv Med. center, Safed, Israel, [3]Dept. of Cell and Chemical Biology, Leiden, Netherlands, [4]Translational Metabolic Lab., Dept. Lab. Med., Radboud Univ. Med. Ctr., Nijmegen, The Netherlands, Nijmegen, Netherlands, [5]Metabolic Unit Ziv Med. center, Safed, Israel, [6]Dept. of Cell and Chemical Biology, Leiden Univ. Med. Ctr., Leiden, Netherlands

Background: SUMOylation involves the attachment of Small Ubiquitin-like Modifier (SUMO) proteins to specific lysine residues on thousands of substrates with target-specific effects on protein function. Sentrin-specific proteases (SENPs) are proteins involved in the maturation and de-conjugation of SUMO. Specifically, SENP7 is responsible for processing polySUMO chains on targeted substrates including the heterochromatin protein HP1α. Methods: we performed exome sequencing and segregation studies in a family with several infants presenting with an unidentified syndrome. RNA and protein expression studies were performed in fibroblasts available from one subject. Results: We identified a kindred with four affected subjects presenting with a spectrum of findings including congenital arthrogryposis, no achievement of developmental milestones, early respiratory failure, neutropenia, and recurrent infections. All died within four months after birth. Exome sequencing identified a homozygous stop gain variant in SENP7 c.1474C>T; p.(Gln492*) as the probable etiology. The proband's fibroblasts demonstrated decreased mRNA expression. Protein expression studies showed significant protein dysregulation in total cell lysates and in the chromatin fraction. We found that HP1α levels as well as different histones and H3K9me3 were reduced in patient fibroblasts. These results support previous studies showing interaction between SENP7 and HP1α, and suggest loss of SENP7 leads to reduced heterochromatin condensation and subsequent aberrant gene expression. Conclusion: Our results suggest a critical role for SENP7 in nervous system development, hematopoiesis, and immune function in humans.

Session Title: Mendelian Phenotypes Poster Session I

PB4746 Exome sequencing of a large Indian cohort of inherited diseases identifies actionable mutations

Authors:

S. Seshagiri[1], S. N[1], S. Thenral[1], I. verma[2], T. Familial Disease Genetics Group[1], R. Gupta[3], V. Ramprasad[1]; [1]MedGenome Labs, Bangalore, India, [2]Inst. of Med. Genetics and Genomics, New Delhi, India, [3]MedGenome Labs Ltd., Bangalore, India

India is the world's most populous country with over 1.4 billion people. Its contemporary population is made of ~4000 anthropological groups that use over 100 languages. Its extraordinary population diversity, in part due to the historical and extant endogamous cultural practices and the ~26 million annual live births is an unprecedented opportunity for genetic discovery, therapeutic development and management of inherited disease burden.
To understand the prevalence of causal variants in patients with a history of inherited genetic disorders from India we created a familial genetic disease study cohort. It included 4697 samples from 1446 families with probands with clinical symptoms in areas of neurology, otolaryngology, ophthalmology, metabolic disorders, nephrology, immunology, skeletal dysplasia, cardiology, gastroenterology, oncology, and others rare disease.
We performed whole exome sequencing of the samples and analyzed them for causal variants using the pedigree and inheritance data. About 68% of the familial samples sequenced were trios. We identified a total 857,403 unique variants, 26% (222,942) of which were not previously reported. Among these, as per ACMG, we prioritized 1,208 (974 SNVs, 193 Indels and 41 CNVs) variants in 1,006 families. This included 596 variants involving 328 genes that were novel and not reported previously. One or more pathogenic variants were identified in 44% of the families. The highest diagnosis rate was obtained for trios that included additional family members (~63%) as compared to singletons where only the proband was sequenced. The highest diagnosis rate of 51% was in families with metabolic disorder. Among the 513 genes prioritized in our study, DYSF, CAPN3, ABCA4, GJB2, GNE, LAMA2, CLCN1, DMD, SGCB and MYO15A were the top 10 genes with highest number of prioritized variants. Among all genes, GJB2, GNE, DMD, SGCB carried the most number of pathogenic variants. Nonsense variant in GJB2 (p.Trp24Ter) was the most common prioritized variant, found in families with otolaryngology symptoms. Hemizygous deletion in the DMD was the most common hotspot CNV in this study. Previously not reported loss-of-function variants in PRKG2 in a skeletal case of dysplasia, USP53 in a case of cholestasis, and GOLGA2 in a case of neuromuscular phenotype were identified. In addition, an inherited missense variant in G6PD linked to Aspirin toxicity symptom was identified and functionally characterized to validate its relevance as a pharmacogenetic marker for pharmacovigilance.
Overall our study has identified genetic variants that confirm and clarify the clinical symptoms while uncovering previously not identified causal variants.

Session Title: Mendelian Phenotypes Poster Session II

PB4747 Expanded Clinical and Neuroradiological Phenotype of *RARS2*-Related Mitochondrial Disorder

Authors:

A. Walimbe[1,2], K. Machol[3,2], S. F. Kralik[4], E. A. Mizerik[2,3], Y. Gofin[5,6], R. Bekheirnia[3,2], C. Gijavanekar[3], S. H. Elsea[3], L. T. Emrick[1,2,3], F. Scaglia[2,3,7]; [1]Div. of Pediatric Neurology and Dev.al NeuroSci., Dept. of Pediatrics, Baylor Coll. of Med., Houston, TX, [2]Texas Children's Hosp., Houston, TX, [3]Dept. of Molecular and Human Genetics, Baylor Coll. Med., Houston, TX, [4]Dept. of Radiology, Baylor Coll. of Med., Houston, TX, [5]Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel, [6]Genetics Inst., Meir Med. Ctr., Kfar Saba, Israel, [7]BCM-CUHK Ctr. of Med. Genetics, Prince of Wales Hosp., Hong Kong, Singapore

RARS2-related mitochondrial disorder is an autosomal recessive mitochondrial encephalopathy caused by biallelic pathogenic variants in the gene encoding the mitochondrial arginyl-transfer RNA synthetase (*RARS2*, MIM *611524, NM_020320.5). RARS2 catalyzes the transfer of L-arginine to its cognate tRNA during the translation of mitochondrially-encoded proteins. The classical presentation of *RARS2*-related mitochondrial disorder includes pontocerebellar hypoplasia (PCH), progressive microcephaly, profound developmental delay, feeding difficulties, and hypotonia. Most patients also develop epilepsy, which presents within the first three months of life with focal or generalized seizures that frequently become pharmacoresistant and lead to a developmental and epileptic encephalopathy (DEE). Here, we describe a 4-year-old boy with developmental delay, hypotonia, and failure to thrive who developed an epileptic encephalopathy consistent with Lennox-Gastaut Syndrome (LGS), previously unreported in this disorder. He was noted to have dysmorphic features including bilateral macrotia, overriding second toes, a depressed nasal bridge, downslanting palpebral fissures, and retrognathia. His exam did not reveal microcephaly. Whole genome sequencing identified two *in trans* variants in *RARS2*, c.36+1G>T, a previously unreported variant that is predicted to affect splicing, and is, therefore, likely pathogenic, and c.419T>G (p.Phe140Cys), a known pathogenic variant. Unlike most patients with *RARS2*-related mitochondrial disorder, our patient did not demonstrate PCH on brain MRI. Severe volume loss of the cerebral hemispheres and thinning of the corpus callosum were noted. Treatment with a ketogenic diet (KD) reduced seizure frequency and enabled him to make developmental progress. Our study highlights the importance of appropriate seizure phenotyping in *RARS2*-related mitochondrial disorder and indicates that patients can develop LGS, for which a KD may be a viable therapeutic option. This work further reports that patients can also present with dysmorphic features and an absence of progressive microcephaly. In addition, this condition may demonstrate neuroradiological features other than PCH on brain MRI. The case reported herein expands the known phenotypic spectrum associated with *RARS2*-related mitochondrial disorder and may help guide the diagnosis and management of patients with this condition.

“Coatopathies”, or disorders of the coatomer complexes, are a group of childhood-onset, multisystem disorders that are growing in number and present with diverse phenotypes including immunodeficiency, intellectual and developmental disabilities (IDD), and skeletal abnormalities. Heterozygous, loss-of-function variants in *COPB2*, encoding a subunit of the coatomer complex I (COPI), were previously reported in individuals presenting with a clinical spectrum of osteopenia, recurrent fractures, and IDD. Here, we describe the molecular and phenotypic features in 5 individuals that were found to have heterozygous variants in *COPB2* via exome sequencing. We identified *de novo* variants leading to either frameshift (p.Lys386Glufs*30, p.Ile414Tyrfs*31), missense (p.Trp396Arg), or splice (c.2484+2dupT, c.894+1G>T) mutations. Clinically, all probands have IDD, including 2 individuals with intellectual disability and 4 individuals with variable degree of motor and speech delays. Spasticity was noted in all of the probands, which is more frequent than reported in the previously published *COPB2* patient cohort. Microcephaly was reported in 1/6 of the probands. Additional neurological features noted include high pain tolerance in 1/6 and neuropathy in 1/6 probands. With regards to the skeletal phenotype, participants were either not known to have osteopenia and fractures (2/6) or were evaluated and confirmed to have a normal bone phenotype (3/6). Interestingly, other connective tissue abnormalities, including joint hypermobility, pes planus and dental anomalies, were noted in one of the participants. In conclusion, we have identified 5 additional individuals presenting with heterozygous variants in *COPB2* and a clinical spectrum of developmental delay, spasticity, and connective tissue abnormalities. Combined with our previously published cohort, developmental delay (in 11/11 individuals) and spasticity (in 9/11 individuals) remain prominent clinical features, while osteoporosis and fractures (in 5/11) are variable. More research is required to further delineate the phenotypic spectrum and long-term outcome in patients with *COPB2*-related disorder.

Session Title: Mendelian Phenotypes Poster Session I

PB4749 Expanding the mutational spectrum in elastin-driven disease through a gene-first approach.

Authors:

T. Luperchio[1], N. Raja[1], E. Hasanzadeh[1], M. Levin[1], M. Chen[1], L. Huryn[2], M. A. Kelly[3], A. E. Justice[4], G. M. Urban[3], K. D. Yu[3], N. A. Walton[5], M. S. Williams[6,3], B. A. Kozel[1]; [1]Natl. Heart, Lung, and Blood Inst., NIH, Bethesda, MD, [2]Natl. Eye Inst., NIH, Bethesda, MD, [3]Dept. of Genomic Hlth., Geisinger, Danville, PA, [4]Geisinger, Danville, PA, [5]Intermountain Precision Genomics, Salt Lake City, UT, [6]Geisinger, Holmen, WI

Elastin is essential in the extracellular matrix and well known to be associated with vascular, skin, and pulmonary conditions. Reduction of elastin dosage (mediated by deletion or stopgain variation of gene *ELN*) is the most common mechanism of disease resulting in supravalvar aortic stenosis (SVAS). Frameshift variants in the 3' end of the molecule are associated with autosomal dominant cutis laxa (ADCL). Despite these genotype-phenotype correlations and the sufficient evidence for haploinsufficency, *ELN* does not demonstrate loss-of-function constraint (pLI=0, o/e=0.64, LEOUF=0.87). In population sequencing databases, missense variation in *ELN* is prevalent though effects on individuals' health are unknown. To understand this phenomenon, we undertook a gene-first approach to understanding the effect of *ELN* missense and splice variation on human health. Using the MyCode Community Health Initiative data, our partners at Geisinger conducted a PheWAS and medical chart review of individuals with rare missense and splice variants of uncertain significance (VUS) in *ELN* and age/sex matched controls (PheWAS only) that revealed vascular disease that was distinct from the phenotypes currently associated with elastin haploinsufficency. Individuals with relevant *ELN* variants were then enrolled in a deep phenotyping study at the NIH. To date, those individuals have displayed near complete penetrance for vascular features, with much of their pathology not captured in the existing medical record. In the first 8 deeply phenotyped individuals, relevant vascular findings include defects of arterial size in 75% (both dilation and narrowing), dissections and aneurysm (12.5%), tortuosity (37.5%) and anatomical variants of the vasculature (50%), suggesting that these VUS may impact both developmental patterning and long-term vascular integrity. While ongoing, this study has already shown that *ELN* variation has a wider mutational spectrum than previously thought, and even missense variants have the potential to confer risk for vascular outcomes. Continued study is needed to further quantify this association.

PB4750 Expanding the neurodevelopmental phenotype of HIVEP2-related disorders

Authors:

S. Finlayson[1], K. Park[1], T. Wenger[2]; [1]Univ. of Washington, Seattle Children's Hosp., Seattle, WA, [2]Univ. of Washington, Seattle Children's Hosp., Seattle, WA

HIVEP2 encodes a zinc finger containing transcription factor that is involved in several neuronal processes. The phenotype of *HIVEP2* related disorders is broad and is characterized by intellectual disability, developmental delay, hypotonia, mild dysmorphic features, hyperphagia, hirsutism, microcephaly, gastrointestinal issues, and behavioral issues including autism spectrum disorder (ASD), hyperactivity, oppositional defiance and anxiety. A recent case series by Mo et. al (2021) sought to characterize the neurodevelopmental profile of *HIVEP2*-related disorders. They reported 12 patients with *HIVEP2* pathogenic variants and used standardized assessments to evaluate levels of adaptive functioning, autism symptomatology, and emotional and behavioral characteristics. Notably, these patients were ascertained from a database of patients with pathogenic variants in genes associated with ASD and intellectual disability. Five patients in their cohort had a formal diagnosis of ASD. Their entire cohort showed impairments in all domains of adaptive behavior, as well as significant impairment in social behavior and emotional/behavioral symptoms. They concluded that individuals with *HIVEP2*-related disorder have impairments in adaptive and social-related behaviors as well as difficulties in emotional and behavioral symptoms. We report a 5-year-old patient initially referred due to macroglossia and concern for Beckwith-Wiedemann. She did not fit clinically with BWS aside from her macroglossia and was ultimately found on exome sequencing to have a frameshift pathogenic variant causing truncation of *HIVEP2*. She received early intervention services for gross motor and language delays but graduated out before age three and was not a candidate for developmental preschool. At age five she attends typical kindergarten class and can write her name. Speech language pathology evaluations had no concerns on pragmatics of speech, social reciprocity, or eye contact. She is described as very friendly and can easily make friends with peers and adults. There have been no concerns regarding her adaptive functioning. Current speech concerns are articulation likely secondary to her macroglossia as well as issues with sentence structure with telegraphic speech. Our patient suggests that there is likely a much broader neurodevelopmental phenotype of *HIVEP2*-related disorders than has been reported in the literature thus far. Particularly we may see pathogenic variants in patients who are referred for reasons other than ASD or intellectual disability, as in our patient with macroglossia as a chief complaint.

Session Title: Mendelian Phenotypes Poster Session III

PB4751 Expanding the phenotype of distal deletions in 22q11.2 deletion syndrome to include hemifacial microsomia: a case report.

Authors:

D. Mahoney[1], J. Black[2], A. B. Boura'a[3], R. Lebel[2], S. A. Tatum[4]; [1]Norton Coll. of Med., SUNY Upstate Med. Univ., Syracuse, NY, [2]Ctr. for Dev., Behavior and Genetics, SUNY Upstate Med. Univ., Syracuse, NY, [3]Crouse Hosp. Neonatal Intensive Care Nursery, Syracuse, NY, [4]Dept. of Otolaryngology, SUNY Upstate Med. Univ., Syracuse, NY

22q11.2 deletion syndrome (22q11.2 DS) is the most frequently diagnosed chromosomal microdeletion and it is highly pleomorphic. It is also referred to by many names, often assigned on the basis of certain phenotypic characteristics: velocardiofacial syndrome (OMIM #192430), DiGeorge syndrome (OMIM #188400), conotruncal anomaly face syndrome (OMIM #217095). This high degree of variability is due to haploinsufficiency of many coding genes, particularly T-box Transcription Factor 1 (TBX1, OMIM #602054), DiGeorge Critical Regions (DGCRs) such as DGCR8 (OMIM #609030), and others. About 85% of cases are caused by a recurrent ~2.54 Mb deletion of low copy number repeats (LCRs) A-D, with the remaining 15% being atypical and often smaller deletions. We saw a 13-month-old female with hemifacial microsomia, aural atresia, cleft lip, unilateral renal agenesis, nystagmus, frequent infections, and short stature. The variant identified in this patient is a 432 kbp distal deletion at 22q11.2, involving clusters C-D. The complexity and variability in 22q11.2 DS has led to the discovery of many associations with deletion size and location which could have significant implications for developmental and clinical management. Specifically, there are several reports of hemifacial microsomia, also known as oculo-auriculo-vertebral spectrum (OAVS, OMIM #164210) or Goldenhar syndrome, in 22q11.2 DS, but only a few reports have described patients with this presentation and atypical distal deletions of 22q11.2, and all have included cluster D. These deletions may in fact be a previously unrecognized genetic etiology of hemifacial microsomia, and it can potentially be asserted that it is no longer appropriate to describe such persons as having “Goldenhar syndrome” since we now understand that hemifacial microsomia is oftentimes a component of the complex phenotype associated with 22q11.2 deletion syndrome. Conversely, this indicates that Goldenhar syndrome should not be accepted as a final diagnosis unless microarray has been employed to exclude 22q11.2 DS.

Session Title: Mendelian Phenotypes Poster Session I

PB4752 Expanding the Phenotype of *ZMIZ1* Syndromic Neurodevelopmental Disorder

Authors:

P. Gupta, L. King, L. Fried; St. Joseph's Univ. Med. Ctr., Paterson, NJ

Introduction: Neurodevelopmental disorder with dysmorphic facies and distal skeletal anomalies (NEDDFSA) is a global neurodevelopmental disorder with highly variable features. Patients often show poor feeding, poor overall growth, and hypotonia from early infancy, followed by mildly delayed motor development, poor language acquisition, and behavioral abnormalities. Intellectual development varies from severe with absent speech to mild with the ability to attend special schools. Common features include dysmorphic facial features with notable eye anomalies, joint hypermobility, and mild skeletal anomalies of the hands and feet. Case Presentation: The patient was born to a 26 year old mother G1P0 at 40 weeks gestation, via normal spontaneous vaginal delivery. Pregnancy was complicated by gestational diabetes and polyhydramnios. APGARS were 9 and 9 at 1 and 5 minutes respectively. Birth weight was 7lbs 11 oz. She was admitted in the NICU for apnea, fever, poor feeding and maternal chorioamnionitis. She was noted to have left eye ptosis, bilateral hemivertebrae at T11and a PFO. Head ultrasound revealed a small 5 mm left choroidal cyst. A SNP microarray was normal and revealed a high density of short runs of allele homozygosity (ROH) observed throughout the genome. She was seen for a follow up evaluation at 3 years of age and noted to have global developmental delay, sloping, small forehead, bitemporal narrowing, prominent metopic ridge, left eye ptosis, bilateral clinodactyly; large toes, bilateral 2/3 toe syndactyly, and persistent mongolian spots on the sacrum. Whole genome sequencing on the patient and both parents was performed at a CLIA certified lab which identified a de novo, heterozygous, pathogenic variant in the *ZMIZ1* gene (c.2416_2423delinsCTTCAAACT; p.Ile806LeufsTer7). Patient has a diagnosis of autosomal dominant neurodevelopmental disorder with dysmorphic facies and distal skeletal anomalies (NEDDFSA). This variant introduces a premature termination codon on exon 22 out of 25. It is expected to result in loss of function which is an expected disease mechanism for *ZMIZ1* in this disorder. It is absent from control population and has not been previously reported in individuals with *ZMIZ1* disorders. Discussion: Patient has a diagnosis of autosomal dominant neurodevelopmental disorder with dysmorphic facies and distal skeletal anomalies (NEDDFSA). Only 33 patients have been previously identified. In addition to the previously described phenotype our patient also presented with hemivertebrae, expanding the known phenotypic spectrum for *ZMIZ1* disorders.

Session Title: Mendelian Phenotypes Poster Session II

PB4753 Expanding the phenotypic spectrum of *RAB11B*-related disorder with a case report of the oldest reported patient.

Authors:

A. Poulos[1], R. Kodvawala[1], J. Owens[2], J. Strader[2], K. Widmeyer[2], A. Shillington[2]; [1]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [2]Cincinnati Children's Hosp., Cincinnati, OH

RAB11B encodes part of the RAS GTPase subfamily involved in regulating vesicular trafficking, exocytotic/endocytotic pathways, and endosome recycling. Five previously reported patients have had pathogenic c.64G>A (p.Val22Met) or c.202G>A (p.Ala68Thr) variants that interfere with the GDP/GTP binding pocket and enhance affinity to SH3BP5. We report the sixth and oldest known patient with *RAB11B*-related disorder. The patient is a 19-year-old female with a history of cortical visual impairment, global developmental delay, intellectual disability, spastic quadriplegic cerebral palsy, microcephaly, eosinophilic esophagitis, and bilateral contractures. At 4 months, she had poor feeding, bilateral clenched fists, and hand wringing that led to an MRI revealing moderate parenchymal loss, gliosis, and prominent extra-axial spaces. She was found to have cortical visual impairment, primary optic atrophy, amblyopia, and esotropia, though she maintains functional vision. By age 5, she had limited mobility due to neuromuscular scoliosis, hypertonicity, and hip and finger contractures. Baclofen, surgery, and physical therapy allowed her to be mobile with a wheeled stander. She stood independently at age 12 but could no longer do so by age 16. Workup for ongoing feeding difficulties at 11 led to a diagnosis of eosinophilic esophagitis. At 18 she developed altered mental status with atypical laughter to no clear stimuli, decreased sleep, and no longer used the 10-20 words she spoke previously. Initial genetics workup at 14 for atypical Rett syndrome was non-diagnostic, but further workup at 18 demonstrated a de novo pathogenic c.64G>A (p.Val22Met) *RAB11B* variant. All six individuals with *RAB11B*-related disorder had intellectual disability, global developmental delay, ataxic and broad-based gait, white matter volume loss, ventriculomegaly, thinning of the corpus callosum, brainstem abnormalities, and vermian hypoplasia. Most individuals also had epilepsy, ophthalmologic abnormalities, microcephaly, and hip dysplasia. It is unclear if her loss of language / mobility and acute change in mental status at age 18 represent neurodegeneration related to *RAB11B* dysfunction, catatonia, or a currently unrecognized etiology. Similarly, it is unclear if her eosinophilic esophagitis could be related to *RAB11B*-related epithelial dysfunction or is unrelated. More research is needed to better understand the neuropsychiatric complications and multi-systemic symptoms associated with *RAB11B*-related disorder.

Session Title: Mendelian Phenotypes Poster Session III

PB4754 Expanding the phonotypic spectrum of WDFY3-related disorder: first case with cerebellar hypoplasia.

Authors:

S. Otsuji[1,2], K. Kato[1], S. Mizuno[2], S. Saitoh[1]; [1]Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan, [2]Aichi Dev.al Disability Ctr., Kasugai, Japan

Introduction: WDFY3 is a large multidomain scaffolding protein implicated in the selective degradation of ubiquitinated protein aggregates by autophagy. PH domain variants cause microcephaly, while variants putatively resulting in haploinsufficiency lead to macrocephaly. Cerebellar malformation has not been reported in a patient with a *WDFY3* variant, and thus a developmental role of WDFY3 in cerebellum is unknown. Here we report on a case with cerebellar hypoplasia, in addition to microcephaly caused by a novel heterozygous missense variant in the PH-domain of WDFY3. **Case report:** The case was 6-year-old Japanese female, who was referred to our department due to developmental delay. She was born to unrelated, healthy Japanese parents at 38 weeks' gestation with a birth weight of 2462g (-1.5SD), a height of 47cm (-0.9SD), and a head circumference of 30.5cm (-2.0SD). She had no family history of neurological disorders. Developmental delay was profound with no meaningful words, and she had a friendly personality. She showed severe microcephaly (-4.0 SD), craniofacial features, and small 5th fingers. She also showed postnatal growth retardation (−2.5 SD). Brain MRI revealed hypoplasia of the posterior cerebellar vermis and caudal medial cerebellar hemisphere but no cerebral or white matter lesions. Whole exome sequencing identified a de novo heterozygous missense variant in the PH-domain of WDFY3 (NM_014991.6:c.7821C>G;p.Ser2607Arg), which was evaluated as likely pathogenic according to the ACMG guideline. **Discussion:** This case report provides the first patient with cerebellar hypoplasia along with microcephaly associated with a de novo heterozygous missense variant in *WDFY3*. WDFY3 is known to regulate Wnt signaling in brain development. In cerebellar development Wnt signaling plays a critical role at embryonic rhombic lip (RL). Therefore, WDFY3 mutant may perturb timely attenuation of Wnt signaling at the embryonic RL. Cerebellar hypoplasia might have been missed in a patient with a WDFY3-related disorder, and serial MRI examination would be warranted.

Session Title: Mendelian Phenotypes Poster Session I

PB4755 Expanding the range of WNT signaling syndromes: a promoter variant in *WNT9B* is a candidate in a case with Femoral Facial syndrome.

Authors:

C. Marvin[1], J. X. Chong[1], K. J. Buckingham[1], K. M. Shively[1], A. F. Rope[2], University of Washington Center for Rare Disease Research, M. J. Bamshad[1,3,4]; [1]Dept. of Pediatrics, Univ. of Washington, Seattle, WA, [2]Genome Med., South San Francisco, CA, [3]Dept. of Genome Sci., Univ. of Washington, Seattle, WA, [4]Seattle Children's Hosp., Seattle, WA

The WNT family of genes encode highly conserved secreted signaling proteins expressed in embryonic and adult tissues. During embryonic development these genes regulate cell growth and differentiation through a canonical WNT/β-catenin pathway and non-canonical pathways without β-catenin. Pathogenic germline variants in WNT genes underlie a range of congenital disorders affecting the skeleton, limbs, genitourinary system, integument, dentition, and face. We report a child with clinical features consistent with Femoral Facial syndrome (FFS), also known as Femoral Hypoplasia-Unusual Facies syndrome, including bilateral femoral aplasia, cleft palate, micrognathia, talipes equinovarus, ventriculomegaly, absent septum pellucidum, and genitourinary abnormalities requiring right orchiectomy and left orchiopexy. While maternal diabetes is a known risk factor for FFS, the etiology of the condition remains unknown. Short read genome sequencing of the proband identified a non-maternally inherited heterozygous c.-2C>G variant in the 5'UTR promoter of *WNT9B*. This variant is predicted to be damaging (CADD 18) and is not present in gnomADv2.1.1, gnomADv3.1.2, or TOPMed freeze 8. *WNT9B* is expressed in mouse craniofacial and hindlimb bud tissue. Homozygous variants in *WNT9B* have been reported in two consanguineous families to underlie renal agenesis and hypoplasia with reproductive tract abnormalities but to date no condition is known to result from heterozygous pathogenic variants in *WNT9B*. Expression studies are planned to confirm the pathogenicity of this variant in *WNT9B* and the mechanism by which it may result in FFS.

Hlth.care NHS Trust, London, United Kingdom

Introduction

A thoracic aortic aneurysm (TAA) is characterised by dilatation of the aorta, which may eventually lead to a dissection (TAAD) or a subsequent fatal rupture. They tend to be asymptomatic and are often not detected till complications occur. TAAD seems to have a monogenic autosomal-dominant mode of inheritance. It can be familial and syndromic, or non-syndromic (~20% familial). Post *ACTA2* (commonest TAAD causative gene), it has become harder to detect other implicated genes due to their low incidence in the TAAD population.From a lab database of >100 TAAD probands (53 with positive family history, 38 sporadic), one of the probands, who had aortic dissection at 48 years was included in the study. The family of the proband was also affected with 2 of his sisters and a daughter having upper borderline sinus of Valsalva measurements (4, 4.2 and 3.9cm respectively). On examination, a complete profile suggestive of MFS, LDS or EDS was not found and were subsequently excluded by testing for *ACTA2*, *FBN1*, *PRKG1*, *TGFBR1/2* and *SMAD3* genes.

Methodology

WES was performed on 3 most distantly related affected individuals from the family pedigree. No known TAAD gene was found to carry a pathogenic variant in all 3 affected individuals. In-silico filtering and analyses of the data was done with an in-house protocol to shortlist candidate genes that were common to all 3 patients by removing heterozygous variants that did not segregate with the disease, had CADD scores <20, and MAF >0.001 in gnomAD and ExAC, and all homozygous variants. The MAF of the most common pathogenic variant in *ACTA2* (R258C, MAF=0.00032) was further utilised to filter the list.

Results

Out of 21,310 variants (original raw VCF file), 7 candidate genes were shortlisted: 6/7 were non-synonymous mutations *(FAT1*, *RNF213*, *KIR3DL2*, *ZNF606*, *PLA2G1B* and *TLR3*), and 1/7 was a non-frameshift deletion (*AMDHD2)*. Out of the 7 candidate genes, 2 were associated with artery wall physiology (*FAT1* & *RNF213*); 2 with immunology; 1 with oxidative injury prevention; 1 with tumour suppression and 1 with carbohydrate and amino-sugar metabolism. The expression profile (>92% in ascending aorta and smooth muscle tissue - Bgee) of *FAT1* & *RNF213* gave further supportive evidence for them as possible causative making them a priority for family segregation analyses, even though *PLA2G1B* and *TLR3* were ranked the highest by the Phenolyser. Exomiser prioritised *NOTCH3*, *RNF213* and *TLR3*. *NOTCH3* was filtered out of the candidate gene list when the *ACTA2* MAF filter was applied.

Conclusions

Family segregation analyses are being performed for these 7 TAAD candidate genes to confirm their association with TAAD phenotype.

Session Title: Mendelian Phenotypes Poster Session I

PB4758 *FGFR3* missense variant in a family with short stature

Authors:

M. Muurinen[1,2,3], O. Mäkitie[1,2,3]; [1]Res. Program for Clinical and Molecular Metabolism, Univ. of Helsinki, Helsinki, Finland, [2]Children's Hosp., Univ. of Helsinki and Helsinki Univ. Hosp., Helsinki, Finland, [3]Folkhälsan Res. Ctr., Helsinki, Finland

Pathogenic variants in the *FGFR3* gene, encoding fibroblast growth factor receptor 3, are known to cause dominantly inherited skeletal dysplasias ranging from lethal thanatophoric dysplasia to achondroplasia (ACH) and hypochondroplasia (HCH). ACH, and the less severe HCH, cause disproportionate short stature with typical findings such as macrocephaly and radiologic abnormalities. The clinical spectrum of these *FGFR3*-related skeletal dysplasias is wide, and in a few cases *FGFR3* variants have been reported to cause isolated short stature. We report a young girl with short stature, who was referred to pediatric care during infancy. Her length was -2.4 SD at birth, -4.0 SD at four months, and -4.0 at 2,5 years. Her father was of normal height and mother had short stature (139 cm) of unknown etiology. Investigations for underlying chronic illness and molecular karyotype of the child were normal. Next, a gene panel study was undertaken to find out the etiology. The gene panel, which included more than 200 genes associated with skeletal dysplasias, identified a novel heterozygous missense variant c.937G>T, p.(Gly313Cys) in the *FGFR3* gene. The variant was not present in large reference populations, and it was predicted to be pathogenic by multiple prediction algorithms. The patient was disproportionate especially in the lower limbs but did not present with the typical clinical picture of ACH or HCH, including macrocephaly and typical facial features. Radiographs showed only very mild abnormalities, including mild metaphyseal changes and slightly short femoral necks. Analysis of parental samples revealed the same variant in the child's mother, who also had short stature but lacked major features typically seen in *FGFR3*-related skeletal dysplasias. We describe a novel missense *FGFR3* variant c.937G>T, p.(Gly313Cys) in a family with significant short stature without typical ACH/HCH. Phenotype relating to this variant has not been published previously. The finding expands the phenotypic range of FGFR3 variants at the milder end of the disease spectrum. New therapies are emerging for FGFR3-related skeletal disorders, and it remains to be established whether these could be used to promote growth even in the milder forms of the disorders.

Session Title: Mendelian Phenotypes Poster Session II

PB4759 Four and a Half LIM Domains 1 variants: only a male matter?

Authors:

M. Cason[1], C. Calore[1], M. Losi[2], L. Bello[1], F. Borrelli[2], G. Canciello[2], F. Manganelli[2], S. Tozza[2], S. Chen[3], M. Bueno Marinas[1], R. Celeghin[1], M. Perazzolo Marra[1], G. Todde[2], G. Frisso[2], M. Taylor[3], R. Lombardi[2], K. Pilichou[1]; [1]Univ. of Padua, Padua, Italy, [2]Univ. of Naples, Naples, Italy, [3]Univ. of Colorado, Denver, CO

Background. Four and a Half LIM Domains 1 (*FHL1* - MIM*300163) is located on the chromosome Xq26.3 and alternative splicing of this gene is leading to three different major isoforms: *FHL1A*, *FHL1B* and *FHL1C*, with tissue specific expression patterns. FHL1A is a zinc-finger protein with multiple roles in biological processes in heart and skeletal muscle. *FHL1* rare genetic variants, inherited as dominant traits, have been associated with Scapuloperoneal myopathy (MIM# 300695) and rare cases of Hypertrophic Cardiomyopathy (HCM). *FHL1*-related cardiomyopathy is poorly characterized due to the few and isolated case series. This study aims to establish the prevalence and clinical characterization in HCM patients with *FHL1* variants.

Materials and Methods. 723 unrelated European/US HCM patients referred from 3 Referral Centers for hereditary cardiomyopathies, underwent whole exome sequencing. Data including personal and family history, physical examination, 12-lead ECG, echocardiography (ECHO) and Cardiac Magnetic Resonance (CMR) were collected for genotype-phenotype correlation. Neuro-muscular examination occurred upon request. Genetic variants were classified according to the current ACMG criteria. Cascade genetic screening was carried out.

Results. Eight of the 723 HCM index cases resulted carrying 5 unique *FHL1* genetic variants: 2 Pathogenic (P) and 3 Likely pathogenic (LP). No P or LP variants in sarcomeric genes were identified in these 8 patients. Interestingly, genetic variants identified affected all three *FHL1* trancripts.

All but one *FHL1* carriers exhibited non-obstructive HCM associated with scapulo-peroneal myopathy, documented by ECG with marked ventricular repolarization abnormalities and high rate of atrial fibrillation, ECHO and CMR showed diastolic ventricular dysfunction, atrial enlargement and variable non-ischemic patterns of late gadolinium enhancement. Cerebral palsy was observed in the *FHL1* carrier with non-obstructive HCM without scapulo-peroneal myopathy.

Four of the 8 families underwent clinical and genetic evaluation. Hemizygous carriers (males) presented frequent events of heart failure often related to arrhythmic episodes and Sudden Cardiac Death (SCD), while female heterozygous carriers showed mild cardiac phenotypes.

Conclusion. Heterozygous and hemizygous *FHL1* carriers display different degrees of a systemic disease characterized by non-obstructive HCM and scapulo-peroneal myopathy. Adverse prognosis is related to male carriers with early onset of HCM, severe diastolic dysfunction, higher risk of SCD risk and/or increased evolution toward heart failure requiring heart transplantation.

Session Title: Mendelian Phenotypes Poster Session III

PB4760 POLD3 deficiency is associated with syndromic severe combined immunodeficiency including neurodevelopmental delay and hearing impairment.

Authors:

C. Mehawej[1], E. Chouery[1], S. Azar-Atallah[1], W. Shebaby[1], V. Delague[2], I. Mansour[3], M. Mustapha[4], G. Lefranc[5], A. Megarbane[1,6]; [1]Lebanese American Univ., Byblos, Lebanon, [2]INSERM UMR_S 910, Marseille, France, [3]Faculty of Hlth.Sci., American Univ. of Sci. and Technology, Beirut, Lebanon, [4]Sheffield Univ., Sheffield, United Kingdom, [5]Université de Montpellier, Montpellier, France, [6]Inst. Jérôme Lejeune, Paris, France

Combined immunodeficiency diseases (CID) represent the most severe forms of inborn errors of immunity. Defective T cell development and/or function, leading to an impairment in adaptive immunity are responsible for these diseases. Genome duplication and maintenance, regulated by the DNA polymerase δ complex has been recently shown to contribute to CID. Biallelic mutations in *POLD1*, encoding the catalytic subunit of this complex or in *POLD2*, encoding an accessory subunit of the DNA polymerase δ have been recently linked to a syndromic CID with or without intellectual deficiency and sensorineural hearing loss. Here we report a homozygous *POLD3* variant (NM_006591.3; p.Ile10Thr) in a Lebanese patient, the product of a consanguineous family, presenting with a syndromic severe combined immune deficiency (SCID) with neurodevelopmental delay and hearing loss. POLD3 is the accessory subunit 3 of the DNA polymerase δ that stabilizes the complex. The homozygous POLD3^{Ile10Thr} variant abolishes POLD3 as well as POLD1 and POLD2 expression. Our findings implicate POLD3 deficiency as a novel cause of syndromic SCID.

Session Title: Mendelian Phenotypes Poster Session I

PB4761 Functional analysis of *ALG1* variants of uncertain significance

Authors:

E. Gillesse[1], P. Au[1,2], F. Bernier[1,2], V. Li[3], J. Parboosingh[1,2], Care4Rare Canada Consortium, A. Innes[1,2], V. Zaremberg[3], R. Lamont[1,2]; [1]Dept. of Med. Genetics, Univ. of Calgary, Calgary, AB, Canada, [2]Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada, [3]Dept. of Biological Sci., Univ. of Calgary, Calgary, AB, Canada

A common issue in the diagnosis of rare genetic diseases is identification of a single heterozygous pathogenic variant without detection of a second compounding variant in a gene associated with an autosomal recessive disorder. If a second variant cannot be identified, a molecular diagnosis cannot be confirmed. This issue may be in part due to technical limitations of first-line genetic tests, such as exome sequencing, which is primarily limited to the detection of small coding variants. In comparison, whole-genome sequencing (WGS) has better coverage across the entire genome and allows detection of all types of genetic variants, including intronic and structural variants. Here, we present two deceased siblings with severe epileptic encephalopathy in association with pachygyria and cerebellar hypoplasia, for whom a known pathogenic, paternally inherited heterozygous variant in *ALG1* was detected by initial exome sequencing. *ALG1* is associated with autosomal recessive type 1 congenital disorder of glycosylation, and was felt to be a good clinical fit for the siblings' phenotype. Using WGS, both siblings were found to carry a maternally inherited duplication of exon 10 of *ALG1*. The is the first report of a copy number variant in this gene. Further, this duplication maintains the transcript reading frame, therefore impact on protein function is not clear. Variant pathogenicity was assessed using a conditional yeast assay, as ALG1 is an essential protein in *Saccharomyces cerevisiae*. We tested our duplication of interest alongside 11 other variants of uncertain significance (VUSs) reported in the ClinVar database. Two known pathogenic and benign variants were also tested to establish assay validity. Expression clones containing the human *ALG1* sequence with the variant of interest were transformed into strains with a haploid *ALG1* knockout and the wild-type yeast *ALG1* sequence under control of an inducible *GAL1* promoter. The pathogenicity of variants was assessed based on growth of transformed yeast in nonselective media against the wild-type *ALG1* allele (glucose). Western blots identified the presence of downstream glycosylation products of ALG1. In summary, we apply a new assay design for testing variants in *ALG1* to clarify the pathogenicity of several reported VUSs, including the first reported copy number variant in this gene. These results will help confirm a molecular diagnosis for the described family, and potentially contribute to the diagnosis of other affected individuals in the future.

Session Title: Mendelian Phenotypes Poster Session II

PB4762 Functional analysis of pathogenic *LAMB1* variants in the nervous system of *Drosophila melanogaster*.

Authors:

R. Yasuda[1,2,3], H. Hashimoto[1,2], M. Oka[1,2], J-W. Mok[1,2], O. Kanca[1,2], T. Mizuno[3], S. Yamamoto[1,2]; [1]Dept. of Molecular & Human Genetics, Baylor Coll. of Med., Houston, TX, [2]Jan & Duncan Neurological Res. Inst., Texas Children's Hosp., Houston, TX, [3]Dept. of Neurology, Graduate Sch. of Med. Sci., Kyoto Prefectural Univ. of Med., Kyoto, Japan

Laminins are made from alpha, beta, and gamma subunits, which are encoded by five *LAMA*, four *LAMB*, and three *LAMC* genes in humans, respectively. Homozygous nonsense variants in *LAMB1* were originally reported in patients with congenital leukoencephalopathy and severe developmental delay. Recently, we reported the first adulthood-onset leukoencephalopathy patient with a rare homozygous missense variant. More recently, heterozygous late-truncation alleles of *LAMB1* were reported in middle-aged to elderly patients with leukoencephalopathy and hippocampal memory defects. Although nonsense, missense, and late-truncating variants in *LAMB1* are associated with a diverse severity of symptoms, the functional consequences of these variants are largely unknown. In addition, while the function of *LAMB1* orthologs has been studied during development in various model organisms, the role of this gene in the mature nervous system has been ill-defined. We have been developing genetic reagents in *Drosophila melanogaster* to study the function of human *LAMB1* and its role in the post-developmental nervous system. *Drosophila LanB1* is orthologous to all four human *LAMB* family genes. First, we found that *LanB1* is expressed in a subset of glial cells in developing and mature fly brains. Second, we found that biallelic knockout of *LanB1* causes lethality, consistent with earlier reports that this is an essential gene in flies. Third, while ubiquitous knockdown of *LanB1* also caused lethality, neuron and glia-specific knockdown failed to induce obvious phenotypes. Fourth, we found that human LAMB1 was not able to rescue the lethality of fly *LanB1* knockout mutants. These data suggest that while fly *LanB1* is an essential gene that is expressed in the nervous system during development and post-development, human LAMB1 may lack the ability to replace the function of the fly gene and additional studies are required to assess the function of this gene in the nervous system. To further assess whether *Drosophila* could be used to study the functional consequences of disease-associated variants, we designed additional transgenic lines that allow expression of human LAMB1 carrying 8 pathogenic variants. While reference and variant LAMB1 fails to induce any scorable phenotypes when overexpressed in various tissues in *Drosophila*, our preliminary data suggests that there are some differences in the subcellular location pattern of variant LAMB1 compared to the reference. In conclusion, while *Drosophila* can be used to extract biological information that is relevant to understand the mechanisms of human *LAMB1*-related disorders, there are some limitations that need to be taken into considerations.

Session Title: Mendelian Phenotypes Poster Session III

PB4763 Functional assessment of human *GLRA2*-variants associated with neurodevelopmental disorders in *Drosophila melanogaster*.

Authors:

P. Bhadane[1,2], R. Marom[3], P. Liu[1], J. Andrews[1,2], K. Jay[1,2], S. Jangam[1,2], J. A. Madden[4], M. Willemsen[5], C. Muss[6], C. Curry[7], S. Yamamoto[1,2], M. Wangler[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Houston, TX, [3]Baylor Coll. Med., Houston, TX, [4]Boston Children's Hosp., Boston, MA, [5]Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [6]Nemours/A.I duPont Hosp. for Childern, Wilmington, DE, [7]Univ California, San Francisco/ Fresno, Carmel, CA

Pathogenic variants in the *Glycine Receptor Subunit Alpha-2 (GLRA2)*, are associated with intellectual and developmental disabilities (IDD), also known as Intellectual developmental disorder, X-linked syndromic, Pilorge type (MIM 301076). We had previously established a *Drosophila* model to study the mechanism of *GLRA2* variants. In this model, we identified that loss-of-function variants lead to *GLRA2*-related IDD in males, and gain-of-function variants result in unique symptoms in female patients. We used proband variant cDNA overexpression and rescue approaches to determine gain- and loss-of-function mechanisms in flies. Here, we describe the molecular and phenotypic characteristics in five additional probands with variants in *GLRA2*. We identified missense variants in *GLRA2* (p. Gly83Arg, p. Lys310Thr and p. Arg352Gln) in four males, including two siblings, from three unrelated families. Two of the variants were maternally inherited, while segregation was not possible in one family. All probands present with variable degree of developmental delay and behavioral abnormalities, including autism spectrum disorder and attention-deficit and hyperactivity disorder. In addition, we identified a *de novo* missense variant (p. Gln220Pro) in a female proband with epileptic encephalopathy, profound intellectual disability, microcephaly, and brain malformations (abnormal cortical gyration and lissencephaly). Ocular findings included myopia in two of the male probands, and retinal dystrophy with nystagmus in the female proband. In addition, two of the probands presented with growth retardation and two of the probands were noted to have craniofacial dysmorphism (features that were not reported in our previously published cohort). We are generating the fly model for these new variants. Functional validation of the variants will be performed using overexpression and rescue experiments to compare with the previously established *GLRA2*-fly model. In summary, we report five novel *GLRA2* variants in probands with a phenotypic spectrum that fits the previously described *GLRA2*-related IDD.

Session Title: Mendelian Phenotypes Poster Session I

PB4764 Functional characterization of the developmental delay-associated 16p12.1 deletion using iPSCs.

Authors:

J. Sun[1,2,3], M. Das[1,2,3], S. Noss[1,2,3], D. Banerjee[1,2,4], S. Girirajan[1,2,5]; [1]The Pennsylvania State Univ., University Park, PA, [2]Dept. of Biochemistry and Molecular Biology, University Park, PA, [3]Molecular, Cellular, and Integrative BioSci.s Graduate Program, The Huck Inst.s of Life Sci., University Park, PA, [4]Bioinformatics and Genomics Graduate Program, University Park, PA, [5]Dept. of Anthropology, University Park, PA

Copy number variants (CNVs) are associated with neurodevelopmental disorders with heterogeneous clinical phenotypes. 16p12.1 deletion (520-kb) is a CNV that is strongly associated with developmental delay, autism, intellectual disability, and craniofacial abnormalities. Previous studies have shown that the 16p12.1 deletion interacts with variants in the genetic background to modulate clinical manifestation, suggesting a "two-hit" model for the phenotypic variability. In this study, we generated the induced pluripotent stem cell (iPSC) model with 16p12.1 deletion to characterize the deletion and its genetic interactions in the context of human genome background. We found that the deletion led to a significant increase in the number of differentially expressed genes (DEGs) as iPSCs converted to neural lineage, suggesting cell type-specific effects of 16p12.1 genes. Among the DEGs, genes such as *DLX1*, *DLX2*, and *DLX5*, which are associated with interneuron differentiation and migration, were expressed at significantly higher levels in the CRISPR/Cas9-mediated deletion line. In agreement with the RNA-seq results, we observed an increased ratio of NKX2.1-positive cells to PAX6-positive cells in neural progenitor cell (NPC) populations by immunostaining, indicating altered dorsal-ventral pattern formation caused by the deletion. Further, we performed RNA sequencing on iPSCs derived from 13 individuals (8 carriers and 5 noncarriers) from three families, as well as NPCs differentiated from the iPSCs. We identified shared and distinct DEGs among families between carrier NPC lines and noncarrier NPC lines, including known risk genes such as *FOXG1*, *CNTN6*, and *KCNQ5*. Gene ontology (GO) analyses of DEGs revealed significant enrichment related to neuronal function, such as "axon guidance", "axonogenesis", and "synapse organization", and signaling pathways, such as "Notch signaling pathway" and "Wnt signaling pathway". In addition, using EdU and TUNEL assays, we also found distinct rates of cell proliferation and apoptosis among families. Overall, our results show the effects of 16p12.1 deletion on brain development, as well as family-specific alterations on cellular phenotypes and transcriptome profiles.

Session Title: Mendelian Phenotypes Poster Session II

PB4765 † Functional filter for whole genome sequencing data identifies hereditary haemorrhagic telangiectasia non-coding *SMAD4* polyadenylation site variants 5kb from coding DNA

Authors:

C. Shovlin[1], Z. Kai[2], D. Murphy[3], D. Li[1], D. Patel[1], A. Bielowka[1], M. E. Bernabeu-Herrero[1], A. Abdulmogith[1], S. McCarley[1], A. D. Mumford[4], S. Westbury[4], M. A. Aldred[5], N. Vargesson[6], M. Caulfield[7], Genomics England Research Consortium, S. Xiao[8]; [1]Imperial Coll., London, United Kingdom, [2]Topgen Biopharm Technology Co. Ltd, Shanghai, China, [3]Imperial Coll. Hlth.care NHS Trust, London, United Kingdom, [4]Univ. of Bristol, Bristol, United Kingdom, [5]Indiana Univ., Indianapolis, IN, [6]Univ. of Aberdeen, Aberdeen, United Kingdom, [7]Queen Mary Univ. of London, Queen Mary University of London, United Kingdom, [8]Univ. of Oxford, Oxford, United Kingdom

Despite whole genome sequencing (WGS), many single gene disorder cases remain unsolved. Since early data analytic steps prioritize protein-coding sequences, we developed GROFFFY which prioritized 44.4% of the human genome based on experimental evidence of functionality, and combined with additional filters (maximum allele frequency 0.0001; minimum combined annotation dependent depletion (CADD) score 10), for WGS analyses in the UK 100,000 Genomes Project (100KGP). Data from patients with hereditary hemorrhagic telangiectasia (HHT), an autosomal dominant trait, were used for validation and variant discovery. At our reference centre, for ~1 in 7 (74/486) clinically-confirmed HHT probands, no pathogenic or likely pathogenic variants were identified by panel tests for known HHT genes (ENG, ACVRL1, SMAD4, GDF2), and recruitment to 100KGP was allowed without prior genetic testing, providing valuable datasets. First, at the time of GROFFFY application, 34 cases had HHT-causative variants already identified by 100KGP clinical pipelines. These provided a validation dataset where GROFFFY-based filtration reduced mean variants per DNA from 4,867,167 to 21,486, retaining intergenic proportions (one-third), and all HHT-causal variants. Second, since a proportion were expected to have conventional loss-of-function variants in known genes, in the "Discovery" dataset of 98 DNAs, GROFFFY was further validated by identifying clusters of variants in HHT gene coding sequences. In 3 DNAs (2 from an affected duo), unique variants were identified in the 3' untranslated region (UTR) of SMAD4. Sited 5.4kb distal to coding DNA, the deletions did not modify or generate microRNA binding sites, but instead disrupted the sequence context of the final cleavage and polyadenylation site necessary for protein production: By iFoldRNA, an AAUAAA-adjacent 16 nucleotide deletion brought the cleavage site into inaccessible neighboring secondary structures, while a 4-nucleotide deletion unfolded the downstream RNA polymerase II roadblock. Clinical correlation supported HHT-SMAD4 phenotypes (SMAD4 germline loss-of-function alleles cause a combined HHT and polyposis/aortopathy syndrome). Monocyte SMAD4 RNA expression differed between patients and controls in resting and cycloheximide-stressed states. Patterns predicted the mutational site for an unrelated clinically diagnosed SMAD4 case, where a complex insertion was subsequently identified. In conclusion, a new type of functional rare variant is described, exposing novel regulatory systems based on polyadenylation. Extension of coding sequence-focused gene panels is required to capture these variants.

PB4766 Further validation of association of bi-allelic variants in *SLC25A10* with developmental and epileptic encephalopathy.

Authors:

M. Yeole[1], P. Majethia[1], M. Jain[1], S. Siddiqui[2], S. Chakrabarty[3], G. Katta Mohan[1,4], A. Shukla[1]; [1]Kasturba Med. Coll., MAHE, Manipal, Manipal, India, [2]Dept. of Neuroimaging and interventional radiology, STAR Inst. of NeuroSci.s, STAR Hosp., Hyderabad, India, [3]Dept. of Cell and Molecular biology, Manipal school of life Sci.s,, MAHE, Manipal, Manipal, India, [4]Coll. of medicine and Hlth. Sci.s, Sultan Qaboos Univ., Muscat, Oman

Background/Objectives: Mitochondrial depletion syndrome 19 (MTDPS19; MIM #618972) is a recently described severe mitochondrial neurodegenerative disorder characterized by developmental delay, refractory seizures, neuroregression, and severe encephalopathy. Currently, one individual has been reported carrying bi-allelic missense variant in *SLC25A10* (MIM #606794).**Clinical details:** We ascertained two individuals from India, proband 1 (P1) and proband 2 (P2). P1, born from a consanguineous union presented with global developmental delay, seizure disorder with progressive encephalopathy features, regression of attained milestones and contractures at all major joints. P2, born from a non-consanguineous union presented with seizure disorder and regression of attained milestones. Singleton exome sequencing (ES) followed by Sanger validation and segregation was performed for the families.On singleton ES, we identified homozygous missense variant, c.449G>A p.(Arg150His) in P1, and c.507C>G p.(Ser169Arg) in P2 in *SLC25A10* (NM_012140.5). Sanger validation and segregation showed the variant in heterozygous state in parents of both the individuals (P1 and P2). This variant is absent in population databases like gnomAD, Singapore genome database, GenomeAsia and our inhouse database of 2849 exomes. *In silico* analysis tools predicted the variant as damaging to the protein function.Previously reported one individual with bi-allelic variants in *SLC25A10* had clinical findings of progressive form of epileptic encephalopathy with hypotonia which were similar to the phenotypes observed in P1 and P2.**Conclusion:** This report of two additional individuals provides further evidence for a novel autosomal recessive mitochondrial depletion disorder caused by pathogenic bi-allelic variants in *SLC25A10*.**Grant References:** 1R01HD093570-01A1(NIH,USA)Indian Alliance/DBT Wellcome Trust funded project, "Centre for rare disease diagnosis, research and training" (IA/CRC/20/1/600002)

Session Title: Mendelian Phenotypes Poster Session I

PB4767 † GAIN OF FUNCTION PATHOGENIC VARIANTS IN*RIT1*CAUSE CENTRAL CONDUCTING LYMPHATIC ANOMALY

Authors:

S. Sheppard[1], S. Paulissen[1], C. McInerney[2], M. March[2], D. Shukla[1], Y. Dori[2], H. Hakonarson[2], D. Li[2]; [1]NICHD/NIH, Bethesda, MD, [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Central conducting lymphatic anomaly (CCLA) is a devastating lymphatic disorder and only 40% of individuals receive a genetic diagnosis. We identified six individuals with CCLA due to pathogenic variants in *RIT1*, including one novel mosaic variant. RIT1 is a RAS GTPase lacking a CAAX domain and is involved in mitogen activated kinase signaling. Germline pathogenic variants cause Noonan syndrome, and mosaic variants have not previously been reported in association with complex lymphatic anomalies. Five out of six individuals, all with germline pathogenic variants, have typical features of Noonan syndrome. All six individuals had CCLA manifesting as pulmonary lymphangiectasia, protein losing enteropathy, pleural effusions, chylopericardium, plastic bronchitis, pleural effusions, and ascites. Dynamic contrast magnetic resonance lymphangiography demonstrated abnormalities of the thoracic duct, dermal backflow, retrograde mesenteric flow, and hepatopulmonary connections.
To evaluate the effect of the RIT1 p.Met90Ile on lymphatic development we conducted *in vitro* and *in vivo* modeling. Spheroid sprouting assay demonstrated significantly increased number of sprouts and cumulative sprout length compared to RIT1 wild type control ($n = 3$, $p < 0.05$). Using the *mrc1a* promoter, transient zebrafish transgenic larvae with mosaic expression of RIT1 p.Met90Ile in the venous and lymphatic endothelium resulted in pericardial edema in 69% (68/98) of larvae, compared to 6% (8/139) of uninjected controls ($p < 0.0001$). Additionally, about 20% (20/98) cystic malformations of the caudal plexus and 67% (66/98) had disorganized vasculature compared to 0% (0/139) and 2% (3/139) of uninjected controls, respectively ($p < 0.0001$; $p < 0.0001$).
In summary, we present the lymphatic phenotype in six individuals due to *RIT1*, including a novel mosaic variant. Our functional models will allow for further investigation of the cellular and molecular mechanisms of lymphatic dysplasia due to *RIT1* activation and facilitate therapeutic development.

Sci., Nagoya, Japan, [9]Ctr. de Référence Maladies Rares "Anomalies du développement et syndromes malformatifs", Ctr. de Génétique, FHU TRANSLAD et Inst. GIMI, CHU Dijon Bourgogne, Dijon, France, [10]Dept. of Pediatrics, Keio Univ. Sch. of Med., Tokyo, Japan, [11]Ctr. for Med. Genetics, Keio Univ. Sch. of Med., Tokyo, Japan

Background: *MYCN*, a member of the MYC proto-oncogene family, regulates cell growth and proliferation. Somatic mutations of *MYCN* are identified in various tumors, and germline loss-of-function variants are responsible for Feingold syndrome, characterized by microcephaly. In contrast, only one megalencephalic patient with a gain-of-function variant in *MYCN*, p.Thr58Met, has been reported, and additional patients and pathophysiological analysis are required to establish the disease entity. **Results:** We identified two unrelated megalencephalic patients with polydactyly harboring *MYCN* variants of p.Pro60Leu and Thr58Met. Functional analyses for MYCN-Pro60Leu and MYCN-Thr58Met revealed decreased phosphorylation at Thr58 which reduced protein degradation mediated by FBXW7 ubiquitin ligase. The gain-of-function mouse model recapitulated the human phenotypes of megalencephaly and polydactyly, while brain analyses revealed excess proliferation of intermediate neural precursors during neurogenesis, which we determined to be the pathomechanism underlying megalencephaly. Interestingly, the kidney and female reproductive tract exhibited overt morphological anomalies, possibly as a result of excess proliferation during organogenesis. **Conclusions:** We established a *MYCN* gain-of-function-induced megalencephaly-polydactyly syndrome, which showed a mirror phenotype of Feingold syndrome, and revealed that *MYCN* plays a crucial proliferative role, not only in the context of tumorigenesis, but also organogenesis.

Session Title: Mendelian Phenotypes Poster Session III

PB4769 Gene expression changes in the ossicles and long bones of the osteogenesis imperfecta mouse (*oim/oim)*: an RNAseq pilot study

Authors:

E. Carter, K. Seide, K. Brookler, C. Raggio, U. Ayturk; Hosp. for Special Surgery, New York, NY

Osteogenesis imperfecta (OI) is a group of genetic connective tissue disorders commonly caused by dominant type 1 collagen gene variants. Common findings include fractures, bone fragility, and hearing loss. Hearing loss is reported in 50-92% of people with OI, but the mechanism is not well understood. This pilot study evaluated mice with OI (*oim/oim*) for gene expression changes that might be linked to the pathogenesis of hearing loss. Identification of cell types and transcripts associated with hearing loss may suggest novel targets for hearing loss therapies in OI. This IACUC-approved study used RNA-seq on ossicles and femora isolated from 12- and 25-week-old *oim/oim, oim*/+, and wild type (WT) mice. Genotypes were detected with PCR and Sanger sequencing, later confirmed using RNA-seq data. Differential gene expression analysis was performed to detect the effects of age and genotype in each tissue type. Principal component analysis identified clear separation by tissue type, but not genotype or age. Yet, multiple age-related changes in pathways previously associated with bone formation and OI pathogenesis were identified, including those associated with *Runx2*-mediated osteoblast differentiation (FDR<0.1, except for female ossicles (FDR=0.22)) and collagen processing (males: FDR<0.1; females FDR=0.12). Genotype-related changes included elevation of osteoblast-associated transcripts (e.g. *Bglap, Col1a1*) in OI compared to wild-type controls. Male OI femurs contained more osteoblast-associated transcripts than WT femurs at 12 weeks; however, these differences diminished with age. *Runx2*-associated genes were significantly altered in female femurs (FDR<0.1), and ossicles from male and female *oim/oim* mice showed altered transcripts associated with endoplasmic reticulum and golgi activity (FDR<0.1). Transcriptional changes associated with *TFAP2A*-signaling due to genotype (FDR<0.1) were identified in both sexes. Inner ear and long bones from *oim* mice exhibit different transcriptomes, likely representing the differences in their cellular content, and age had a significant effect on the expression of osteogenic transcripts on all genotypes with the exception of male heterozygotes. This finding underscores the importance of evaluating for sexual dimorphism and aging in translational studies. RNA-seq confirmed the significance of previously identified biological processes in OI pathogenesis, and suggests a novel pathway, *TFAP2A*-signaling, that has previously been associated with temporal bone anomalies in patients with craniofacial disorders and specification of inner ear neurons.

Session Title: Mendelian Phenotypes Poster Session I

PB4770 † Generation and characterization of a novel mouse model for Free Sialic Acid Storage Disorder.

Authors:

M. Hackbarth[1,2], J. D. Burke[2], G. Elliott[2], L. Garrett[2], P. Leoyklang[2], P. Zerfas[2], D. Springer[2], M. Sabir[2], L. Pollard[3], M. Huizing[2], W. Gahl[2], M. Malicdan[2]; [1]Univ. of Maryland Sch. of Med., Baltimore, MD, [2]NIH, Bethesda, MD, [3]Greenwood Genetic Ctr., Greenwood, SC

Background: Free Sialic Acid Storage Disorder (FSASD) is an autosomal recessive lysosomal storage disorder due to biallelic mutations in *SLC17A5* and resulting in sialin transporter deficiency and subsequent lysosomal accumulation of free sialic acid in tissues and biological samples. FSASD manifests as a spectrum of clinical severity, ranging from mild developmental delay with progressive neurodegeneration, to severe infantile disease with fatal outcomes. Given the lack of approved therapies, the development of a reliable animal model is crucial for advancing preclinical translational studies.
Methods: Utilizing CRISPR/Cpf1 genome editing, we generated the *Slc17a5*^{R39C} mouse model carrying the most prevalent *SLC17A5* variant observed in FSASD patients. Extensive phenotyping was performed through biochemical, molecular, behavioral, and histological assays.
Results: *Slc17a5*^{R39C} mice displayed Mendelian distribution at birth, but homozygous animals exhibited increased perinatal lethality, with 25% dying within four weeks. Progressive neurodegeneration was evident, characterized by gait abnormalities, tremors, and discoordination. Neurological evaluations revealed significant ataxia and impaired motor performance compared to wildtype littermates. A significant proportion of mutant mice exhibited seizures. Additionally, urinary analysis demonstrated a five-fold increase in free sialic acid levels, establishing that the *Slc17a5*^{R39C} mouse is a bona fide model of the disease. Histological examination revealed hypomyelination in the corpus callosum, cerebellum, and spinal cord tracts, along with a reduction in Purkinje neurons in the cerebellum. Ongoing investigations aim to elucidate the spatiotemporal progression of these findings.
Conclusion: The *Slc17a5*^{R39C} mouse model faithfully replicates the biochemical and neurological phenotypes observed in FSASD. This model represents a valuable tool for investigating the underlying molecular mechanisms and exploring potential therapeutic interventions, particularly regarding neurodevelopmental aspects. With its relevance to human FSASD, the *Slc17a5*^{R39C} mouse provides a reliable mammalian model for future translational studies. This model holds promise for identifying longitudinal biomarkers and determining optimal treatment windows, thus enabling the development of molecular and pharmacological interventions to slow or halt disease progression.

Session Title: Mendelian Phenotypes Poster Session II

PB4771 † Generation and characterization of novel *Clec16a* knockout (*Clec16a*$^{\Delta UBC}$mCAT$^{+/+}$) mouse model where catalase overexpression is targeted to mitochondria (mCAT)

Authors:

M. Bakay[1], B. P. Strenkowski[1], R. Morrow[2], R. Pandey[1], A. Angelin[2], D. Wallace[2,3], H. Hakonarson[1,3]; [1]The Ctr. for Applied Genomics, The Children's Hosp. of Philadelphia, Philadelphia, PA, [2]The Ctr. for Mitochondrial and Epigenomic Med., The Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Dept. of Pediatrics, the Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA

GWAS have shown consistent association of the *CLEC16A* SNPs with several autoimmune diseases and most recently Parkinson disease. While the exact role of CLEC16A in health and disease is still being elucidated the protein plays a critical role in the regulation of autophagy, mitophagy, endocytosis, and intracellular trafficking. To investigate the CLEC16A role on a whole organism level we have created a *Clec16a* whole-body, inducible-knockout mouse model (*Clec16a*$^{\Delta UBC}$). These global *Clec16a* KO mice exhibit dysregulated mitophagy/autophagy and have a complex phenotype with marked immune dysfunction, rapidly progressing sensory neurodegeneration and severe lipodystrophy. Herein, considering 1) the role of CLEC16A in regulating mitochondrial health through mitophagy and 2) several positive effects in mCAT mice as a result of enhancing antioxidant activity of mitochondria, we investigated if genetic interventions rescue the *Clec16a*$^{\Delta UBC}$ phenotype by improving mitochondrial function. We generated a novel stain by crossing *UBC-Cre-ER*^{T2}*-Clec16a*$^{loxP/loxP}$ with mCAT mice to continue exploration of *Clec16a*$^{\Delta UBC}$ for loss-of-function studies. Ten-week-old mice were treated with tamoxifen for four consecutive days to create experimental *Clec16a*$^{\Delta UBC}$ ± mCAT$^{+/+}$ groups. We established a novel mouse strain and confirmed the *Clec16a* deletion and mCAT overexpression on DNA, RNA, and protein levels. A pilot experiment using 48 mice of both sexes revealed that catalase overexpression in mitochondria (mCAT) partially rescued the lipodystrophic phenotype by significantly slowing the progressive weight loss. Molecular studies are under way to evaluate if ubiquitous catalase overexpression targeted to mitochondria has positive effects in *Clec16a*$^{\Delta UBC}$mCAT$^{+/+}$ mice on neuronal and autoimmune phenotypes and how it attenuates alterations previously observed in mitophagy-related proteins, endoplasmic reticulum (ER) stress, and oxidative phosphorylation (OXPHOS). mCAT partially rescued the lipodystrophic phenotype in the novel mouse strain by significantly slowing the progressive weight loss. We propose to explore the use of mCAT overexpression to correct the phenotype arising from CLEC16A loss-of-function. Results of this study are likely to inform our understanding of how to improve mitochondrial health withstands dysregulated mitophagy. We hypothesize that using the novel *Clec16a*$^{\Delta UBC}$mCAT$^{+/+}$ model for testing drugs with modulatory effects on mitophagy, aiming at compensating for the attenuated CLEC16A activity, will be more successful and will present feasible candidates for future targeted interventions in individuals with *CLEC16A* risk variants.

Session Title: Mendelian Phenotypes Poster Session III

PB4772 Genetic analysis of Bardet-Biedl Syndrome: unraveling novel mutations and insights from consanguineous families

Authors:

N. Kakar[1], A. Gul[1], F. Rehman[2], N. Wasif[3]; [1]Dept. of Biotechnology, BUITEMS, Quetta, Pakistan, [2]Dept. of Pathology, Bolan Med. Coll., Quetta , Pakistan, Quetta, Pakistan, [3]Inst. of Human Genetics, Ulm Univ., Ulm, Germany, ulm, Germany

Bardet-Biedl Syndrome (BBS) is a rare monogenic disorder characterized by a spectrum of clinical features, including retinitis pigmentosa, polydactyly, obesity, renal anomalies, and intellectual disabilities. To date, mutations in 26 genes are known to cause BBS Syndrome. The aim of this study was to identify the underlying genetic cause and clinical manifestations of BBS syndrome in four consanguineous families segregating homozygous mutation. we performed exome sequencing in four highly consanguineous families from Pakistan affected with BBS syndrome. We were able to identify novel mutations in different BBS genes including a homozygous 1bp deletion (c.775delA) in MKKS (BBS6), resulting in a frameshift variant (p.Thr259Leufs*21), a duplication mutation in BBS5 was identified as c.159_180dup, causing a frameshift variant (p.Ser61Lysfs*32). Furthermore, a novel missense mutation, c.2014G>A (p.A672T), was detected in the BBS12 gene in a consanguineous family. Lastly, we report a homozygous mutation, c.183_184delTT, in the BBS5 gene. Clinical examination of the affected individuals of all four consanguineous families reveals phenotypic variability, highlighting the complex nature of BBS syndrome. We have thus revealed mutation across BBS genes including BBS5, BBS6, and BBS12.In summary, our study provides comprehensive insights into the clinical spectrum of BBS, and novel mutations associated with Bardet-Biedl Syndrome contribute to understanding the pathophysiology of BBS.

PB4773 Genetic Analysis of Segawa Disease Patients in Japan

Authors:

H. Fujioka[1,2], H. Shintaku[2], N. Nakano[2], T. Sakaguchi[2], T. Hamazaki[2]; [1]Kansai Univ. of Welfare Sci., Kashiwara, Japan, [2]Dept. of Pediatrics, Graduate Sch. of Med., Osaka Metropolitan Univ., Osaka, Japan

Background: Segawa disease is a rare autosomal dominant inherited disorder characterized by dopa-responsive dystonia (DRD) with diurnal fluctuation. Patients exhibit mutations in the GCH1 gene, which codes GTP cyclohydrolase I (GTPCHI). Dopamine production in the central nervous system is diminished due to a partial shortage of tetrahydrobiopterin, a co-factor of amino acid decarboxylase, which catalyzes L-dopa into dopamine. No common mutation has been reported. Some mutations are detected by gene sequences, while some are large exon deletions detected using the MLPA method.Methods: Patients exhibiting symptoms of DRD or other related involuntary movements who asked to join our study underwent measurement of biopterin and neopterin concentration in their cerebral spinal fluid and GCH1 gene analysisfrom January 2008 to December 2022. Results and Discussion: A total of 228 patients participated, of whom 68 patients (29.8%) from 53 families exhibited mutations in their GCH1 gene. Among them, 14 patients had point mutations; 20 patients from 14 families, frame-shift mutations; 14 patients from 11 families, mutations in their introns; 13 patients from 10 families, large exon deletions; 3 patients from 2 families, nonsense mutations; and 3 patients, multiple mutations in their alleles. One patient who was negative for GCH1 analysis exhibited some mutations in the PARK2 gene in a study at another institute. In our study, mutations in the GCH1 gene were detected in 29.8% of participants. Among families with mutations in the GCH1 gene, 25.9% were point mutations. The same number of families had frame-shift mutations. Intron mutations were found in 20.7% of all families. Large deletions were also found in 18.8% of families. Nonsense mutations and compound-hetero-mutations were found in two families each (3%). Conclusion: We analyzed the GCH1 gene and detected mutations in 53 families. No common mutation was detected. Many participants exhibited DRD symptoms at a young age.

Session Title: Mendelian Phenotypes Poster Session II

PB4774 Genetic background of hereditary spastic paraplegias in the Czech Republic

Authors:

A. Meszarosova[1], P. Seeman[2], I. Soldatova[2], M. Bittoova[2], P. Lassuthova[1], D. Safka Brozkova[1]; [1]Neurogenetic laboratory, Dept. of Pediatric Neurology, Second Faculty of Med., Charles Univ. and Univ. Hosp. Motol, Prague, Czech Republic, [2]GENNET, Ctr. of Clinical Genetics, Prague, Czech Republic

Introduction: Hereditary spastic paraplegia (HSP) is a rare highly heterogeneous disabling disorder manifesting with a progressive gait impairment. The disorder is caused by pathogenic variants in almost 100 known genes. We comprehensively mapped the genetic background of HSP in the Czech Republic since, until now, molecular-genetic data related to this European region has not been available. **Patients and Methods:** A total of 647 patients with a suspected diagnosis of HSP were examined using various methods. In 380 patients, only a separate examination of the *SPAST* gene (Sanger sequencing and MLPA) was performed. A total of 270 patients (predominantly pre-excluded SPG4) underwent NGS sequencing. Among these patients, 100 had early disorder onset (< 20 years of age) and the remaining 170 had onset in adulthood. **Results:** Of the total number of 647 examined patients, a genetic diagnosis was found in 171 examined (clarified 26% of examined patients). A total of 98 patients were diagnosed with SPG4 (4 diagnosed by NGS). Another 73 patients were diagnosed using NGS with other types of SPG. As expected, the most common diagnosis was SPG4 (58% of all clarified). Of the other more frequently occurring types, we detected SPG3 (6/3.5%), SPG7 (9/5.3%), SPG10 (7/4.1%), SPG11 (8/4.7%) and SPG31 (7/4.1%). Five patients were diagnosed with X-linked adrenoleukodystrophy that can manifests clinically as spastic paraparesis. We also diagnosed rare and recently described types of HSP (*KPNA3, HPDL*). In seven cases the de novo occurrence was confirmed; in all cases with early onset. Very rare types of complicated HSP (*KCNJ10, KCNA2, KY, NFU, FAR1*) were detected only in the group with early onset. In three cases, different neurological disorder was finally diagnosed (Wilson disease; Galloway-Mowat syndrome; Wieacker-Wolf syndrome); spastic paraparesis was only the primary manifestation. Segregation analysis and follow-up examination of family members genetically confirmed the diagnosis of HSP in another 62 related individuals. **Discussion:** As expected patients with SPG4 make up the largest group. The inconsistency of the methods and the partial overlap of the examined groups introduces an initial bias; the percentage of SPG4 cases is probably slightly overestimated. In patients with early onset, we emphasize the importance of a segregation analysis and a broader assessment of exome data. According to our results, we estimate the prevalence of the HSP in the Czech population to be approximately 2.5:100,000. All authors declare no conflict of interest. The research meet the criteria of Declaration of Helsinki. Supported by Ministry of Health of the Czech Republic number NU22-04-00097.

Session Title: Mendelian Phenotypes Poster Session III

PB4775 Genetic Blueprint of Congenital Muscular Dystrophies with Brain Malformations

Authors:

K. Flannery[1], S. Safwat[1,2], E. S. Cauley[3], A. Horvath[4], E. P. Hoffman[5], C. Walsh[6], M. A. Salih[7], M. Mokhtar[8], A. El Beheiry[2], E. Abdalla[2], M. Manzini[1]; [1]Dept. of NeuroSci. & Cell Biology, Child Hlth.Inst. of New Jersey, Rutgers-Robert Wood Johnson Med. Sch., New Brunswick, NJ, [2]Dept. of Human Genetics, Med. Res. Inst., Alexandria Univ., Alexandria, Egypt, [3]Dept. of Pharmacology & Physiology, The George Washington Univ., Washington, DC, [4]Dept. of Biochemistry & Molecular Med., The George Washington Univ., Washington, DC, [5]Sch. of Pharmacy & Pharmaceutical Sci., Binghamton Univ., Binghamton, NY, [6]Div. of Genetics & Genomics, Manton Ctr. for Orphan Disease Res., Howard Hughes Med. Inst., Boston Children's Hosp., Boston, MA, [7]Div. of Pediatric Neurology, Dept. of Pediatrics, King Saud Univ. Coll. of Med., Riyadh, Saudi Arabia, [8]Dept. of Radiodiagnosis & Interventional Radiology, Faculty of Med., Alexandria Univ., Alexandria, Egypt

Congenital muscular dystrophies (CMDs) are characterized by infantile hypotonia, motor delay, and progressive muscle atrophy. Severe brain involvement is also observed in subtypes such as the dystroglycanopathies Muscle Eye Brain disease (MEB) and Walker Warburg syndrome (WWS), which have 18 known disease genes, and merosin-deficient CMD (MDC1A), which is caused by mutations in *LAMA2*. Whole exome sequencing (WES) is a remarkable tool for identifying genetic variants that cause CMDs, yet many individuals remain without a genetic diagnosis. In addition, rare variants that do not directly impact protein sequence including intronic, synonymous, and noncoding regulatory variants are often overlooked. Here, we present a cohort of patients from ethnically diverse populations in three groups: one group with WWS (52 individuals from 48 families), one group with MEB (18 individuals from 16 families), and one group with MDC1A (21 individuals from 21 families). Standard analysis of variants that impact protein sequence yielded a genetic diagnosis rate of 72.9% (35/48) for WWS, 50% (8/16) for MEB, and 85.7% (18/21) for MDC1A. Additional analysis of frequently overlooked variant classes yielded several variants of interest that were previously undetected: two in the WWS group, two in the MEB group, and four in the MDC1A group. These variants require experimental validation but could improve genetic diagnosis rates to 77.0% (37/48) for WWS, 62.5% (10/16) for MEB, and 100% (21/21) for MDC1A. To expand these analyses to additional populations, we recruited a second cohort of patients diagnosed with severe CMDs with brain malformations from Egypt (12 patients from 11 families) and achieved a genetic diagnosis rate of 85.7% (6/7) for dystroglycanopathies and 100% (4/4) for MDC1A. Additionally, a regulatory variant was predicted in the remaining unsolved dystroglycanopathy case, resulting in a potential genetic diagnosis for all patients. Our findings indicate that disease-causing noncoding variants can often be detected through WES, which may be sufficient on its own to genetically diagnose all MDC1A cases. However, other strategies such as whole genome sequencing and RNA-seq are likely necessary to provide a genetic diagnosis for all dystroglycanopathy cases.

Session Title: Mendelian Phenotypes Poster Session I

PB4776 Genetic diagnosis of different dyslipidemia in Iran.

Authors:

B. Rabbani[1], N. Mahdieh[1,2], M. Agli-Moghadam[2], S. Esmaeli[1], S. Nematolahi[1], L. Hejazi[2]; [1]Growth and Dev. Res. Ctr., Tehran, Iran, Islamic Republic of, [2]Rajaie cardiovascular research center, Tehran, Iran, Islamic Republic of

Dyslipidemias affecting about 1 in 600 worldwide are defined by abnormal lipid profile. Affected individuals may show different phenotypes from being asymptomatic to milky plasma, vague abdominal pain, lipemia retinalis, nausea, vomiting, eruptive xanthomas, hepatosplenomegaly and pancreatitis. In addition to lifestyle and eating habits, genetic factors play a leading role for developing hyperlipidemias. These genetic agents are still unknown in Iran as the crossroad of the Middle East. In this study, a genetic investigation is described to unravel the involving genes in this heterogeneous population.Clinical features of the studied patients were documented. Family history and pedigrees were taken. In the first step, the following genes were sequenced *APOA5, APOC2, LDLR, APOA1, APOE, LDLRAP1 (ARH)* and *GPIHBP1*. Then, negative patients were subjected to WES to identify their causing variants.Clinical features, family pedigrees and genetic data of 63 patients were analyzed in this study. *LDLR* variant was the most common cause accounting for 8 patients. Two novel variants were identified in *LDLRAP1* and *APOA5* genes. The e2 and e4 alleles of *APOE* gene were found in 7 patients. We are analyzing the data of WES sequencing.Due to the large number of affected individuals in Iran, there should be a national planning for genetic study throughout the country since this study is the starting point. Genetic studies help for family planning and management of lifestyle and genetic counseling could decrease the burden of dyslipidemia in families.

Session Title: Mendelian Phenotypes Poster Session II

PB4777 Genetic disorders associated with dental problems in a pediatric orthodontic population

Authors:

E. Severin; Carol Davila Univ Med Pharm, Bucharest, Romania

Background: Dental anomalies associated with genetic disorders are conditions characterized by deviations from normal development and eruption of teeth and adjacent tissues, causing both morphological and functional or aesthetic changes, in both primary and permanent dentition. These anomalies can have a significant impact on the oral and general health of children, hence early evaluation and proper treatment are essential in preventing complications and additional costs.**Study aim:** The study based on our experience and a systematic review aimed to study the impact of genetic makeup on oral health in general and pediatric orthodontic population.**Materials and Methods:** The study population consisted of 526 pediatric patients between 6 and 14 years of age who presented with dental anomalies and were referred to the dental clinic. Clinical and radiographical assessments were performed, followed by detailed investigation into the personal and family medical history of the orthodontic patient.Patients with dental anomalies suggestive of certain genetic disorders underwent genetic testing, which included karyotyping or targeted gene panel sequencing. Informed consent was obtained from the guardians of the pediatric patients.**Results:** The prevalence of dental anomalies observed in this study is higher than that of the general population. Various oro-dental abnormalities were noted among orthodontic patients. The most common abnormality was hypodontia followed by microdontia, and supernumerary teeth, as well as functional abnormalities such as malocclusion, especially in the permanent dentition. The highest number of dental abnormalities was observed among patients with Down syndrome. Oro-dental anomalies (determined by genetic background) were the cause of oral health problems.**Conclusions:** Evaluating the prevalence of dental anomalies among children and diagnosing them in an early stage can help prevent complications and additional costs by ensuring prompt and adequate treatment. Therefore, it is crucial for pediatricians to anticipate the development of syndromic dental anomalies and refer patients to appropriate dental services. Performing a preventive dental examination in children aged 7 can aid in early detection and treatment of dental anomalies, ultimately improving the overall oral and general health of syndromic patients.

PB4778 Genetic landscape of developmental and epileptic encephalopathy in Mali

Authors:

S. Bamba[1], M. Dembele[1], W. Ji[2], S. Diarra[1], A. Yalcouyé[3], L. Cisse[4], A. Maiga[5], L. Jeffries[2], S. Lakhani[2], G. Landoure[6], H3AFRICA CONSORTIUM; [1]USTTB, Bamako, Mali, [2]Yale Univ., New Haven, CT, [3]USTTB, Mali, Bamako, Mali, [4]Teaching Hosp. of Point G, Bamako, Mali, [5]Univ. of Sci., Techniques and Technologie, Bamako, Mali, [6]CHU du Point G, Bamako, Mali

Background Developmental and epileptic encephalopathy (DEE) is a severe neurological disorder characterized by seizures, developmental delay, and progressive cognitive impairment. Its genetic basis remains largely unelucidated. Recent advances in genetic technologies have provided new opportunities for gene identification. **Objectives** We studied three families from Mali sharing phenotypes of DEE, caused by novel variants in the *GRIN1*, *SYNJ1* and *RARS2* genes. **Methods** Patients were examined by neurologists and DNA was obtained from whole exome sequencing (WES). Brain imaging was performed to exclude structural causes and refine the phenotype description. In addition, several bioinformatics tools were used to assess the deleteriousness of the variants, and putative variants were confirmed with Sanger sequencing in all available family members. **Results** Five patients from three unrelated families were enrolled. The mean age at diagnosis was 2.6 years (ranging from 25 days to 7 years) and symptoms started during the neonatal period with convulsive seizures and myoclonus that became refractory to antiepileptic drugs. The first patient was a boy, 25-month-old from a consanguineous family, born from a normal pregnancy and an uneventful delivery was referred for uncontrolled neonatal seizures. Symptoms started on day 4 after birth with myoclonic seizures, spasms in flexion of the upper limbs, and tonic seizures involving the four limbs. Two affected individuals (one male and one female) aged 7 and 2 years, from healthy consanguineous parents were referred for motor acquisition delay. The disease started in the first 10 days after birth with generalized tonic-clonic seizures. Neurological examination showed delayed motor acquisition, hypotonia, and general muscle amyotrophy in the four limbs and a multidirectional nystagmus in the older patient with bilateral Babinski sign. Two other affected siblings from non-consanguineous healthy parents. were seen for psychomotor delay and visual loss. Symptoms started with tonic and clonic seizures. Neurological examination found a psychomotor acquisition delay, visual loss, and clonic seizures in both patients. WES identified novel variants homozygous (p.Leu589Pro) in *GRIN1*, and *(*p.*Arg380Gln) in SYNJ1* and compound heterozygous (p.His141Arg and p.Ile150Thr) in *RARS2* genes. Several predictor tools predict these variants to be pathogenic or likely pathogenic. **Conclusion**
This study revealed novel variants in known genes associated with severe forms of DEE. This is the first report of molecularly diagnosed cases in Mali and contributes to providing further evidence of the implication of these genes.

Session Title: Mendelian Phenotypes Poster Session I

PB4779 Genetic modifiers of *FIG4* pathology

Authors:

G. Lenk[1], x. cao[2], V. Mikusevic[3], J. A. Mindell[3], M. Meisler[4]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Univ. of Michigan Hlth.System, Ann Arbor, MI, [3]NINDS, Bethesda, MD, [4]Univ Michigan, Ann Arbor, MI

Loss-of-function mutations of *FIG4* are responsible for neurological disorders in human and mouse. Loss-of-function of *FIG4* reduces the abundance of the signaling lipid $PI(3,5)P_2$, which regulates the activity of several lysosomal ion channels and transporters We investigated two functionally related genes for their potential to ameliorate *FIG4* pathology: *PIP4K2C*, another $PI(3,5)P_2$ biosynthetic gene, and *CLCN7*, a lysosomal transporter that is inhibited by $PI(3,5)P_2$.

Loss-of-function mutations of the phosphoinositide kinase *PIP4K2C* result in elevated abundance of $PI(3,5)P_2$. This suggested that we might be able to compensate for deficiency of *FIG4* by **reduced** expression of *PIP4K2C*. To test this hypothesis in a whole animal model, we crossed *Fig4*$^{-/-}$ mice with *Pip4k2c*$^{-/-}$ mice. The neonatal lethality of *Fig4* null mice on the C57BL/6J strain background was rescued by reduced expression of *Pip4k2c*. In addition, the enlarged lysosomes characteristic of *Fig4* null cells was reduced by heterozygous loss of *Pip4k2c*.

A gain of function mutation of *CLCN7* encoding ClC-7 results in enlarged lysosomes and phenocopies *Fig4*$^{-/-}$ mice. We therefore tested the ability of **reduced** *CLCN7* expression to compensate for loss of *FIG4*. In *FIG4* null HAP1 cells, knock-out of *CLCN7* corrected lysosomal swelling and partially corrected lysosomal hyperacidification. In the *Fig4* null mouse, reduction of ClC-7 by expression of the dominant negative *CLCN7* variant p.Gly215Arg improved growth and neurological function and increased lifespan by 20%.

These data indicate that reducing expression of *CLCN7* or *PIP4K2C* provides potential targets for treatment of *FIG4* deficiencies such as Charcot-Marie-Tooth Disease Type 4J.

Session Title: Mendelian Phenotypes Poster Session II

PB4780 Genetic profile of early onset Alzheimer's disease and unspecified dementia based on rare variants from pooled whole genome sequencing data

Authors:

S. Karachanak-Yankova[1,2], D. Serbezov[1], L. Balabanski[3], D. Belejanska[1], S. Mehrabian[1], M. Petrova[1], L. Traykov[1], D. Toncheva[1]; [1]Med. Univ.-Sofia, Bulgaria, Sofia, Bulgaria, [2]Sofia Univ., St. Kliment Ohridski, Sofia, Bulgaria, [3]CellGenetics Lab., Sofia, Bulgaria

Alzheimer's disease has been studied in many genetic and genomic analyses. Early onset Alzheimer's disease (EOAD) accounts for less than 5% of Alzheimer's disease cases, but it can be due to mutations in single genes established in a small fraction of families. On the other hand, unspecified dementia has been underrepresented in genetic research. In order to broaden the understanding of the single gene causes of these two forms of dementia, we have used the cost and time effective approach of whole genome sequencing of pooled DNA samples. Since whole genome sequencing data can not be used to infer individual haplotypes we have focused on rare variants which can be highly pathogenic on their own. We have collected blood DNA samples from 49 EOAD and 50 unspecified dementia patients. Equal amounts of DNA were used to construct pooled DNA samples, which were sent for 100 x whole-genome sequencing. Reads were aligned to the reference genome (GRCh37/hg19) and variants were annotated using wANNOVAR. We extracted all single nucleotide variants with rs numbers called by gnomAD. Among these we have chosen only those that have MAF < 0,001 in gnomAD non-Finish Europeans. The EOAD pool contained 5 151 635 variants, whereas the unspecified dementia pool 5 097 536 variants, among which 156 and 195 variants respectively have rs numbers and have MAF < 0,001 in gnomAD. None of these variants is found in EOAD related genes. For most of the detected variants there is insufficient available literature. Still, the interesting finding is the presence of rare variants in genes related with disorders of the brain. Thus, among EOAD patients there are variants in: *ACOT7* -regulating neuronal fatty acid metabolism; *ARSB* - progressive neurodegeneration related; *ATP8A1* -phospholipid transporter; *BCAT1*- major contributor to brain glutamate production; *KCNJ6*- in 'Down syndrome critical region'; *MACROD2*- autism susceptibility; *TNR* -neural extracellular matrix protein. The unspecified dementia pool contained variants in: *AMD1* - involved in polyamine biosynthesis; *ATRX* -chromatin remodeling; *CIAO1* - iron-sulfur cluster assembly; *CNTN4* - Ig cell adhesion molecule;*CSMD1* - complement control protein; *FAM151B* - involved in dendritic branching; *FAR1* - for reduction of fatty acids to fatty alcohol; *FRMPD4* - leading to intellectual developmental disorder; *TRPC5* - from transient receptor family. These findings point to the fact that neurological and psychiatric disorders can show overlapping etiology and that certain genetic variants can present with pleiotropic effect. Acknowledgment: The work is funded by the Bulgarian National Science Fund, project KP-06-N33/5 from 13.12.2019.

Session Title: Mendelian Phenotypes Poster Session III

PB4781 Genetic Underpinnings of Non Syndromic High Myopia in South Korea: Focus on Early Onset High Myopia

Authors:

Y. Seo[1], S. Choi[2], S. Kim[3], J. Han[4]; [1]Dept. of ophthalmology, Yonsei Coll. of medicine, Yongin, Korea, Republic of, [2]Eyereum Eye Clinic, Seoul, Korea, Republic of, [3]Inst. of Vision Res., Dept. of Ophthalmology, Severance Hosp., Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of, [4]Inst. of Vision Res., Dept. of Ophthalmology, Gangnam Severance Hosp., Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of

High myopia significantly impacts patients during their productive years. In South Korea, the prevalence of myopia (96.5%) and high myopia (20.6%) is notably high. Our study investigated the clinical and genetic aspects of non-syndromic high myopia in a South Korean cohort. The study involved 36 individuals from 27 families, with mean age 27.84±21.99 years. Criteria included a refractive error of less than -9.0D or axial length over 28mm, and early onset high myopia (EoHM), defined as a refractive error of less than -6.0D before age 10. Among the probands, 25% were EoHM. Females constituted 63.3% of the affected individuals. Genetic causes were identified in 11% of patients, including genes associated with Stickler syndrome (*COL2A1* c.1772del:p.(Gly591ValfsTer38)), pseudoxanthoma elasticum (*ABCC6* c.2542del: p.(Met848CysfsTer83)), and retinitis pigmentosa (*RP1* c.6181del : p.(Ile2061SerfsTer12)). All genetically solved cases were EoHM, related to syndromic diseases or inherited retinal dystrophies, and none were found in non-EoHM probands. These findings emphasize the role of genetic analysis in EoHM for early detection of systemic diseases or inherited retinal dystrophies, leading to appropriate genetic counseling.

Session Title: Mendelian Phenotypes Poster Session I

PB4782 Genome sequencing from 50 autism trios identified novel candidate genes with mixed inheritance pattern in the Qatari population

Authors:

V. Gupta, A. Ben-Mahmoud, F. Alshaban, H-G. Kim; Neurological Disorders Res. Ctr., Qatar BioMed. Res. Inst., Hamad Bin Khalifa Univ., Qatar Fndn., Doha, Qatar

The advent of next-generation sequencing (NGS) has revolutionized human genetics in rare genetic disorders, improving the diagnostic yield and reducing the turnaround time. While exome sequencing is commonly used for molecular diagnosis, genome sequencing (GS) has emerged as a more powerful alternative due to its extensive coverage. Despite challenges related to deep reads and managing large dataset, GS has successfully identified genetic variants associated with autism spectrum disorder (ASD). To address the underrepresentation of genetic studies on autism in the Middle East, we conducted GS on 50 trios of independent simplex autism families from Qatar with unknown etiology. They included 14 consanguineous and 36 non-consanguineous simplex families, consisting of 41 males and 9 females. Our analysis revealed diverse variants, including *de novo*, homozygous, X-linked, and compound heterozygous variants, totalling 42 missense, 2 frameshift, 2 nonsense, 1 splicing, 1 in-frame 3 nucleotide deletion,1 start loss, and 1 >200 CGG repeats of FMR-1 variants. They were found in 30 known and 20 novel candidate genes, providing an aetiologic diagnosis. The pathogenicity of these variants was substantiated by high CADD scores, their low frequency in gnomAD, reported sporadic variants, and direct physical interaction with known ASD genes. Of the participants, comprising 41 males and 9 females, 40 individuals had syndromic and 10 had non-syndromic ASD. The cohort comprised individuals from various backgrounds, including 33 Qatari (66%), 5 Syrian (10%), 2 Egyptian (4%), 2 Yemeni (4%), 2 Sudanese (4%), 1 Saudi Arabian (2%), 1 Algerian (2%), 1 Jordanian (2%), 1 Indian (2%), 1 Tunisian (2%), and 1 Palestinian (2%).The most common phenotypes observed among the probands included autism, intellectual disability, epilepsy, developmental disorders, and language/speech delay. Our preliminary findings illustrate the mixed inheritance patterns in autism families in Qatar, characterized by a high rate of consanguinity (52%). Additionally, our results highlight the association of ASD with fundamental cellular processes such as ion transport pathway, ubiquitin pathway, neuron migration, and transcription activity, which are crucial for normal cognitive development and function.

Session Title: Mendelian Phenotypes Poster Session II

PB4783 † Genome sequencing identifies second molecular diagnoses in individuals with Phelan-McDermid syndrome.

Authors:

R. Gore[1], R. Duncan[2], S. Byers[1], C. Jodarski[1], N. Reynolds-Lallement[1], M. Kamen[1], J. Yan[1], K. Lewis[1], D. Zeltser[2], B. Seifert[1], R. Ghosh[1], M. Similuk[1], M. Walkiewicz[1], A. Thurm[2]; [1]Natl. Inst. of Allergy and Infectious Diseases, NIH, Bethesda, MD, [2]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Introduction: Phelan-McDermid syndrome (PMS) is a genetic condition caused by deletions of chromosome 22q13.3 and pathogenic variants in the *SHANK3* gene. Features typically include intellectual disability, hypotonia, and absent speech, though there is considerable variability even among individuals with the same molecular finding. Our study aimed to determine the extent to which additional Mendelian molecular diagnoses exist, with exploratory questions about contribution to phenotypic variability in a cohort of patients with PMS.
Methods: Individuals with a prior diagnosis of PMS were recruited from a larger natural history study and offered genetic counseling, genome sequencing, and chromosomal microarray. Samples were collected via blood and saliva, and data was analyzed via phenotype informed and agnostic approaches. Results were CLIA-validated with Sanger analysis and returned to participating families by a genetic counselor.
Results: Fifteen individuals underwent comprehensive genetic testing. This group was 53% female, 80% white, and ranged in age from 7-48 years (mean=23). Sixty percent had a known 22q.13.3 deletion including *SHANK3* and 40% had a pathogenic variant in *SHANK3*. Genome sequencing identified a second molecular diagnosis in 7/15 participants (46.7%). Overall, 4/7 of these additional molecular diagnoses were related to neurological phenotypes, including: Charcot-Marie-Tooth disease, type4B3 (*SBF1* NM_002972.4:c.5507C>G; hemizygous due to 22q deletion), spinal muscular atrophy, lower extremity-predominant, 2A, autosomal dominant (SMALED2A) (*BICD2* NM_001003800.2:c.2108C>T), spastic paraplegia 7 (*SPG7* NM_003119.4:c.861dup and c.1045G>A), and 16p11.2 deletion syndrome. We also identified a secondary finding in *TTR* (NM_000371.4:c.424G>A) associated with TTR-related amyloidosis, as well as incidental findings in *ATM* (NM_000051.4:c.3137T>C) linked to susceptibility to breast cancer and related to the patient's family history, and in *MPEG1* (NM_001039396.2:c.181C>T) associated with Immunodeficiency 77 and the patient's personal history of recurrent respiratory infections, asthma, and folliculitis.
Discussion: Unexpectedly, nearly half of the patients in our cohort had a second molecular diagnosis on genome sequencing in addition to their known diagnosis of PMS. Our findings suggest that these "second hits" in genes related to neurological phenotypes may be an underappreciated source of variability among individuals with rare neurodevelopmental disorders and may warrant expanded research in larger patient cohorts.

Behavioral health disorders represent a major medical challenge in pediatrics, but the genetic risk factors have been understudied. To date, most of our knowledge of the genetic architecture of psychiatric disease comes from large-scale genome-wide association studies (GWAS). However, there is a scarcity of genomic data from families with multiple individuals affected by neuropsychiatric disease. For the past two years, we have conducted an IRB-approved translational research study in which we applied state-of-the-art-genomics — whole-genome sequencing and RNA-seq — to multiplex families affected by neuropsychiatric disorders, including bipolar and psychotic disorders, depression/suicidality, and autism spectrum disorder (ASD). Until now, we have sequenced 211 individuals from 58 families, comprising more than 30 Tbp of sequencing data. All individuals and available family members were comprehensively phenotyped using standard measures by a psychologist and gave informed consent to participate in the research. We analyzed genomic variants within each family to identify rare variants that might contribute to these complex, multifactorial conditions. So far, we have identified phenotypically relevant findings in 16% of families. For example, we enrolled two males with hemizygous *MECP2* variants, one of whom manifested only the psychiatric features associated with X-linked recessive *MECP2* disease. In addition, we identified *de novo* variants in strong susceptibility genes such as *SCN8A, SHANK*3, and *NRXN10* in 29% of families. We also identified rare coding variants in candidate novel susceptibility genes — *NCAN, ZSWIM6, GRIN2B*, and several *CACNA1x* cluster genes — in an additional 41% of families. To further assess the contribution of common DNA variants to disease risks in our cohort, we performed polygenetic risk score analyses for four phenotypes - major depressive disorder, bipolar disorder, attention-deficit/hyperactivity disorder (ADHD), and ASD. Interestingly, families enrolled in this study had overall higher susceptibility to ADHD compared to the 1000 Genomes population. The observed higher ASD susceptibility was specific to affected probands and was not observed among the family members. Our results suggest that while neuropsychiatric disorders that affect children have complex multifactorial etiologies, family-based genomic studies identify medically relevant variants and compelling new candidate genes.

PB4785 Genome-Wide Sequencing Implicates Monogenic Disruption of Vascular Integrity in Childhood-Onset Essential Hypertension

Authors:

E. Wonkam Tingang[1], M. Gupta-Malhotra[2], I. Copeland[3], Y. Han[1], A. Jajoo[1], A. Haldipur[1], S. Brown[1], T. Billawala[1], N. Hall[3,4], D. Scott[3,5,6], N. Lie[1,3,4], E. Banfield[1], J. Posey[3], N. Hanchard[1,3]; [1]Childhood Complex Disease Genomics Section, Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Dept. of Cardiology, Baylor Coll. of Med., San Antonio, TX, [3]Dept. of Molecular and Human Genetics, Baylor Coll. of Med., Houston, TX, [4]USDA ARS Children's Nutrition Res. Ctr., Baylor Coll. of Med., Houston, TX, [5]Texas Children's Hosp., Houston, TX, [6]Dept. of Molecular Physiology and Biophysics, Baylor Coll. of Med., Houston, TX

Childhood-onset essential hypertension (COEH) is characterized by elevated blood pressure of unknown etiology diagnosed before age 18. COEH affects ~2.1% of children in the United States, with a higher prevalence among those of self-reported African ancestries. Unlike adult-onset essential hypertension, the genetic underpinnings of COEH are unknown, but its early onset, high heritability, low correlation with environmental factors, and low prevalence, suggest a role for monogenic variation. We examined evidence for Mendelian inheritance in COEH by performing genome sequencing in 49 probands and their relatives. We identified six candidate genes with strong evidence of their involvement in hypertension in ten families (20.4%; 10/49), including *SYNE1* (three families), *HMCN1* (two), *TNS1* (two), *FBN2* (one), *THBS2* (one), and *PCDH7* (one). We also identified 14 genes with moderate evidence for involvement in hypertension in 14 families (28.5%; 14/49), with 25 families remaining unsolved (51%; 25/49). The probands of the families with identified candidates (strong and moderate, N= 24 families) were generally young (mean age = 13.6 +/- 2.9 years) without known cardiovascular disease comorbidities such as high blood cholesterol, diabetes, or obesity (91.7%; 22/24). Implicated variants in almost all candidate genes (91.7%; 22/24) showed evidence of autosomal recessive inheritance, with the resulting candidate genes (90%; 18/20) estimated to be intolerant to homozygous loss of function and predominantly expressed in vessels (80%; 16/20). All identified variants (42 missense, one stopgain, and one splicing) were predicted to be damaging to the resulting protein by multiple in silico tools and were either novel or exceedingly rare (frequency <1%) in population databases. *SYNE1*, *HMCN1*, and *TNS1* have a presumed role in activating Rho-kinase (ROCK), a protein that regulates myosin chains phosphorylation and contractility in vascular smooth muscle cells. We showed that rare, putatively protein-damaging, recessively inherited variants in *SYNE1* are strongly enriched in our cohort and among individuals of African ancestries. Knockdown of *SYNE1* in vascular smooth muscle cells resulted in increased stiffness and contractility that could be rescued by the vasodilator Fasudil (a ROCK inhibitor), consistent with the postulated role for *SYNE1* in regulating vascular tone. Cell-based assays for the other candidates and functional validations using mouse models constitute our next steps. Our results suggest that genes associated with COEH are mainly involved in vascular tone regulation, offering insights to potential therapeutic precision medicine in the future.

Rare variants contributing to Mendelian disease can occur in different allelic configurations: monoallelic (heterozygous), biallelic (homozygous or compound heterozygous), and multigenic/multiallelic. Variant transmission patterns can vary amongst different population structures, influencing the relative contributions of *de novo* and new variants to recessive or complex traits. To investigate allelic transmission in presumed recessive traits, we established a cohort study of 281 unrelated families from the Middle East and North Africa (MENA), with 241/281 (85.8%) of the families noted to have parental consanguinity from familial-history reports. The MENA cohort, comprising 726 individuals, included 335 affected subjects with neurodevelopmental disorders (NDDs) and thus served as a valuable resource for 'disease gene' discovery. Family-based exome sequencing and rare variant analyses yielded molecular findings in 127 families, including 115/281 (40.9%) with known disease genes/loci and 12/281 (4.3%) with novel candidate disease genes. Overall, 121 non-overlapping NDD genes/genomic loci were uncovered, including 106 (87.5%) distinct genes with single nucleotide variants (SNVs) and small indels and 15 (12.5%) different genomic intervals associated with copy number variants. Most variants (74%) were homozygous due to parental consanguinity; as anticipated, these variant loci were embedded within absence-of-heterozygosity blocks, derived through identity-by-decent. Notably, one case featured a homozygous whole-gene deletion of *SLC13A5* generated by *Alu/Alu*-mediated genomic rearrangement. Other allelic configurations, including *de novo* heterozygosity (11%), X-linked hemizygosity (3.1%), and biallelic compound heterozygosity (1.6%), were observed. Large genomic rearrangements (8.7%) and chromosomal abnormalities (1.6%) were also uncovered. Remarkably, 59.8% of the identified SNVs in known disease genes were novel variants. Proposed novel and candidate NDD-associated genes, including *CAPZA2, CCDC53, CDK9, COG3, GOLGA2, LIMCH1, NAV2, PPP1R3F, STX6, TRAK2, UGGT1, USP19,* are currently undergoing further studies. These findings highlight the power of integrating family-based genomic analysis, comprehensive clinical phenotyping, and international collaborative data sharing to delineate allelic series and expedite the discovery of novel NDD genes/loci, paving the way for a deeper understanding of the underlying neurobiology of disease.

PB4787 Hermansky-Pudlak Syndrome: Using AAV vectors to understand the development of HPS1 pulmonary fibrosis

Authors:

M. Behan[1], G. Nieto-Alamilla[2], S. Abudi[2], M. Hossain[2], W. Introne[2], W. Gahl[3], M. Malicdan[4]; [1]NHGRI, Bethesda, MD, [2]NIH, Bethesda, MD, [3]NHGRI (NIH), Bethesda, MD, [4]NIH, Bethesda, MD

Introduction: Hermansky-Pudlak Syndrome type 1 (HPS-1) is a rare autosomal recessive multisystemic disease caused by loss-of-function mutations in *HPS1*. Regardless of the mutation, all HPS-1 patients present with adult-onset pulmonary fibrosis (HPS1-PF) leading to death. The current treatment for HPS pulmonary fibrosis is lung transplantation, which is associated with significant morbidity. Dysfunctional alveolar epithelial type II cells (ATII) have been implicated in the pathogenesis of HPS1-PF. In this study, we investigated the role of ATII cells in HPS1-PF and evaluated the potential for gene complementation to rescue their dysfunction. Methods: We generated Hps1 knockout (HPS1-KO) mice by targeting the promoter region up to intron 3, and humanized knock-in (HPS1-KI) mice with the common human 16bp duplication HPS1 mutation using CRISPR/Cas genomic engineering. We utilized adeno-associated virus (AAV) vectors to deliver the human *HPS1* or eGFP open reading frame both intranasally (local delivery) and intravenously (systemic administration). After various timepoints, we collected lung samples and performed histological immunofluorescent assays. Results: HPS1-KO and HPS1-KI mice exhibited deficient Hps1 expression, along with characteristic features of HPS1, including oculocutaneous albinism, hypertrophy and accumulation of lamellar bodies in ATII cells, and a bleeding diathesis. These mice also exhibited enhanced pulmonary fibrosis in response to bleomycin challenge. Using different AAV vectors, we confirmed tropism of AAV containing eGFP to ATII cells via both systemic and local administration and saw evidence of eGFP transduction of macrophages and ATI cells, suggesting that Hps1 deficient ATII cells may still act as progenitor stem cells for the alveolus. Additionally, AAV-HPS1 delivered to Hps1 mice showed normalized HPS1 expression in the lungs after two weeks and evidence of reduced collagen deposition in comparison to untreated mice when challenged with bleomycin. Treated mice also showed a reduction in ATII cell hypertrophy after six months. Conclusion: This study provides evidence for the involvement of ATII cells in the manifestation of HPS1-PF and highlights the potential for gene complementation to rescue their dysfunction. Our findings contribute to a better understanding of HPS1-PF pathogenesis and offer insights for developing novel therapeutic strategies. Ongoing experiments will explore Hps1-deficient ATII cell proliferation, differentiation, and fibroblast recruitment capabilities following gene complementation.

Session Title: Mendelian Phenotypes Poster Session I

PB4788 Heteroplasmic pathogenic m.12315G>A variant in *MT-TL2* presenting with MELAS syndrome and depletion of nitric oxide donors

Authors:

F. Scaglia[1], M. Snyder[1], Y. Manor[2], S. F. Kralik[3], E. Mizerik[3], C. Gijavanekar[3], S. Elsea[3], K. Machol[4], L. Emrick[4]; [1]Baylor Col Med, Houston, TX, [2]Chaim Sheba Med. Ctr., Tel Hashomer, Israel, [3]Baylor Coll. of Med., Houston, TX, [4]Baylor Coll. Med., Houston, TX

The *MT-TL2* m.12315 G>A heteroplasmic pathogenic variant has previously been reported in two individuals with milder clinical phenotypes predominantly associated with myopathic features. Herein we report the case of a child with this heteroplasmic variant who developed neurological regression and stroke-like episodes similar to those observed in mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS). Biochemical evaluation revealed depletion of arginine on plasma amino acid analysis and low z-scores for citrulline on untargeted plasma metabolomics analysis. These findings suggest that her stroke-like episodes may be due to decreased availability of nitric oxide. The use of intravenous arginine during stroke-like episodes and enteral citrulline supplementation for home use normalized her biochemical values of arginine and citrulline. Untargeted plasma metabolomics showed the absence of nicotinamide and 1-methylnicotinamide, and plasma total glutathione levels were low, thus nicotinamide riboside and N-acetylcysteine therapies were initiated which led to normalization of metabolomics results. This report expands the clinical and metabolic phenotype associated with the rare mitochondrial variant m.12315 G>A to include neurological regression, stroke-like episodes, and decreased availability of nitric oxide donors. Individuals with this heteroplasmic variant should undergo in-depth biochemical analysis to include untargeted plasma metabolomics, plasma amino acids, and glutathione levels to help guide a timely and targeted approach to treatment.

Ctr., New York, NY, [10]Ctr. for Mendelian Genomics, Clinical Inst. of Genomic Med., UMC Ljubljana, Ljubljana, Slovenia, [11]Dept. of Med. Genetics, Univ. of Helsinki, Helsinki, Finland

ZFR codes for an RNA-binding protein characterized by its DZF (domain associated with zinc fingers) domain and of unknown function. ZFR is ubiquitously expressed in human tissues, with a high expression in the brain from early development stages to adulthood.Using next-generation sequencing and/or molecular karyotyping, we report 6 variants in *ZFR* associated with a novel neurodevelopmental disorder in 9 affected individuals from 6 unrelated families. The variants are *de novo* or autosomal dominantly inherited and include three frameshift, one nonsense, one missense variant and one large deletion encompassing *ZFR*. All *ZFR* variants were predicted to be damaging using *in silico* tools and likely lead to a loss-of-function (LOF). ZFR exhibits a high intolerance to loss-of-function (LOF) variants (pLI=1; observed/expected score=0.05). Considering these findings alongside the observed variants, it strongly indicates that haploinsufficiency is the probable underlying mechanism of the disease. Affected individuals present with neurodevelopmental abnormalities including speech delay/abnormalities, intellectual disability or learning difficulties, and global developmental delay. In addition, microcephaly, distinctive facial features and/or hypotonia were reported for some subjects.We investigated the impact of *ZFR* loss of function variants utilizing *in vivo* functional characterization of zebrafish model. Specific splice-site targeting morpholinos were used to knock-down *zfr* expression. Consistent with the human presentation, 5dpf morphant larvae exhibited microcephaly associated with swimming behavior defects.Collectively, our data indicate that heterozygous variants in *ZFR* lead to a novel neurodevelopmental disorder that can be recapitulated by knocking-down *zfr*, the orthologous gene, in zebrafish, highlighting the role of ZFR in brain development.

Session Title: Mendelian Phenotypes Poster Session III

PB4790 HiFi read sequencing reveals causative complex structural variants in a Japanese patient with severe mental retardation and microcephaly.

Authors:

K. Yanagi[1], M. Yamamori[1], A. Igarashi[1], K. Satou[1], Y. Matsubara[2], T. Kaname[1]; [1]Genome Med., Natl. Ctr. for Child Hlth.and Dev., Setagaya, Tokyo, Japan, [2]Natl. Ctr. for Child Hlth.and Dev., Setagaya, Tokyo, Japan

[Background] Long-read sequencing has made it possible to detect complex structural variants that may be difficult to detect with short-read sequencing analysis. These include repeat expansion, large insertion, inversions, deletions or translocations. We describe a successful identification of complex structural variants that are responsible for symptoms by HiFi read sequencing. [Patients] The proband was a 1-year and 3-month-old Japanese girl born at 38 weeks and 3 days gestation, normal vaginal delivery, weight 3038 g, length 48.5 cm, and OFC 30.7 cm. Her parents were healthy and nonconsanguineous. She presented severe mental retardation, microcephaly, and hypoplasia of the corpus callosum. Her facial appearance was round with arched eyebrow, low nasal root, short nose, anteverted nares and large ears. [Whole-genome analysis] We first performed short-read sequencing on the trio and segregated a CNV gain and a loss on chromosome 14 in the proband. Since detailed analysis led to the suspicion of chromosomal abnormalities, we next conducted HiFi read sequencing on the proband. [Results] Mapping to T2T-CHM13v2.0 clearly showed a CNV loss of approximately 10.7 Mb at 14q12-q13.2 including *FOXG1* and a CNV gain of approximately 2 Mb at 14q11.2 including *SUPT16H* and *CHD8*. In addition to the CNV variants, a translocation 14q13.2-14qter to 22qter was detected.[Conclusion] HiFi read sequencing clearly presented complex unbalanced chromosomal translocation. Haploinsufficiency of *FOXG1* is known to cause Rett syndrome which phenotype includes postnatal growth retardation and microcephaly, hypotonia, epilepsy, stereotypic movements and feeding problems. On the other hand, microduplication of *SUPT16H-CHD8* was shown to cause developmental delay, intellectual disability, autism spectrum disorders and macrocephaly. The proband presented severe mental retardation and microcephaly, but not stereotypic movements. We conclude both of the deletion of 14q12-q13.2 and microduplication of 14q11.2 may be responsible for the symptoms in this case.

Session Title: Mendelian Phenotypes Poster Session I

PB4791 High-content microscopy screening for drug discovery in Cohen Syndrome.

Authors:

M. Choung[1], F. Vacca[1], R. Da Costa[1], H. Barakullah[1], H. Riezman[2], M. Ansar[1,3]; [1]Dept. of Ophthalmology, Univ. of Lausanne, Jules Gonin Eye Hosp., Fondation Asile Des Aveugles, Lausanne, Switzerland, [2]Dept. of Biochemistry, Univ. of Geneva, Geneva, Switzerland, [3]Advanced Molecular Genetics and Genomics Disease Res. and Treatment Ctr., Dow Univ. of Hlth.Sci., Karachi, Pakistan

Cohen syndrome (CS) is a rare autosomal recessive disorder caused by biallelic mutations in the *VPS13B* gene. Over 100 pathogenic variants have been identified so far, mostly truncating loss-of-function mutations. It affects an estimated 50,000 individuals worldwide and is characterised by multiple clinical features, including acquired microcephaly, developmental delay, intellectual disability, neutropenia, and retinal degeneration. VPS13B is part of the chorein domain protein family, which in mammals also includes the VPS13A, -C, and -D proteins as well as the autophagy factor ATG2. These are peripheral membrane proteins with different sub-cellular localisations, but they all share similar structural features and have been proposed to act as lipid transport proteins at organellar membrane contact sites. Precise VPS13B function and the selectivity for transported lipids are not yet established, but the protein is localised at the Golgi complex, and fragmentation of this organelle is the more evident hallmark of *VPS13B*-deficient cells. We make use of this cell-autonomous morphological defect in the Golgi complex to develop a fluorescence microscopy-based assay for high-throughput screening of small molecules. We screened the Prestwick chemical library, composed of 1280 FDA-approved compounds. We identified two different classes of compounds that efficiently recover Golgi morphology in *VPS13B* knockout Hela cells: glucocorticoid receptor agonists and lysosomotropic drugs, which act as functional inhibitors of acidic lipases. For a selected number of hits, the results were further confirmed in patient-derived fibroblasts. We performed lipidomic analysis and found a general reduction in sphingolipids in *VPS13B* KO cells. Among sphingolipids, a more striking decrease was observed in the C18 n-acyl species of sphingomyelin (SM). These SM species, while of low abundance, are strongly enriched in COPI vesicles and are proposed to play a crucial role in Golgi to ER transport, linking this observation with the Golgi phenotype. Interestingly, all tested lysosomotropic drugs were able to recover the cellular level of C18 SM species in *VPS13B* KO cells, indicating a potential mechanism of action for this class of drugs. In conclusion, we developed a robust cell-based assay for the screening of small molecules and identified potential drug candidates for CS. We propose phenotypic screening as a valuable option for drug pre-selection before testing in animal models.

Session Title: Mendelian Phenotypes Poster Session II

PB4792 Highly penetrant normal-tension glaucoma risk allele maps to chromosome 12q13 and is associated with extracellular matrix dysregulation in a large family.

Authors:

W. Presley[1], S. Garnai[1], B. Guan[2], S. E. Moroi[3], B. Blevins[1], N. Michaels[1], B. Bohnsack[4], J. A. Rosenfeld[5], R. A. Lewis[5], L. Burrage[5], S. Ketkar[5], S. H. Jeong[1], R. B. Hufnagel[2], J. E. Richards[1], J. Stein, D[1], L. Prasov[1]; [1]Univ. of Michigan, Ann Arbor, MI, [2]Natl. Eye Inst., NIH, Bethesda, MD, [3]The Ohio State Univ., Columbus, OH, [4]Ann and Robert H. Lurie Children's Hosp. of Chicago, Chicago, IL, [5]Baylor Coll. of Med., Houston, TX

Glaucoma describes a group of ocular conditions characterized by degeneration of the optic nerve and is a leading cause of vision loss worldwide. While intraocular pressure (IOP) remains the largest modifiable risk factor for this disease, an estimated 30% of cases are classified as normal-tension (pressure) glaucoma (NTG) - progressive optic neuropathy despite a normal IOP measurement during clinic hours. A subset of NTG patients fail to respond to traditional IOP-lowering therapy. Understanding the molecular pathogenesis of NTG is critical to developing new therapies, and disease gene discovery in rare, highly penetrant familial cases remains one substantive approach to this end. Our group identified a 54-member pedigree with early onset, severe NTG that continued to progress despite multiple effective IOP-lowering surgeries. Genomic linkage and segregation analyses suggest an autosomal dominant inheritance pattern, but that there are multiple NTG risk alleles of high effect present in this family. Most cases, however, map to a linkage region on chromosome 12q13 with a multipoint parametric Logarithm of Odds score of 2.6 (calculated using a dominant, fully penetrant model). This region overlaps a known optic neuropathy GWAS peak and contains approximately 50 genes. RNAseq analysis from affected and unaffected familial blood samples revealed dysregulation of extracellular matrix (ECM) genes tracking with the chromosome 12 haplotype. Specifically, a Panther Gene Ontology analysis showed a downregulation of ECM structural constituents (FDR $7.3x10^{-8}$), as well as genes that function in fibrinogen, fibronectin, and integrin binding (FDRs $1.6x10^{-2}$, $2.6x10^{-3}$, and $7.1x10^{-3}$ respectively) and collagen metabolism (FDR $2.4x10^{-2}$). We have also identified a second family with NTG that is poorly responsive to traditional therapy and appears to be attributable to a variant in the same region of chromosome 12. Functional analyses for candidate gene variants within the linkage region are underway. Overall, these data support a role for ECM dysregulation in NTG pathogenesis. ECM proteins are an intriguing target as they are the primary components of the lamina cribrosa, a structure that both provides key support for the optic nerve and represents the major site of axonal damage across the different forms of glaucoma. Uncovering the genetic basis of glaucoma in these families, particularly for ECM regulation, will inform future screening and may lead to new non-IOP based treatment options for NTG and other forms of glaucoma.

Session Title: Mendelian Phenotypes Poster Session III

PB4793 HUWE1-related neurodevelopmental disorder: expanding the phenotype.

Authors:

K. Baranano[1], K. Hogan[2], M. Li[2]; [1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [2]Rush Univ., Chicago, IL

HUWE1 (HECT, UBA, and WWE Domain Containing E3 Ubiquitin Protein Ligase1) encodes an E3 ubiquitin ligase involved in targeting specific proteins for ubiquitination and degradation. HUWE1 is located on the X chromosome. The largest cohort (21) of individuals was described in 2018, but since that time, based on family involvement in social media groups, there are likely hundreds more who have been diagnosed, as well as undiagnosed adults. We describe a large series of previously unpublished individuals affected by HUWE1-related neurodevelopmental disorder. Common findings include a characteristic overall facial gestalt, especially in boys, global developmental delay, epilepsy, autism spectrum disorder, structural brain differences and short stature. Craniosynostosis is only seen with variants at one particular residue, R110. Cognitive function tended to be higher in affected girls than boys. We propose a set of management guidelines based on review of the literature and these findings.

Session Title: Mendelian Phenotypes Poster Session I

PB4794 Hyperammonemia, Hypocarnitinemia, Rhabdomyolysis and Pancreatitis in a Patient with Undiagnosed 3MethylcrotonylCoA Carboxylase Deficiency

Authors:

S. Yano, J. Borelli, R. McGowan; Univ. of Southern California, Los Angeles, CA

Background: 3methylcrotonylCoA carboxylase (3MCC) deficiency, which is an autosomal recessive disorder of leucine metabolism. The incidence is approximately 1in 40,000. This disorder is one of the most common organic acidemias diagnosed by newborn screening (NBS). Screening for many organic acidurias including 3MCC deficiency started in California in 2005. Adults born before the introduction of this expanded NBS were not tested for 3MCC deficiency. 3MCC deficiency is thought to be a benign condition since most cases are asymptomatic although metabolic decompensation, including hypoglycemia and hyperammonemia associated with hypocarnitinemia, is reported in rare cases. Some of the NBS programs have decided to exclude 3MCC deficiency and some of the individuals are no longer followed. We report on a 24-year-old male who developed a life-threatening episode triggered by strenuous exercise and was diagnosed with 3MCC deficiency. **Case Study:** We report a case of a 24-year-old previously healthy male who was hospitalized following a 13-mile hiking trip in harsh conditions due to dehydration, acute onset of emesis, generalized muscle weakness, altered consciousness due to hyperammonemia (217uM), respiratory failure requiring assisted ventilation, rhabdomyolysis with creatine kinase (CK) level of 2,977 (later increased to 8,887) units/L and renal failure. High plasma amylase and lipase levels suggesting pancreatitis were noted on admission. Throughout his clinical course, hypocarnitinemia was diagnosed. The patient was treated with carnitine (50mg/kg/d). Plasma acylcarnitine profile and urine organic acids analysis resulted after discharge showing increased plasma C5OHcarnitine, urine 3methylcrotonylglycine, and 3hydroxyisovalerate to establish the diagnosis of 3MCC deficiency. A low plasma C2carnitine was also noted. The whole exome study showed a homozygous pathogenic variant in the MCCC2 gene (c.994C>T). **Discussion**: While 3MCC deficiency is considered a benign condition, those not treated with carnitine may have more significant health risks than previously thought. Our case developed hyperammonemia causing altered consciousness as a symptom of 3MCC deficiency, a previously under-reported complication of this disorder. We also found the patient to have rhabdomyolysis and pancreatitis, which have not been reported to the best of our knowledge. Unexpected life-threatening episodes observed in our case may indicate the need for carnitine supplementation even for asymptomatic individuals with 3MCC deficiency and also raise a question as to whether NBS should include this condition.

Session Title: Mendelian Phenotypes Poster Session II

PB4795 Hyperproliferative lymphatic sprouting arising from *EPHB4* mutations can be rescued through mTOR inhibition in a cell-based model system of central conducting lymphatic anomaly.

Authors:

M. Battig[1], M. E. March[1], S. E. Sheppard[2], C. Kao[1], C. Seiler[1], D. Li[1], H. Hakonarson[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]NICHD/NIH, Rockville, MD

Central conducting lymphatic anomaly (CCLA) is a severe disorder characterized by dilated lymphatic channels and lymphatic channel dysmotility, resulting in chylothorax, pleural effusions, and lymphedema. The genetic etiology of this disorder is not well characterized, though pathogenic variants in RAS/MAPK signaling pathway genes such as *KRAS* and *ARAF* have recently been described. We have previously identified a kinase-inactivating mutation in *EPHB4* (c.2334+1G>C:p.L778_G779insLMLG) found in a patient with CCLA. *EPHB4* encodes ephrin type-B receptor 4, which binds ephrin B2 and regulates vascular processes such as angiogenesis and vascular remodeling. Here, five *EPHB4* missense variants and the insertional mutant are compared through functional studies using transduced human dermal lymphatic endothelial cells to better understand the molecular mechanism by which these mutants cause CCLA. Immunoblotting revealed that these mutations led to increased Akt/mTOR signaling. In an *in vitro* model of lymphangiogenesis, spheroids harboring the *EPHB4* mutations exhibited greater sprouting of capillary-like structures than their wild-type counterpart. Additionally, when these spheroids were treated with VEGF-C, a potent inducer of lymphangiogenesis, the increase in sprouting was greater for the mutants than for the wild-type. Furthermore, while ephrin B2 was able to suppress lymphangiogenic sprouting induced by VEGF-C of spheroids expressing wild-type *EPHB4*, it failed to curtail sprouting when these mutations were present. Finally, suppression of mTOR activity was evaluated using rapamycin (mTORC1 inhibitor) and OSI-027 (dual mTORC1/2 inhibitor). Both inhibitors were able to effectively rescue the phenotype, as observed by the reduction of sprouting to basal levels. These findings offer insight into how mutations in *EPHB4* disrupt its negative regulatory function, resulting in uncontrolled lymphangiogenesis, and how mTOR inhibitors may have therapeutic benefits in patients with CCLA and other disorders stemming from upregulation of Akt/mTOR signaling.

Session Title: Mendelian Phenotypes Poster Session III

PB4796 Identification and functional analysis of *RRAS2* variants in patients with Noonan-like phenotype

Authors:

T. Kaname[1], T. Iida[1], T. Kimura[2], H. Go[3], A. Igarashi[1], K. Fukunaga[1], T. Aoki[1], K. Yanagi[1], T. Hidai[1], M. Yamamori[1], K. Satou[1], T. Kosho[4], I. Inoue[2], Y. Matsubara[5]; [1]Dept Genome Med, Natl Ctr Child Hlth Dev (NCCHD), Tokyo, Japan, [2]Natl. Inst. of Genetics, Mishima, Japan, [3]Dept Pediatr, Fukushima Med Univ Schl Med, Fukishima, Japan, [4]Shinshu Univ. Sch. of Med., Matsumoto, Japan, [5]Natl. Ctr. for Child Hlth.and Dev., Tokyo, Japan

RASopathies are a clinically defined group of genetic syndromes caused by pathogenic variants in genes that encode components or regulators of the Ras/MAPK pathway. The RRAS2 gene abnormlity has recently been reported as one of the RASopathies caused by aberrant RAS/MAPK signalling. RRAS2, a member of the R-Ras subfamily, is a signaling molecule located in the plasma membrane. Like other RAS proteins, it is thought to regulate cell proliferation and differentiation via the RAS/MAPK pathway. Here, we report two patients with Noonan-like phenotype and functional analysis of *RRAS2* variants identified in them. One patient was an 8-year-old boy. He presented with mild developmental delay, characteristic facial features (hypertelorism, down slanted palpebral fissures, broad nasal root, low-set ears, Macrotia, mid-face hypoplasia), VSD, anal atresia. Another patient was a 2-year-old, 10-month-old boy. He presented with macrocephaly (+5.1 SD), characteristic facial features (prominent forehead, thick lower lip vermilion, hypertelorism, low-set, posteriorly rotated ears), bilateral cryptorchidism, bilateral hydronephrosis grade 2 and hepatomegaly.
After written informed consent from their parents, whole-exome sequencing and filtering analyses in trios were performed and recurrent and novel de novo variants in RRAS2, p.Gly23Val and p.Gly24Glu, were identified in the patients, respectively. We functionally analysed these variants by expressing the RRAS2 proteins in HEK293 cells and zebrafish embryos. Injection of RRAS2 mRNA (wild-type (WT), p.Gly23Val) into zebrafish embryos showed significant embryonic deformation and abnormal 4-day embryo jaw development in the mutant RRAS2 expression. Next, to measure RRAS2 activity, an activity assay system was then constructed in HEK293 cells using a luciferase reporter gene built into a serum response element (SRE), the binding site for the transcription factor ELK1, which is activated by ERK downstream of the RAS/MAPK pathway. Each RRAS2 was expressed in the HEK293 cells using an expression vector, showing the activity of RRAS2 p.Gly23Val and p.Gly24Glu was 2.45-fold and 3.06-fold higher than wild-type, respectively.
We concluded that the *RRAS2* p.Gly23Val and p.Gly24Glu found in the affected patients are gain-of-function variants, and that the patients were Noonan syndrome caused by enhanced activity of the RAS signalling pathway.

Session Title: Mendelian Phenotypes Poster Session I

PB4797 Identification and Functional Evaluation of Autosomal Recessive Non-Syndromic Hearing Impairment Genes in Rwanda

Authors:

E. Uwibambe[1], A. Wonkam[2], L. Mutesa[1]; [1]Univ. of Rwanda, Kigali, Rwanda, [2]Dept. of Genetic Med., JHU, Baltimore, MD

The incidence of hereditary hearing impairment (HI) is higher in developing countries compared to developed countries. More than 120 independent genes have been identified as responsible for almost 50% of profound HI. Non-syndromic HI is the most common form accounting for 70% of HI cases of which 80% are autosomal recessive. Reported mutations in GJB2, GJB6, and GJA genes are the most common cause of HI but studies among Cameroonian and South African participants did not identify a significant association, hence the need for further genetic exploration of responsible genes in African population. In Rwanda, more than 50% of HI among children is attributed to hereditary causes but no genetic evidence has been established. This study aims at identifying and evaluating genes responsible for autosomal recessive non-syndromic hearing impairment (ARNSHI) among Rwandan population. We have recruited 80 families with HI and 100 control individuals without HI or family history of HI. One proband per affected family has been recruited together with one unaffected sibling, both parents, and at least one affected sibling or other affected relative for blood sampling. Standard audiometry including air and bone conduction has been performed for every individual recruited, and clinical history has been taken to exclude exposure to ototoxic drugs or infections including prenatal exposure and other environmental causes of HI. Twenty-seven affected families comprising 105 individuals have been sequenced thus far. The preliminary results have shown that the gene variants that are associated with HI in Rwanda include *TCM1, MYO7A, MYO15A, USH2A, CDH23, PDZD7, CACNA1H, MYO3B, COL4A3, ERCC4, DIABLO, DMXL2, ANKRD22, KCNE1,* and *NCOA3.* For each family recruited, we will exome-sequence samples of the affected members and use Sanger sequencing to follow up variants segregating in their parents and non-affected sibling, and controls. At the end of the study, we expect to establish a dataset of genes that cause ARNSHI in Rwanda with possible novel ARNSHI genes that have not yet been reported in the African population. This will help to advance the science of HI and establish appropriate medical care including proper genetic counseling necessary for affected individuals and families as well as plan for prevention and control measures against genetic HI.

Session Title: Mendelian Phenotypes Poster Session II

PB4798 Identification of a novel pathogenic *SPTLC1* variant associated with juvenile amyotrophic lateral sclerosis born to an asymptomatic father with a mosaicism.

Authors:

S. Okubo[1], H. Naruse[1], A. Sudo[1], H. Ishiura[2], J. Mitsui[3], T. Matsukawa[1], W. Satake[1], O. Yasushi[4], S. Tsuji[5], T. Toda[1]; [1]Dept. of Neurology, Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [2]Dept. of Neurology, Okayama Univ. Graduate Sch. of Med., Dentistry and Pharmaceutical Sci., Okayama, Japan, [3]Dept. of Precision Med. Neurology, Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [4]Dept. of Neurology, Natl. Ctr. of Neurology and Psychiatry, Tokyo, Japan, [5]Inst. of Med. Genomics, Intl. Univ. of Hlth.and Welfare, Chiba, Japan

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease of the motor system, affecting upper and lower motor neurons. We experienced a 21-year-old female patient presenting with progressive muscle atrophy and weakness beginning at the age of six. Both parents were healthy without any neurological abnormalities. Neurological examination revealed cognitive decline, symmetrical weakness predominant in the distal upper extremity, muscular atrophy including the tongue, absent tendon reflexes in the upper extremities, exaggerated Achilles tendon reflexes, and positive Babinski signs. Neurophysiological testing at age 21 revealed both acute and chronic denervation without evidence of sensory neuropathy. Blood and cerebrospinal fluid examinations were unremarkable. These findings met the Awaji criteria for probable ALS and the Gold Coast criteria. Employing whole genome sequence analysis, we searched for rare variants (minor allele frequencies < 0.01) in 52 reported ALS-causative genes. The patient did not possess rare or known pathogenic variants, except for a heterozygous variant, p.Ala20Thr (c.58G>A) (NM_006415), in exon 2 of *SPTLC1* gene. This variant was absent in population databases including gnomAD, 38KJPN, and 1,163 in-house healthy control individuals. Multiple in silico predictors predicted the variant as deleterious. Interestingly, p.Ala20Ser variant involving the same amino acid has been reported to cause exon 2 skipping. A reverse transcription polymerase chain reaction (RT-PCR) analysis of the total RNA prepared from cultured lymphoblastoid cell lines revealed that the size of the RT-PCR products was consistent with that of the wild type allele, indicating that this variant does not result in exon 2 skipping. While the mother had the wild-type sequence of *SPTLC1*, the father was suspected to have a mosaic variant by inspection of the electropherogram of the direct nucleotide sequence analysis. Droplet digital PCR confirmed that relative abundance of the variant was 17% in the father's peripheral blood leukocytes. Although interpretation of the pathogenicity of p.Ala20Ser as likely pathogenic is not sufficient based on the ACMG guideline, we consider that the mosaicism in the unaffected father along with the specific phenotype of the patient as juvenile ALS supports the pathogenicity. *SPTLC1* is a gene encoding a subunit of serine palmitoyltransferase (SPT).
Recently, *SPTLC1* variants clustering in exon 2 have been shown to cause juvenile ALS. Further investigation on the functions of the mutant SPTLC1 will be needed to further clarify the pathogenetic mechanisms underlying juvenile ALS.

Session Title: Mendelian Phenotypes Poster Session III

PB4799 Identification of *CSNK2A1* variants in four unrelated Okur-Chung neurodevelopmental syndrome patients with microcephaly expands the clinical phenotypic spectrum of the disorder.

Authors:

S. Ramadesikan[1], I. Showpnil[1], A. Daley[1], E. Varga[1], M. Pastore[2], E. Sites[2], D. Bartholomew[2,3], P. White[1,3], R. K. Wilson[1,3], R. Stottmann[1,3], D. C. Koboldt[1,3]; [1]Steve and Cindy Rasmussen Inst. for Genomic Med., The Res. Inst. at Nationwide Children's Hosp., Columbus, OH, [2]Div. of Genetic and Genomic Med., Nationwide Children's Hosp., Columbus, OH, [3]Dept. of Pediatrics, The Ohio State Univ. Coll. of Med., Columbus, OH

Nearly 40% of neurodevelopmental disorders are caused by *de novo* coding variants, many of which impact genes that are critical in embryonic brain development. In this study, we describe four patients from three unrelated families who shared several clinical features characteristic of an underlying syndromic neurodevelopmental condition, including microcephaly, dysmorphic features, hypotonia, intellectual disability, and developmental delays. Clinical whole exome sequencing and research genome sequencing under an IRB-approved study protocol revealed that all affected individuals harbored heterozygous pathogenic missense variants in the gene *CSNK2A1*. *CSNK2A1* encodes a Serine/Threonine kinase called casein kinase 2 alpha subunit 1 (also known as CK2A1), which phosphorylates nearly four hundred downstream target proteins in cells, thereby participating in many essential cellular processes that aid in neuronal development and homeostasis. *De novo* heterozygous alterations in *CSNK2A1* cause autosomal dominant Okur- Chung neurodevelopmental syndrome (OCNDS; OMIM #617062). Of the three variants (c.468T>A p.D156E, c.137G>T p.G46V, c.149A>G p.Y50C) identified in this study, two are novel ((c.468T>A p.D156E, c.137G>T p.G46V) and previously unreported in literature. Notably, while most reported variants are *de novo*, one of the variants in this study (c.137G>T p.G46V) was inherited and segregated across multiple affected individuals in the family, an observation reported only once previously.
This recently identified syndrome has an evolving clinical phenotype predominantly characterized by dysmorphic features, intellectual disability, global delays, gastrointestinal and immunological manifestations, with microcephaly currently considered an infrequent occurrence. Interestingly, we report microcephaly in three of our four patients, two of whom are related and share the inherited variant. Detailed phenotypic analysis revealed that microcephaly has been reported in ~35% of *all* patients reported in literature (including this study) with no apparent genotype-phenotype correlation. Our findings highlight the recurrence of microcephaly in OCNDS and the need for progressive neurological evaluation of OCNDS patients as part of their clinical management.

Session Title: Mendelian Phenotypes Poster Session I

PB4800 Identification of de Novo Variants in Genes Involved in Ubiquitylation in Patients with Chronic Recurrent Multifocal Osteomyelitis (CRMO)

Authors:

A. Cox[1], B. W. Darbro[2], X. Bing[2], E. Phillippi[2], G. Velez[3], R. M. Laxer[4], Y. Zhao[5], V. B. Mahajan[3], H. El-shanti[2], A. G. Bassuk[2], P. J. Ferguson[2]; [1]Univ. of Rochester Med. Ctr., Rochester, NY, [2]Univ. of Iowa, Iowa City, IA, [3]Stanford Univ., Palo Alto, CA, [4]Hosp. for Sick Kids, Toronto, ON, Canada, [5]Seattle Children's Hosp., Seattle, WA

Chronic recurrent multifocal osteomyelitis (CRMO) is a rare autoinflammatory disease characterized by bone pain and sterile inflammatory osteolytic lesions. Often children are also diagnosed with psoriasis, Crohn disease, or other inflammatory conditions, and these more common diseases are frequently present in close relatives of probands with CRMO. Because patients present with a family history of autoimmune/autoinflammatory disease including some families with CRMO-affected siblings, CRMO is likely a genetic disease.

Genetic analyses of both patients with CRMO and mouse models of inflammatory bone disease have implicated the involvement of *Pstpip2*, *FBLIM1*, *FGR*, and *MLKL* variants in disease pathogenesis. Recently, in collaboration, *FGR* variants were identified in both a mouse strain (*Ali18*) with paw inflammation and systemic reduced bone density, and in a proband who harbored a *de novo* missense variant. This proband is part of a cohort of 105 families with a child or children with CRMO. We performed whole exome sequencing of the probands and their parents to identify candidate genes involved in the pathogenesis of CRMO. The families were investigated for coding *de novo* variants.

Over one hundred coding *de novo* variants were identified, including multiple variants in genes known to be involved in ubiquitylation. Dysregulated ubiquitylation has been implicated in other autoinflammatory disorders including those caused by germline or somatic pathogenic variants in *OTULIN*, *TNFAIP*3, and *UBA1*. The *de novo* variants identified in the patients with CRMO are in genes directly involved in ubiquitylation and also known to regulate NF-kB and/or inflammasome activation. Functional analysis of top candidate variants is currently underway.

This study is the largest genetic analysis of patients with CRMO to date. CRMO is a rare autoinflammatory disease with a mostly elusive genetic etiology and our results highlight the genetic complexity of its pathogenesis. These findings, in combination with prior knowledge gained by analysis of other families and mouse models of inflammatory arthritis, support a linked network of genes and biological processes which are aberrant in diseased patients.

Session Title: Mendelian Phenotypes Poster Session II

PB4801 Identification of different genetic variants causing recessive neurodevelopmental syndromes with intellectual disability in Pakistan.

Authors:

A. Rasheed[1], S. Fatima[1], T. Sultan[2], F. Alzahrani[3], A. Iftikhar Butt[1], G. Seo[4], F. Alkuraya[5], S. Naz[1]; [1]Univ. of Punjab, Lahore, Pakistan, [2]Children's Hosp. & the Inst. of Child Hlth., Lahore, Pakistan, [3]King Faisal Specialist Hosp. & Res. Ctr., Riyadh, Saudi Arabia, [4]3billion inc., Seoul, Korea, Republic of, [5]King Faisal Specialist Hosp. & Res. Ctr., Riyadh, Saudi Arabia

Neurodevelopmental disorders (NDDs) affect about 3 to 5% of the population worldwide. These conditions disrupt the development, physiology, and functioning of the brain. Motor function, communication, cognition, learning, and language may also be affected. We studied NDD syndromes in nine Pakistani families. Patients were identified and recruited from a hospital in Lahore and Rahim Yar Khan. Clinical examinations were completed by doctors at the hospitals. The patients displayed intellectual disability and global developmental delay with additional phenotypes which included facial dysmorphism, microcephaly, abnormal movements of the head and eyes, hypotonia, or epilepsy in some affected individuals. We employed exome sequencing to identify the molecular basis of NDD in the patients. Exome data were filtered to obtain homozygous variants having allele frequencies of less than 1% in various population databases. Variants shared by multiple patients in a family were selected. The missense variants were further prioritized based on the conservation of affected amino acids in 100 vertebrate species. Compound heterozygous variants were also checked in case no predicted homozygous pathogenic variant was observed. Variant segregation for each family was verified by PCR amplification of DNA samples of all participants followed by Sanger sequencing. We identified known variants in *MAN2B1, SAMHD1,* and *VPS13B* as well as six novel variants in *EPG5, ERRC8, ETHE1, RNASEH2A,* and *UBE4A,* as causing various recessive neurodevelopmental syndromes. Our work extends the allelic spectrum of NDD. It facilitates genetic counseling of the participating families and will help in prenatal diagnosis to those inclined to its use.

Session Title: Mendelian Phenotypes Poster Session I

PB4803 Identification of novel mutations in *MCPH1* gene in Pakistani family with microcephaly

Authors:

S. Irshad[1], z. riaz[2]; [1]Sch. of Biochemistry and Biotechnology, Univ. of the Punjab, Lahore, New York, NY, [2]Sch. of Biochemistry and Biotechnology, Univ. of the Punjab, Lahore, Lahore, Pakistan

Background: Primary microcephaly (MCPH) is a congenital, static, and non-progressive neurodevelopmental disorder associated with reduced head circumference (< 4 standard deviations). About 28 known genes are associated with the MCPH. The study was carried out to probe molecular basis and genetic variants involved with MCPH in an affected Pakistani family to better understand the etiology and prevalence of the disorder. **Methods:** The individuals of the ascertained Pakistani family presented primary microcephaly, along with intellectual disability, speech disorder, and motor delay. By ensuring ethical compliance and patient consent, blood samples were collected from affected individuals. DNA was extracted using the salting out method followed by whole-exome sequencing and Sanger sequencing to identify causative genetic variants or mutations. In silico studies were performed to predict the effect of mutations on the structure of target proteins. **Results:** Two missense allelic variants (NM_024596.5: c.139G>C and NM_024596.5: c.211G>C) of *MCPH1* gene were detected in a Pakistani family. In silico analysis was performed to evaluate the effect of the mutant protein. The mutation in genes affects the activities of proteins NM_024596: p. Val47Leu and NM_024596: p. Val71Leu respectively by disruption in protein structure. The mutations were predicted to have higher pathogenicity scores and have significantly influenced the prevalence of MCPH. We reported two novel genetic variants for the first time from the Pakistani population causing MCPH. **Conclusions:** Mutations in *MCPH1* gene are one of the major cause of MCPH in the populations where consanguine marriages are common. The novel mutations identified in this study will help to understand the etiology of the disorder and the mechanisms of mutated proteins.

Session Title: Mendelian Phenotypes Poster Session II

PB4804 Identification of novel variants responsible for monogenic diabetes in Tunisia using Whole Exome Sequencing : impact on diagnosis and treatment.

Authors:

Inst. of Nutrition and Food Technology, 11 rue Jebel Lakhdar, Bab Saadoun, 1007 Tunis, Tunisia., Tunis, Tunisia, [7]Lab. of Clinical Biochemistry and Hormonology, Inst. Pasteur de Tunis, BP 74, 13 Place Pasteur, 1002 Tunis, Tunisia, Tunis, Tunisia, [8]Lab. of Clinical Immunology, Inst. Pasteur de Tunis, BP 74, 13 Place Pasteur, 1002 Tunis, Tunisia., Tunis, Tunisia, [9]Inst. Natl. de Nutrition de Tunis, Tunis, Tunisia

Introduction: Monogenic Diabetes (MD) are atypical form of diabetes that consist 3 to 6% of all cases of diabetes. This prevalence is underestimated due to the overlapping clinical features with type 1 and type 2 diabetes. Hence, genetic testing is the most appropriate tool for an accurate diagnosis. Studies carried out in Europe, Asia and the United States have reported clinical, phenotypic and genetic heterogeneity in MD. However, epidemiological studies of these atypical and syndromic forms of diabetes are scarce in Low- and Middle-Income countries, such as Tunisia. The genetic structure of Tunisian population is characterized by a rich and heterogeneous landscape resulting from the admixture of ethnic groups originating from North Africa, Europe, Near East and sub-Saharan Africa. The aim of this study is to identify genetic loci and causative mutations in Tunisian suspected MD patients using Whole Exome Sequencing “WES”. Through this study, we hope to aid clinicians in making better choices for the treatment of diabetic patients. **Materials and Methods:** WES was performed among 10 diabetic patients recruited from collaborating medical center. Inclusion criteria were: young age of diabetes onset ≤ 40 years old, Family history of diabetes in at least two generations and absence or low pancreatic autoantibodies titers. The pathogenicity of genetic variation was assessed using combined filtering and bioinformatics prediction tools. The online ORVAL tool has been used to predict the potential pathogenic variants combinations. Then, Sanger sequencing was carried out to confirm likely pathogenic predicted mutations among patients and to check for familial segregation. Finally, for novel variants, we completed structural modeling to study their impact on protein function. **Results:** We identified pathogenic variants located in *ABCC8, RFX6, GCKR, PDX1, KANK 1, PPP1R3A, TTC8, ALMS1* and *WFS1*genes. We highlighted the presence of syndromic forms of diabetes including Bardet-Biedl syndrome, Alström syndrome and Wolfram syndrome as well as the presence of isolated diabetes with considerably lower penetrance for symptoms associated with Wolfram syndrome. Idiopathic type 1 diabetes was also identified in one patient. **Conclusion:** In this study, we emphasized the importance of genetic screening for MD using WES in patients with familial history of diabetes among admixed and under-represented populations. An accurate diagnosis with molecular investigation of MD may improve the therapeutic choice for better management of patients and their families. Additional researches are required to better understand phyisiopathological mechanisms of MD.

Session Title: Mendelian Phenotypes Poster Session III

PB4805 Identification of UBE3A substrates through an *in vivo* ubiquitin activated interaction trap (UBAIT) approach in Drosophila

Authors:

B. Geier, L. Reiter; Univ. of Tennessee HSC, Memphis, TN

Autism spectrum disorder (ASD) is a complex and chronic condition associated with difficulties in social interactions, communication, and obsessive interests. Although the underlying causes of ASD remains elusive, duplications of the 15q11.2-q13.1 region, also known as the Prader-Willi/Angelman critical region (PWACR), are found in approximately 1-3% of all ASD cases, making this duplication one of the most common cytogenetic abnormalities found in ASD. Within the PWACR is the paternally imprinted gene *UBE3A*, which encodes for ubiquitin ligase E3A (UBE3A/E6AP). Mutations affecting *UBE3A* maternal expression levels can result in Duplication 15q (Dup15q) or Angelman syndrome (AS). Notably, both disorders have high rates of ASD and epilepsy, emphasizing the need for substrate identification. Previous efforts to pair cell culture with immunoprecipitation and mass spectrometry have thus far only identified a select few proteins as valid UBE3A ubiquitin substrates. Our lab has implemented an in vivo approach using the ubiquitin-activated interaction trap (UBAIT) in living *Drosophila melanogaster*. The UBAIT system covalently traps proteins ubiquitinated by *Drosophila* UBE3A (Dube3a), allowing for subsequent purification and identification via mass spectrometry. Analysis of UBAIT-purified peptides revealed enrichment and overlap in our global (*actin-GAL4*), neuronal (*nSyb-GAL4*), and glial (*repo-GAL4*) cell groups. Due to the high volume of Dube3a substrate candidates and physical time constraints, we focused our downstream validation studies on proteins with strong homology between *Drosophila* and humans that were in a size range more manageable for in vitro ubiquitination assays. We are currently verifying which candidate Dube3a substrates are poly-ubiquitinated in a Dube3a-dependent manner using both *in vitro* ubiquitination and GFP pulldown assays. We found that both synapse-associated protein 47kD (Sap47) and annexin B10 (AnxB10) are true Dube3a substrates in these assays. We will continue screening candidate fly proteins *in vitro* and subsequently validate their mammalian homologs. Not only will this research contribute to our understanding of the proteins dysregulated in Dup15q syndrome, AS, and ASD, but it will provide an improved resolution regarding the cell type(s) where UBE3A plays a functional role.

Session Title: Mendelian Phenotypes Poster Session I

PB4806 Identification of variants underlying biparietal perisylvian polymicrogyria in Finnish families

Authors:

I. Järvelä[1], R. A. Paetau[2], A. Acharya[3], **Y. Rajendran**[3], I. Schrauwen[3]; [1]Dept. of Med. Genetics, Univ. of Helsinki, Helsinki, Finland, [2]Dept. of Child Neurology, Univ. of Helsinki, Helsinki, Finland, [3]Ctr. for Statistical Genetics, Gertrude H. Sergievsky Ctr., and the Dept. of Neurology, Columbia Univ. Med. Ctr., New York, NY

Bilateral perisylvian polymicrogyria (BPP) is the most common form of regional polymicrogyria (PMG) that belongs to malformations of cortical development (MCDs). BPP is characterized by overfolding of the cerebral cortex and abnormal cortical layering. The major clinical features include oromotor dysfunction, dysarthria, and hemiparesis. Cognitive impairment and epilepsy are common. By now, more than 50 genes are reported to underlie PMG covering about 20% of cases. Mosaicism has been identified in some cases. The aim of this study was to identify genetic background of BPP in the Finnish families. A total of 22 Finnish families with BPP were enrolled in the study. There were 18 trios, three duos and one singleton case. In all cases brain imaging using MRI showed BPP. All participants were studied using exome sequencing (ES) (Illumina Inc, San Diego, CA) from peripheral blood DNA. Of them, eight ES negative cases were also analyzed using optical genome mapping (OGM) (Bionano Inc,San Diego). In addition, deep sequencing (200x) of buccal DNA samples was applied for nine cases negative for conventional ES and OGM. Buccal DNA was extracted using the Oragene assisted DNA collection kit (DNA Genotek) to identify mosaic variants that may be specific to ectodermal lineage cells. The results were confirmed by Sanger sequencing. To date, pathogenic (P) or likely pathogenic (LP) variants were found in 6/22 (27 %) patients using conventional ES. Of them, four were de novo/likely de novo (*SCN3A, TUBA1A, DDX23 and TUBB2B*), one autosomal recessive (*CCDC82*), one X-linked (*TAF1*) and one VUS (*AFF2*). In addition, two novel candidate genes were found (*RUFY4 and BOC*). Preliminary analyses of deep sequencing revealed a novel variant in *NEDD4L and one in SON* in two cases respectively. Full results will be presented at the meeting. The study was approved by the ethics committees of the Hospital District of Helsinki and Uusimaa and the Institutional Review Boards of Columbia University (IRB-AAAS3433). Written informed consent was obtained from healthy adult subjects and the parents/legal guardians of minors and study subjects. The authors report no conflict of interests. Grants: Helsinki University Central Hospital subsidiaries TLK0278 and TRTR019. NIH R21NS123325.

Session Title: Mendelian Phenotypes Poster Session II

PB4807 *IFIH1* gain of function variants in three individuals: The multifaced continuum of type I Interferonopathy

Authors:

S. Shimada; NIH, North Bethesda, MD

Background: Melanoma differentiation-associated gene 5 (MDA5), encoded by *IFIH1*, plays a critical role in activating type I interferon signaling and is essential for the immune response against viral infections. Gain-of-function variants in IFIH1 have been associated with type 1 interferonopathy, leading to the development of Aicardi-Goutieres syndrome (AGS) and Singleton Merten syndrome (SMS). The presence of overlapping symptoms between the neuroinflammatory phenotype of AGS and the systemic inflammatory phenotype of SMS suggests a shared disease spectrum. In this study, we report three individuals with clinical features that overlap between AGS and SMS, and provide a comprehensive review of previously reported cases to further elucidate the spectrum of type I interferonopathy. **Methods**: Extensive clinical investigations were conducted in the individuals. Whole-exome sequencing and research variant analyses were performed in three pedigrees to investigate the clinical features associated with variants in *IFIH1*. Segregation of variants was performed using Sanger sequencing. Additionally, in vitro analyses were conducted to measure the interferon activity of the identified variants in mammalian cells. **Results**: De novo variants in *IFIH1* were identified in all three individuals. The interferon activities observed in the variants without exogenous dsRNA ligand indicated their pathogenic nature; constitutive activation of MDA5 confirmed a gain-of-function mechanism. The clinical presentations among the probands showed variability, with one individual presenting a classical phenotype of AGS type 7 and the others displaying overlapping features of AGS and SMS. Notably, there was no strict correlation between the identified genotypes and the observed clinical phenotypes, suggesting the involvement of additional factors in disease severity and comorbidities. Furthermore, glycome abnormalities observed in a proband with early mortality may signify secondary findings related to the inflammatory response in Type I interferonopathies. **Conclusion**: This study emphasizes the clinical heterogeneity of type I interferonopathy and supports the concept that AGS type 7 and SMS represent different manifestations along a disease spectrum. A comprehensive understanding of the genotype-phenotype correlations and underlying disease mechanisms is crucial for improving the diagnosis and treatment strategies for individuals with IFIH1 variants. Further research is warranted to unravel the complexities of these disorders and identify potential therapeutic targets to mitigate the impact of type I interferonopathies.

Session Title: Mendelian Phenotypes Poster Session III

PB4808 Impact of processed pseudogene insertions in genetic testing as cause of monogenic diseases: insertion in CLCN1 gene causing Myotonia Congenita

Authors:

J. Pinto Basto[1], K. Tripolszki[1], J. Martini[1], K. Kampe[1], V. Karageorgou[1], M. Almuhaizea[2], C. Pereira[1], S. Weissgraeber[1], O. Paknia[1], P. Bauer[1]; [1]CENTOGENE, Rostock, Germany, [2]• King Faisal Specialist Hosp. & Res. Ctr. (KFSH & RC), Riyadh, Saudi Arabia

In this work, we report the first case of autosomal recessive myotonia congenita associated with a homozygous insertion of a processed pseudogene in the *CLCN1* gene. Myotonia congenita is a rare skeletal muscle channelopathy characterized by muscle stiffness and an inability of the muscle to relax after voluntary contraction (myotonia). It is caused by mutations of *CLCN1* gene (7q34), which encodes human skeletal muscle chloride channel 1. We report on a 3-year-old female patient, presenting with myotonia at the age of 14 months. Her parents are consanguineous, and she has a 13-year-old brother who is similarly affected. To identify the causative variant, genome sequencing (GS) was performed. During the analysis, single nucleotide variants, copy number variations and structural variants were also considered. PCR amplification and Sanger sequencing of the inserted region and the breakpoint were also performed to further investigate the identified structural variant. GS and Sanger sequencing were also performed for the affected sibling. Using GS, only one event remained as a good candidate. We identified a deep intronic homozygous insertion of ~750bp located in intron 14 of the *CLCN1* gene. The breakpoints were detected by the structural variant caller and further investigated by the visualization tool. The group of discordant reads at the breakpoint in intron 14 of *CLCN1* have mates that map to the *UQCRH* gene on chromosome 1. The sequence of the inserted region was obtained by targeted PCR amplification and Sanger sequencing and was determined to map exclusively to the coding region and UTR of the *UQCRH* gene. Since the inserted region showed the hallmarks of a retrotransposition event (antisense poly(A) tail, target site duplication, coding sequence of *UQCRH*), the retrotransposition of a processed mRNA was suspected. Considering that the inserted sequence is located in a deep intronic position, it is possible that splicing is impacted. The same event was identified in the affected brother in homozygous form further supporting the role of this variant as a genetic cause of the phenotype in this family. To our knowledge, this is the third reported case of a processed pseudogene insertion causing a monogenic disorder. Structural variant analysis in GS is challenging, time consuming and not regularly performed in the routine diagnostic testing. Untargeted screening of processed pseudogenes insertions is effectively performed by structural variant analysis in GS. This further emphasizes the role of GS as a first-tier approach in rare disorder diagnostics.

Rios[9], C. Wise[10], J. Zhang[1], C. Zhao[4], N. Wu[1]; [1]Peking Union Med. Coll. Hosp., Beijing, China, [2]Qilu Hosp. of Shandong Univ., Jinan, China, [3]Baylor Coll. of Med., Houston, TX, [4]Ocean Univ. of China, Qingdao, China, [5]Peking Union Med. Coll., Beijing, China, [6]Peking Union Med. Coll. Hosp. Chinese Academy of Med. Sci., Beijing, China, [7]Peking Union Med. Coll. Hosp., Chinese Academy of Med. Sci., Beijing, China, [8]RIKEN Ctr. for Integrative Med. Sci., Tokyo, Japan, [9]Texas Scottish Rite Hosp. for Children, Dallas, TX, [10]Scottish Rite for Children, Dallas, TX

Idiopathic scoliosis (IS) is the most common form of spinal deformity. Although many genetic risk loci have been identified, the pathophysiological mechanisms are poorly understood. In this study, we summarized IS-associated loci based on previous genetic association studies and mapped these loci to candidate genes using location-based or function-based strategies. Enrichment of rare variants in these candidate genes was determined in 411 Chinese individuals with severe IS (Cobb > 40°) versus 3,800 Chinese controls. A genome-wide association study (cases=6,449, controls=158,068) in East Asian population and an exome-sequenced European-ancestry IS cohort were included for validation. Zebrafish *epha4a/b* mutants, *efnb3b* morphants, and *ngef* crispants were used to explore the mechanism of *EPHA4* pathway-related IS. As a result, rare variants in *EPHA4* were significantly enriched in patients with IS (P=0.045, OR=4.09), with three rare coding variants identified in three patients. Two of the three variants (c.1443+1G>C and c.2546G>A, p.Cys849Tyr) were subsequently revealed to be *de novo* and could convey deleterious effects on *EPHA4*. Via searching for noncoding variants and structural variants, we found a *de novo* splicing variant (c.1318+10344A>G) in *EPHA4* and a *de novo* 4.46 Mb deletion that includes *EPHA4* from two additional patients with IS. In addition to rare variants, common variants in *EPHA4*, after aggregation, also showed significant enrichment (P=0.023) in the East Asian IS cohort. By investigating rare variants in other genes in the *EPHA4* pathway, we identified two dominantly inherited variants in *NGEF* (c.1A>G, p.Met1? and c.857C>T, p.Ala286Val), which encodes a downstream molecule in the *EPHA4* pathway. The *epha4a/b* mutant and *ngef* crispant zebrafish recapitulated the IS phenotype. In addition, perturbations of the *epha4* pathway led to disorganized neural patterning and abnormal swimming behavior of zebrafish, suggesting a dysfunction of the central pattern generators (CPGs). Therefore the impairment of neural patterning and CPGs may underlie the pathogenesis of IS.

Session Title: Mendelian Phenotypes Poster Session II

PB4810 Indian Siblings with Waardenburg Syndrome Living Beyond the Age of 40 Years: Diagnosis and Management

Authors:

M. Pradeep Kumar[1], M. Gomathi[2]; [1]Kovai Med. Ctr. and Hosp., Coimbatore, India, [2]Karpagam Academy of Higher Ed., Coimbatore, India

Waardenburg syndrome (WS) is a rare genetic disorder of neural crest cells inherited in autosomal dominant fashion with the prevalence of 1:50,000 live births. The hallmark features of WS are pigmentary defects, dysmorphic craniofacial features, upper limb abnormalities, neurological defects, intestinal anomalies and while some individuals may exhibit sensorineural hearing loss. Based on the phenotypic variations WS is divided into four subtypes WSI to IV and confirmed by genetic testing. There are limited cases reported in India. This article aims to report the rare WS siblings' diagnosis, treatment, and genetic counselling to their family members. We present our first case of 47 years old woman born as first child to a nonconsanguineous couple, without any pregnancy complications. She presented with severe developmental delay, short stature, microcephaly, intellectual disability, dsytopia canthorum, syndactyly, skeletal disabilities, language deficits, patch of white hair at the frontal area, light colored eyes, and Hirschsprung disease. The second case of 44 years old male sibling born as second child showed intellectual disability, aphasia, hypotonia, sensorineural hearing loss, Hyperkeratotic papules over limbs, brachydactyly, dislocated shoulders, hiatus hernia, and gastroesophageal reflux disease. MRI imaging studies showed cortical malformations and ventriculomegaly in both patients. There was no similar history in their parents or other siblings. According to Read and Newton, the first case was diagnosed as WS type 4 (shah WS) and the second case diagnosed as WS type 3 (Klein WS). The genetic testing confirmed the missense variant C>T at exon 7 of paired box 3 gene (PAX3) on chromosome 2 in both patients caused WS. (NM_181458:exon7:c.C1003T:p.P335S). This finding extends the prevailing knowledge of mutations of the PAX3 gene in WS3 and WS4 patients. This is considered as the first case report of type 4 of WS associated with PAX3 mutation in India. As it is a genetic disease, there is no definitive treatment for Waardenburg syndrome, but symptomatic treatments like surgery for skeletal abnormalities and intestinal disabilities. Since it is autosomal dominant disorder, other unaffected two siblings were undergoing carrier screening test and provided with genetic counselling. <!--EndFragment-->

Coll. and Associated Kalawati Saran Children's Hosp., New Delhi, India

Introduction: Disorders with epilepsy are genetically and phenotypically heterogeneous. Advancement in genetic testing has led to rapid identification of underlying etiology in epilepsy with its emerging role in the field of precision medicine. **Methods:** A total of 145 families (153 individuals) with epilepsy with/without NDDs were recruited from October 2019 to January 2023 after obtaining informed consents from the family. Epilepsy syndrome classification was done as per the International League Against Epilepsy (ILAE) 2022 definition and classification of epilepsy syndromes. Targeted and/or genomic testing was carried out after detailed clinical evaluation. Genetic counseling and therapy were evaluated for individuals with a definitive molecular diagnosis. **Results:** Our cohort comprises of 86 (56%) males and 67 (44%) females from 145 unrelated families. Consanguinity was noted in 38% (55/145) of the families. According to the recent ILAE nosology and classification, epilepsy syndrome classification could be made in 63 of 145 families (43%). Fifty-three families had a diagnosis of neonatal and infantile-onset syndromes. Of these, six were defined as genetic epilepsy with febrile seizure plus, 20 as infantile epileptic spasm syndrome, 18 as early-infantile DEE, four as epilepsy of infancy with migrating focal seizures, four as Dravet syndrome and one with etiology-specific DEE. Among the five families with childhood-onset syndromes, one was diagnosed with epilepsy with myoclonic-atonic seizures, two with Lennox-Gastaut syndrome, and two with epileptic encephalopathy with spike-and-wave activation in sleep. The other five families fell in the group of progressive myoclonic epilepsies. Definitive molecular diagnosis was achieved in 79 out of 145 families (55%): five (6%) by targeted testing, three by chromosomal microarray (4%), twelve (16%) by Mendeliome, and 59 (74%) by exome sequencing (ES). Monogenic disorders were identified in 71 families, and imprinting and microdeletion disorders in four families each. Forty-three (57%) of 75 disease-causing variants were novel. Two novel disease-gene associations with pathogenic variants in *GCSH* and *KCNH5* were identified. Reproductive counseling was offered to 91% (72/79) of families. Therapeutic implications were noted for 27% of individuals (21/79) with a definitive diagnosis.**Conclusion:** We herein present a systematic cohort elucidating the epilepsy syndrome classification and its genetic landscape observed in the Indian population. We emphasize the utility of ES as an effective first-tier test with substantial potential for precision medicine in epilepsies.

PB4812 Integrating genetic, demographic, and clinical variables to predict neurodevelopmental outcomes in children with congenital heart defects.

Authors:

E. Hernandez[1], T. A. Miller[1], M. W. Russell[2], J. W. Newburger[3], W. K. Chung[4], W. Gaynor[5], E. Goldmuntz[6], J. F. Cnota[7], M. Yandell[1], M. Tristani-Firouzi[1]; [1]Univ. of Utah, Salt Lake City, UT, [2]Univ. of Michigan, Ann Arbor, MI, [3]Harvard Med. Sch., Boston, MA, [4]Columbia Univ., New York, NY, [5]Children's Hosp. of Philadelphia, Philadephia, PA, [6]Children's Hosp. of Philadelphia, Philadelphia, PA, [7]Cincinnati Children's Hosp., Cincinnati, OH

Congenital heart defects (CHD) have been a subject of intense investigation, with recent large-scale sequencing efforts shedding light on the genetic factors underlying their etiology. However, the precise impact of genetics on clinical outcomes remains less understood. In this study, we employed Bayesian Networks, an explainable Artificial Intelligence approach, to unravel the complex relationships between clinical variables, demography, and genetics in a cohort of children with single ventricle CHD (N=304). Our findings demonstrate the interconnected nature of these variables and their combined impact on clinical outcomes. As isolated variables, a damaging genetic variant in a gene related to abnormal heart morphology and prolonged ventilator support following cardiac surgery increased the probability of having a low Mental Developmental Index (MDI) score at 14 months of age by 1.9- and 5.8-fold, respectively. However, when present in combination, these variables synergistically elevated the probability of a low MDI score by 10-fold. Genetic information also had predictive value for favorable neurodevelopmental outcomes. For instance, the absence of a damaging variant in a known syndromic CHD gene and a shorter post-operative ventilator support were associated with a 1.7- and 2.4-fold increase in the probability of a normal MDI score, respectively. When combined, these factors substantially increased the likelihood of a favorable outcome by 59-fold. Our analysis underscores the modest genetic contribution to neurodevelopmental and growth outcomes as isolated variables, with an even greater impacts when considered in the context of specific clinical variables. These results emphasize the importance of comprehensively capturing and quantifying the effects of damaging genomic variants within the context of multiple conditionally dependent variables, including pre- and post-operative factors, as well as demography. This study deepens our understanding of the intricate interplay between genetics and clinical outcomes in CHD and lays the foundation for personalized patient management.

Introduction: The considerable size and complex structure of the Indian population produces a profound burden of inherited neurodevelopmental disorders (NDDs). This poses a huge challenge in health care, as India continues to be classified as a lower-middle-income country (LMIC). **Methods:** We recruited a total of 600 families with NDDs, consented under an IRB with appropriate ethical approvals starting in fall of 2019. Deep phenotyping was collected and genomic evaluation has been completed for 523 families (588 individuals). An exome first or a sequential genetic testing strategy was used, in which targeted tests or chromosomal microarray (CMA) was followed by exome sequencing (ES)/genome sequencing.**Results:** Of the 523 families which have undergone a full evaluation, consanguinity was noted in 188 (36%) families. Notably, 546 (93%) affected individuals are of pediatric age group. Disease-causing variants were detected in 321 families (61%): 29 families by targeted testing (9%), 16 by CMA (5%), 52 by Mendeliome (16%), 190 by solo ES (59%), 3 by duo ES (1%), and 31 by trio ES (10%). Overall, 230 monogenic disorders were identified in 291 families (91%) and 25 chromosomal disorders in 30 families (9%). The spectrum of monogenic disorders comprised of 31 families with epilepsy as a core symptom (10%), 60 with leukodystrophies (19%) including 28 families with hypomyelinating disorders, 32 with metabolic disorders (10%), 63 with syndromic intellectual disability (ID, 20%) including 41 families with *de novo* syndromic ID, 28 with developmental epileptic encephalopathy (9%), 23 with mitochondrial disorders (7%), 15 with neuromuscular disorders (5%), 7 with hereditary spastic paraplegias (2%) and 32 with other heterogeneous NDDs (10%). Significant phenotypic and genotypic insights of the cohort include (i) Identification of either novel or extremely rare disease-causing variants in 20 genes: *GCSH, PIDD1, TMEM163, KCNH5, FILIP1, SNRPN, DCHS2, CLIP1, TRIM23, SLC25A10, KCNK18, GPAT, NDUFB6, MRPL49, CSMD3, UNC50, FAF1, EPB41L3, VPS36, FAM160B1* (ii) Fifty-three percent novel disease-causing variants (160/305), thus contributing to population specific variants (iii) Identification of probable founder variants (*ISCA1, RNASEH2C, CYB5R3*).**Conclusion:** This study delineates a systematic cohort of deep phenotyping and pertinent use of targeted and broad-spectrum genomic tests to decipher the etiology of inherited NDDs. A definite genetic diagnosis resulted in informed genetic counselling, management, and prevention of known disorders as well as deciphering novel phenotypes and genotypes in a lesser explored population.

Understanding the molecular mechanisms involved in physiological and pathological bone formation requires knowledge of global transcriptional changes during osteogenesis. Previous studies of osteogenesis have identified the involvement of various types of genes, such as those that encode for transcription factors (TFs) and long noncoding RNAs (lncRNAs), as well as alternative spliceoforms and multiple signaling pathways that include TGF-β/BMP, Notch, Hedgehog, NELL-1, PTHrP, FGF, WNT, HIPPO, JNK, MAPK, and estrogen receptor signaling. Here, we differentiated mesenchymal stem cells (MSCs), derived from normal human induced pluripotent stem cells, into preosteoblasts and osteoblasts and performed bulk RNA-seq from 60 samples and single-cell RNA-seq data analysis. We identified distinct and temporally dynamic gene expression profiles that are enriched for various biological functions and gene expression patterns of TF and lncRNA genes that are highly correlated during osteogenic differentiation. Expression levels of lncRNAs were found to be significantly correlated with those of their neighboring TFs, splicing factors, and protein-coding genes, which in turn are known to regulate skeletal development, ossification, and phosphorus and phosphate metabolism. Importantly, we identified *KLF16* as a key TF using TF-TF regulatory network analysis and as a key driver gene using gene co-expression network analysis. Overexpression of *Klf16* inhibited matrix maturation and mineralization during MC3T3-E1 osteogenic differentiation. Moreover, *Klf16* haploinsufficient mice showed increased whole-body bone mineral density, femoral bone volume to total tissue volume, trabecular bone thickness, and cortical bone area, which supported our predicted TF and co-expression network modules and confirmed the inhibitory role of *KLF16* in bone formation. *KLF16* previously has been identified as one TF of a set of TFs associated with osteoporosis by comparing microarray data of bone marrow MSCs from osteoporosis patients and controls (Liu *et al*., 2019. PMID: 31007729). Our approach serves as a model system for understanding and identifying candidate genes involved in normal and pathological osteogenic differentiation and developing more effective therapeutic strategies for bone diseases.

Session Title: Mendelian Phenotypes Poster Session I

PB4815 Investigating the role of *RAB5A* variants in bipolar disorders: Insights from Drosophila models

Authors:

B. Adhikari[1,2], J. Andrews[1,2], M. Wangler[1,2], J. Holder[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Houston, TX

Background: Studies of neuropsychiatric diseases are challenging due to the lack of available models that accurately replicate the complexity of these disorders. Recently, genetic variants in *RAB5A* have been associated with bipolar disorder (BPD). RAB5A, a protein in the small G-protein family, plays a crucial role in intracellular vesicle trafficking. In this study, we developed *Drosophila* models expressing *RAB5A* BPD-associated variants to investigate their functional roles. We hypothesized that *RAB5A* variants would cause morphological, behavioral, and survival abnormalities in flies expressing them.Methods:*Drosophila* overexpression models were developed with multiple *RAB5A* BPD-associated variants using the UAS/Gal4 system to drive the expression of the human cDNA. Nubbin-Gal4, and Elav-Gal4 drivers were used to express *RAB5A* in wing tissues and the central nervous system (CNS), respectively. To achieve ubiquitous expression, Actin-Gal4, and Tubulin-Gal4 drivers were utilized. Lethality was assessed by comparing the number of observed eclosing adults to the number of expected progeny (O/E). Motor dysfunction was evaluated through climbing assay, while survival analysis was conducted and analyzed using the log-rank test in Kaplan-Meir plot. Results: We observed that ubiquitous expression of $RAB5A^{D136N}$ led to complete lethality (O/E=0), while expression in wings resulted in partial lethality (O/E=0.24). However, when expressed in the CNS, $RAB5A^{D136N}$ expression did not induce lethality (O/E=1.39). Surviving Nubbin-Gal4; UAS- $RAB5A^{D136N}$ progeny showed significantly altered wing morphology, including modified wing shape, missing anterior and posterior cross-veins, thickening of the longitudinal veins with the appearance of extraneous vein formation. Also, old Nubbin-Gal4 flies (>10 days) showed a significant increase in wing damage than age-matched controls. Elav-Gal4 flies showed significant motor dysfunctions upon agitation than controls, which increased with age. We assessed the lifespan of $RAB5A^{D136N}$ flies and observed a decrease in survival compared to wild-type flies (Log-rank test, P=<0.0001).Conclusion: Our study indicates that $RAB5A^{D136N}$ when expressed ubiquitously, leads to lethality and targeted overexpression within wing tissues results in significant alterations in wing morphology. Furthermore, its expression in the CNS does not induce lethality but contributes to motor dysfunction. These findings provide functional validation that *RAB5A* variants associated with BPD may be deleterious and highlight the potential of Drosophila models for further investigation of BPD and its underlying mechanisms.

Session Title: Mendelian Phenotypes Poster Session II

PB4816 Investigating the role of Rbfox2 in Splicing and the Transcriptional Network of the SWI/SNF Complex in myoblast fusion

Authors:

T. Govindarajan, S. Kawamoto; Natl. Heart, Lung, and Blood Inst. (NHLBI), Bethesda, MD

The coordinated expression of myogenic transcription factors and splicing regulators is crucial in cardiac and skeletal muscle growth, repair, and development. Rbfox2, a member of the Rbfox family proteins, regulates alternative splicing, mRNA stability, and microRNA biogenesis in cardiac and skeletal muscle. Using the BioID proximity approach, we identified novel protein interactors that are specifically bound proximal to Rbfox2 isoforms, enabling us to understand better the shared and distinctive roles of each isoform in skeletal muscle development. This study is particularly important in investigating the non-splicing functions of Rbfox2 isoforms and associated signaling pathways in skeletal muscle development.

Session Title: Mendelian Phenotypes Poster Session III

PB4817 Is*JKAMP*gene associated with autosomal recessive “intellectual disability, autism spectrum disorder and seizures?” A Compound heterozygosity for two VUSs of *JKAMP* gene in a 22 yo female with global developmental delay, profound ID, ASD, and seizures.

Authors:

M. Hajianpour[1], J. Lundberg[1], L. Cortez[1], R. J. Simmons[2]; [1]Albany Med. Coll./ Albany Med Hlth.System, Dept. of Pediatrics, Div. of Med. Genetics and Genomics, Albany, NY, [2]Community Care Physicians, Clifton Park, NY

Is *JKAMP* gene associated with autosomal recessive “intellectual disability, autism spectrum disorder and seizures?” A Compound heterozygosity for two VUSs of *JKAMP* gene in a 22 yo female with global developmental delay, profound ID, ASD, and seizures. Proband is a 22-year-old female with a history of prematurity (34 weeks gestation, weighing 6lbs), regressed speech and language at ~3 years of age. She can currently say "baba, I want" only. She has severe autism with occasional aggression, profound intellectual disability (functioning at a 2 yo child), hypotonia (noticed at 7months of age) and seizures (started at 8 months of age) with a normal EEG and brain CT scan (at 8m), and normal repeat EEG with brain MRI (at 19m). On physical examination at 22 years of age, her weight and height were in normal range with a BMI of 20.44 kg/m^2. Her head circumference was in low normal range (~10%ile for age). She had some dysmorphic features, such as flat occiput, receding forehead, low anterior and posterior hairlines, synophrys, long eye lashes; deep-set eyes; overfolded upper and lateral helix; uplifted and fleshy earlobes; low nasal bridge; micrognathia, moderate retrognathia; tapering fingers; pes cavus; talipes calcaneovarus; and mild 2-3 toes syndactyly. She is toe walking with an unsteady gait. **GENETIC WORK-UP:** Routine chromosome analysis, Chromosome microarray analysis, Molecular studies for Rett syndrome and Fragile X syndrome, Sub-telomeric FISH, Plasma amino acids, Urine organic acids, Acylcarnitine profile, Mitochondrial genome sequencing with del/dup analysis were all Normal. **Whole exome sequencing (WES)** TRIO showed two variants of uncertain significance (VUSs) in the JKAMP gene: **c.443 A>G/ p.(E148G) Pat & c.878del/ p.(F293Sfs*34) Mat. DISCUSSION:** The JKAMP gene is a candidate gene with a potential relationship to the phenotype in our proband. This gene plays a role in regulating Jun N-terminal kinase (JNK) activity. A homozygous frameshift variant has been reported in a family with two affected siblings in association with intellectual disability, epilepsy, obsessive-compulsive disorder, autism, and dysmorphic features. - These Variant have not been observed at significant frequency in large population cohorts (gnomAD). - They have not been previously published as pathogenic or benign to our knowledge. - In silico analysis supports that these variants have a deleterious effect on protein structure/ function. **CONCLUSION:** Further research is needed to explore a possible link between the identified variants in the JKAMP gene and human disease, and/or association of Kemp gene with autosomal recessive intellectual disability, ASD, and seizures.

PB4818 Joint analysis of phenotypically diverse rare disease cohort reveals new diagnostic genes

Authors:

M. Moldovan[1], S. Kobren[1], R. Reimers[2], X. Li[1], D. Traviglia[1], J. Willett[3], J. Krier[4], I. Kohane[1], Undiagnosed Diseases Network Tool Building Coalition Working Group, S. Sunyaev[1]; [1]Harvard Med. Sch., Boston, MA, [2]Rady Children's Inst. for Genomic Med., San Diego, CA, [3]McGill Univ., Montreal, QC, Canada, [4]Atrius Hlth., Boston, MA

Here, we harmonized and jointly called whole genome variants from a cohort of ~4,300 patients with diverse sets of symptoms enrolled in the Undiagnosed Diseases Network (UDN). Unlike previous cohort-based analyses which focus on specific disease categories, the UDN accepts any undiagnosed patients experiencing a broad range of pediatric- and adult-onset symptoms. In addition to genomic sequencing, patients undergo thorough, on-site clinical evaluations, resulting in a wealth of clinical data available for analysis. We inferred the functional impacts of coding variants using CADD scores and intronic variants using SpliceAI scores coupled with experimental data from a massively parallel splicing assay. We identified four genes across twelve patients with a significant excess of deleterious de novo variants, recapitulating seven known diagnoses and highlighting two new diagnoses. In addition, we developed a statistical approach to identify compound heterozygous variants in individual patients and uncovered four known and two novel gene-disease associations. In our analyses, we employ a highly accurate mutational model with base-pair resolution, which increases our statistical power. Finally, by considering genes harboring deleterious variants and applying gene set enrichment analysis on phenotypically-similar patient subgroups, we identified recurrently perturbed pathways, four of which covered seventeen distinct genes across patients, recapitulating six known diagnoses.Our pipeline for identification of putative disease-causing variants includes expert clinical evaluations of the concordance between candidate diagnostic variants and affected patient presentations. To streamline and standardize this process, we developed an objective, semi-automated, quantitative approach to reduce manual case review time. When applied to candidate diagnostic variants discovered in our analyses, clinical evaluations revealed high correlation between identified gene candidates and diagnostic feasibility. Taken together, these results demonstrate that comprehensive, cohort-based analyses of diverse, suspected Mendelian disorders can provide valuable insights into new disease genes and pathways, ultimately paving the way for improved diagnostics and targeted therapeutics.

Session Title: Mendelian Phenotypes Poster Session II

PB4819 Language and neural networks in Smith Magenis Syndrome.

Authors:

X. Tran[1], A. Gropman[2]; [1]Children's Natl. Hosp., Washington, DC, [2]Children s Natl. Hosp., Washington, DC

Background: Smith Magenis Syndrome (SMS) is caused by a heterozygous deletion in chromosome 17p11.2, or mutation of the RAI1 gene. SMS affects 1:15,000 to 1:25,000 in the US and can have a highly variable presentation, often associated with mild-moderate intellectual disability, and speech/language delay (Smith *et al* 2001, Gropman *et al* 2006, Le Gouard *et al* 2021). It can present with concomitant autism spectrum disorder (ASD), behavioral and sleep disturbances, seizure, hypotonia, and distinct facial and body dysmorphologies. SMS is associated with generalized epileptiform activity (Goldman *et al* 2006), cerebellar vermis hypoplasia, thin corpus callosum and brain stem, and decreased gray matter (Boddaert *et al* 2004, Maya *et al* 2014). **Objectives:** Aim 1. Characterize language profiles in children with SMS. Aim 2. Characterize baseline neural network activity using clinical electroencephalogram (EEG). **Methods:** Subjects with SMS who had existing EEG at Children's National Hospital were selected. Behavioral profiles were obtained based on chart review. Raw EEG files were located through NeuroWorkBench, visually reviewed and exported using Persyst. EEG data files were imported into MATLAB and processed using EEGLAB (Delorme & Makeig, 2004). Artifact subspace reconstruction and Adaptive Mixture Independent Component Analysis were used to remove artifacts. Fast Fourier Transfer was applied to the cleaned EEG data. Spectral power was calculated via Welch's method and phase coherence was calculated using EEGLAB *newcrossf* function. **Results:** 5 subjects with SMS were identified, all had behavioral profiles in line with the previously described clinical spectrum of SMS (seizure, language delay, cognitive delay, ADHD, ASD, self-injurious behaviors, sleep disorder, and scoliosis). Among the 3 subjects with EEG, 1 had EEG with bioccipital epileptiform activity, while 2 had EEG without epileptiform activity. Group level analysis was not performed because raw EEG data was only available for 1 subject. Brain MRIs were notable for centrum semiovale dysplasia, abnormal myelin sheath formation, and abnormal brainstem segmentation. **Discussion:** Due to different underlying structural abnormalities seen on each subject's MRI, baseline EEGs are expected to differ in spectral power and connectivity between subjects. Source-based localization, involving co-registering each subject's EEG to their own brain MRI, may be a more optimal analysis technique compared to generalized group-level analysis. To expand our study, we are in the process of acquiring EEG and MRI from the National Institute of Health's pre-existing SMS natural history study.

Session Title: Mendelian Phenotypes Poster Session III

PB4820 Lateral meningocele syndrome without lateral meningoceles: A case report to expand the phenotype.

Authors:

D. Rubadeux[1], J. W. Owens[2], A. Shillington[2]; [1]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [2]Cincinnati Children's Hosp., Cincinnati, OH

Lateral meningocele syndrome (LMS), also known as Lehman syndrome, is caused by pathogenic variants in exon 33 of *NOTCH3*. Variants in this final exon of *NOTCH3* interrupt the regulatory PEST domain, leading to enhanced NOTCH3 signaling due to prolonged cellular half-life. Patients with LMS are expected to have multiple lateral meningoceles, developmental delay, neonatal hypotonia, dysmorphic facial features, and feeding difficulties. Common findings include ligamentous laxity, short stature, hernias, cryptorchidism, congenital cardiac abnormalities, and hearing loss. Less common findings include proptosis, Wormian bones, paresthesia, urinary incontinence, and skin hyperextensibility. To date, 20 cases of LMS have been reported, with approximately half having completed confirmatory genetic testing.

We report an 8-year-old male patient with a history of prenatal polysubstance exposure to benzodiazepines and opiates, autism, cerebral palsy, feeding difficulties, severe developmental delay, intellectual disability, and self-injurious behavior. He received an Autism/ID Xpanded gene panel at 7 years of age, which revealed a c.6663C>G (p.Y2221*) pathogenic variant in exon 33 of *NOTCH3*. Following diagnosis of LMS, a spine MRI at age 7 showed a ventral sacral extradural arachnoid cyst but no lateral meningoceles. The patient's most recent exam noted multiple dysmorphic features including prominent metopic ridging, broad forehead, down-slanting palpebral fissures, high arched palate, long narrow philtrum, mild pectus excavatum, and wide-based gait. His stature is short for his age (117.5 cm, 1%ile), with a weight of 26.4 kg (43%ile).

Here, we document the 21st reported individual with LMS and the 12th case of molecularly confirmed LMS**.** The patient shares the dysmorphic facial features, ongoing G-tube dependence, failure to thrive, developmental delay, and congenital cardiac abnormalities seen in other individuals with LMS. His overall functioning is lower than other reported LMS cases, including a 9-year-old patient without intellectual disability who shares this p.Y2221* variant, which may be related to our patient's prenatal polysubstance exposure. However, the additional features that cannot be explained by environmental factors suggest significant variable expressivity associated with truncating variants in exon 33 of *NOTCH3*. His lack of lateral meningoceles expands the phenotype for this condition, as all previously reported patients with molecularly confirmed LMS had multiple lateral meningoceles before the age of 8, with the average age of identification being approximately 4 years.

Univ., Beijing, China

Introduction: Leigh syndrome spectrum (LSS) is the most frequent clinical manifestation of pediatric mitochondrial disorders (MD) characterized by neurodegeneration, bilateral symmetrical lesions in the basal ganglia and/or brain stem and impaired oxidative phosphorylation. Defects in more than 100 genes spanning the nuclear and mitochondrial genome have been associated with LSS, suggesting a high level of genetic heterogeneity. This study aimed to provide new insights into natural history of LSS by investigating the largest genetically diagnosed LSS collection to date.Methods: Clinical, survival, onset, and neuroimaging data of 527 genetically confirmed LSS patients from China, Japan, Germany, and France were reviewed. A gradient boosting tree-based machine learning classifier was developed to predict 3-year survival.Results: Pathogenic variants were identified in 124 distinct genes, with 57% of cases showing autosomal recessive, 37% maternal, 4% X-linked, and 2% autosomal dominant inheritance. Most frequent MD genes causing LSS were *MT-ATP6*, *MT-ND3*, and *MT-ND6*, while the most common nuclear genes were *ECHS1, SURF1*, and *PDHA1*. Overall, 20% of the 527 LSS patients were deceased at the timepoint of last assessment. Median age of death was 2 years (range= 0.1-14 years), with 60% of patients dying within the first three years of life. Median age of onset was 0.75 years (range= 0-11 years) and patients were in median followed up for 40 months (range= 0-380 months). Time from onset to death was in median 1.2 years (range= 0-13 years). Phenotypic analysis revealed 280 distinct Human Phenotype Ontology (HPO) terms, with a median of 9 HPO terms (range: 3-35) per patient. Global developmental delay, hypotonia and lactic acidosis were the most frequent phenotypes. Poorest 5-year survival was associated with defects in *MT-ND5, HSD17B10, MT-ATP6* (m.8993T&gtC/G, m.9176T&gtC), and *ALDH5A1* (≤50%). The developed model predicting survival showed an average prediction accuracy of 86% and outperformed genotype, clinical and MRI information alone. Most important features of the model were age of onset, increased MRS lactate levels as well as lesions in medulla oblongata and caudate nucleus.Discussion: This study presents findings from the largest genetically defined, systematically phenotyped LSS cohort, providing natural history of LSS. The remarkable accuracy and performance of our model provide a favourable and assuring indication of its potential in guiding clinical trial design and decision-making. Finally, the predicted survival by our model offers a promising outcome measure that serves as important guidance for future clinical trials.

Session Title: Mendelian Phenotypes Poster Session II

PB4822 Leveraging an animal model of CHD8-related syndrome to interrogate brain circuits: CHD8 heterozygous mice display decreased impulsivity in the differential reinforcement of low rate responding assay, but no difference in attention or motivation, compared to wildtype mice.

Authors:

S. Dhanani[1], T. Sohrabi[1], M. Begum[1], D. F. Rivas[1], P. Balsam[1], R. A. Muhle[2]; [1]Columbia Univ./New York State Psychiatric Inst., New York, NY, [2]Columbia Univ./ New York State Psychiatric Inst., New York, NY

Loss of function mutations in *CHD8* are often associated with autism, intellectual disability, and bodily overgrowth. Mouse models of CHD8 loss have commonalities, including avoidance of open areas, increased sniff time, and larger brain volume. The use of operant conditioning to determine differences in attention, motivation, and impulsivity between *Chd8*$^{+/-}$ mice and their wildtype (WT) littermates has not been fully assessed.
We tested an all-male cohort of 8 *Chd8*$^{+/-}$ and 8 WT food-restricted mice, starting at 8 weeks old. Med Associates operant boxes were used to assess for sustained attention (SA), motivation using progressive ratio (PR), and impulsivity via the differential reinforcement of low rate responding (DRL) assays, sequentially. *SA task*: a visual cue predicting which of 2 levers could earn a reward was reduced from 10 to 0.25sec. *PR task:* the number of lever presses to receive a reward doubled after each reward received. *DRL assay:* the mice received a reward only if they abstained from pressing the lever within a specified time interval, with a training period increasing the interval by 2sec every 2-3 days, until reaching a 36sec interval that was tested for 10 days. 2-way ANOVA or an unpaired parametric t-test was used to test statistical significance. In the DRL assay, nonlinear regression curves (a one phase decay curve to latencies < 4sec, and a Gaussian curve to latencies > 4sec) were fit to histograms of the summed lever press latencies, binned in 1sec intervals.
We did not find differences in the ability of *Chd8*$^{+/-}$ mice to sustain attention to a visual cue in the SA task, or in their motivation to press increasing numbers of times in the PR task, suggesting CHD8 loss does not impair attention or motivation. In the DRL assay, *Chd8*$^{+/-}$ mice adapted more quickly to the task, which rewarded ability to wait between presses. A Gaussian curve fit to the lever press latencies of the *Chd8*$^{+/-}$ mice in the 36sec interval tasks was significantly shifted to the right of the WT mice ($p < 0.0001$). Greater numbers of burst presses (latencies < 1sec) by the WT mice was not significant during the 36sec interval testing sessions ($p = 0.3963$), but when considering the entire training period was significant for the interaction of session x genotype ($p = 0.0023$ for session X genotype), as well as for subject and session ($p < 0.0001$ for subject and for session, $p = 0.1159$ for genotype).
These aspects of DRL performance suggest that *Chd8*$^{+/-}$ are more accurate in the timing of behavior and better able to inhibit repetitive initiation of behavior. These behaviors implicate basal ganglia circuits involving reward, and can inform our understanding of behavioral differences in people with CHD8-related syndrome.

Session Title: Mendelian Phenotypes Poster Session III

PB4823 Leveraging identity-by-descent to identify novel loci associated with esophageal ulceration

Authors:

J. Baker[1], G. Evans[1], R. Bohlender[2], H-H. Chen[3], A. S. Petty[4], C. Huff[2], D. Samuels[5], J. Below[6]; [1]Vanderbilt Univ., Nashville, TN, [2]U.T. MD Anderson Cancer Ctr, Houston, TX, [3]Academia Sinica, Taipei, Taiwan, [4]Vanderbilt Univ. Med. Ctr., Nashville, TN, [5]Vanderbilt Univ. Sch. of Med., Nashville, TN, [6]Vanderbilt Univ Med Ctr., Nashville, TN

Background: Esophageal ulceration is characterized by open sores that break the lining in the esophagus. These ulcers commonly form on the lower end of the esophagus near the connection to the stomach. These ulcers can cause discomfort or pain while swallowing, acid reflux, and chest pain. Esophageal ulcers are typically the result of gastroesophageal reflux disease (GERD) and when left untreated can develop into Barrett's esophagus. Very little concrete information is available about the etiology of esophageal ulceration but heritability for GERD and Barrett's esophagus have been estimated as 30% and 40%, respectively, indicating that esophageal ulcers may also have similar genetic causes. The lack of clarity of the genetic etiology of Esophageal ulcers limits our ability to determine the definitive cause of the condition, ultimately hindering the determination of an appropriate treatment. Large DNA biobanks can provide an opportunity to elucidate some of the genetic causes of esophageal ulceration by enabling researchers to leverage cryptic relatedness through shared identical-by-descent (IBD) genomic segments resulting from recent common ancestry. **Methods and Results:** Phasing was performed using SHAPEIT4 and then pairwise IBD segments ≥3 cM were identified using hap-IBD for 69,819 individuals of European ancestry in BioVU, Vanderbilt University Medical Center's biobank. We defined cases of esophageal ulceration as individuals who have a record of the PheCode 530.12, which is composed of ICD codes 530.2, 530.20, 530.21 (ICD-9), and K22.1 (ICD-10) on two or more unique dates. Controls were defined as individuals without any mention of a PheCode in the exclusion ranges (530-530.99, 532-532.99). We performed IBD mapping genome-wide on a set of 142 cases and 48,156 controls to identify enrichment of IBD sharing in case-case pairs compared to case-control pairs. We identified one unique, genome-wide significant enrichment signal on chromosome 10 that exceeded the family-wise error rate correction (6e-5). Using UCSC genome browser we identified 11 genes within this signal. None of these genes had any previous association with related esophageal phenotypes in OMIM. There were also no variants within this signal region from the GWAS Catalog that had been associated with phenotypes relevant to esophageal ulceration pathology. **Conclusions:** We were able to identify a novel genome-wide significant signal for esophageal ulceration using IBD mapping. These results highlight how our IBD-based approach can leverage cryptic relatedness within biobanks to identify novel associations with heritable diseases.

Session Title: Mendelian Phenotypes Poster Session I

PB4824 Long telomeres promote clonal hematopoiesis with aging by delaying replicative senescence

Authors:

M. Tassia[1], E. DeBoy[2], K. Schratz[2], S. Yan[1], R. McCoy[1], M. Armanios[2]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Telomere length predicts the replicative potential of cells, and short telomere length signals cellular senescence. We identified individuals with germline heterozygous loss-of-function mutations in *POT1*, a protein which binds single-stranded DNA at the 3'-end of telomeres. These mutations affected both POT1 stability and telomere DNA-binding. *POT1* variant carriers possessed long telomere lengths relative to age-matched controls, and their leukocyte telomere length was maintained over a 2-year period when compared with unaffected relatives where expected telomere shortening was observed. Variant carriers with long telomeres developed multiple neoplasias, ranging from benign to malignant, and the tumor spectrum affected multiple organs - manifesting as melanoma, thyroid cancer, and sarcoma often associated with hematologic malignancies. To investigate the mechanisms driving these observations, we performed whole genome sequencing on whole-blood-derived hematopoietic progenitors collected from two *POT1* mutation carriers and compared these genomes to those collected from a non-carrier relative. Genomic analyses revealed elevated somatic mutation burden dominated by clock-like C>T mutation signatures, supporting the hypothesis that *POT1* haploinsufficiency delays replicative senescence. *POT1* mutation carriers also possessed somatic variants canonically associated with driving clonal hematopoiesis of indeterminant potential (CHIP), where mutations in *DNMT3A* and *JAK2* were most common. Phylogenetic analyses estimated CHIP-driver mutations emerged early in life and were sustained with age, propagating to high frequency by adulthood. Using population genetic simulations, we constructed a non-Wright-Fisher evolutionary model that extended our empirical findings - presenting an age-dependent evolutionary model where *POT1* loss-of-function mutations and long telomeres promote CHIP through replicative longevity, and telomere shortening limits the propagation of somatic mutations over time. Together, our results support a role for long telomere length in promoting clonal evolution with age; and the clinical phenotype is associated simultaneously with both cancer and CHIP predisposition. Our findings underscore the importance of telomere shortening as tumor suppressive mechanism with aging.

Session Title: Mendelian Phenotypes Poster Session II

PB4825 Long Term Renal Transplant Success is Possible in Hypoparathyroidism, Sensorineural Deafness, and Renal Dysplasia Syndrome: A Familial Case Series.

Authors:

L. Alvey[1], V. Viswanath[1], J. Owens[2], A. Shillington[2]; [1]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [2]Cincinnati Children s Hosp., Cincinnati, OH

Hypoparathyroidism, Sensorineural Deafness, and Renal Dysplasia (HDR) Syndrome, formerly known as Barakat syndrome, is caused by autosomal dominant loss of function *GATA3* variants. Renal disease is common and presents in 72.2% of patients with HDR syndrome. 40% of renal disease is due to congenital anomalies of the kidney and urinary tract, while the remaining cases demonstrate variably progressive disease. Prognosis of HDR Syndrome is primarily dependent upon the severity of renal disease, and current treatment includes routine monitoring and standard treatments for chronic kidney disease. To date, four patients with end stage renal disease from molecularly confirmed HDR syndrome have had renal transplants; however, there is minimal long-term data regarding the efficacy of renal transplants in these patients.Here we present a family of 4 genetically confirmed HDR syndrome patients, which is most notable for a patient having undergone a successful living donor renal transplant 27 years prior. In this family, a 41-year-old female with a history of hearing loss, UTIs, and hematuria was diagnosed with HDR syndrome via genetic testing which found a pathogenic c.608_609del (p.Gly203Glufs*100) variant in *GATA3*. This variant was also identified in her 5-year-old female daughter, 4-year-old male son, and 74-year-old father. Her father was diagnosed with ESRD at age 46 and had a living donor kidney transplant at age 47. His transplant was well tolerated until age 73. Workup at that time revealed acute renal failure with acute tubular necrosis, advanced global glomerulosclerosis, moderate arteriosclerosis, and severe interstitial fibrosis / chronic tubular interstitial changes. Renal failure likely occurred due to the expected lifespan of a grafted kidney rather than as a result of HDR syndrome.The reported family presented to clinic with a clinical diagnosis of Alport syndrome due to their familial renal disease and congenital hearing loss. These congenital symptoms are frequently seen in HDR syndrome; however, the kidney disease / hearing loss in Alport syndrome is explicitly progressive over years to decades and not found at birth. In addition to highlighting discrepancies between Alport syndrome and HDR syndrome, this family also establishes that long term successful renal outcomes are possible in HDR syndrome. Our findings suggest that kidney transplantation should be readily offered to individuals with end stage renal disease due to HDR syndrome.

Session Title: Mendelian Phenotypes Poster Session III

PB4826 Long-read sequencing reveals novel transcripts induced by misexpression of DUX4 in FSHD muscle

Authors:

D. Zheng[1], A. van den Heuvel[2], A. Mahfouz[1,3], S. Bennett[4], S. Tapscott[4], S. Van Der Maarel[1]; [1]Leiden Univ. Med. Ctr., Leiden, Netherlands, [2]Univ. Utrecht, Utrecht, Netherlands, [3]Delft Univ. of Technology, Delft, Netherlands, [4]Fred Hutchinson Cancer Ctr., Seattle, WA

DUX4 is a germline transcription factor that is expressed during early embryogenesis and subsequently silenced in most somatic tissues. Misexpression of DUX4 in skeletal muscle is considered the major cause of Facioscapulohumeral muscular dystrophy (FSHD). DUX4 activates a cascade of downstream events leading to muscle wasting. Besides protein-coding genes, DUX4 also regulates expression of several classes of repetitive elements, and is known to affect RNA processing. Because of these complexities using data from short-read sequencers limits our understanding of the complex transcriptional events provoked by DUX4. We combined SMRT long-read isoform sequencing with short-read RNA-seq of DUX4-inducible myoblasts to investigate the full-length transcriptome landscape inflicted by DUX4. In the presence of DUX4, we observed a more intricate transcriptional landscape, which was distinguished by the emergence of novel isoforms for the known genes, as well as a considerable number of extensive alternative splicing events. In addition, DUX4-dependent transcriptional activation of 1275 novel (i.e. unannotated) intergenic isoforms (652 intergenic loci) was identified and verified by corresponding short-read RNA-seq data, bulk RNA-seq data of primary myotubes, and embryonic scRNA-seq data. Our analysis of public DUX4 ChIP-seq data and ATAC-seq data obtained from DUX4-expressing myoblasts and human embryonic stem cells, respectively, revealed 399 intergenic isoforms (361 intergenic loci) to be directly regulated by DUX4 expression. Intergenic loci with predicted coding transcripts could be confirmed in Ribo-seq data of DUX4-expressing myoblasts, indicating that these novel intergenic transcripts are translated into novel polypeptides. Taken together, our study elaborates on the transcriptional features induced by DUX4 and reveals unannotated transcripts at transcriptome and translatome levels. These can be considered potential biomarkers for disease diagnosis, progression, and therapeutic intervention in FSHD, as well as being explored for their role in cleavage-stage embryos.

Session Title: Mendelian Phenotypes Poster Session I

PB4827 Loss of function in *RBBP5* results in a syndromic neurodevelopmental disorder associated with microcephaly.

Authors:

S. Jangam[1,2], K. Jay[1,2], Y. Huang[3], A. Huang[3], J. Wan[3], O. Chorin[4], A. Rothschild[4], O. Barel[5], M. Mariani[6], M. Iascone[7], H. Xue[8], Undiagnosed Disease Network, J. Hunag[8], C. Mignot[9], K. Boris[9], V. Saillour[10], S. Yamamoto[1,2], O. Kanca[1,2], H. Bellen[1,11], C. Palmer[3,12], S. Nelson[3], M. Wangler[1,2], J. Martinez-Agosto, A[3,12]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Neurological Res. Inst., Texas Children's Hosp., Houston, TX, [3]UCLA, Los Angeles, CA, [4]Sheba Med. Ctr., Ramat Gan, Israel, [5]Sheba Med Ctr, Ramat-gan, Israel, [6]Santa Anna Gen. Hosp., Italy, Italy, [7]Laboratorio di Genetica Medica, Bergamo, Italy, [8]Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China, [9]AP-HP Sorbonne Univ., France, France, [10]Laboratoire de biologie médicale multisites Seqoia, Paris, France, [11]Jan and Dan Duncan Neurological Res. Inst., Houston, TX, [12]Dept. of Psychiatry and Biobehavioral Sci., Los Angeles, CA

We are investigating the *RB binding protein 5 (RBBP5)* gene as a novel neurodevelopmental disorder candidate. *RBBP5* is a member of COMPASS (COMplex of Proteins Associated with SET1) epigenetic modifier protein complex that methylates Histone 3 lysine-4 (H3K4). Chromatin dysregulation has been associated with various syndromes, but *RBBP5* has not yet been implicated in human disease. We have identified four unrelated individuals through the Undiagnosed Diseases Network (UDN) with *de novo* heterozygous pathogenic variants in *RBBP5*. Two missense and two nonsense variants were identified in probands with neurodevelopmental symptoms, including global developmental delay, intellectual disability, microcephaly, and short stature. We examined the variants using bioinformatic analysis, protein structure modeling, and *in vivo* functional characterization. The expression of the frameshift variants in cell lines does not result in the expression of the RBBP5 protein, confirming that these are loss-of-function alleles. Both missense variants p.T232I and p.E296D affect evolutionarily conserved amino acids and are expected to interfere with the interface between RBBP5 and the histones. To analyze the variants *in vivo*, we used the *Drosophila melanogaster* as a model organism. Loss of the fly *Rbbp5* leads to developmental phenotypes, including microcephaly and loss of H3K4 trimethylation in the larval stage. In human cDNA rescue experiments, $RBBP5^{Ref}$, and $RBBP5^{T232I}$ fail to rescue the loss of *Rbbp5*. However, expression of $RBBP5^{Ref}$ induces a more severe reduction in brain size than *Rbbp5* null larvae. Expression of $RBBP5^{T232I}$ results in a similar microcephaly phenotype as null animals, suggesting $RBBP5^{T232I}$ is a loss-of-function allele. In overexpression paradigms, ubiquitous expression of $RBBP5^{Ref}$ leads to late larval lethality and, when expressed in the eye (tissue specifically), causes a small eye phenotype. Expression of either $RBBP5^{Ref}$ or $RBBP5^{E296D}$ results in a more severe small eye phenotype than $RBBP5^{T232I}$, again indicating $RBBP5^{T232I}$ is a loss-of-function allele. Here, by demonstrating $RBBP5^{T232I}$ is a hypomorphic allele, we are supporting that de novo heterozygous variants in RBBP5 are associated with a novel syndromic neurodevelopmental disorder. We conclude that RBBP5 nonsense and missense variants result in similar neurodevelopmental phenotypes. Our future work will focus on determining the mechanism of the missense $RBBP5^{E296}$ allele in the rescue paradigm and identifying the downstream dysregulated genes resulting from RBBP5 loss-of-function.

Session Title: Mendelian Phenotypes Poster Session II

PB4828 Loss of GFAP causes optico-retinal abnormalities and vision impairment.

Authors:

K. Grønskov[1], M. V. K. Sarusie[1], C. Rönnbäck[2], C. Jespersgaard[1], S. Baungaard[3], Y. Ali[4], L. Kessel[2], S. T. Christensen[3], K. Brøndum-Nielsen[1], K. Møllgård[3], T. Rosenberg[2], L. A. Larsen[5]; [1]RigsHosp.et - Kennedy Ctr.t, Glostrup, Denmark, [2]RigsHosp.et - Glostrup, Glostrup, Denmark, [3]Univ. of Copenhagen, Copenhagen, Denmark, [4]Univ. of, Copenhagen, Denmark, [5]Univ Copenhagen, Copenhagen, Denmark

Glial Fibrillary Acidic Protein (GFAP), is major constituent of the intermediate filament of astrocytes within the central nervous system and the retina. During mammalian brain development GFAP is expressed in radial glial cells (RGCs), but previous studies of mouse or human tissues have not identified GFAP expression in retinal neural progenitor (RNP) cells. Monoallelic missense variants in *GFAP* cause Alexander disease (AxD) which is characterized by Rosenthal fibers (protein aggregations including GFAP). Currently, no phenotypic consequence of GFAP haploinsufficiency is known, and recent rodent experiments suggest that antisense oligonucleotide-mediated suppression of GFAP expression can reverse the disease progression in AxD.We investigated a six-generation family with ten individuals presenting with visual impairment, retinal dysplasia and pseudopapilledema. Whole genome sequencing of three affected individuals revealed a rare novel loss-of-function variant in *GFAP*, which segregated with disease in the family. The variant, c.928dup, results in frameshift and translation into a 421 aa protein p.(Met310Asnfs*113) (wild type GFAP is 431-438 aa). We analysed a series of human embryonic tissues and identified strong GFAP expression in RNPs within the developing eye at 35-51 days post conception. Experiments using zebrafish models verified that the c.928dup variant does not result in extensive GFAP protein aggregation. Analysis of zebrafish loss-of-function *gfap* mutants, showed that depletion of Gfap causes vision impairment and retinal dysplasia, characterized by a significant loss of Müller glia cells and photoreceptor cells. Our findings provide novel insight into the function of GFAP in retinal development and the consequence of GFAP deficiency.

PB4829 Loss of TBCK alters bone cell homeostasis resulting in altered bone morphology.

Authors:

E. Durham[1], A. Black[1], K. Katsura[1], E. M. Gonzalez[1], D. Layo-Carris[1], E. Lubin[2], A. Diaz[1], E. Bhoj[1]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Univ. of Pennsylvania/PSOM, Philadelphia, PA

In 2016, we and others discovered mutations in TBC1 Domain Containing Kinase (TBCK) that cause a complete loss of TBCK protein, leading to a multisystem disorder characterized by pediatric neurodegeneration. Recently, through clinical analysis of dozens of children with this rare disorder, we have also determined that this syndrome is associated with an abnormal craniofacial form, as well as a bone fragility phenotype resembling severe osteoporosis that is far more pronounced than would be predicted by just hypotonia/deconditioning. To study this devastating and fatal disease, we have established a biorepository of patient fibroblast samples. We found that, when given osteogenic media for 21 days, patient-derived fibroblasts both failed to differentiate and presented with altered signaling in genes related to osteoclast function, indicating that these cells have altered differentiation potential compared to control fibroblasts. Our lab also acquired a systemic knockout mouse model that recapitulates the neurologic phenotype seen in patients. Though tbck-/- mice experience perinatal lethality, we have begun to investigate the impact of TBCK loss in heterozygous adult mice (tbck+/-) relative to their TBCK (tbck+/+) littermates, as several compound heterozygous mutations have been identified to be pathogenic in patients with TBCK-encephloneuropathy syndrome. We hypothesize that, though TBCK Syndrome is associated with compete loss of TBCK protein, direct and/or indirect effects of this mutation may impact bone development and health even in heterozygotes. In an adult cohort of heterozygous (tbck+/-) and unaffected (tbck+/+) mice (n=7/genotype), we found no difference in skull endocast volume between genotypes, using uCT and 3D Slicer software. However, cephalometric analysis indicated differences in tbck+/- skulls. Heterozygous calvaria were altered with a wider and longer shape as compared to unaffected littermates. Additionally, histomorphometric investigations showed altered suture morphology. Our results confirm system-wide effects of TBCK loss, specifically in bone. This current work is a first step in establishing a novel pathway between these pathogenic mutations and systemic bone health. With adverse bone phenotypes noted in over half of the documented TBCK Syndrome patients, our continued objective is to identify therapeutically targetable mechanisms of TBCK-related craniofacial and bone abnormalities.

Session Title: Mendelian Phenotypes Poster Session I

PB4830 Maternal and *De Novo* Variants in *MYBPC3* Result in Presentation of Severe Neonatal Mixed Hypertrophic and Non-compaction Cardiomyopathy.

Authors:

A. Repp, T. Lee; Columbia Univ. Irving Med. Ctr., New York, NY

Introduction Variants in the cardiac myosin binding protein-C (*MYBPC3*) gene are the most common cause of familial hypertrophic cardiomyopathy (HCM), a leading cause of sudden cardiac death. A heterozygous autosomal dominant gene mutation of the *MYBPC3* gene typically presents milder phenotype, incomplete penetrance, and later age of onset. Our case poses a unique presentation of biallelic *MYBPC3* mutations via one *de novo* and one inherited variant.

Case Presentation A five-week-old female presented with new mixed phenotype HCM/NCCM with moderately diminished left ventricular (LV) systolic function. Non-invasive ventilatory support was used throughout her hospital course. She remained on milrinone for inotropic support, and high-dose intravenous diuretics to maintain a stable clinical status. Her echocardiogram prior to OHT demonstrated an LV ejection fraction of 32 % by 5/6 area x length [normal range 54-74%]; LV end diastolic volume 32.8 ml [Z-score 3.24]; LV mass 39.3 g [Z-score 3.95].

Genetic Testing and Results Given severity of symptoms, rapid genome sequencing (rGS) was sent versus the standard cardiomyopathy panel, and the patient was concurrently listed for cardiac transplant. rGS resulted in two variants in the *MYBPC3* gene: a *de novo* heterozygous pathogenic variant (c.1227-13 G>A) and maternal heterozygous likely pathogenic variant (c.1224-80 G>A). The maternal aunt is also a carrier of the likely pathogenic variant c.1224-80 G>A. The mother and maternal aunt both have had cardiac screening with echocardiogram and have no clinical findings.

Discussion The cardiogenetic team determined, with consideration of the patient's early-onset disease, that the *de novo* variant (c.1227-13 G>A) is the main cause of the severe, mixed HCM/NCCM phenotype, and that the maternal variant likely played little role in the patient's clinical outcome. This has informed the genetic counseling that has been provided to the family. Cardiac screening every three to five years for gene-positive phenotype-negative family members has been recommended. If the family were to do preimplantation genetic testing, they were counseled to test for the *de novo* variant.

Conclusion *MYBPC3*-cardiomyopathy is classically an autosomal dominant disorder. However, this case emphasizes the need for clinicians to consider varied inheritance patterns and additive pathogenic and likely pathogenic variants. Particularly in pediatrics, it is vital to consider how these genes play a role, especially in infants with severe disease. Clinicians should therefore maintain a lower threshold for rapid whole exome or genome sequencing in pediatric populations with severe disease presentation.

Session Title: Mendelian Phenotypes Poster Session II

PB4831 † Metabolic Liver Transplant: A Single Cooperative from 2005-2022

Authors:

C. Heuston[1], N. Yazigi[1], U. Ekong[1], K. Chapman[2]; [1]Georgetown, Washington, DC, [2]Children's Natl., Washington, DC

Liver transplant (LT) can increase quality and length of life for patients with inherited metabolic diseases (IMDs) who suffer severe and unpredictable complications despite strict dietary and medical management. With advancements in surgical techniques and immunosuppression, LT has been increasingly used as a therapeutic option for IMDs to compensate for enzyme insufficiencies. To gain a better understanding of the metabolic outcomes and potential benefits of LT, we retrospectively analyzed biochemical markers such as ammonium and serum amino acid levels, dietary treatment, and growth in 61 individuals with specific types of IMDs from our cohort of 99 who received LTs at the Medstar Georgetown University Hospital between 2005 and 2022. Of the 61 patients with intoxication-type IMDs, there was a relaxation in diet, discontinuation of nitrogen scavengers (if used prior to transplant), and overall increase in height and weight post-liver transplant. In patients with maple syrup urine disease (MSUD), the average isoleucine levels decreased from 270.6±142.9 and to 148.6±76.4 post-LT (p-value 0.006). In patients with urea cycle disorders (UCD), average serum ammonium decreased from 64.6±37.3 to 35.8±17.2 post-LT (p-value 0.01). Patients with methylmalonic aciduria (MMA) had statistically significant decreases in both isoleucine (p-value 0.04) and ammonium levels (p-value 0.03) post-LT. No statically significant changes in amino acids levels were found in patients with propionic acidemia (PA). For individuals with moderate to severe presentations of intoxication-type IMDs, LT is a viable medical option that achieves good metabolic outcomes and improves quality of life.

Session Title: Mendelian Phenotypes Poster Session III

PB4832 Microcephaly with or without Chorioretinopathy, Lymphedema and Mental retardation (MCLMR) syndrome in a patient from India

Authors:

P. Kaur, A. Kaur, A. Kumari, R. Daniel, A. Arora, D. Katoch, I. Panigrahi; Postgraduate Inst. of Med. Ed. and Res., Chandigarh, India

Microcephaly with or without chorioretinopathy, lymphoedema, or mental retardation syndrome (OMIIM #152950) is a rare autosomal dominant syndrome caused due to pathogenic variations in *KIF11* gene on chromosome 10q23. Microcephaly, eye abnormalities, intellectual disability and lymphodema have been observed in 91%, 72%, 67%and 47% respectively of *KIF11* mutation. We hereby report first case from India with deletion in KIF11 gene. A 15 months old male child presented with pedal odema which was noticed since birth. He had smooth perinatal transition and the developmental milestones were achieved at normal age. On examination his weight for age was 8.9 kg (-0.68 Z), height for age was 75 cms (-1.04 Z) and head circumference was - 39.5 cms (-4.53Z). He appeared to have dysmorphic features with microcephaly, sloping forehead, prominent metopic suture, upward slanting palpebral fissures, long philtrum and thin upper lip. Additional abnormalities detected were bilateral simian crease and bilateral pedal edema. His fundus examination revealed marked tessellation with well defined areas of white appearing chorioretinal atrophic patches. Focussed exome sequencing revealed contiguous heterozygous deletion of 643 bp, spanning genomic location chr10:g.(92613040_92613130)_(92613377_92613619) encompassing exonic regions 7 to 8 of the *KIF11* gene. To further confirm the results, c-DNA study was done. The results showed amplified PCR product of 729 bp in control, mother and father of index case while PCR product of 729 and 395 bp in index case depicting and confirming heterozygous deletion of 334 bp. Majority of the reported mutations in *KIF11* are point mutations . In 2018 first patient with MCMLR syndrome with a microdeletion (209Kbp) on chromosome 10q23.3 encompassing *KIF11* gene was reported. Chorioretinopathy is the specific eye abnormality, other findings reported are retinal folds, microphthalmia, and myopic and hypermetropic astigmatism. The lymphedema is confined to the dorsum of the feet and resolves spontaneously. The overall penetrance of the *KIF11* mutation can be considered to be high (95%) and variable expressivity is reported. In our case parents were clinically unaffected, fundus examination was normal and c-DNA PCR did not reveal deletion in KIF11 gene in parents, pointing towards the denovo origin of the deletion in proband. This report will also be of interest to the opthalmologists as the fundus appearance in this syndrome mimics Familial Exudative Viteroretinopathy, an inherited retinal vascular disease.

PB4833 Molecular Characterization of short stature & its syndromes in consanguineous families from Pakistan.

Authors:

T. Ishaq[1,2], F. Alzehrani[3], G. Seo[4], H. A. Ishaq[5], F. S. Alkuraya[3], O. Makitie[6,7], S. Naz[2]; [1]Yale Sch. of Med., New Haven, CT, [2]Sch. of Biological Sci. Univ. of the Punjab., Lahore, Pakistan, [3]King Faisal Specialist Hosp. and Res. Ctr., Riyadh, Saudi Arabia, [4]3billion inc, Seoul, Korea, Republic of, [5]Dept. of Radiology, Government Teaching Hosp. Shahdara, Lahore, Pakistan, [6]Dept. of Molecular Med. and Surgery and Ctr. for Molecular Med., Karolinska Inst.,, Stockholm, Sweden, [7]Children's Hosp., Univ. of Helsinki and Helsinki Univ. Hosp., Helsinki, Finland, Helsinki, Finland

Short stature may be an isolated finding caused due to growth hormone deficiency or can be accompanied by various skeletal defects. Skeletal dysplasias are a heterogeneous group of heritable disorders characterized by abnormalities of cartilage and bones which affect the shape and size of the skeleton along with disproportion of long bones and spine abnormalities. We analyzed and characterized recessively inherited short stature disorders with or without skeletal dysplasia in twelve families from the Punjab region of Pakistan. Radiographs were obtained for the probands. DNA samples from each family were first screened for a common *GHRHR* pathogenic variant and the non-coding *RMRP* gene by Sanger sequencing. Samples from families negative for variants in these genes were selected for exome sequencing to elucidate the genetic causes. The data were analyzed using Franklin software or 3billion automated pipeline. Homozygous variants having an allele frequency less than 0.01in various public databases were selected. Several *in silico* tools were used to check the pathogenicity of each variant. Sanger sequencing was completed to ascertain co-segregation of variant with the phenotype in each family. Patients in four families had short stature only while the remaining exhibited skeletal dysplasia. Initial screening revealed that affected members of one family were homozygous for a known pathogenic variant of *RMRP* while patients in three families were homozygous for a *GHRHR* variant. Exome sequencing and subsequent analysis identified novel homozygous splice-site variants in *NPR2* and *TG* in two families. Patients of the other families had previously reported variants in *EVC2*, *GH1*, *PAPSS2* and *PCNT* with the same variant in the latter gene accounting for the disorder in two families. All variants were rare in public databases as well as absent in the DNA of 200 ethnically matched controls. Our study revealed genetic heterogeneity of short stature and its syndromes and identified few founder mutations in the Pakistani population.

PB4834 Molecular detection of Sickle Cell Anemia & Classic Haplotypes in the β-globin gene *(HBB)* cluster by means of SNPs, in a group of samples from Bolívar department, for a better understanding of this rare disease in Colombia.

Authors:

M. DIAZ-MATALLANA[1], E. Benavides-Benítez[2], I. Briceño[1], J. Martínez-Lozano[1], J. Bernal[2]; [1]Univ. de La Sabana, Chía, Colombia, [2]Univ. del Sinú Elías Bechara Zainúm - Seccional Cartagena, Cartagena, Bolívar, Colombia

INTRODUCTION. The best known hemoglobinopathy is sickle cell disease (SCD), also called sickle cell anemia. According to the National Organization for Rare Disorders in the United States (NORD), the frequency of sickle cell anemia varies from country to country. Mutations in the *HBB* gene (β globin cluster) are common in people from Africa, the Mediterranean, the Middle East, India, & in people from the Caribbean and regions of Central and South America but can be found in individuals of any ethnic origin.GENERAL OBJECTIVE. Characterize hematological, biochemical, & molecularly SCD, likewise, detect classic haplotypes by DNA sequencing in a group of blood samples from the department of Bolívar, Colombia. METHODOLOGY. This work corresponds to an analytical cross-sectional study, with convenience sampling. Colombian blood samples were collected after informed consent from volunteers from several municipalities in the Bolívar department (n=287), but also samples from the Pacific region (n=13), Providencia Island (n=5), & Bogotá [abnormal hemoglobins: blood on filter paper (n=4)] were included. Data were obtained: (1) hematological (hemograms, reticulocytes); (2) Biochemical tests: dHPLC technique was used to determine Hemoglobin (Hb); (3) DNA sequencing data & classical haplotype detection through five SNP markers (designed oligonucleotides based on SNPs: *rs334, rs3834466, rs28440105, rs10128556, rs968857*).RESULTS. 103 samples have been identified by *rs334* through Sanger´s Sequencing technique. When contrasting the results of identification between *rs334* SNP Vs. Hb Chromatograms, a coincidence was found in 39 samples out of 43 samples analyzed, therefore, when comparing these techniques, a concordance of 90.7% was found. 25 samples out of 38 samples previously analyzed by *rs334* were classified into classical haplotypes CAR (12), BEN (8), CAM (2), SEN (1), & ATP-I (2). In this study, the greatest frequency of the CAR haplotype (48%), is similar to that observed in a previous study where CAR haplotype was the highest (58%). Other studies suggest that the largest proportion of individuals arriving in the Americas from Africa originated from BEN (70%) & small proportions from the CAR (17%) & SEN (13%). These SNPs-based classification have not been performed before in Colombia. The integration of different components used in this research will not only provide new knowledge into the approach & follow-up of SCD, but also a better understanding of the clinical manifestations of the disease. The results of this work will make it possible to expand the data or records of carriers & those affected, which will benefit patients & their families.

Session Title: Mendelian Phenotypes Poster Session III

PB4835 Molecular diagnosis of retinal dystrophies in a northeast population of Mexico

Authors:

R. Villafuerte-de la Cruz, J. Valdez-Garcia, A. Rojas-Martinez; Tecnologico de Monterrey, Monterrey, Mexico

Inherited retinal dystrophies (IRDs) are characterized by progressive degeneration of photoreceptors, resulting in vision loss, that may develop from birth through to late middle age. IRDs exhibit both genotypic and phenotypic heterogeneity. The purpose of this work was to know which alleles are most frequently related to IRDs in this population. All the patients had clinical diagnosis of IRDs. Using next generation sequencing (NGS), a genetic targeted panel which includes 330 genes was done to a cohort of 126 non-related patients. In total, 94 patients were solved (74.6%), 10 patients were partially solved (7.9%) and 22 patients were unsolved (17.5%). The most common mode of inheritance in this cohort was autosomal recessive. The three most common mutated genes in this cohort were *USH2A* (28.7%), *ABCA4* (15%), *RPGR* and *PROM1* (3.2%). Phenotypically, in isolated cases retinitis pigmentosa was found in 42.1%, followed by macular dystrophies 16.7% and cone rode dystrophy in 11.9%. For syndromic cases, Usher type 2 was the most common, it was found in 19.1%. It is important to emphasize that within *USH2A* patients, 25 had a pathogenic variant involving exon 13, but just 9 were homozygous. This work shows different allelic distribution compared to other works in Mexicans. Even if we didn't find any *RPE65* patient, it is possible that some other genetic therapies arrived soon for some of these patients.

Session Title: Mendelian Phenotypes Poster Session I

PB4836 Molecular outlook in RASopathies - a five years' experience

Authors:

I. Focsa[1,2], A. Pavel[2], D. Prepelita[3,2], L. Bohiltea[3,4], V. Plaiasu[4], A. Trifa[5], A. Tutulan-Cunita[2], D. Stambouli[2]; [1]Univ. of Med. and Pharmacy Carol Davila, Bucharest, Romania, [2]Cytogenomic Med. Lab., Bucharest, Romania, [3]Univ. of Med. and Pharmacy “Carol Davila”, Bucharest, Romania, [4]Natl. Inst. "Alessandrescu-Rusescu", Bucharest, Romania, [5]"Victor Babes" Univ. of Med. and Pharmacy, Timisoara, Romania

RASopathies are a group of genetic disorders caused by pathogenic variant in genes that encode components of RAS/mitogen activated protein kinase (MAPK) pathway. Inappropriate activation of the pathway leads to a series of overlapping clinical manifestation including: short stature, various degree of cognitive difficulties, cardiovascular malformations, skeletal anomalies and a predisposition to develop tumors. These group of diseases encompasses neurofibromatosis type 1 (NF1; OMIM 162200), Noonan syndrome (NS; OMIM 163950), Noonan syndrome with multiple lentigines (NSML; OMIM 151100), Noonan syndrome-like disorder with loose anagen hair (NSLH OMIM 607721), cardiofaciocutaneous syndrome (CFCS, OMIM 115150), Costello syndrome (CS, OMIM 218040), and Capillary malformation - arteriovenous malformation (CM-AVM; OMIM 608354).Here we present a cohort of 75 individuals, with a clinical suspicion of RASopathy, who were referred to our laboratory for molecular diagnosis. An NGS gene panel including RASopathies, schwannomatosis and differential diagnosis genes was run. Forty-three cases (57%) had a positive result, among which a majority, twenty-nine cases (31%), was molecularly confirmed with NF1. The second most frequent RASopathy identified in our cohort was NS (eight cases; 18,6%), five (11,6%) individuals carrying pathogenic variant in *PTPN11* while the other three (7%) cases harboring single nucleotide changes in *SOS1, KRAS and LZTR1,* respectively. The rest of the molecularly diagnosed cases was represented by one case (2,3%) each of NSLH (genomic changing in *SHOCH2*), CFCS (*BRAF*-impacted), CS (*HRAS*-affected), CM-AVM (*RASA1*-modified). Surprisingly, on two individuals clinically diagnosed with NF1 and NS, pathogenic variants in *NF2* and *CHD7* genes were detected, assigning the conclusive diagnosis as NF2 and CHARGE syndrome. Fifteen (47%) among molecularly undiagnosed cases follow the deletion/duplication analysis. Two exon deletions (exon 2 and exon 23) in *NF1* were identified. As deep intronic variants, large genomic rearrangements or variants in additional genes could be the molecular substratum of the remaining negative cases, comprehensive genomic testing may be considered.The advance of NGS technologies helps to identify more causal genes, to expand the phenotypic spectrum and to classify the disorders, being a useful tool for establishing the final diagnosis, which is crucial for an appropriate follow up and an accurate genetic counselling.

Session Title: Mendelian Phenotypes Poster Session II

PB4837 Monoallelic GATA2 mutation in a patient with multiple recalcitrant warts and critical COVID19

Authors:

S. Biglari[1], L. Youssefian[2], N. Mozafari[3], S. Zaresharifi[3], A. Saeidian[4], H. Hakonarson[5], V. Béziat[6], J-L. Casanova[7], H. Vahidnezhad[8]; [1]Dept. of Genetics and Molecular Biology, Sch. of Med., Isfahan Univ. of Med. Sci., Isfahan, Iran, Islamic Republic of, [2]UCLA, Los Angeles, CA, [3]Skin Res. Ctr., Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of, [4]Children s Hosp. of Philadelphia, Philadelphia, PA, [5]Children's Hosp. of Philadelphia, Philadelphia, PA, [6]St Giles Lab. of Human Genetics of Infectious Diseases, Rockefeller Branch, Rockefeller Univ., New York, NY, [7]The Rockefeller Univ., New York, NY, [8]Univ. of Pennsylvania, Philadelphia, PA

Introduction:

The life-threatening coronavirus disease 2019 (COVID-19) affects less than 1 in 1,000 healthy people under 50 without underlying conditions. In some patients, life-threatening COVID-19 may be caused by monogenic inborn errors of immunity (IEI) to SARS-CoV-2 with incomplete or complete penetrance. Three patients with *GATA2* deficiency were hospitalized for COVID-19 pneumonia, albeit of moderate severity.

METHODS:

In this study, the patient's peripheral blood DNA was sequenced by whole-exome sequencing (WES). Additionally, with a novel bioinformatic pipeline, we utilized whole-transcriptome sequencing (RNA-Seq) to detect pathogenic viral (including 926 different viruses) concomitantly, the causal human pathogenic variant, and the consequences of detected sequence variants in the host. The proband, a 26-year-old female presented with generalized recalcitrant warts and bilateral sensorineural hearing loss, was born to healthy, non-consanguineous parents. She had no severe infections since birth, but three years later, early in Iran's COVID-19 pandemic, she appeared with fever, cough, and shortness of breath for one week at the emergency department. After four days in the ICU, she died of severe respiratory distress syndrome.

RESULTS

Analysis of both WES and RNA-Seq data, including multistep filtering of the variants, led to the identification of a heterozygous variant in *GATA2*: NM_001145661, c.1075-1102del28, p.W360Sfs*18, which was confirmed by Sanger sequencing and was an out-of-frame 28-bp deletion. Additionally, RNA-Seq unaligned reads to the human genome were applied to a catalog of 926 different viruses, and α-HPV-2 was detected in a biopsied wart, while it was absent in the normal skin of the patient.

DISCUSSION

A monogenic susceptibility to COVID-19 is considered, and some IEI patients, with autosomal TLR3 and X-chromosome-linked TLR7 deficiencies, have been reported to develop critical pneumonia. Three hospitalized *GATA2* patients with moderate COVID-19 have been reported so far. Here, we report the first *GATA2* patient with multiple warts and lethal COVID-19.

Session Title: Mendelian Phenotypes Poster Session III

PB4838 Monogenic genes in nephrolithiasis: comparative approaches in gene discovery.

Authors:

Y-R. Huang[1], J. Chang[1], E. Su[1], M. Baum[2], D. Bodner[3], F. Hildebrandt[4], F. R. Schumacher[5], C-H. Wu[6]; [1]Case Western Reserve Univ., Cleveland, OH, [2]Boston Children's Hosp., Boston, MA, [3]Univ. Hosp., Cleveland, OH, [4]Boston Children's Hosp, Boston, MA, [5]Case Western Reserve Univ, Cleveland, OH, [6]Univ. Hosp./Case Western Reserve Univ, Cleveland Heights, OH

Introduction: Nephrolithiasis, also known as urolithiasis, kidney stones or urinary stones, are solid masses made of minerals and salts that develop in the urinary tract. The etiologies of nephrolithiasis are complex and the overall contributing risk factors to this disease are driven by a combination of genetic, metabolic, and environmental factors. Evidence shows significant contribution of genetic factors and family history to kidney stones.
Methods: We analyze the discovery methods of monogenic causes of nephrolithiasis. The monogenic causes of nephrolithiasis have been summarized into five main approaches: biochemistry, candidate gene, linkage, whole exome sequencing (WES), and others. For comparison, we picked another metabolic disease, diabetes mellitus (DM), to analyze the differences among their gene discovery and perform proportion test for analysis.
Results: There are currently 57 genes identified as monogenic causes of nephrolithiasis. Before 1985, biochemistry was the only method to discover the monogenic causes of nephrolithiasis. This approach was unique for nephrolithiasis, but not seen in DM. After 1985, the most widely used strategies for gene discovery have been the candidate gene and linkage analysis approaches. Twenty out of the 57 monogenic causes of nephrolithiasis were identified by candidate gene; and 25 out of the 57 were identified by linkage analysis. There were no significant differences observed in the analysis of monogenic causes of nephrolithiasis and diabetes with regard to candidate gene and linkage analysis methods (p value= 0.92 and 0.75 respectively). The introduction of next-generation sequencing (NGS) strategies, accelerated the pace of discovery of diseases-causing genes. However, in nephrolithiasis, only 2 out of the 57 monogenic causes were identified by WES. Six out of 36 monogenic causes of diabetes were identified by WES. In comparison, WES is underrepresented in the discovery of the monogenic causes of nephrolithiasis (p value=0.028).
Discussion: Since 2013, WES and whole genome sequencing (WGS) have discovered nearly three times as many genes as conventional approaches. With the introduction of WES and WGS, the discovery of novel monogenic causes of diseases has accelerated rapidly, however, only 2 monogenic causes of nephrolithiasis were discovered by WES. This may suggest that WES was underutilized in the discovery of the monogenic causes of nephrolithiasis, and may have great potential to lead to novel discovery.

Session Title: Mendelian Phenotypes Poster Session I

PB4839 Mosaicism for two distinct *PTEN* variants in PTEN hamartoma and blood

Authors:

L. Garlisi Torales[1], K. Woodis[1], A. D. Britt[2], L. Surrey[2], A. Srinivasan[2], A. Ganguly[3], D. Li[2], D. Adams[2], S. Sheppard[4]; [1]NICHD/NIH, Rockville, MD, [2]Children's Hosp. of Philadelphia, Philadelphia, PA, [3]Univ. of Pennsylvania, Philadelphia, PA, [4]NICHD/NIH, Rockville, MD

The *PTEN* gene encodes the phosphatase and tensin homolog tumor suppressor. Pathogenic germline variants in *PTEN* cause PTEN Hamartoma Tumor Syndrome (PHTS), which can present with a range of vascular malformations, hamartomata, tissue overgrowth, and cancer predisposition, including breast, endometrial, thyroid, colorectal, and renal, and melanoma. Less commonly, patients can carry mosaic *PTEN* variants. Patients with mosaicism may be under-diagnosed but can present with major and minor criteria for PHTS.PTEN hamartoma of the soft tissue (PHOST) is a vascular anomaly that is often intra-muscular in the extremities. Histopathologically, it presents with the proliferation of fibroadipose tissue in the muscle and different types of disorganized vessels, which may be slow flow or fast flow. One of the differential diagnoses for slow flow PHOST is fibroadipose vascular anomaly (FAVA), and can be difficult to distinguish on imaging or histopathology.A 12 year-old female patient presented with a vascular malformation in her right ankle with pain and limited mobility, initially diagnosed with FAVA with negative genomics. Re-biopsy and subsequent genetic testing reveal two distinct mosaic *PTEN* variants in multiple tissues. Penn GDL Somatic Overgrowth and VM v3 panel performed on genomic DNA isolated from tissue biopsy revealed a somatic, pathogenic *PTEN* variant (c.683delA 2.0-2.1% mosaicism level). *PTEN* sequencing on genomic DNA from leukocytes revealed a different variant with higher mosaicism level (c.202_209+18delins27 (splice donor), 20-30% mosaicism level). Neither variant was found on genomic DNA isolated from saliva sample using the Penn GDL Somatic Overgrowth and VM v3 panel. She was diagnosed with PHTS with low grade mosaicism.This case demonstrates important concepts in genetic testing of patients with vascular anomalies. Genetic testing can be used to define and differentiate PTEN hamartoma from FAVA. Testing of additional samples, as well as using updated sequencing technology with deeper coverage, led to identification of the genetic cause. Furthermore, in most cases, genetic testing can direct medical care. However, to our knowledge, there are no guidelines regarding cancer screening in individuals with *PTEN* mosaicism. Further work is needed to understand the risk of cancer in individuals with *PTEN* mosaicism (i.e., whether this should be based on the distribution of the variants).

Session Title: Mendelian Phenotypes Poster Session II

PB4840 Mouse knockout shows *Sumo1* is essential for embryonic development and contributes to adult organ function.

Authors:

Y. Gu, D. L. Nelson; Baylor Coll. of Med., Houston, TX

Protein Sumoylation is a posttranslational modification that conjugates the small ubiquitin-like modifier (Sumo) to target proteins through covalent bond. The SUMO family includes *SUMO1-5*; *SUMO1-3* are ubiquitously expressed while *SUMO 4* and *5* are tissue-specific. *SUMO1* mutation has been reported in individuals with cleft lip and reduced levels of SUMO1 in heart have been found in heart failure. In a search for genetic modifiers of Fragile X associated Tremor/Ataxia syndrome (FXTAS) and Fragile X associated Primary Ovarian Insufficiency (FXPOI), we identified *SUMO1*. To understand *SUMO1* function in normal development and potential roles in modification of FXTAS and FXPOI, we created a new *Sumo1* knockout first mouse model using the EUMMR ES cell HEPD0731_5_10. Surprisingly, the majority of mid-to-high percentage chimeras (4 of 5) showed neck skin lesions in adults, but germline transmission was eventually achieved. When *Sumo1* heterozygous males were crossed with *Sumo1* heterozygous females, no homozygous mice were produced, indicating embryonic lethality. *Sumo1* homozygous embryos die before embryonic day 11.5 (E11.5). Curiously, among 135 offspring from *Sumo1* heterozygous mating, 103 were heterozygous while only 32 were wild type, with no homozygous knockouts. Recovery of wild type pups was reduced (33% verse 24%) possibly indicating that gametes carrying the *Sumo1* mutation had an advantage over the wildtype gametes during fertilization. To confirm this result, we set up mating of heterozygous mice with C57BL/6 wildtype mice. We identified 68 wildtype (42%) and 93 heterozygous (58%) pups out of 161 offspring, an 8% deviation from the expected numbers, consistent with results from crossing heterozygous mice and supporting the notion of a gametic advantage. *Sumo1* heterozygous mice showed a significant reduction in weight, especially in mid-to-late adulthood. Heterozygous males have small testes and kidneys while enlarged hearts in heterozygous females indicate heart failure, with increased weight in their spleen, kidneys and lungs. This new *Sumo1* knockout model provides a novel tool to study protein Sumoylation in embryonic development, fertilization, growth and adult organ function. In ongoing work, we found brain weight reduction in *Sumo1* heterozygous females and uneven expression of *Sumo1* in cerebral cortex at advanced ages, suggesting roles in protein Sumoylation in mature brain function. Studies of the effects of *Sumo1* reduction on a mouse FXTAS model are underway.

PB4841 Multi-omics uncover dysregulated cerebellar pathways associated with neurodegeneration in a mouse model of Chediak-Higashi Syndrome.

Authors:

M. Talbert, S. Greene, F. Frost, M. Morimoto, D. Maynard, C. Toro, W. Gahl, M. Malicdan; NIH, Bethesda, MD

Background: Chediak-Higashi Syndrome (CHS) is a rare autosomal recessive disorder caused by bi-allelic mutations in the lysosomal trafficking regulator (*LYST*) gene. It is characterized by partial oculocutaneous albinism, bleeding diathesis, immune deficiency, and progressive neurodegeneration. The underlying function of LYST remains unclear. Animal models, such asthe beige mouse (*bg*), with a spontaneous loss-of-function mutation in the C-terminal region of LYST, have provided valuable insights into the pathogenesis of CHS. While the *bg* mouse exhibits immunologic and bleeding phenotypes characteristic of CHS, it lacks a neurodegenerative phenotype.**Methods:** To further investigate the function of LYST, we utilized CRISPR/Cas9 genomic engineering to generate a *Lyst* knockout model ($Lyst^{\Delta/\Delta}$). Our approach involved targeting exons 4 to 53, effectively deleting a majority of the open reading frame of murine *Lyst*. We conducted molecular and phenotypic characterization, as well as comprehensive multi-omics profiling.**Results:** Molecular characterization of tissues from $Lyst^{\Delta/\Delta}$ mice confirmed the deletion of *Lyst*, as both transcript and protein levels were undetectable. Phenotypic characterization of $Lyst^{\Delta/\Delta}$ mice revealed that they are viable and, similar to *bg* mice, have lighter pigmentation of the coat and skin and exhibit prolonged bleeding times. Compared to *bg*, the $Lyst^{\Delta/\Delta}$ develop signs of ataxia by 9 months, mirroring the neurodegenerative aspects of CHS. To further investigate the function of Lyst, we performed transcriptomic and lipidomic analyses on the cerebellum and cortical brain tissues from $Lyst^{\Delta/\Delta}$ and wild type mice at 1 month and 18 months of age. Bulk RNA sequencing analysis revealed a higher number of differentially expressed genes in the cerebellum of older $Lyst^{\Delta/\Delta}$ mice, suggesting progressive cerebellar involvement. Untargeted lipidomics highlighted significant differences in lipid levels between wild type and $Lyst^{\Delta/\Delta}$ in mice in cerebral cortex and cerebellum.**Conclusion:** Our findings demonstrate that the $Lyst^{\Delta/\Delta}$ model recapitulates key features of the human CHS phenotype, including CHS-associated neurodegeneration. This model provides a reliable platform for studying the function of LYST and exploring future therapies for CHS. Through comprehensive molecular, phenotypic, and multi-omic characterization of $Lyst^{\Delta/\Delta}$, we have gained a better understanding of the underlying mechanisms driving CHS, paving the way for the development of targeted interventions for this devastating disorder.

PB4842 *MUSK*-related disorder severity is predicted by protein domains and allele combinations

Authors:

B. Cocanougher, L. Francescatto, S. Liu, A. Behura, M. Anneling, D. G. Jackson, K. Deak, C. Hornik, M. K. ElMallah, C. E. Pizoli, E. C. Smith, K. Tan, M. T. McDonald; Duke Univ., Durham, NC

Purpose: Biallelic loss-of-function variants in the muscle specific kinase (*MUSK*) gene lead to clinically variable neuromuscular weakness. This variability in *MUSK*-related disorders ranges from fetal demise to adult-onset limb-girdle weakness. How combinations of specific variants contribute to disease severity remains incompletely explored. Individual domains are important for separate functions, such as agrin binding (Ig1 domain), Wnt binding (Frz domain), DOK7 binding (juxtamembrane domain), and phosphorylation of downstream signaling targets (tyrosine kinase domain). Are variants that impact one domain more severe than variants that impact another?
Methods: We report one new case of neonatal onset *MUSK*-related congenital myasthenic syndrome (CMS). In the literature, we identify 45 additional cases of *MUSK*-related disorders; 23 of these cases were *MUSK*-related CMS and 21 were *MUSK*-related fetal akinesia deformation sequence. We analyze 1) null variants for which no protein is expressed and 2) missense variants and intragenic deletions, which result in altered protein products. For missense variants, we ask if disease severity is correlated with the protein domain that is directly impacted by the mutation. Next we ask whether the combination of variant types, such as null + null, null + missense, or missense + missense, predicts severity. Lastly, we combine these analyses to ask whether the combination of protein domain and allele combination types synergistically contribute to disease severity.
Results: Biallelic null variants are the most uniformly severe allele combination, resulting in fetal loss. Homozygosity for the *MUSK* p.I575T variant, which disrupts DOK7 binding, also results in fetal loss and is the most severe missense variant. Variants that disrupt the Ig1 domain are the most severe type of missense variant in *MUSK*-related CMS. The kinase domain is the most commonly mutated domain; kinase domain mutations have the widest range of disease severity. A mathematical model to predict disease severity by integrating variant location and allele combinations is developed.
Conclusions: The severity of *MUSK*-related disorders is impacted by both the location of missense variants within protein domains and the combination of allele types. The approach developed may be generally applicable to autosomal recessive disorders related to genes which code for proteins with multiple domains and multiple functions.

Session Title: Mendelian Phenotypes Poster Session III

PB4844 Natural history and molecular characterization of patients with Metaphyseal Enchondromatosis with D-2-Hydroxyglutaric aciduria (MCHGA)

Authors:

C. Montano[1], E. Wohler[2], J. Kim[2], G. Gottesman[3], L. Burrage[4], G. Ascone[1], C. Ferreira[1], N. Sobreira[2]; [1]Natl. Human Genome Res. Inst./NIH, Bethesda, MD, [2]McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD, [3]Shriners Hosp. for Children, Tampa, FL, [4]Baylor Coll. Med., Houston, TX

Metaphyseal enchondromatosis with D-2-hydroxyglutaric aciduria (MCHGA; OMIM 614875) is characterized by D-2-hydroxyglutaric aciduria and multiple enchondromas. MCHGA has been reported in 12 probands, all presenting in infancy with widespread enchondromatosis. Five probands had global developmental delay, and four had vascular malformations. While its molecular cause is not well known, four probands had somatic mosaic isocitrate dehydrogenase 1 (*IDH1*) gain-of-function variants identified in blood. One patient developed acute myeloid leukemia, but other malignancies had not been reported in probands with MCHGA to date. To better understand the phenotypic spectrum of patients with MCHGA, we characterized the natural history and molecular findings of ten additional patients investigating their germline and/or somatic DNA with whole exome sequencing and/or digital PCR targeting the p.Arg132Cys and p.Arg132His variants in *IDH1* with a sensitivity of >0.1% VAF.
All probands presented with widespread enchondromas in early childhood and normal cognition. While four had motor developmental delay secondary to skeletal deformities, and three had vascular anomalies, none had hypotonia or other dysmorphic features as previously described in patients with MCHGA. Two adult probands presented with chondrosarcoma, and a third pediatric patient had an enchondroma of the skull base with borderline chondrosarcoma characteristics. Ours is the first report of an association between MCHGA and chondrosarcomas. Eight patients underwent molecular testing; most (7/8) had positive findings. Two patients had *IDH1*-p.Arg132Cys variants identified in their enchondromas (VAF 26-46%) as well as in blood (0.8%) or saliva (1.5%). Three patients with either negative or unavailable somatic testing had positive molecular testing in saliva or blood (VAF 0.4-5.5%). On the other hand, two patients with an *IDH1*-p.Arg132Cys variant in the tumor tissue had negative testing for that variant in blood or saliva. The proband with the most severe phenotype exhibited a third *IDH1* variant (*IDH1*-p.Arg132Gly) in bone marrow (VAF 37%), which had not been previously described.
Our novel findings of the association of chondrosarcomas and vascular anomalies with MCHGA, as well as the identification of low levels of mosaicism detected in saliva or blood, highlight the exciting possibility of early non-invasive diagnosis of MCHGA with digital PCR and the importance of thoughtful tumor surveillance in these patients.

Session Title: Mendelian Phenotypes Poster Session I

PB4845 Neuroaxonal dystrophy with osteopetrosis syndrome caused by a novel biallelic missense homozygous variant in *SCYL2*

Authors:

D. Chitayat, O. Greenberg, Y. Fisher, A. Staines, P. Shannon; Univ. of Toronto, Toronto, ON, Canada

Neuroaxonal dystrophy with osteopetrosis syndrome (OMIM # 600329) was first by Fitch et al., (1973) in a consanguineous Moroccan Jewish family. Further cases were reported by Ambler et al., (1983), Jagadha et al., (1988), and Reese et al., (1995) suggestive of a single gene disorder with autosomal recessive inheritance. However, to date, no genetic variant was linked to this disease. We report sibs, born to consanguineous Pakistani parents. Both were identified prenatally with cerebral ventriculomegaly and agenesis of the corpus callosum. Autopsy done on both showed similar abnormalities including facial dysmorphism including high arched palate, flattened nasal tip with anteverted nose, a long philtrum and micrognathia. Hands showed bilateral clinodactyly. Radiographic images were suggestive of osteopetrosis. Brain histopathology showed dilated ventricles, agenesis of the corpus callosum and hypoplastic pyramids and peduncles. Microscopic examination revealed multiple axonal swellings in the central and peripheral nerve systems. The bones demonstrated thin metaphyseal cortical bone with calcified chondroid and hypertrophic osteoclasts with intracytoplasmic inclusions. Electron microscopy from the spinal cord revealed aggregates of irregular membrane bound organelles in neuronal axons. Trio whole exome sequencing identified SCYL2 (NM_017988) c.902G>A; p. Arg301His, variant, heterozygous in parents and homozygous in affected fetuses. This variant was previously classified as a variant of unknown significance. SCYL2 is a regulatory protein pseudokinase linked to Clathrin-coated vesicle trafficking. Mutations in other proteins of this system have been associated with neuro-developmental disorders SCYL2 truncating variants have recently been implicated in arthrogryposis as well. We suggest the SCYL2, p. Arg301His variant as the first described pathogenic mutation in neouroaxonal dystrophy with osteopetrosis syndrome. Ref: Fitch et al., Arch. Path. 95: 298-301, 1973; Ambler et al., Neurology 33: 437-441, 1983. Jagadha et al., Acta Neuropath. (Berlin) 75: 233-240, 1988; Rees et al., Pediat. Neurosurg. 22: 321-327, 1995

PB4846 Neurofilament light chain levels in cerebrospinal fluid is useful for evaluating the disease activities of cerebral adrenoleukodystrophy

Authors:

T. Kakumoto[1], T. Matsukawa[1], H. Ishiura[2,1], H. Mori[3], S. Tsuji[1,4], T. Toda[1]; [1]The Univ. of Tokyo, Bunkyo-ku, Tokyo, Japan, [2]Okayama Univ., Okayama, Japan, [3]Jichi Med. Univ., Tochigi-ken, Japan, [4]Intl. Univ. of Hlth.and Welfare, Chiba-ken, Japan

Objective: Adrenoleukodystrophy (ALD) has a poor prognosis when it progresses to the cerebral form (CALD). The aim of this study is to investigate whether cerebrospinal fluid (CSF) neurofilament light chain (cNfL) serves as a sensitive biomarker for evaluating the disease activity of ALD and for assessing response to hematopoietic stem cell transplantation (HSCT). **Methods:** First, we conducted a cross-sectional study of 45 male ALD patients confirmed to carry pathogenic variants in *ABCD1*. The cNfL levels in the patients with the cerebral form of ALD (CALD) or the cerebello-brainstem form of ALD (CBALD) were compared with those in patients with adrenomyeloneuropathy (AMN). The Spearman's rank correlation coefficient was used to investigate the correlation between cNfL levels and brain-MRI-based Loes severity scores. Next, a longitudinal analysis was performed on a subset of the cross-sectional study population that underwent multiple CSF examinations. A longitudinal analysis of cNfL levels was further conducted to investigate the response to HSCT. **Results:** The cNfL levels in 22 patients with CALD were significantly higher than those in 18 patients with AMN (median, 5,550 vs 1,420 pg/mL; $p<0.001$). The cNfL levels in five patients with CBALD were markedly high (median 10,100 pg/mL). Logistic regression analysis revealed that the cutoff cNfL level of 1,920 pg/mL showed good sensitivity (95.5%) and specificity (83.3%) for distinguishing CALD from AMN. cNfL levels showed a positive correlation with the Loes scores of brain lesions ($p<0.001$). A longitudinal analysis revealed that the cNfL levels in three AMN patients who later converted to CALD was increased above the cutoff cNfL level at the time of conversion or increased even during the period of AMN, whereas the cNfL levels in four AMN-staying patients were consistently below the cutoff cNfL level for 3.5-10.9 years. In ten ALD patients who underwent HSCT, their cNfL levels decreased 3-24 months after HSCT. In the two patients who showed progressive cognitive decline, whose substantial increase in the cNfL was observed. **Conclusions:** The cNfL level is useful for evaluating the disease activities of CALD and CBALD. Longitudinal measurement of cNfL level may be a good biomarker to detect the conversion of AMN to CALD. The cNfL level may reflect the response to HSCT.

Session Title: Mendelian Phenotypes Poster Session III

PB4847 Neurogenetic syndromes with cerebral palsy revealed by whole-exome sequencing

Authors:

N. Okamoto[1], E. Nishi[1], Y. Hasegawa[1], K. Yanagi[2], T. Kaname[2], F. Miya[3], M. Yamada[4], H. Suzuki[5], T. Takenouchi[6], K. Kosaki[3]; [1]Dept. of Med. Genetics, Osaka Women's and Children's Hosp., Izumi, Osaka, Japan, [2]Dept. of Genome Med., Natl. Res. Inst. for Child Hlth.and Dev., Tokyo, Japan, [3]Ctr. for Med. Genetics, Keio Univ. Sch. of Med., Tokyo, Japan, [4]Ctr. for Med. Genetics, Keio Univ., Tokyo, Japan, [5]Inst. of Med., Univ. of Tsukuba, Tsukuba, Japan, [6]Dept. of Pediatrics, Keio Univ. Sch. of Med., Tokyo, Japan

[Background] Cerebral palsy (CP) is a group of permanent disorders characterized by abnormalities in movement or posture. It is attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. CP-like disorders may clinically resemble CP, but do not fulfill CP criteria and often have a progressive course and/or neurodevelopmental regression. Common environmental and genomic factors may cause CP. The number of genetic conditions associated with CP has rapidly increased with the development of molecular analyses. The aim of the present study was to delineate the genotypic and phenotypic spectra of children with CP. We performed whole-exome sequencing (WES) or whole-genome sequencing (WGS). We established a molecular diagnosis in 21 out of 31 families with CP or CP-like disorders. **[Methods]** Blood samples were collected from patients and their parents after they provided written informed consent. WES or WGS was used to identify causative variants. The present study was included in the Initiative on Rare and Undiagnosed Diseases project, which was established in Japan to provide accurate diagnoses, discover etiologies, and, ultimately, provide cures for rare and undiagnosed diseases. **[Results]** Causative variants in 11 different genes were identified in 21 (68%) out of 31 probands: *CTNNB1* (n = 4), *KIF1A* (n = 3), *SPAST* (n = 3), *NKX2-1* (n = 2), *CYP2U1* (n = 2), *ATP1A3*, *GNAO1*, *HPDL*, *PLP1*, *PYCR2*, and *TBCD* (n=1). Brothers with *TBCD1* variants showed cerebellar atrophy. **[Conclusion]** Some CP or CP-like disorders may have unique characteristics in the form of a constellation of clinical symptoms, which may facilitate their recognition and shorten the diagnostic process. For example, pathogenic variants in the *CTNNB1* gene have been identified in patients with various diseases, including neurodevelopmental disorder with spastic diplegia and visual defects. The present results will broaden the known clinical manifestations of neurogenetic syndromes with CP or CP-like disorders. A definitive genetic diagnosis is beneficial for the genetic counseling and clinical management of individuals. The present results indicate that CP without apparent environmental factors needs to be included in the current recommendation of WES or WGS in the diagnostic evaluation of individuals with neurodevelopmental disorders.

Session Title: Mendelian Phenotypes Poster Session I

PB4848 New phenotypic features in Osteoglophonic dysplasia.

Authors:

A. Othman[1], H. Babcock[1], C. Gill[2], J. Fraser[3,4,5], D. Regier[5], K. Simpson[5], C. Ferreira[1]; [1]Skeletal Genomics Unit, Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [2]Dept. of Orthopaedic Surgery, Univ. of Texas Southwestern Med. Ctr. and Scottish Rite Hosp. for Children, Dallas, TX, [3]Prenatal Pediatrics Inst., Children's Natl. Hosp., Washington, DC, [4]Ctr. for Genetic Med. Res., Children's Natl. Hosp., Washington, DC, [5]Rare Disease Inst., Children's Natl. Hosp., Washington, DC

Osteoglophonic dysplasia (OGD) is a rare autosomal dominant skeletal disorder with 16 patients described. It is caused by distinct monoallelic *FGFR1* pathogenic gain-of-function variants—currently five causative variants are known. The *FGFR1* gene encodes a fibroblast growth factor receptor protein crucial for the osteogenesis of the axial and craniofacial skeleton. Classical features of OGD include pancraniosynostosis, prominent forehead, proptosis, widely-spaced eyes, low-set ears, midface retrusion, short nose, prognathism, impacted teeth, and rhizomelic shortening of the limbs. Radiographs show a characteristic copper-beaten appearance of the skull and multiple long bone lytic lesions corresponding to non-ossifying fibromas. Patients can develop hypophosphatemia related to increased levels of FGF23, a phosphaturic hormone. Here, we present two previously unreported, unrelated pediatric patients with OGD due to the pathogenic variant c.1141T>C, p.(Cys381Arg) in exon 9 of the *FGFR1* gene, which is predicted to disrupt the transmembrane domain of the gene. Both patients were initially given a diagnosis of Pfeiffer syndrome, an allelic but distinct syndromic craniosynostosis disorder caused by other gain-of-function variants in *FGFR1*. Both patients exhibited the traditional clinical and radiological features of the syndrome. Interestingly, the two patients showed increased frontal temperature and sensitivity to heat with excessive sweating. Their physical examination also revealed a common bilateral overlapping pattern of the toes with the second and fourth toe either overlapping or underriding the third. These two features have not been reported in the literature before. This report aims to highlight the importance of distinguishing OGD from allelic disorders (Pfeiffer syndrome and others) and expand upon the previously reported clinical phenotype of OGD including possible genotype-phenotype correlations.

Session Title: Mendelian Phenotypes Poster Session II

PB4849 NGS driven identification of a rare homozygous variant in the *GNE* gene, causing hereditary inclusion body myopathy type 2

Authors:

Z. Ali[1], J. Klar[2], A. Fatima[3], U. Abdullah[4], K. Khan[5], S. Baig[6], N. Dahl[7]; [1]Univ. of Swat, Pakistan, Charbagh, Swat, Pakistan, [2]IGP, Uppsala, Sverige, Sweden, [3]Aga Khan Univ., Karachi, Karachi, Pakistan, [4]UIBB, PMAS-Arid Agriculture Univ., Rawalpindi, Pakistan, [5]Lurie Children s Hosp., Chicago, IL, [6]Dept. of Biological and BioMed. Sci., Aga Khan Univ., Karachi 74000, Pakistan, Karachi, Pakistan, [7]Uppsala Univ, Uppsala, Sweden

Hereditary inclusion body myopathy type 2 (HIBM2; OMIM: 600737) is a rare autosomal recessive neuromuscular disorder caused by mutations in the *GNE* (OMIM: 603824) gene. The associated clinical manifestations are non-specific including foot drop, gradual progressive weakness in distal and proximal extremities of lower and upper limbs (sparing quadriceps muscles). Muscle biopsy show inclusion bodies and rimmed vacuoles within affected muscles. The clinical presentation in inclusion body myopathies are non-specific and genetic investigations using whole exome sequencing (WES) has now emerged as an important diagnostic tool. We identified a novel homozygous *GNE* missense variant in three Pakistani siblings with myopathy. Two additional siblings and parents were healthy. Data from WES were filtered against a recessive model of inheritance, disease relevance, presence in population databases, or predicted to be benign by various bioinformatics tools. The analysis revealed a single homozygous gene variant in the *GNE* gene (NM_001190384:c.289T>C; p.(Tyr97His)) in the three affected children. The two healthy siblings were either heterozygous or homozygous for the wild type allele and the parents were heterozygous for the *GNE* gene variant. The identified variant is highly conserved and was predicted to be ’deleterious’ by various bioinformatics prediction tools. Bidirectional Sanger sequencing was used to confirm the segregation of the *GNE* gene variant. The present study expands the mutations spectrum in the *GNE*-gene, with possible implications for improved understanding of disease pathophysiology. Furthermore, the current study highlights the importance of NGS, in particular WES, for a specific diagnosis in hereditary myopathy.

Session Title: Mendelian Phenotypes Poster Session III

PB4850 *NKX6-2*- related leukodystrophy: natural history study, clinical phenotype, biomarkers, and gene therapy

Authors:

K. Zhelcheska, V. Chelban, H. Houlden; UCL Queen Square Inst. of Neurology, London, United Kingdom

Background/ Objectives: Hypomyelinating leukodystrophies are a heterogeneous group of genetic disorders characterized by detectable myelin deficiency in the brain with a wide spectrum of phenotypes. A phenotype associated with bi-allelic mutations in the *NKX6.2* gene that leads to spastic ataxia 8 (SPAX8), autosomal recessive, with hypomyelinating leukodystrophy, has been described. Despite the discovery of various other genetic forms of hypomyelinating leukodystrophies, many remain unsolved.**Methods:** The study included affected individuals with spastic ataxia and hypomyelination from unrelated families, and homozygosity mapping and exome sequencing were implemented to identify and characterize the causal variants in *NKX6-2*.**Results:** 33 individuals from 21 families carrying compound heterozygous and homozygous pathogenic variants in *NKX6-2* were identified. The key neuroimaging feature in most cases was of hypomyelination.**Conclusion:** Phenotypic and neuroimaging expression in *NKX6-2* mutations vary from a complex, neonatal onset at the severe end to a childhood onset at the milder end of the spectrum. We plan to expand our analysis to conduct a natural history study to evaluate disease progression, and to identify serial biomarkers. There is an important need to develop gene transfer methods to replace and rescue *NKX6-2* protein loss.

Session Title: Mendelian Phenotypes Poster Session II

PB4852 Novel and recurrent variants in *PAX6* in four patients with ocular phenotypes from Southeast Asia

Authors:

E. Tan, J. Goh, A. Lai, H. Wei, S. Jamuar; KK Women's and Children's Hosp., Singapore, Singapore

Aniridia is an autosomal dominant condition characterized by the complete or partial absence of the iris, often with additional presentations such as foveal hypoplasia, nystagmus, cataract, glaucoma, and other ocular abnormalities. Most cases are caused by heterozygous mutations in the paired box 6 gene (*PAX6*) which codes for a transcription factor that regulates eye development. We report the identification of *PAX6* variants in four patients of different ethnic backgrounds with ocular phenotypes. Two of the variants are recurrent single-nucleotide substitutions - one is a substitution in the first codon which had been reported in a Chinese patient with complete aniridia, while our patient had bilateral aniridia. Another recurrent variant maps to intron 5 of the canonical transcript and also exon 5a of an alternative transcript. The substitution is predicted to facilitate its transcription over the canonical transcript, causing it to be expressed at a level that is higher than normal. This patient did not have aniridia but had left eye proptosis and rotatory nystagmus. He also had olfactory neuroblastoma, and eventually passed away from the recurrence and progression of a frontotemporal tumor. The other two pathogenic variants are novel, and are found in two patients with isolated aniridia. One is a single nucleotide duplication in exon 11 while the other involves duplication of 8 nucleotides in exon 13. Both are predicted to lead to premature termination of translation. For the recurrent variants, the comparison of phenotypes for patients with identical variants would shed light on the mechanisms of pathogenesis; and the discovery of two novel variants expands the spectrum of *PAX6* mutations.

Session Title: Mendelian Phenotypes Poster Session III

PB4853 Novel biallelic splice-site variants in *ATP8A2* causing cerebellar ataxia, impaired intellectual development and disequilibrium syndrome-4.

Authors:

D. Raghavan MS[1], V. K Gowda[2], U. kinhal[2], A. S Manjunath[2], .. Babu G[3], A. Srivastava[4]; [1]Sanjay Gandhi Post graduate Inst. of Med. Sci.sSanjay Gandhi Postgraduate Inst. of Med. Sci., Lucknow, India, [2]Indira Gandhi Inst. of child Hlth., Bangalore, India, [3]Head bioinformatics Progenesis India .Ltd, Chennai, India, [4]Sanjay Gandhi Postgraduate Inst. of Med. Sci., Lucknow, India

Recessively inherited variants in ATP8A2 are the genetic basis of cerebellar ataxia, impaired intellectual development and disequilibrium syndrome 4 (CAMRQ4: OMIM#615268). ATP8A2 is a P4 ATPase (adenosine triphosphate) that function in the transport of aminophospholipids, and plays an important role in vesicular trafficking, cellular survival of neurons and cell signaling through active transport of phospholipids across the cell membrane. We included five cases from four families with biallelic pathogenic / likely pathogenic variants in ATP8A2 gene identified by solo whole exome sequencing. The variants identified were validated by Sanger sequencing in patients and parents. The age of presentation ranged from 1 to 14 years with onset of disease in neonatal period to infancy in all cases. Male: female ratio was 4:1. The common features identified in all were severe developmental delay with none attaining neck control, speech delay with absence of expressive and receptive language, hypotonia noted since birth, feeding difficulties, visual impairment, ptosis, areflexia, involuntary movements and microcephaly. The onset of movement disorder was before 6 months of age: choreoathetosis in four and dystonia in one case respectively, Visual complaints noted were optic atrophy (3/5), ophthalmoplegia (3/5), hypopigmented iris (1/5) and infero-nasal lens dislocation (1/5). Facial dysmorphism was noted in all with a varying combination of broad forehead, up turned nose, low set ears, triangular face, and gum hypertrophy. Hearing was impaired in 3/5 cases. Neuroimaging, Electroencephalogram and nerve conduction studies were normal in all. Splice variants (c.780-2A>G, c.3272+1G>A and c.3019-1G>A) in homozygous state were identified of which two were novel. Variant c.3272+1G>A was recurrent and appeared in two unrelated families. All were pathogenic/ likely pathogenic as per ACMG classification. Minigene assay followed by Western blot confirmed pathogenicity of the identified splice site variants. AutoMap analysis showed shared regions of homozygosity suggesting a founder effect for the recurrent variant. The unusual features reported were facial dysmorphism in all, lens dislocation and iris hypopigmentation in one case. To conclude, The ATP8A2 mutation series shows multi system involvement including both upper and lower motor neurons, basal ganglia, cerebellum, optic nerve and retina, auditory system. This series is the first from India and adds to the existing literature on the disease.

PB4854 Novel facial gestalt and cancer risk in patients with Beckwith-Wiedemann spectrum caused by CDKN1C mutations

Authors:

S. Klein[1], E. Hathaway[1], A. George[1], J. Kalish[2]; [1]CHOP, Philadelphia, PA, [2]Children s Hosp. of Philadelphia, Philadelphia, PA

Introduction: Beckwith-Wiedemann Spectrum (BWSp) is caused by genetic and epigenetic alterations in genes on chromosome 11 that regulate cell growth and division. Dysregulation of the maternally expressed cell cycle regulating gene *CDKN1C*, cyclin-dependent kinase inhibitor 1C, occurs in about 60% of cases of BWSp. However, given the variable phenotype in BWSp due mosaic alterations in most patients with BWSp, the specific phenotype and role *CDKN1C* is not well defined. Here, we study the role of *CDKN1C* in the broader BWSp phenotype caused by *de novo* or maternally inherited variants. In families, the mutation can be present for several generations prior to an affected child being born from a carrier mother. Notably, patients with *CDKN1C* variants may not present with classic BWS and tumor risk compared to the broader BWSp population. **Methods:** We performed a comprehensive literature search using the terms "BWS", "Beckwith-Wiedemann Syndrome/Spectrum", and "*CDKN1C*" to identify 116 cases of BWS-*CDKN1C*. We then assessed a previously unreported cohort of 15 patients with BWSp with *CDKN1C* variants to identify a facial dysmorphia pattern that can be distinguished from other patients with BWSp. The facial features were described by at least two geneticists and compared/contrasted to reach a consensus list of features for each patient. Cardinal and suggestive BWS features were also evaluated for all patients reported and tumor risk was established based on available reports. **Results:** The most common phenotypes were macroglossia (96%), macrosomia (48%), ear creases (86%), and abdominal wall differences (74%). Facial features distinct from other epigenotypes of BWSp included down-slanting palpebral fissures with almond-shaped eyes, hypertelorism, and telecanthus. Tumors within this group, of 131 total patients, included four cases of neuroblastoma (3%), one case of acute lymphoblastic leukemia (<1%), and one case of melanoma (<1%). No cases of hepatoblastoma or Wilms tumor (the most common BWSp tumors) were reported. **Conclusion:** Overall, this study identifies unique features associated with *CDKN1C* variants in BWSp, specifically a facial gestalt, enabling more accurate clinical correlation and management. These findings also clarify the cancer risk associated with BWSp and *CDKN1C* variants, guiding surveillance, and treatment strategies. Lastly, identifying the etiology enables more precise counseling and family planning.

Session Title: Mendelian Phenotypes Poster Session II

PB4855 Novel mutations in BLOC-1 and BLOC-2 HPS genes in patients with non-syndromic ocular albinism: using NGS to improve diagnosis and follow-up

Authors:

R. Artuso[1], L. Tiberi[1], C. Rocca[2], S. Bargiacchi[1], G. Bacci[3], E. Marziali[3], P. Fortunato[3], S. Landini[1], E. Dirupo[1], L. Zaroili[1], D. Vergani[1], E. Sieni[4], M. Coniglio[4], L. Pieri[5], R. Caputo[3], A. Peron[1,2]; [1]Med. Genetics Unit, Meyer children's Hosp. IRCCS, Florence, Italy, [2]Dept. of Clinical and Experimental BioMed. Sci. "Mario Serio", Univ. of Florence, Florence, Italy, [3]Pediatric Ophtalmology Unit, Meyer Children's Hosp. IRCCS, Florence, Italy, [4]Dept. of Paediatric Oncohematology, Meyer children's Hosp. IRCCS, Florence, Italy, [5]Ctr. for Bleeding Disorders and Coagulation, Careggi Univ. Hosp., Florence, Italy

Background: Hermansky-Pudlak syndrome (HPS) is an autosomal recessive disorder characterized by oculocutaneous albinism (OCA) or ocular albinism (OA), a bleeding diathesis, and, in specific subtypes, organ involvement (pulmonary fibrosis, granulomatous colitis, or immunodeficiency). To date, 11 HPS subtypes (HPS-1 to HPS-11) have been molecularly identified. Methods: We performed trio exome sequencing in paediatric patients diagnosed with OCA/OA at Meyer Children’s Hospital, Florence. Results: In seven7 paediatric patients with apparently isolated OCA/OA we unexpectedly identified pathogenic variants in HPS-associated genes. Six were novel variants in *BLOC1S5, HPS3, BLOC1S3, HPS6* and three were previously deported changes in *HPS6 and HPS5.* All the novel variants were classified as pathogenic and most of them are frameshift, as previously reported.All patients showed an apparently isolated ocular phenotype with no organ involvement. Only one of two siblings with variants in *BLOC1S5* developed a pilocytic astrocytoma, deemed to be unrelated to HPS. Conclusions: Our results reinforce genotype-phenotype correlations for BLOC-1 and BLOC-2 deficiency, improving also the recognition of mild phenotypes. Reporting novel variants especially in *BLOC1S5* and *BLOC1S3* is important given the small number of patients described in the literature. Also, exome sequencing allowed reaching a molecular diagnosis that was more accurate than the clinical one and starting specific hematologic follow-up.

Session Title: Mendelian Phenotypes Poster Session III

PB4856 Novel pathogenic variants identified in BBS genes through Genome Sequencing - BBS1 exon 10-11 deletion, BBS9 stop-gain SNV.

Authors:

J. Li[1], E. Tavares[1], J. L. Duncan[2], A. Vincent[1], E. Heon[1]; [1]The Hosp. for Sick Children, Toronto, ON, Canada, [2]UCSF, San Francisco, CA

Background: Bardet-Biedl syndrome (BBS) is a rare autosomal recessive disorder that causes severe visual loss in affected patients. Approximately 80% of the clinically examined BBS cases have been associated with variants in over 21 BBS genes with ~ 20% cases remaining unsolved by the clinical genetic testing. This study aims to identify the causative variants in the unsolved BBS cases using whole genome sequencing (GS). Method: Two BBS cases were recruited after negative clinical genetic testing results. Genomic DNA of the patients was extracted from peripheral blood. GS was analysed with a comprehensive variant filtering protocol. Structural variants, transposable elements, and single nucleotide variants (SNVs) were first filtered with BBS gene panel. Pathogenic variants identified in BBS genes were confirmed by visualizing read files and segregation analysis via Sanger sequencing. Results: Case 1: A female affected with BBS carried the most common pathogenic variant in BBS1, NM_024649.5(BBS1): c.1169T>G; p.(Met390Arg), identified through clinical genetic testing. Following GS, comprehensive variant filtering identified a heterozygous novel structural variant NM_024649.5(BBS1): c.830+554_1110+1052del; p.(Asp278Metfs*3). The 3kbp deletion in BBS1 was predicted to cause a loss in exons 10-11, resulting in frameshift and premature stop codon. A different BBS1 exon 10-11 deletion has been reported in ClinVar as pathogenic. Segregation analysis of the deletion confirmed maternal inheritance. Case 2: This BBS patient did not have any pathogenic variants identified through clinical genetic testing. Comprehensive variant filtering of the GS identified two rare (gnomAD AF < 0.01%), highly conserved (phylopVert100 > 9) stop-gain SNVs in exons 8 and 9 of BBS9. Segregation analysis confirmed that NM_198428.3(BBS9): c.724G>T; p.(Gly242*) was on the paternal allele, and NM_198428.3(BBS9): c.966G>A; p.(Trp322*) was inherited from the mother. While p.(Trp322*) was reported once in ClinVar, p.(Gly242*) has not been reported yet. p.(Gly242*) is located in the PTHB1 N-terminal domain, and loss-of-function BBS9 variants are known to be pathogenic by causing an absent or disrupted protein product. Conclusion: Here we report a novel large exonic deletion on BBS1 and a novel stop-gain SNV on BBS9, both suggested pathogenic by ACMG classification. Unsolved BBS patients could benefit from GS for a more conclusive diagnosis. The identification of the two novel BBS variants reinforces the importance of GS in rare disease diagnosis.

PB4857 Novel pathogenic variants identified in TRAPP genes in families with Neurodevelopmental Disorders

Authors:

R. Mohammad, R. Maroofian, H. Houlden; UCL Queen Square Inst. of Neurology, London, United Kingdom

Transport Protein Particle (TRAPP) complex plays a pivotal role in ER-to-Golgi transport and contributes to the regulation of multiple membrane trafficking pathways. The precise interaction of different proteins between cellular compartments is fundamental to conducting specialised functions. In humans, TRAPP proteins fall under two related complexes: TRAPP II and TRAPP III. While TRAPP proteins are all related, it is evident that some proteins function independently of the complex. As a result, variants in the genes that encode these proteins have been associated with a spectrum of human diseases, including an emerging set of disorders known as TRAPPopathies, which comprise of Neurodevelopmental Disorders (NDDs). This study used a large-scale, genotype-first approach where 33 causal candidate variants were found in 41 patients with undiagnosed rare NDDs, some of which have been collected as part of the SYNAPS project. Exome sequencing data was screened in 14 known TRAPP genes linked to NDDs. Seven novel homozygous variants were identified in TRAPPC6B c.267+3A>G, c.445+5G>T, TRAPPC9 c.676T>G (p.Tyr226Asp), c.1351G>A (p.Gly451Ser), c.2279-3C>G and TRAPPC11 c.560+3A>T, c.373A>G (p.Arg125Gly) that show evidence of pathogenicity with some of them confirmed by Sanger sequencing. This study provides valuable genomic data for future functional studies to better understand the role of the TRAPP complex in membrane trafficking pathways and how pathogenic variants in TRAPP genes can lead to NDDs. By developing our understanding of the pathogenic mechanisms involved, we hope that this will aid in the development of potential therapeutic targets.

PB4858 Novel phenotype associated with homozygous pathogenic variant in the *POP1* gene

Authors:

M. Michelson, K. Yosovich, S. Bahar, M. Ginsberg, D. Lev; Wolfson Med Ctr, Holon, Israel

The biallelic variants of the *POP1* gene are associated with the anauxetic dysplasia (AAD OMIM 607095), a rare skeletal dysplasia, characterized by prenatal rhizomelic shortening of limbs and generalized joint hypermobility. Affected individuals usually have normal neurodevelopmental milestones. Here we present three cases from the same family with a pathogenic homozygous *POP1* variant and completely novel phenotype: a girl with global developmental delay and autism, microcephaly, peculiar dysmorphic, features, and multiple congenital anomalies. Two consequent pregnancies were terminated due to multiple congenital malformations. Fetal DNA samples revealed the same homozygous variant in the *POP1* gene. RNA expression studies revealed decreased transcript of the POP1 compared to the control. To our knowledge, this is the first report of a new syndrome, associated with a pathogenic variant in *POP1*. Our findings expand the phenotypic spectrum of POP1-related disorder.

Session Title: Mendelian Phenotypes Poster Session III

PB4859 Novel *PRKACA* variant in a patient of with multiple congenital anomalies

Authors:

Y. Saito, Y. Kuroda, Y. Enomoto, T. Naruto, K. Kurosawa; Kanagawa Children's Med. Ctr., Yokohama, Japan

Introduction: *PRKACA* and *PRKACB* code for the homologous Cα- and Cβ-subunits of cyclic AMP (cAMP) - dependent protein kinase A (PKA). Heterozygous variants in *PRKACB* cause Ellis-van Creveld syndrome-like multiple congenital anomalies. Clinical features comprise intellectual disability, bilateral postaxial polydactyly, congenital heart defects, and teeth abnormalities. In 2020, Palencia-Campos et al. reported three unrelated patients had the similar phenotype with a heterozygous recurrent variant in *PRKACA* (NM_002730.4) c.409 G>A, p.(Gly137Arg). We describe a female patient with an Ellis-van Creveld syndrome-like phenotype associated with a novel variant in *PRKACA*.Case report: The proposita, first child of nonconsanguineous Japanese parents with an unremarkable family history, was born at 40 weeks gestation. The birth weight was 2725 g (-1.1 SD), length 48.7 cm (-0.6 SD), and occipitofrontal circumference 31.0 cm (-2.0 SD). She had bilateral postaxial polydactyly, syndactyly, atrioventricular septal defect, and right renal agenesis. Her development was delayed; she began speaking meaningful words at 17 months and walking at 23 months. At age three years six months, her gross IQ was 66. She had facial dysmorphism, hirsutism, hyperpigmentation, and hypodontia. Karyotype was 46,XX. Whole exome sequencing revealed a de novo heterozygous variant c.601G>T, p. (Gly201Cys) in *PRKACA*. The variant is not included in the public databases gnomAD, jMorp, ClinVar, and Human Genetic Variation Database. The identified variant in *PRKACA* shows a high CADD score of 26.3. *PRKACA* is a constrained gene intolerant of missense variation (z-score: 2.97). The variant was classified as likely pathogenic according to the ACMG guidelines for the interpretation of sequence variants (PS2, PM2, PP3, PP4). Conclusion: Notably, both the variant detected in our patient and those reported previously are in the functionally important protein kinase domain. Further, the present patient had additional features not previously reported including distinct facial appearance and intellectual disability. Together with these results, our patient will confer to delineate the phenotypic spectrum of the *PRKACA*-related Ellis-van Creveld syndrome-like phenotype.

Ctr., Pediatrics Ctr. of Excellence, Myelin Disorders Clinic, Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Background: Dravet syndrome and generalized epilepsy with febrile seizures plus type 1 (GEFSP1) are two important epileptic syndromes in children whose etiology is often imputed to variants in SCN1A and SCN1B, respectively. Herein, we aimed to identify the genetic causes of epilepsy in 5 Iranian families with complex phenotypes.**Methods**: Five patients from five unrelated families were recruited and their clinical features, brain magnetic resonance imaging, and electroencephalography data were analyzed. To investigate the underlying genetic factor(s), the patients were subjected to solo whole-exome sequencing (WES) and in silico analysis were performed to predict the pathogenicity of each identified variant.**Results**: Four novel homozygous variants in SCN1A were identified including NM_001202435.1:c.3139G>T;p.(Glu1047*), NM_001202435.1:c.2632delA;p.(Met878Cysfs*2), NM_001165964.1:c.2331+1G>T;p.(Leu794fs*11), NM_ NM_001165964.1:c.1105_1106insCA;p.(Ser369Glnfs*11). These candidate variants were confirmed using Sanger sequencing. In silico analyses categorized all novel variants as likely pathogenic. We also identified a few clinical manifestations associated with Dravet Syndrome including communication delay, hearing problem, diminished eye contact, and autistic spectrum disorder. Besides, dysphagia, severe digestive problems, and malnutrition were identified in association with GEFSP1.**Conclusion**: We introduced rare extra-neurological findings of Dravet syndrome and GEFSP1 in five unrelated patients harboring variants in SCN1A/1B. This study highlights the beneficial application of solo WES that in complex childhood epileptic syndromes.

Session Title: Mendelian Phenotypes Poster Session II

PB4861 Novel*TAF1*variants associated with reduced RAP74 phosphorylation in patients with X-linked intellectual disability

Authors:

T. Wang[1], M. Han[1], C. Skinner[2], R. Wang[1], S. Srikanth[2], F. Abidi[2], T. Niranjan[1], R. Stevenson[2], C. Schwartz[2]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Greenwood Genetic Ctr., Greenwood, SC

TATA box binding protein associated factor 1 (TAF1) is the largest subunit of the basal transcription factor II D (TFIID), which directs assembly of the pol II preinitiation complex. TAF1 consists of multiple functional domains that possess activities involving promoter binding, histone acetylation, and protein phosphorylation. Previous studies showed that both N- and C-terminal domains have serine kinase activity that selectively phosphorylates transcription factor, RAP74 of TFIIF complex. Pathogenic *TAF*1 variants have been reported in patients with X-linked intellectual disability (XLID) and dystonia-parkinsonism syndromes, however, the underlying mechanism remains poorly understood. We characterized two novel *TAF1* missense mutations that co-segregate with intellectual disability phenotypes in large, multiplex XLID families. One, c.A61C (p.Met21Leu), is in the N-terminal domain and the other, c.4283A>C (p.Gln1428Pro), is in the C-terminal domain. Both variants involve highly conserved amino acid residues and are predicted to be deleterious by *in silico* analysis. Affected males from these families share variable intellectual disability and dysmorphic features. To assess impact of these two variants on TAF1 function, we investigated RAP74 phosphorylation in lymphoblasts from affected males and normal controls using a RAP74 phosphorylation-site specific antibody. Our studies identified a consistently reduced RAP74 phosphorylation in lymphoblasts from one male carrying Met21Leu and two males carrying Gln1428Pro from the two XLID families as compared to normal controls. RAP74 regulates basal transcription by facilitating the assembly of preinitiation complex and modulating Pol II-elongation and pausing. Transcriptome studies are being carried out to identify the transcriptional profile of dysregulated genes that are critical to development of intellectual function. These studies imply a novel mechanism of reduced RAP74 phosphorylation due to pathogenic variants in *TAF1* associated with intellectual disability.

Session Title: Mendelian Phenotypes Poster Session III

PB4862 Null and missense mutations of *ERI1* cause a recessive phenotypic dichotomy in humans

Jerome Lejeune, Paris, France, [2324]Baylor Coll. of Med., Houston, TX, [25]IMS, RIKEN, Tokyo, Japan

ERI1 is a 3’-to-5’ exoribonuclease involved in RNA metabolic pathways including 5.8S rRNA processing and turnover of histone mRNAs. Its biological and medical significance remain unclear. Here, we uncover a phenotypic dichotomy associated with bi-allelic *ERI1* variants by reporting eight affected individuals from seven unrelated families. A severe spondyloepimetaphyseal dysplasia (SEMD) was identified in five affected individuals with missense variants, but not in those with bi-allelic null variants, who showed mild intellectual disability and digital anomalies. The *ERI1* missense variants cause a loss of the exoribonuclease activity, leading to defective trimming of the 5.8S rRNA 3’ end and a decreased degradation of replication-dependent histone mRNAs. Patient-derived induced pluripotent stem cells (iPSCs) showed impaired *in vitro* chondrogenesis with down-regulation of genes regulating skeletal patterning. Our study establishes a previously unreported entity and provides a model showing more severe effect of missense alleles than null alleles within recessive genotypes, suggesting a key role of ERI1-mediated RNA metabolism in human skeletal patterning and chondrogenesis.

Session Title: Mendelian Phenotypes Poster Session I

PB4863 Panel based sequencing of the undiagnosed leukodystrophies in Iran.

Authors:

N. Mahdieh[1], B. Rabbani[2], M. Soveizi[3], A. Tavasoli[4], A. Rabbani[2], M. Ashrafi[4]; [1]Rajaie cardiovascular research center, Tehran, Iran, Islamic Republic of, [2]Growth and Dev. Res. Ctr., Tehran, Iran, Islamic Republic of, [3]Azad Univ., North Tehran Branch, Tehran, Iran, Tehran, Iran, Islamic Republic of, [4]Tehran Univ. of Med. Sci.s, Tehran, Iran, Islamic Republic of

Leukodystrophies are a large heterogeneous group of genetic diseases affecting white matter of central nervous system. They are associated with motor loss and cognition problems. Their diagnosis is challenging and half of the patients are undiagnosed. Genetic testing helps to confirm the diagnosis. 152 patients referred to the tertiary hospital were evaluated for genetic testing. Among 44 patients which were not genetically diagnosed, further they underwent panel sequencing and Whole exome sequencing (3 patients). *ARSA* and *SURF1* gene was mutated in 3 patients; *GALC, FUCA1, POLG, EIF2B5, GJC2* each had causal variant in 2 patients, *SUMF1, RNASET2, PEX7 , PEX13, HSD17B4, EIF2B3, EIF2B4, POLR3A, POLR3B , FAM126A, PLA2G6 , RARS, HEXB , GLB1, PPT1,CLN6 , NAGLU , NDUFS1, NDUFS7, and SDHAF1* each gene had pathogenic variant in 1 patient. In 40 patients (90%) the gene and the causal variants were determined; 4 patients did not show any variant that should go for WES. This study was performed from 2016 to 2019; although there have been more patients genetically diagnosed throughout the country but they are being published in future and should further extend our knowledge of the genetic heterogeneity in this region. Early diagnosis of these patients will provide family planning and further future treatments, and managements at earlier stage for some of the patients.

Session Title: Mendelian Phenotypes Poster Session II

PB4864 Patient-derived iPSC model of CLN3 disease.

Authors:

E. Dwojak; Eunice Kennedy Shriver Natl. Inst. of Child Hlth.and Human Dev., Bethesda, MD

CLN3 disease or Juvenile Neuronal Ceroid Lipofuscinoses (JNCL) is a rare, autosomal recessive, pediatric disease. Classic syndromic presentation of the disease includes vision loss, cognitive decline, behavioral dysfunction, seizures, loss of motor function, and significantly reduced lifespan. A vision-only presentation involves later-onset and slower progression of vision loss, without other systemic involvements. The disease is caused by changes on the *CLN3* gene which encodes the lysosomal/endosomal membrane protein, battenin. Over 100 disease-associated variants have been identified in the *CLN3* gene to date, with the most common being a 966-base pair deletion. The exact function of battenin is still being characterized, but its absence is associated with abnormal glycerophosphodiesters accumulation and a lysosomal disorder phenotype. The pathophysiology is complex and not completely understood therefore there is a need for better disease models. We developed and characterized CLN3 patient-derived iPSCs to use as a model for elucidating the disease pathophysiology in different associated cells and tissues. Skin biopsies from six study participants with various genotype and phenotype in an NIH IRB-approved CLN3 natural history study (NCT03307304) were expanded into fibroblasts and reprogrammed into iPSCs using non-integrating Sendai virus technology. CLN3 genotype was confirmed by Sanger sequencing. G-banding karyotype analysis verified that the cells are diploid without significant chromosomal abnormality. Immunocytochemistry and flow cytometry verified pluripotency of the iPSCs. Histopathology of excised teratomas confirmed pluripotent potential of the reprogrammed iPSCs to differentiate into all three germ layers. In addition to these characterizations, we will further discuss characterization of CLN3-specific cellular phenotype, preliminary transcriptomic analyses, and future applications of these iPSC cell models.

Session Title: Mendelian Phenotypes Poster Session III

PB4865 Peripheral nervous system disruption revealed by tissue-specific transcriptome analysis in a humanized mouse model of familial dysautonomia

Authors:

R. Harripaul[1], E. Morini[2], M. Salani[3], E. Logan[2], E. Kirchner[2], J. Bolduc[4], J. Bolduc[2], A. Chekuri[2], B. Currall[5], R. Yadav[6], S. Erdin[2], M. Talkowski[2], D. Gao[2], S. Slaugenhaupt[2]; [1]Massachusetts Gen. Hosp., Cambridge, MA, [2]Massachusetts Gen. Hosp., Boston, MA, [3]MGH, SOMERVILLE, MA, [4]Canada, [5]Boston, MA, [6]MGH, HMS and Broad Inst., Boston, MA

Familial Dysautonomia (FD) is a rare recessive neurodevelopmental disease caused by a splice site mutation in the Elongator acetyltransferase complex subunit 1 (*ELP1*) gene. The mutation induces tissue-specific skipping of exon 20 and reduction of *ELP1* protein primarily in the central and peripheral nervous systems (CNS and PNS, respectively). FD patients exhibit complex neurological phenotypes due to loss of proprioceptive neurons including severe gait ataxia, respiratory failure, and spinal deformities. While the PNS involvement in FD has been well-documented at the histological level, the mechanisms that govern the tissue-specificity and preferential neuronal loss due to Elp1 reduction have not been characterized. This study shows *ELP1* reduction has a direct impact and convergent dysregulation in PNS tissues. We investigated the molecular mechanisms underlying FD using a humanized phenotypic mouse model that recapitulates the human mRNA splicing defect with varying tissue-specific *ELP1* protein levels in a collection of neuronal tissues, including the dorsal root ganglion (DRG), trigeminal ganglion (TG), medulla (MED), cortex, and spinal cord (SC). FD PNS transcriptomes (DRG and TG) had significantly more differentially expressed genes (DEGs) than those in the FD CNS transcriptomes (MED, SC, and Cortex) when compared to control neuronal mouse tissues. In addition to DEGs in each tissue, we identified genes tightly co-expressed and functionally dependent on the level of full-length *ELP1* transcript, defined as *ELP1* dose-responsive genes. Combining the DEGs and *ELP1* dose-responsive genes yielded tissue-specific dysregulated FD signature genes, further forming FD-dysregulated gene networks in PNS. These networks highlighted direct connections between *ELP1*, tRNA genes and a group of genes related to amine- metabolism and synaptic signalling, unifying the seemingly unrelated functions of *ELP1*. Notably, the transcriptomic dysregulation in PNS tissues was similar and enriched for neuronal subtype markers of peptidergic nociceptors and myelinated neurons, pinpointing the specific types of neurons known to be affected in FD. This study identified critical, tissue-specific peripheral nervous system gene networks that underly neuronal development and FD molecular pathology.

Session Title: Mendelian Phenotypes Poster Session I

PB4866 Personalized precision medicine of strategic health action in Niemann-Pick type a/b disease: Case report

Authors:

L. Moreno Giraldo[1], J. Sanchez-Vargas[2]; [1]Univ. del Valle, BOGOTA, Colombia, [2]Univ. Libre, Cali, Colombia

Niemann-Pick diseases (NPD) are lysosomal storage diseases caused by acid sphingomyelinase (ASM) deficiency, which catalyzes the hydrolysis of sphingomyelin (SM) to ceramide and phosphocholine. As a result, the SM and its precursor lipids accumulate in the lysosomes of the cells of the reticuloendothelial system, which produces an abnormal functioning, leading to the inability to degrade macromolecules, forming intracellular inclusions that are deposited in different organs such as the liver, spleen, lungs and brain. There are 5 subtypes, NPD-A and NPD-B are caused by variants in the sphingomyelin phosphodiesterase 1 (SMPD1) gene, which lead to abnormal or defective protein formation, which prevents the movement of lipids out of cells. It has been described that NPD worldwide affects 1 in 120,000-150,000 people and is characterized by autosomal recessive inheritance. We present the case of a 20 month old lactating female patient, with a diagnosis of global developmental delay associated with chronic protein-calorie malnutrition, dysmorphic fasciae, and hepatosplenic syndrome. In the initial approach, infectious and lymphoproliferative diseases were ruled out. Given the clinical complexity of the patient, a targeted clinical exome was requested, finding two variants, one of clinical pathogenic significance and the other probably pathogenic in the SMPD1 gene (compound heterozygous). The enzymatic activity of lysosomal enzymes was requested, pathologically increased biomarker lyso-SM-509 was found, and pathologically decreased ASM activity. Results with which a phenotype-genotype correlation is made with the NPD-A/B. With a defined and precise diagnosis, it is possible to guide health actions, follow-up guidelines, heritability risk assessment through an index case in order to find other possible carriers, carry out complete genetic counseling, implement and start targeted treatments that reduce the morbidity and mortality associated with this pathology, given that there are currently several studies in different phases of research on molecules that may intervene in the natural history of the disease.

Background/objectives: Primary Microcephaly is the observation of head circumference >2.5 SDs below the mean for a given sex, age, and ethnicity. It is caused by biallelic variants of 30 genes.
Methods: We analyzed the family through exome sequencing and linkage analysis. The consequences of the candidate variant were explored at cellular and molecular levels by immunofluorescence, immunoblotting, transient expression of tagged proteins, pulldown assay coupled with mass spectrometry, RNA-seq, and knockdown of Polr3a in chicken embryos.
Results: We studied a large six-generation Pakistani family with seven affected members manifested primary microcephaly. The genetic analysis identified a biallelic variant (NM_007055.3: c.40A>G; p.(Lys14Glu)) of *POLR3A*. Studying further patients, we were able to find four compound heterozygous variants of *POLR3A* in two unrelated patients manifesting microcephaly and variable features of global developmental delay, seizures, hypotonia, and dental abnormalities, featuring leukodystrophy. Pathogenic variants in *POLR3A* are known to cause hypomyelinating leukodystrophy but have never been implicated in the etiology of microcephaly. Patient-derived primary fibroblasts and ectopically expressed HeLa cells revealed reduced immunoreactivity of POLR3A. The variant plausibly compromises the interaction of POLR3A with crucial proteins involved in mTOR signaling and gene expression pathways and exerts effects on the differential expression of genes involved in translation and cell cycle. Knocking down of Polr3a in chicken embryos shows striking features of reduced brain size.
Conclusion: Our findings suggest that biallelic disruption of *POLR3A* should be considered in molecular diagnosis of primary microcephaly. Notably, mTOR signaling contributes to determining normal brain size.

PB4868 Phenome-wide association study of Sickle Cell Trait in NIH's All of Us Research Program

Authors:

A. Awan[1], H. C. Ramirez[1], T. M. Ferrara[1], A. Williams[1], A. Buscetta[1], R. P. Naik[2], P. Joseph[3], J. M. Keaton[1], J. C. Denny[1], V. L. Bonham[1], H. Mo[1]; [1]NHGRI/NIH, Bethesda, MD, [2]Johns Hopkins Univ., Baltimore, MD, [3]NIAAA/NIH, Bethesda, MD

The HbS variant of HBB gene is highly prevalent worldwide, especially among individuals of African descent. Although individuals with Sickle Cell Trait (SCT), carrying one HbS allele, typically remain asymptomatic, rare cases link carrier status to adverse clinical outcomes. The NIH's All of Us Research Program is a disease-neutral biobank that includes a diverse group of participants with whole genome sequencing (WGS) data linked to Electronic Health Records (EHRs). The goal of this study was to investigate the association of SCT with clinical outcomes, especially vascular occlusive complications. We identified carriers of HbS with rs334. Among the 39,020 individuals of genetically predicted African descent with both WGS and EHR data, 3,363 individuals carried one HbS allele and 73 carried two. Those who had two HbS alleles were excluded from further analysis. We then performed a phenome-wide association study (PheWAS) to compare carriers of a single HbS allele with non-carriers. The phenotypes that had the strongest association with HbS carriers were anemia during pregnancy (OR=2.35 [1.90-2.91]), iron deficiency anemias (OR=1.49 [1.28-1.73]), aseptic necrosis of bone (OR=2.20 [1.58-3.06]), and pulmonary embolism and pulmonary infarction (OR=1.67 [1.34-2.08]). To evaluate the impact of other concomitant hemoglobinopathies, we examined ClinVar variants of the entire HBB gene and extracted the clinically relevant SNPs from All of Us. We excluded individuals who carried any non-HbS hemoglobinopathy variants, especially beta-thalassemia and HbC, from the cohort, resulting in 3,162 single HbS carriers and 31,798 non-carriers. We performed a second PheWAS and observed that the phenotypes most strongly associated with this cohort were anemia during pregnancy (OR=2.27 [1.81-2.84]), iron deficiency anemias (OR=1.49 [1.27-1.74]), gout (OR=1.48 [1.21-1.81]), and abnormal results of kidney function study (OR=2.81 [1.71-4.62]). The association with aseptic necrosis of bone changed to (OR=1.06 [0.68-1.67]), and pulmonary embolism and infarction to (OR=1.40 [1.10-1.78]), below Bonferroni cut-off). Overall, our findings are consistent with previous research. This study demonstrates that the previously reported associations of SCT with vascular occlusion phenotypes, except for the kidney, may be related to concomitant hemoglobinopathies. The current findings provide new insights into phenotypic variations among individuals with SCT. Considering the high prevalence of HbC and beta-thalassemia alleles, it is important for clinicians to investigate other hemoglobinopathies to determine the risks of vascular occlusive complications in SCT.

Session Title: Mendelian Phenotypes Poster Session I

PB4869 Phenotype associations from a comprehensive database of long-chain fatty acid oxidation disorder gene variants

Authors:

H. Richbourg[1], J. Vockley[2], O. K. Japalaghi[1], V. Rangel Miller[1], M. AlSayed[3], M. Kiel[4], S. Mercurio[4], P. Baker, II[5], S. Daugherty[1], A. Khan[6], L. Korngut[7], D. McKnight[8], N. Miller[1]; [1]Ultragenyx Pharmaceutical Inc., Novato, CA, [2]UPMC Children s Hosp. of Pittsburgh and Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA, [3]Coll. of Med., Al-Faisal Univ., Riyadh, Saudi Arabia, [4]GENOMENON, Ann Arbor, MI, [5]Univ Colorado, Aurora, CO, [6]M.A.G.I.C. (Metabolics and Genetics in Canada) Clinic Ltd, Calgary, AB, Canada, [7]Dept. of Clinical NeuroSci.s, Univ. of Calgary, Calgary, AB, Canada, [8]Invitae Corp., San Francisco, CA

Background: Long-chain fatty acid oxidation disorders (LC-FAOD) are a group of six rare, life-threatening conditions typically detected through elevations in plasma acylcarnitine profiles, identified either through newborn screening (NBS) or by testing patients who present clinically. Combined, they are the most common inborn errors identified by NBS. Confirming a diagnosis with genetic testing is critical as limited functional testing is available. However, correlation of clinical and biochemical features with genotype is incomplete, and numerous variants of uncertain significance (VUS) have been reported. This abstract presents findings from a comprehensive database of disease-associated variants.
Methods: This comprehensive database of variants in the six genes associated with LC-FAOD (*ACADVL*, *CPT1A*, *CPT2*, *HADHA*, *HADHB*, *SLC25A20*) integrates data from a systematic review of published medical literature using the Mastermind Genomic Search Engine, a sponsored LC-FAOD gene panel clinical testing program, NBS results, clinical & biochemical phenotypes, and ACMG variant classifications. These data were used to analyze relationships between genotype and phenotype.
Results: As of APR 2023, the database reported 5324 variants from 3146 individuals with one or more LC-FAOD gene variants, representing 947 unique variants: 640 (68%) pathogenic (P) or likely pathogenic (LP) and 294 (31%) VUS. 1830/3146 (58%) patients had a genetic diagnosis (at least two P/LP): *ACADVL*, 678/37%; *HADHA*, 552/30%; *CPT2*, 410/22%; *SLC25A20*, 70/4%; *CPT1A*, 61/3%; *HADHB*, 59/3%. Of 722 unique genotypes observed, 501 (69%) were seen in only one patient. Phenotypic data were reported for 870 patients and overall, the five most frequent phenotypes include hypoglycemia (26%), rhabdomyolysis (22%), myalgia (21%), myoglobinuria (18%), elevated creatine kinase (16%). Beyond these, key phenotypes include*: -* *ACADVL* (n=251): cardiomyopathy (35%)- *CPT2* (n=253): rhabdomyolysis (50%)
- *HADHA* (n=228): retinopathy (21%)
-*HADHB* (n=49): peripheral neuropathy (35%)-*SLC25A20* (n=47): hyperammonemia, arrhythmia (32%)
- *CPT1A* (n=42): liver abnormality (50%).
Notably, for patients under 1 year, hypoglycemia was most common (128; 45%), and for patients over 12 years, myoglobinuria was most common (56; 52%).
Conclusions: Databases are critically important in rare diseases where clinical information on variants is scarce, and VUS are frequent, making it challenging to establish a molecular diagnosis. Genotype-phenotype data increase the diagnostic yield from genetic testing and are an important tool for clinicians to provide prognostic information to patients with LC-FAOD.

Session Title: Mendelian Phenotypes Poster Session II

PB4870 Phenotype semantic similarity-based approach for patient clustering and disease prioritization

Authors:

Y. Hu[1], C. Liu[2], C. Weng[2], K. Wang[3]; [1]Children s Hosp. of Philadelphia, Philadelphia, PA, [2]Columbia Univ., New York, NY, [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Human Phenotype Ontology (HPO)-based analysis has recently become popular for the genomic diagnostics of rare diseases. Such analysis relies mainly on statistical approaches and machine learning to prioritize a list of disease-causing genes for a patient. However, these methods do not effectively use the information on the phenotypes of diseases. It is challenging to efficiently measure similarity between a patient's phenotypes to another patient and match a patient's phenotypes with disease phenotypes. Here, we propose EHRclust, a patient clustering and disease ranking algorithm that measures patient-patient/patient-disease similarity scores based on HPO concepts for EHR data analysis. EHRclust removes time-based batch effects and explicitly models posterior odds by quantifying the likelihood of a pre-specified disease based on the observed set of phenotypes. To evaluate the performance of EHRclust, we simulated HPO terms for a group of patients based on 30 complex diseases. In simulation data, we weaken the underlying phenotypic difference between patients by generating data with "imprecision" and "noise". The disease prediction results of EHRclust on 5 different similarity measures showed that they consistently achieved high accuracy (>95%) in the top 3 candidate diseases. We also applied EHRclust to real datasets with 149 Friedreich Ataxia, Neurofibromatosis, or Marfan Syndrome patients. By using the batch effect removal algorithm, EHRclust is able to identify cluster variations with less informative data. The separation of patients agrees well with diseases, with only 9(6%) patients misclassified in other disease clusters. Current evaluations show that EHRclust offers a proper balance of clustering accuracy and stability. As the scale of EHR studies continues to grow, we believe EHRclust will offer a valuable tool for biomedical researchers to disentangle complex clinical heterogeneity and improve the diagnosis accuracy.

PB4871 Phenotype-based prioritization strategy accelerates the identification of real causal variants in Titinopathy patients.

Authors:

Y. Lei[1], W. Yang[2], S. Chan[1]; [1]Dept. of Paediatrics and Adolescent Med., Li Ka Shing Faculty of Med., The Univ. of Hong Kong, Hong Kong, China, [2]Univ. of Hong Kong, Pokfulam, China

The application of next-generation sequencing has led to the identification of over 600 genes associated with neuromuscular diseases (NMD). However, despite this progress, many patients still lack genetically diagnosis due to clinical and genetic heterogeneity of NMD. The traditional NGS data analysis strategy involves annotating and filtering variants based on population frequency, inheritance model, and predicted pathogenicity. Nonetheless, a substantial number of variants that spanning multiple genes will remain even after filtration. It is laborious to investigate each variant manually, and the presence of different genes further complicates the identification of true causal variants. In this study, using phenotype-based prioritization strategy, 6 patients from 4 families were identified casual variants in *TTN* gene. Whole-genome sequencing was conducted for all patient, and whole-exome sequencing was done for their parents. Alignment was performed using the Burrows-Wheeler Aligner, and the GATK best practice pipeline was employed for SNV/Indel calling. The Human Phenotype Ontology (HPO) website was used to convert the clinical presentations into HPO terms, and Exomiser was used for variants prioritization. All identified variants were validated via mRNA and Sanger sequencing. Applying the phenotype-based prioritization strategy, we found 7 variants in the *TTN* gene in the patients and parents. These variants included 4 nonsense variants, 2 splicing variants, and 2 frameshift variants. Further mRNA and Sanger sequencing validated the existence of these 7 variants. Clinical presentations play a crucial role in NMD diagnosis. However, the traditional analysis strategy fails to consider them comprehensively, requiring researchers to manually incorporate clinical information while investigating each variant. This strategy is inefficient for heterogeneous diseases like NMD. To overcome this limitation, we leveraged the Human Phenotype Ontology (HPO) and Exomiser to prioritize variants based on phenotype-disease similarity and genotype pathogenicity. The proposed strategy efficiently identifies true causal variants. This strategy significantly improves the NMD diagnosis rate and shortens the diagnostic odyssey for patients.

Session Title: Mendelian Phenotypes Poster Session I

PB4872 Phenotypic Characterization of Patients with Cleidocranial Dysplasia (CCD)

Authors:

E. Mitchell[1], K. Wade[1], C. Stole[1], N. Sobreira[2], I. Ickow[1], J. Hoover-Fong[1]; [1]Johns Hopkins Univ., Baltimore, MD, [2]Johns Hopkins Univ, Crownsville, MD

Cleidocranial Dysplasia (CCD) is a rare mendelian disease with autosomal dominant inheritance associated with severe abnormalities in bone development. CCD is caused by heterozygous pathogenic variants in *RUNX2* and *CBFB*, proteins that form a heterodimeric transcription factor which regulates osteogenesis. Clinical hallmarks of CCD include hypoplastic or absent clavicles, delayed closure of fontanelles, mild proportionate short stature, and dental anomalies including supernumerary and missing teeth. There is variable expressivity within and among families which has led to inconsistent phenotypic characterization of patients with CCD. In order to elucidate phenotypic variation in CCD, our group has assembled a cohort of 117 patients with CCD from 76 families across five countries for comprehensive phenotyping. The overall goal is to utilize these data with genomic analysis to establish genotype-phenotype correlations between variants in RUNX2 and CBFB as well as potential genetic modifiers of the CCD phenotype. We first conducted a literature search to identify previous phenotypic findings, and then we established a standardized protocol for both physical and oral examination. To better understand the psychosocial and socioeconomic effects of CCD participants, and their caregivers/family members, participants also completed validated quality of life surveys. In total, participants completed 1) a comprehensive physical examination by a skeletal dysplasia specialist, 2) an oral examinations from a craniofacial orthodontist or dentist, 3) a survey of medical history and quality of life, 4) provided DNA samples and detailed family history in the form of pedigrees and 5) conferred access to previous medical records. Physical data was collected manually then transcribed and stored in a Research Electronic Data Capture (REDCap) database. Survey data were collected using Qualtrics. Here we describe four novel and/or poorly defined phenotypes seen in our cohort: osteoporosis/osteopenia, anterior crossbite, knee deformities, and hearing loss/impairment. Future directions include combining these and other phenotypic findings with genomic data to identify genotype-phenotype correlations as well as potential genetic modifiers of CCD disease manifestations. Overall these results will help us better define the CCD phenotype and understand the pathophysiology.

Session Title: Mendelian Phenotypes Poster Session II

PB4873 *PHOX2B* non-polyalanine repeat mutations detected in autopsy cases of sudden unexpected infant death.

Authors:

A. Ueda[1], H. Naito[1,2], Y. Kakimoto[1], M. Osawa[1]; [1]Tokai Univ., Isehara, Kanagawa, Japan, [2]Kindai Univ., Osakasayama, Osaka, Japan

Congenital central hypoventilation syndrome (CCHS) is characterized by impaired ventilatory response to hypercapnia and hypoxemia during sleep. This autosomal dominant disorder is caused by the single gene of paired-like homeobox 2B (*PHOX2B*), which is in turn associated with various phenotypic disorders. Most patients carry expansions of the repetitive alanine tract. Furthermore, the minor part carries non-polyalanine repeat mutation (NPARM) of frameshift, nonsense, and missense, which more often result in severe complications of Hirschsprung disease and neural crest-derived tumors. The diagnosis of sudden infant death syndrome (SIDS) as a cause of death has decreased in mortality statistics for decades. One reason for the decrease is circumvention by examiners because of indistinguishable disorders such as accidental suffocation in bed. Other broad criteria such as sudden unexpected infant death (SUID) and sudden unexpected death in infancy are preferably chosen to indicate causes for such equivocal unclassifiable infant deaths. The involvement of CCHS in SIDS/SUID has been investigated for forensic autopsy cases because of its similarity of nocturnal onset. No apparent involvement of CCHS in SIDS cases has been demonstrated in earlier studies. This report describes a specific investigation of the relation of *PHOX2B* variation with SIDS/SUID. For this study, We analyzed 93 DNA samples of less than one-year-old Japanese SUID cases that were autopsied in our department. These 58 male and 35 female subjects had a mean age of 3.4 months. Unrelated adult Japanese volunteers (n = 942) were used as the control. No polyalanine tract expansion was detected in SUID cases. The allelic frequencies of repeat contractions and SNP (rs28647582) in intron 2 were not significantly different from that in those control group. Further extensive sequencing revealed a heterozygous NPARM of c.905A>C in a sudden death case of a one-month-old male infant. This missense mutation (p.Asn302Thr), registered as rs779068107, was annotated to ‘Affected status is unknown’ but it might be associated with sudden death. NPARM was more plausibly related to sudden unexpected death than expansions because of severe clinical complications. This finding indicates possible CCHS involvement in forensic autopsy cases without an antemortem diagnosis.

Session Title: Mendelian Phenotypes Poster Session III

PB4874 Pontocerebellar hypoplasia type 9: A report of 17 new patients

Authors:

M. Zaki[1], M. Y. Issa[1], H. M. Elbendary[1], S. Abdel Ghafar[2], K. Rafat[1], M. S. Abdel-Hamid[2]; [1]Clinical Genetics Dept., Human Genetics and Genome Res. Inst., Natl. Res. Ctr., Cairo, Egypt, [2]Med. Molecular Genetics Dept., Human Genetics and Genome Res. Inst.,Natl. Res. Ctr., Cairo, Egypt

Pontocerebellar hypoplasia (PCH) is a clinically and genetically heterogeneous group of neurodegenerative disorders of intrauterine onset with 17 different subtypes (PCH1-17). PCH9 is characterized by global developmental delay, postnatal microcephaly, epileptic encephalopathy, and distinctive neuroimaging features comprising cortical atrophy, hypogenesis of corpus callosum, hypomyelination, variable degrees of cerebellar and pontine hypoplasia and figure 8 shape hypoplastic midbrain. It is caused by a biallelic variant in the adenosine monophosphate deaminase 2 (*AMPD2*) gene which is also convicted in autosomal recessive spastic paraplegia 63. Herein, we describe 17 patients from 15 unrelated families from Egypt with PCH9. They were 10 males and 7 females with ages ranging from 3 months to 4y. Parental consanguinity was in 93% of patients. Microcephaly, severe global developmental delay, spasticity, myoclonic, and less frequent generalized seizures were evident in all patients. Fourteen patients were identified by target gene sequencing based on clinical-radiological features while 3 by whole exome sequencing due to the absence of the classic neuroimaging findings. Molecular results presented 14 different variants in the *AMPD2* gene including 12 novel ones. Our report expands the radiological and mutational spectrum of *AMPD2*. To our knowledge, this is the largest series of PCH9 from the same ethnicity.

Session Title: Mendelian Phenotypes Poster Session II

PB4876 Prediction of future Mendelian disease genes: implications for rare and common diseases

Authors:

J. X. Chong[1,2], A. J. Marcello[1], S. Khanam[1], B. M. Werness[3]; [1]Univ. of Washington, Seattle, WA, [2]Brotman-Baty Inst., Seattle, WA, [3]Amazon (unrelated to work at Amazon), Seattle, WA

Approximately ~4,500 genes have been implicated to date to underlie Mendelian conditions (MCs) and ~150 new genes for MCs are discovered each year. In Mendelian gene discovery research, annotations including selective constraint, predicted function, and conservation, as well as variant-level annotations like pathogenicity predictors and frequency are used to prioritize candidate variants and genes in order to identify the underlying gene. Widely-used gene-level constraint metrics include LOEUF, pLI, MOEUF, UNEECON-g, and s_{het}, a per-gene measure of the reduction in fitness for heterozygous carriers of a loss of function variant. These metrics have, by design, lower or minimal sensitivity for genes that underlie MCs that are recessive, have an age-of-onset past reproductive age, have modest or low effects on reproductive fitness, or are only caused by gain-of-function variants (i.e., not caused by loss-of-function). So, while these metrics help prioritize candidate genes for many severe childhood MCs, they are likely to miss many future gene discoveries across the full landscape of MCs.

We used machine learning to develop an ensemble model to predict protein-coding genes that are likely to underlie MCs or "future discoveries." Our model incorporates thousands of features spanning many metrics including conservation, constraint, gene expression, co-expression, gene structure, protein structure, protein-protein interactions/connectivity, regulatory structure, and pathogenicity predictors. All features were selected to minimize leakage, or accidentally training our model on a feature that may directly reveal whether a gene is already known to underlie a MC. We validated our model by excluding 889 genes that were first implicated in a MC or reported as not associated with a phenotype in mutant mice after 2016, followed by training on the remaining genes. Then, we tested our model's performance in the excluded set of 889 genes and achieved high precision (0.977) and recall (0.985). Our model predicts a total of 15,695 protein-coding (>85% of all coding) genes underlie a MC, suggesting that >11,000 genes underlying a MC remain to be discovered. These predictions have implications not just for Mendelian genomics but other areas of human genetics that utilize known genes for Mendelian conditions to identify or prioritize among a gene set of interest.

Session Title: Mendelian Phenotypes Poster Session III

PB4877 Prenatal exome sequencing and in vivo modeling in zebrafish reveals new candidate genes to explain fetal brain anomalies.

Authors:

H. Yousaf[1,2], K. L. Gilmore[3], B. C. Powell[4], N. L. Vora[3], E. E. Davis[1]; [1]Stanley Manne Children's Res. Inst., Ann & Robert H Lurie Children's Hosp. of Chicago, Chicago, IL, [2]Natl. Inst. for Biotechnology and Genetic Engineering Coll., Pakistan Inst. of Engineering and Applied Sci. (NIBGE-C, PIEAS), Faisalabad, Pakistan., Faisalabad, Pakistan, [3]Dept. of Obstetrics and Gynecology, Div. of Maternal-Fetal Med., The Univ. of North Carolina Sch. of Med., Chapel Hill, NC, [4]Dept. of Genetics, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Fetal brain anomalies cause considerable healthcare burden with ~1/1,000 affected newborns every year in the US. The current paradigm for prenatal diagnosis, using karyotype and chromosomal microarray, explains the disease in ~40% of cases. This leaves the majority of the cases undiagnosed, thus complicating counseling, prenatal management, and parental decision-making. To identify underlying etiology of this population, we combined prenatal imaging with prenatal trio exome sequencing (ES) and have achieved a diagnostic rate of ~22%. Here, we present our experience with 39 fetus-parent trios with brain malformations that were undiagnosed as defined by a negative microarray, and no pathogenic or likely pathogenic variants in phenotypically overlapping OMIM genes. In these 39 trios, prenatal imaging revealed cerebellar hypoplasia in 16 (41%) and ventriculomegaly in 15 (38%) cases as the most prevalent findings. Corpus callosum agenesis and absent *cavum septi pellucidi* were observed in 13 (33%) fetuses. Less common manifestations include microcephaly (17%), hydrocephaly, anencephaly and holoprosencephaly in less than 12% of cases. Out of the 39 trios, we found that 14 (35%) have isolated brain malformations while 25 (64%) showed additional extracranial features; skeletal anomalies are the most prevalent finding, occurring in 80% of multisystemic cases. In our cohort, four families have at least two pregnancies with similar or related clinical presentation. Only one out of 39 fetuses are living while the rest did not survive either due to intrauterine fetal demise, elective termination, or neonatal death. ES data underwent unbiased filtering, revealing candidate genes in 22/39 (56%) of the trios leaving 17 families without a plausible molecular candidate gene for the primary phenotype. Candidate genes have been prioritized for in vivo modeling in zebrafish based on identification of other cases from gene matching platforms, presence of a zebrafish ortholog, gene size, and embryonic expression pattern. We are systematically performing gene targeting with CRISPR/Cas9 genome editing and transient suppression to establish relevance to brain anomaly and test pathogenicity of missense variants. Using this paradigm, we have identified *SNAPIN* as a novel cause for fetal brain anomalies and are pursuing additional candidates such as *TXNDC11*, *WWC3*, and *ZNF667*. Together, our genetic analysis paradigm coupled to an experimentally tractable *in vivo* model has the potential to improve diagnostic rates and to expand our understanding of genes critical for fetal brain development.

Session Title: Mendelian Phenotypes Poster Session II

PB4879 Protein family FAM241 (C4orf32 and C10orf35): a potential role in lysosomes.

Authors:

Q. Doctrove, Y. N. Park, G. M. Lenk, M. H. Meisler; Univ. of Michigan, Ann Arbor, MI

Inactivation of *FIG4*, *VAC14*, and other genes that regulate lysosome function, result in enlargement of the lysosome compartment and the appearance of vacuolated cells. In order to identify additional genes that regulate lysosome size and acidity, we carried out a genome-wide screen in HAP1 cells using the GeCKOv2 CRISPR library (Lenk et al., Sci. Rep. 2019). The knockout of FAM241B (C10orf35) resulted in enlarged lysosomes, suggesting a role in lysosomal homeostasis. The two members of this protein family, FAM241 A and B, encode small proteins of 132 and 121 residues with 25% amino acid sequence identity and 53% sequence similarity. There is a predicted transmembrane domain near the C-terminus. Both genes are present in vertebrate genomes, beginning with jawed fish. *FAM241B* is deleted from the bird genome. We confirmed widespread expression of *FAM241* A and B in mouse tissues, at an abundance of approximately 4 and 40 transcripts per million in whole brain, respectively. *FAM241B* encodes two transcripts of comparable abundance that differ by one noncoding exon of 79 bp. Knockout of Fam241 A or B, and the double knockout, did not impair fertility, reduce lifespan, or result in visible abnormalities. RNAseq of brain RNA from double knockout mice detected only minor differences from wildtype mice in gene expression. Analysis of the subcellular distribution of FAM241 A and B is in progress.
Supported by NIH GM24872.

Session Title: Mendelian Phenotypes Poster Session III

PB4880 Proteomic analysis reveals differential protein expression with respect to blood transfusion in Sickle Cell Disease (SCD) patients.

Authors:

A. Kulshrestha, M. E. Garrett, M. W. Foster, M. J. Telen, A. E. Ashley-Koch; Duke Univ. Med. Ctr., Durham, NC

Sickle cell disease (SCD) is characterized by a single mutation in the beta hemoglobin gene. Although patients have the same underlying mutation, the clinical outcomes are highly variable. Blood transfusions are commonly used to ameliorate the symptoms of SCD. To understand the relationship between use of blood transfusion as therapy for SCD and protein expression, we performed a mass spectrometry-based proteomic analysis of plasma samples from 109 adult patients with known transfusion histories from the Outcome Modifying Genes in SCD (OMG-SCD) cohort, quantifying 1190 proteins. We performed logistic regression to identify differentially expressed proteins, incorporating age, sex, and disease genotype as covariates.

Thirteen proteins,
namely *VASN*, *IBP7*, *PI16*, *CADM1*, *FBLN3*, *HEG1*, *APOL1*, *CD44*, *PCOC1*, *CO7*, *LYVE1*, *ATL4*, and *PTGDS*, were differentially expressed in the highly transfused subset of patients (n=37 with > 20 transfusions) after adjusting for False Discovery Rate (FDR), with *APOL1* being expressed at a lower level and the remaining proteins expressed more highly. To exclude false signals arising from other SCD symptoms, we also conducted proteomic analyses on stroke, acute chest syndrome, leg ulcers, and pain. None of the identified proteins were FDR significant in these other analyses. We found that two proteins, *CO7* and *PCOC1*, were also FDR significant proteins identified in proteomic analysis of a composite end-organ damage severity score, suggesting their potential relevance to disease severity. We further investigated the proteomic landscape in a subset of severe SCD cases (SS genotype, n = 91) with respect to transfusion history. In addition to the previously identified 13 proteins, three novel proteins, *NEGR1*, *COMP*, and *CAD13*, were identified.

Our study highlights the utility of plasma proteomics to uncover the complex molecular landscape underlying SCD. The identified proteins, including some previously associated with SCD pathophysiology, as well as others newly identified by this study, offer valuable targets for further investigation and potential development of precision therapeutic interventions. To further elucidate the biological implications, we are exploring the pathways associated with these identified proteins. By unraveling the intricate biological mechanisms and pathways involved in severe SCD, we aim to contribute to the advancement of personalized medicine approaches and provide valuable insights into the molecular profiles specific to severe SCD.

Large-scale genomic studies have reported sporadic variants of the PTPRM gene in various neurodevelopmental disorders, including autism spectrum disorder, developmental disorder, epilepsy, and schizophrenia. To substantiate the pathological role of PTPRM, we recruited 10 copy number variants (CNVs) encompassing deletions, duplication, and triplication. These CNVs, ranging in size from 14.2 kb to 1.18 Mb, were observed in 11 individuals with neurodevelopmental disorders, who exhibited a variety of associated features, including mood disorders, ADHD, depression, autism, learning difficulties, and language/speech delays. Genomic alignment of these CNVs identified the smallest overlapping region at 18p11.23, pinpointing PTPRM as the common gene affected in all CNVs (deletions, duplication, and triplication). In addition to this discovery, our exome sequencing analysis identified three missense and one nonsense variants in PTPRM in unrelated individuals with syndromic intellectual disability. The presence of overlapping clinical features among individuals with both single nucleotide variants and CNVs involving PTPRM provides compelling evidence for the contribution of PTPRM haploinsufficiency to the observed clinical presentations in these patients.To validate this hypothesis, we knocked down PTPRM in cultured hippocampal neurons. Remarkably, this manipulation resulted in attenuated dendritic arborization and disrupted synaptic formation, underscoring the critical role of PTPRM in these essential neuronal processes. Additionally, structural modeling of missense variants located within functional domains of PTPRM predicted to induce severe steric hindrance, ultimately destabilizing the protein. Collectively, our findings strongly establish PTPRM as the causative gene underlying neurodevelopmental disorders, emphasizing its pivotal role in the pathogenesis of these conditions. This research shed significant light on the crucial involvement of PTPRM in normal brain development, highlighting its importance in understanding neurodevelopmental processes.

PB4882 Puzzling out the genetic bases of hereditary cardiovascular diseases: Application of an integrative approach in a deeply clinically characterised Italian cohort.

Authors:

B. Spedicati[1,2], S. Lenarduzzi[2], M. Dal Ferro[3], A. Paldino[3], D. Mazzà[2], S. D'Errico[1], G. Sinagra[1,3], P. Gasparini[1,2], G. Girotto[1,2]; [1]Dept. of Med., Surgery and Hlth.Sci., Univ. of Trieste, Trieste, Italy, [2]Inst. for Maternal and Child Hlth.–I.R.C.C.S. "Burlo Garofolo", Trieste, Italy, [3]Cardiovascular Dept., Azienda Sanitaria Univ.ria Giuliano Isontina (ASUGI), Trieste, Italy

Background: Hereditary cardiovascular diseases (hCVDs) are a major cause of morbidity and mortality worldwide. They include several nosological entities which may also lead to sudden cardiac death, as cardiomyopathies (CMs), arrhythmic disorders (i.e. channelopathies), and vascular disorders (i.e. aortopathies and pulmonary arterial hypertension). In this light, a large cohort of deeply clinically characterised Italian hCVD patients was selected with the final goal of providing a detailed genetic picture of these disorders in Italy.
Methods: 440 Italian hCVDs patients were referred to the Medical Genetics Unit of the I.R.C.C.S. "Burlo Garofolo" (Trieste, Italy) and nine subjects were recruited through the Regional Register of Sudden Cardiac Deaths of Friuli-Venezia Giulia (Italy). All patients underwent Whole Exome Sequencing (WES) analysis firstly focused on an *in-silico* panel of 66 genes responsible of hCVDs. Multiplex Ligation-dependent Probe Amplification (MLPA) analysis of selected genes was performed in patients affected by hypertrophic (HC) and arrhythmogenic right ventricular cardiomyopathies (ARVC) and negative to WES analysis. Copy Number Variants (CNVs) were confirmed by Nanopore technology (MinION - Mk1C).
Results: 89% of patients were affected by CMs, 7% by channelopathies, and 4% by aortopathies and pulmonary arterial hypertension. WES allowed the molecular characterisation of 23% of patients, with the highest detection rate in familial cases (38% vs 15% in sporadic ones). *TTN*, *MYH7*, *MYBPC3*, *FLNC*, *PKP2* and *DSP* resulted the most commonly mutated genes explaining 75% of cases. Noteworthy findings of this study are: 1) the identification in two patients affected by HC and coming from the Veneto region of the c.913_914delTT, p.(Phe305Profs*27) heterozygous variant in the *MYBPC3* gene (NM_000256.3): a founder effect of this variants in patients from the Veneto region has been described and our finding further supports this hypothesis; 2) the discovery of a novel 3Mb deletion including *DSG2*, *DSC2*, and *TTR* genes firstly hypothesised through WES CNV analysis and confirmed by Nanopore technology in a patient affected by ARVC; 3) the detection in 3/9 sudden death patients of three novel missense variants in the *RYR2* gene, highlighting how the first clinical manifestation of *RYR2*-related arrhythmias may frequently be sudden death.
Conclusions: This study underlines the importance of an integrative approach to provide the correct molecular diagnosis in hCVDs patients, thus emphasising the complexity of the genetic background of these disorders and providing crucial information for patient management and recurrence risk estimation.

Intracranial aneurysm (IA) is a local dilatation of cerebral arteries which preferentially occurs at arterial bifurcations and affects around 3% of the population. The weakening of the artery wall induced by IA can lead to sub-arachnoid haemorrhage, a severe type of stroke. Genetic risk factors have been linked to IA formation, without yet explaining its pathophysiology. Thus, identifying novel susceptibility genes based on the analysis of familial cases may help in elucidating IA pathophysiology.
We recruited a large pedigree with 6 IA carriers, and sequenced the whole exomes of 3 affected relatives. We identified 16 rare functional variants shared between these family members. To reduce the number of variants of interest, we performed identity-by-descent (IBD) analysis from genotyping array data on 5 affected members. Only one variant remained shared between all 5 carriers, which resides in the *CTSO* gene (c.946G>A). Searching for other *CTSO* variants, we analysed the WES data from 93 additional index cases with familial forms of IA. We found one other *CTSO* variant (c.128C>T) in a second large pedigree with 5 IA carriers. The presence of each variant was then confirmed by capillary sequencing in all affected members of each family.
Next, we investigated the function of the papain-like cathepsin encoded by *CTSO*. Its depletion in vascular smooth muscle cells (VSMCs) was associated with increased levels of fibronectin in the extra-cellular space as well as with augmented VSMCs stiffness. The same effect was observed with the expression of the two mutated forms of CTSO identified in familial cases, the protein being poorly secreted in these conditions.
In conclusion, by familial investigations, we identified *CTSO* as a putative novel susceptibility gene for IA, which encodes for a cathepsin acting as an extracellular protease targeting fibronectin. The reduced CTSO secretion observed in the presence of the familial variants may affect the composition and mechanical properties of the extracellular matrix of the cerebral artery wall. This could contribute to the increased risk of developing IA in subjects expressing the *CTSO* variants.

PPFIA3 encodes the Protein-Tyrosine Phosphatase, Receptor-Type, F Polypeptide-Interacting Protein Alpha-3 (PPFIA3), which is a member of the LAR protein-tyrosine phosphatase-interacting protein (liprin) family involved in synaptic vesicle transport and presynaptic active zone assembly. The protein structure and function are well conserved in both invertebrates and vertebrates, but human diseases related to PPFIA3 dysfunction are not yet known. Here, we report 16 individuals with rare heterozygous *PPFIA3* variants who have developmental delay, intellectual disability, hypotonia, dysmorphisms including microcephaly or macrocephaly, autistic features, and epilepsy. To determine the pathogenicity of *PPFIA3* variants *in vivo*, we generated transgenic fruit flies expressing either human PPFIA3 wildtype (WT) or variant protein using GAL4-UAS targeted gene expression systems. Ubiquitous expression with Actin-GAL4 showed that the *PPFIA3* variants had variable penetrance of pupal lethality, eclosion defects, and anatomical leg defects. Neuronal expression with elav-GAL4 showed that the *PPFIA3* variants had seizure-like behaviors, motor defects, and bouton loss at the 3rd instar larval neuromuscular junction. Altogether, in the fly overexpression assays, we found that the *PPFIA3* variants in the N-terminal coiled-coil domain exhibited stronger phenotypes compared to those in the C-terminal region. In the loss-of-function fly assay, we show that the homozygous loss of fly Liprin-α leads to embryonic lethality. This lethality is partially rescued by the expression of human PPFIA3 WT, suggesting human PPFIA3 function is partially conserved in the fly. However, the rare *PPFIA3* variants failed to rescue lethality. Altogether, the human and fruit fly data reveal that the rare *PPFIA3* variants are dominant negative loss-of-function alleles that perturb multiple developmental processes and synapse formation.

Session Title: Mendelian Phenotypes Poster Session II

PB4885 RASopathy-linked variants in men with spermatogenic failure

Authors:

A-G. Juchnewitsch[1], K. Lillepea[1], K. Pomm[2], A. Dutta[1], A. Valkna[1], E. Tamp[3], E. Mahyari[4], V. Kübarsepp[1,2], L. Nagirnaja[4], G. Belova[1], O. Poolamets[2], K. Aston[5], D. Conrad[4], L. Kasak[1], M. Punab[1,2], M. Laan[1]; [1]Univ. of Tartu, Tartu linn, Estonia, [2]Tartu Univ. Hosp., Tartu linn, Estonia, [3]East Tallinn Central Hosp., Tallinn, Estonia, [4]Oregon Hlth.& Sci. Univ., Beaverton, OR, [5]Univ of Utah, Salt Lake City, UT

RASopathies are congenital syndromes caused by germline disease-causing variants in 21 genes of the RAS/MAPK pathway[1]. Patients are typically diagnosed in childhood based on phenotypic features, including distinct facial features, affected development and growth, neurologic, cardiac, gastrointestinal, or dermatological conditions. Cryptorchidism (CR) has been observed in ~80% of male cases with Noonan syndrome (NS), the most prevalent RASopathy. We have recently reported a cryptorchid adult patient with spermatogenic failure (SPGF) carrying a likely pathogenic (LP) variant in *SOS1*, the 2nd most frequently affected gene in NS, and proposed the RAS/MAPK pathway as a novel genetic etiology in congenital CR among SPGF patients[2].

We aimed at a systematic analysis of RASopathy-linked variants in idiopathic SPGF patients with (n=151) and w/o CR (n=368), as well as normozoospermic reference subjects (n=323). All men were recruited to the ESTonian ANDrology (ESTAND) cohort and phenotyped at the Andrology Clinic, Tartu University Hospital[3]. The prevalence of CR in Estonian full-term newborn boys is ~1%[4]. Rare disease-causing variants were filtered, interpreted, and prioritized based on known and in silico predicted clinical /functional consequences. The final pathogenicity assessment followed the RASopathy-specific variant interpretation guidelines[5], including gathered extended clinical and family data.

Eight SPGF patients and one subfertile normozoospermic man carried five previously reported and four novel LP/P variants in six RAS/MAPK pathway genes (*PTPN11*, *SOS1*, *SOS2*, *MAP2K1*, *LZTR1*, *SPRED1*). None of these cases were diagnosed with RASopathies before the study. All men presented congenital genitourinary anomalies, including six patients with CR. The prevalence in CR cases (1 in 25) was over 40-fold higher compared to the general population (1 in 1000), whereas no difference was observed for SPGF cases w/o CR and the reference men. RASopathy genes with identified LP/P variants are expressed in adult testis, including spermatogenic and somatic cell types. These data suggest that disease-causing variants in the RAS/MAPK pathway represent a novel identified genetic cause of SPGF and are enriched in patients with CR. Translational research is needed for genetic testing in CR patients to facilitate timely personalized management.

PB4886 Reduced *clic4* and *itgb1* expression in a zebrafish crispant model of *crim1* loss of function.

Authors:

T. Le[1], S. Htun[2], J. Lauzon[3], Y. Sun[4,5], E. Ullah[6], R. Hufnagel[6], B. P. Brooks[6], S. Baranzini[4,5], A. Slavotinek[1,2]; [1]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH, [2]Div. of Med. Genetics, Dept. Pediatrics, UCSF, San Francisco, CA, [3]Alberta Children's Hosp, Calgary, AB, Canada, [4]Dept. of Neurology, UCSF, San Francisco, CA, [5]Inst. of Human Genetics, UCSF, San Francisco, CA, [6]Natl. Eye Inst., NIH, Bethesda, MD

Heterozygous deletions predicting haploinsufficiency for *CRIM1* have been identified in two families with autosomal dominant, colobomatous macrophthalmia with microcornea and coloboma (MACOM). We present an additional patient with retinal coloboma and a heterozygous deletion involving *CRIM1* as further evidence for the role of *CRIM1* in the etiology of coloboma. We also report 4 members of a family without eye defects, but with hydronephrosis/megaureter that required surgery. All 4 had del(2)(p22.3p22.2) chr2:g.35816791_37319473del that included *CRIM1* and 5 other genes. *Crim1* encodes a type I transmembrane protein that is expressed at the cell membrane of lens epithelial and fiber cells at the stage of lens pit formation. Murine lines with decreased *Crim1* expression have reduced numbers of lens epithelial cells and defective adhesion between lens epithelial cells and between lens epithelial and fiber cells, among other findings. We used CRISPR/Cas9 to make a stable model of *crim1* deficiency, generating zebrafish that were homozygous for a 2 basepair (bp) deletion, c.379_380delCT: p.Leu127Gly*fs**2 (NM_212821.1) and verified reduced *crim1* expression with qRT-PCR. A comparison of eye to head size in homozygous *crim1* crispants and controls showed smaller eyes in the crispants, but the ratio of eye to head size at 48 hpf was significantly increased. This difference was not significant at 72 hpf and we did not observe colobomas. RNA-Seq using whole eyes from *crim1* crispants and controls at 72 hpf showed downregulation of *clic4*, a gene that is expressed at the cell membrane and that is required for integrin-mediated cell adhesion. Prior published work crossing *Crim1* and *Itgb1 floxed* mice showed that 1/4 of the compound heterozygous mice displayed iris coloboma with detachment of the lens epithelial cells from the fiber cells, consistent with an interaction between *Crim1* and *Itgb1*. qRT-PCR in *crim1* crispants and controls showed significantly reduced *clic4* and *itgb1* expression in the *crim1* crispants. As *Itgb1* is expressed in the lens and anchors the anterior epithelium and lens fibers to the lens capsule, we hypothesize that the reduced *clic4* expression in c*rim1* crispants disrupts lens cell adhesion by compromising *itgb1* function and *itgb1*-mediated cell adhesion. Our findings provide data on additional patients with *CRIM1* haploinsufficiency and the underlying pathogenesis of MACOM.

Session Title: Mendelian Phenotypes Poster Session I

PB4887 Reduced genomic diversity in functionally relevant genes modifies the risk of neurodevelopmental phenotypes compared to cancer in individuals with germline *PTEN* variants

Authors:

A. Kim[1,2], L. Yehia[1], C. Eng[1,3,4,5,6]; [1]Genomic Med. Inst., Lerner Res. Inst., Cleveland Clinic, Cleveland, OH, [2]Cleveland Clinic Lerner Coll. of Med., Case Western Reserve Univ., Cleveland, OH, [3]Ctr. for Personalized Genetic Hlth.care, Med. Specialties Inst., Cleveland Clinic, Cleveland, OH, [4]Taussig Cancer Inst., Cleveland Clinic, Cleveland, OH, [5]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [6]Germline High Risk Cancer Focus Group, Case Comprehensive Cancer Ctr., Case Western Reserve Univ., Cleveland, OH

Individuals with germline *PTEN* alterations (PHTS) have a wide spectrum of clinical features ranging from cancer to neurodevelopmental disorders (NDD), including autism spectrum disorder (ASD). However, factors that underlie such phenotypic variability remain elusive, making it impossible to predict clinical outcomes. Here, we investigate germline genomic diversity (locus-homozygosity) as a modulator for the development of cancer versus NDD in PHTS. Genotype data of 376 individuals of European ancestry with PHTS were collected. Study participants included individuals with PHTS and NDD (n=117) and no-NDD (n=259), the former including n=57 with ASD. Homozygosity burden was measured by the ratio of the number of homozygous variants to the total number of genotyped loci. Sets of functionally relevant genes pertinent to NDD were curated for targeted analyses. Conservative filtration of homozygous variants was applied to identify variants in exonic or splicing sites for pathway analysis and with deleterious effects for collapsed variants analysis. Logistic regression models were performed with 10-fold cross validation to predict NDD/ASD phenotype. We found genome-wide level of homozygous common variants (MAF≥0.01) but not rare variants (MAF<0.01) was non-significantly increased in the NDD group. However, targeted analyses revealed significant enrichment of homozygous common variants in genes involved in inflammatory processes and low-confidence genes associated with NDD. Notably, in the ASD subgroup, homozygous common variants were enriched in genes involved in differentiation, inflammatory processes and chromatin structure regulation, high-confidence genes associated with NDD, and regions with pathogenic copy number variants. Pathway enrichment analysis of genes harboring selected homozygous variants revealed pathways germane to NDD/ASD, including neuroinflammation, axonal guidance, and synaptogenesis signaling. Collapsing analysis with more stringent filtration of homozygous variants identified suggestive candidate NDD/ASD genes, including *GABRA4* (p=0.029) and *CX3CR1* (p=0.016). Finally, prediction models for NDD/ASD using homozygosity burdens as predictors, after adjusting for sex, were validated. These models achieved 72% accuracy and 72% area under the curve (AUC) for NDD classification and 89% accuracy and 80% AUC for ASD classification. Thus, a higher burden of homozygous common variants, implying reduced genomic diversity, in genes with biological functions pertinent to NDD/ASD exists, may modify the risk of developing NDD/ASD phenotype, and could serve as a predictive marker of NDD/ASD in patients with PHTS.

PB4889 Residual Neuropathy target esterase activity predicts phenotypic onset among *PNPLA6* disorders

Authors:

J. Liu[1], Y. He[2], C. Madu[1], M. Han[1], C. Lwin[1], H. Qian[3], Z. Yong[3], L. Dong[4], G. Arno[5], A. Moore[6], A. Webster[7], M. Michaelides[8], L. Huryn[1], B. Guan[9], R. Hufnagel[10]; [1]Ophthalmic Genetics and Visual Function Branch, Natl. Eye Inst., Bethesda, MD, [2]Fermentation Facility, Biochemistry and Biophysics Ctr., Natl. Heart, Lung, and Blood Inst., Bethesda, MD, [3]Visual Function Core, Natl. Eye Inst., Bethesda, MD, [4]Genetic Engineering Core Facility, Natl. Eye Inst., Bethesda, MD, [5]UCL Inst. of Ophthalmology, London, United Kingdom, [6]Ophthalmology Dept., UCSF Sch. of Medicin, San Francisco, CA, [7]Moorfields Eye Hosp, London, United Kingdom, [8]UCL Inst. of Ophthalmology, Univ. Coll. London, London, United Kingdom, [9]NIH, Bethesda, MD, [10]Natl. Eye Inst., NIH, Bethesda, MD

Pathogenic variants in the *patatin like phospholipase domain containing 6* (*PNPLA6*) gene cause a spectrum of neurological disorders that include spastic paraplegia type 39, Gordon-Holmes, Boucher-Neuhäuser, Laurence-Moon, and Oliver-McFarlane syndromes. Patients display a pleiotropy of clinical characteristics that include vision loss, gait disturbance, anterior hypopituitarism, and hair anomalies. *PNPLA6* encodes Neuropathy target esterase (NTE), an enzyme involved in phospholipid homeostasis in the nervous system. Yet it remains unclear how pathogenic variants in the *PNPLA6* gene affect NTE that ultimately contributes to the observed spectrum of patient phenotypes. Here, we investigated the relationship between NTE activity and clinical manifestations in human and mouse.

Clinical meta-analysis was performed on reported (PubMed, 2008-2023) and newly recruited patients. DNA constructs encoding full-length NTE underwent site directed mutagenesis to produce the patient specific variants. NTE activity was determined as previously published (PMID:12791540). Mouse visual function and structure assays were performed on the Espion E3 system, Optodrum, and Spectralis. Statistical analyses were performed in Prism.

Biallelic pathogenic *PNPLA6* variants were detected in a cohort of 23 patients. Clinical meta-analysis of 118 individuals indicated that missense variants located within the enzymatic domain associate with the severe forms of the disease, revealing a key role NTE activity has on disease pathogenesis. Measuring the esterase activity of 46 disease-associated and 20 benign variants observed across *PNPLA6*-associated clinical diagnoses and general population databases (gnomAD v2.1.1, 2023), respectively, resolved uncertainty in classification of all variants tested. Calculating the overall NTE activity of affected individuals revealed a striking relationship between NTE activity and clinical manifestations, where activity in patients with retinopathy and endocrinopathy was significantly lower to those without visual or endocrinological symptoms. This phenomenon was recaptured in a *Pnpla6* murine allelic series, where mice with similar activities to patients with retinopathy experienced reduced visual function and retinal thickness compared to littermate controls and mice who had similar activities to patients without retinopathy. Overall, our research has discovered not only a novel genotype:activity:phenotype relationship of the *PNPLA6* disorder spectrum predicated on the residual activity of NTE, but also a robust functional assay that can unambiguously classify *PNPLA6* variants.

PB4890 Resolving missing heritability among individuals with oculocutaneous albinism: A rare haplotype, comprised of two common *TYR* variants (p.S192Y and p.R402Q), and evidence of OCA individuals with digenic inheritance.

Authors:

S. Loftus[1], M. F. Gillis[1], L. Lundh[1], L. L. Baxter[2], D. E. Watkins-Chow[3], F. X. Donovan[4], NISC Comparative Sequencing Program, W. S. Oetting[5], W. A. Gahl[1], W. J. Pavan[3], D. R. Adams[6]; [1]Med. Genetics Branch, NHGRI, NIH, Bethesda, MD, [2]Ctr. for Precision Hlth.Res., NHGRI, NIH, Bethesda, MD, [3]Computational and Statistical Genomics Branch, NHGRI, NIH, Bethesda, MD, [4]Cancer Genomics Unit, NHGRI, NIH, Bethesda, MD, [5]Dept. of Experimental and Clinical Pharmacology, Univ. of Minnesota, Minneapolis, MN, [6]Office of the Clinical Director, NHGRI, NIH, Bethesda, MD

Oculocutaneous albinism (OCA) is a rare, heterogeneous disorder characterized by reduced pigmentation of the skin, hair and eyes. Critically, individuals also present with visual-developmental changes including foveal hypoplasia and optic nerve misrouting, which contribute to low vision. The majority of OCA individuals possess biallelic variants in *TYR* (OCA types 1A and 1B) or *OCA2* (OCA type 2). Additional genes found to contribute to OCA include *TYRP1* (OCA type 3), *SLC45A2* (OCA type 4), *SLC24A5* (OCA type 6), and *LRMDA/C10ORF11* (OCA type 7), *DCT* (OCA type 8). Unfortunately, not all individuals with OCA are provided with a complete molecular diagnosis after undergoing molecular diagnostic testing. This missing genetic heritability has ranged from 10-50% depending on an individual's residual pigmentation and the country of origin in which these large studies have been performed. We used high-depth custom capture sequencing to evaluate 352 OCA probands. This cohort was enriched for individuals who had undergone previous diagnostic testing and exhibit missing genetic heritability. The largest contributing TYR pathogenic allele was a rare haplotype which arose by recombination and defined by two common variants (p.S192Y and p.R402Q) in cis-orientation (cis-YQ). This rare cis-YQ allele comprised 19.1% (57/298) of OCA type 1 (*TYR*-associated) alleles. These two common alterations are positioned at the terminal ends of diametrically opposing alpha helices involved in copper molecule coordination at the TYR protein active site. Our protein modeling predicts a synergistic impact of the two variants. These results suggest that phasing of common variants p.S192Y and p.R402Q at the *TYR* locus is critical for diagnosis. In addition, we have identified 7 OCA probands who possess deleterious variants in two distinct OCA genes. Each proband harbors a rare predicted deleterious variant in OCA2 and an additional predicted deleterious rare variant in either *TYR* or *TYRP1*. This suggests that a digenic inheritance model for OCA should be considered. Our results highlight that molecular diagnostic screening pipelines need to be reassessed to better capture DNA variation that contributes to OCA. Such variation may occur in patients with other rare disorders that present with missing heritability.

Session Title: Mendelian Phenotypes Poster Session II

PB4891 Responsible and related genes for triplet repeat diseases are involved in the ubiquitin proteasome system

Authors:

H. Hohjoh[1], H. Shimizu[2]; [1]Juntendo Univ., Tokyo, Japan, [2]Natl. Ctr. of Neurology and Psychiatry, Kodaira, Japan

Fragile X syndrome (FXS) and Huntington's disease (HD) belong to the family of triplet repeat diseases caused by an abnormal expansion of trinucleotide repeats in the causative genes, *i.e.*, the *Fragile X mental retardation 1* (*FMR1*) and *Huntingtin (HTT)* genes, respectively. The *FMR1* gene encodes an RNA binding protein involved in the stabilization and translational regulation of messenger RNAs. In mutant *FMR1*, the CGG triplet is abnormally expanded, inhibiting the expression of *FMR1* and causing FXS. The *HTT* gene is thought to have a variety of functions in cells. Disease-causing *HTT* carries abnormal expansion of CAG repeat in exon 1, which is translated into polyglutamine and causes abnormal aggregation of HTT protein, and the aggregated HTT protein is harmful in the brain. Unwanted and defective proteins, including aggregates, are systematically degraded within the cell. Therefore, dysfunction of the intracellular proteolytic system is thought to be related to the accumulation and formation of disease-causing gene products. The ubiquitin-proteasome system (UPS) is the primary ubiquitin-dependent proteolytic pathway. We investigated the UPS in cells, where disease-causing genes and related genes were knocked down by RNA interference (RNAi). Mouse Neuro2a cells, a mouse neuroblastoma cell line, were subjected to gene silencing for *Fmr1*, *Fmr1 autosomal homolog 1 (Fxr1)* and *discs large MAGUK scaffold protein 4* (*Dlg4*) genes, which are associated with FXS, by RNAi, and UPS activity was examined. The results indicated that knockdown of *Fmr1*, *Fxr1* and *Dlg4* genes resulted in increased ubiquitination and that *Fmr1*- and *Fxr1*-knockdown further increased proteasome activity. Knockdown of these genes also affected process formation in N2a cells. Therefore, the findings suggest that these genes are involved in the UPS, and that UPS may contribute to neurite outgrowth. As for the *Htt* gene, *Htt*-knockdown studies are ongoing. We would like to discuss the results, including *Htt* data, at the conference.

Background: Achondroplasia (ACH), the most common short-limbed skeletal dysplasia, is characterized by impaired endochondral ossification resulting from gain-of-function pathogenic variants in the fibroblast growth factor receptor 3 (FGFR3) gene, a negative regulator of endochondral bone growth. People with ACH are at risk for several significant co-morbidities, including brainstem compression due to foramen magnum stenosis, sleep-disordered breathing, chronic otitis media with conductive hearing loss, and symptomatic spinal stenosis. Infigratinib is an oral, selective FGFR1-3 tyrosine kinase inhibitor being investigated for treating children with ACH.

Methods: PROPEL 2 (NCT04265651) is a phase 2 dose-finding, open-label study of infigratinib in children 3−11 years with ACH who participated for ≥6 months in PROPEL (NCT04035811), a non-interventional clinical assessment study. The PROPEL 2 dose-escalation (DE) phase includes 5 ascending dose cohorts from 0.016 to 0.25 mg/kg/day. Primary endpoints: safety; change from baseline in annualized height velocity (AHV); infigratinib pharmacokinetics.

Results: Children enrolled in PROPEL 2 DE completed ≥6 months of treatment at the assigned dose. Cohorts 1-3 (n=37; 0.016, 0.032, 0.064 mg/kg/day) did not show a significant increase in AHV and these doses were assessed as non-efficacious. Treatment at the cohort 4 dose (0.128 mg/kg/day) resulted in an increase in AHV from baseline of 1.52 cm/year in children ≥5 years old (n=11; p=0.02). Infigratinib at the cohort 5 dose (0.25 mg/kg/day, n=10, month 6) resulted in a significant mean increase from baseline of 3.03 cm/year (p=0.0022). In cohort 5, collagen X marker, a biomarker of endochondral ossification, showed a median increase of 28% from baseline at month 6 (n=6). Infigratinib was well tolerated with no serious AEs or AEs leading to study discontinuation, with most AEs mild/moderate in severity. At the cohort 5 dose, no grade 3 AEs or treatment-related AEs were reported.

Conclusion: Oral infigratinib in children with ACH was well tolerated and showed dose-dependent increases in AHV, with a significant mean change from baseline of +3.03 cm/year at the cohort 5 dose (0.25 mg/kg/day). The safety and efficacy of this oral, once-daily dose of infigratinib will be further explored in a phase 3 randomized controlled study. If these phase 2 data are confirmed, infigratinib could potentially offer children with ACH the first effective oral therapy to improve growth, enhance functionality and decrease medical complications.

Session Title: Mendelian Phenotypes Poster Session I

PB4893 Return of individual genetic results in 47,107 individuals with autism.

Authors:

P. Feliciano[1], J. Wright[1], I. Astrovskaya[1], S. Barns[1], A. J. R. Goler[1], J. Hall[1], B. Han[1], T. SPARK Consortium[1], A. Wong[1], N. Volfovsky[1], W. Chung[2]; [1]Simons Fndn., New York, NY, [2]Columbia Univ., New York, NY

SPARK (SPARKforAutism.org)— the largest recontactable cohort of people with autism spectrum disorder (ASD) — has performed whole-exome or genome sequencing and publicly released this data from 47,107 individuals with autism and 67,704 of their first-degree family members. A major goal of the SPARK cohort is to form a partnership with participants and return research results to them. SPARK returns ACMG likely pathogenic (LP) and pathogenic (P) variants from a pre-defined list of 586 genes, 48 recurrent CNVs and chromosomal aneuploidies associated with autism and neurodevelopmental conditions. Of the 47,107 people with autism, we identified 4,057 potentially LP/P variants in 333 unique genes, 193 unique chromosomal band locations and 6 aneuploidies in 3,872 people with autism (8.2%). Among the 3,872 people with putative genetic diagnoses, 13% (n = 520) were previously known, matching the diagnosis provided by the participant. We performed confirmatory testing in a CLIA/CAP-certified clinical lab on 2,013 variants and found that 87% of variants (n = 1,757) were confirmed and interpreted as Likely Pathogenic/Pathogenic (LP/P), 11% (n = 214) were analytically confirmed and interpreted as variants of uncertain significance, one variant was analytically confirmed and interpreted as likely benign, and 2% were not analytically confirmed. Of the 1,757 confirmed LP/P variants, 4% were already known to the participant. Of the remaining 1,682 new genetic diagnoses, 209 occurred in individuals who previously reported having had genetic testing, but no genetic diagnosis was made. The frequency of cognitive impairment was higher in individuals with a history of genetic testing (46%) compared to individuals with no history of previous genetic testing (34%). Among the new single-gene diagnoses, the most common were in: *SHANK3*, *SCN2A*, *NF1*, *PTEN*, and *CHD8*, with each explaining no more than 2% of the total new diagnoses. The most common CNVs in new diagnoses were: 16p11.2 del/dup (3.5%), 2p16.3 del (*NRXN1*) (1.6%), and 15q11 dup (1.2%). As expected, the genetic heterogeneity was high, with 15% of the new diagnoses occurring in just one or two individuals. Overall, our results show that an autism-related genetic result can be identified in at least 8% of individuals ascertained through an autism research cohort. All participants in SPARK—with and without genetic diagnoses—are available for recontact to the entire research community using SPARK's Research Match platform.

Session Title: Mendelian Phenotypes Poster Session II

PB4894 Risk of Alzheimer's disease associated with *ABCA7* tandem repeat expansions across multiple ethnicities.

Authors:

P. Valdmanis[1], E. Kaufman[2], S. Smukowski[1]; [1]Univ of Washington, Seattle, WA, [2]Univ. of Washington, Seattle, WA

Genome-wide association studies (GWAS) are plagued by an inability to locate the relevant functional variant at a given locus. Tandem repeats often have an outsized influence on gene expression and are implicated in over 50 disorders. One such repeat is a 25bp variable number tandem repeat (VNTR) that is present in ATP binding cassette subfamily A member 7 (*ABCA7*). *ABCA7* is a well-established risk factor for Alzheimer's disease (AD). We examined multiple GWAS SNPs associated with AD in *ABCA7* and by integrating long-read and short read data, we surprisingly found that risk alleles tag repeat length in an allele-specific manner. For example, an average of 87 repeat copies are present in homozygous carriers of the rs3764650 risk allele compared to 65 repeat copies in heterozygous individuals and 53 copies in individuals homozygous for the reference allele ($p<0.001$ by one-way ANOVA with multiple testing correction). Interestingly, this effect was specific to samples of European descent as the SNP had no influence on repeat length in samples of African ancestry. Nevertheless, an African-specific sentinel GWAS variant (rs115550680) is adjacent to the 25bp VNTR in its own mini-VNTR with implications for appropriate *ABCA7* splicing. Moreover, in a set of 7,968 cases and 6,792 controls from the Alzheimer's Disease Sequencing Project, we found increased repeat length in samples of both African and European ancestry. Of relevance, increases in *ABCA7* repeat length are associated with aberrant splicing leading to mRNAs with premature termination codons. Expanding our analysis to additional tandem repeats genome-wide revealed VNTRs with significantly expanded repeat length in Black, Hispanic, and non-Hispanic White individuals with AD, while re-enforcing the significant hit at *ABCA7*. Collectively, converging lines of genetic and functional evidence implicate *ABCA7* VNTR length as a risk for AD.

Session Title: Mendelian Phenotypes Poster Session III

PB4895 RNA sequencing for the diagnosis of scoliosis

Authors:

H. Du[1], Q. Li[2], Z. Zhou[1], S. Zhao[3], N. Wu[2]; [1]Peking Union Med. Coll., Beijing, China, [2]Peking Union Med. Coll. Hosp., Beijing, China, [3]Baylor Coll. of Med., Houston, TX

Scoliosis is the lateral curvature of the spine in the coronal plane. A fraction of scoliosis are caused by Mendelian diseases. In a previous study, the overall genetic diagnostic rate of early-onset scoliosis was 20.6%. The genetic causes of most scoliosis patients remain unclear. Recently, transcriptome sequencing combined with whole genome/exome sequencing (WGS/ES) has been increasingly utilized to facilitate the diagnosis of various Mendelian disorders and demonstrated significant gain in diagnostic power. No study has explored the effectiveness of transcriptome sequencing in facilitating the genetic diagnosis of scoliosis. In this study, we aim to explore the utility of skin-derived fibroblast transcriptome sequencing in the genetic diagnosis of scoliosis. We included 181 scoliosis patients who underwent surgical correction at Peking Union Medical College Hospital, including 68 congenital scoliosis (CS) patients, 66 idiopathic scoliosis (IS) patients, and 47 syndromic scoliosis patients. We performed transcriptome sequencing on cultured skin fibroblasts derived from patients' skin tissue. We also performed WGS (160/181)/ES (21/181) on DNA extracted from peripheral blood of each patient. We first analyzed the WGS/ES data from 181 patients and obtained a genetic diagnosis in 41 patients, with a diagnostic rate of 22.7%. After performing a combined analysis of WGS/ES data and transcriptome sequencing data, we further identified the genetic diagnoses in 11 patients, raising the diagnostic rate to 28.7%. The diagnostic rates for CS, IS, and syndromic scoliosis patients were 29.4% (20/68), 15.2% (10/66), and 46.8% (22/47), respectively. Transcriptome sequencing identified the aberrant transcriptional events in 32 patients out of the 52 diagnosed patients. Among the 11 patients who could only be diagnosed with the aid of transcriptome data, 6 had copy number variations, 2 had single-allele gene expression of pathogenic mutations for autosomal recessive inherited diseases, and 3 had low-quality variants that were filtered in WGS/ES-centered analysis. Our study indicates that transcriptome sequencing can aid the interpretation of WGS/ES data and improve the genetic diagnostic rate of scoliosis patients. Our study also highlights the heterogeneity of genetic causes in scoliosis.

Session Title: Mendelian Phenotypes Poster Session I

PB4896 *SGMS2*and Juvenile Open-Angle Glaucoma: A Novel Connection in a Multi-generational Filipino Family

Authors:

E. Collantes[1,2], J. Flores-Anotado[3], S. De Arrigunaga[2], A. Dumdum[3], M. Guevarra[4], M. de Guzman[5], B. Hidalgo[3], V. Guzman[3], M. Rivera-Francia[3], J. Wiggs[2]; [1]Manila Doctors Hosp., Manila, Philippines, [2]Massachusetts Eye and Ear, Boston, MA, [3]Western Visayas Med. Ctr., Iloilo, Philippines, [4]Cardinal Santos Med. Ctr., San Juan, Philippines, [5]Asian Hosp. and Med. Ctr., Muntinlupa, Philippines

SGMS2 (sphingomyelin synthase 2) pathogenic variants cause Calvarial Doughnut Lesions with Bone Fragility (CDL) (MIM 12655). A recurrent nonsense mutation (c.148 C>T, p.Arg50*) has been found in 4 of 6 reported families and interestingly affected members of one of these families also exhibit congenital glaucoma with variable expressivity. We report on a large Filipino family with CDL and juvenile-onset open-angle glaucoma (JOAG), expanding the phenotypic spectrum of *SGMS2*-related disease.

Seventeen members of a four-generation family underwent comprehensive eye exams, skull radiography, and DNA extraction. Whole genome sequencing was performed, using data pre-processing, germline short variant discovery, and joint variant calling pipelines developed by the Broad Institute's Genomics Platform. The seqr platform was used to screen genomic data for mutations in genes associated with early-onset glaucoma. If no such mutations were found, the data was filtered to retain only rare, pathogenic, protein-altering variants. Sanger sequencing was done to validate variant segregation.

Six family members diagnosed with JOAG presented with a mean diagnosis age of 25.5 years, with 83% blind in at least one eye, a mean intraocular pressure of 29.4 mmHg, and glaucomatous optic nerves. No mutations were identified in known disease-causing genes and after variant filtering, a known recurrent heterozygous stop gain mutation, *SGMS2* c. 148C>T (p.Arg50*), was identified in all subjects with JOAG. Ten family members had abnormal skull radiographs, including all 6 JOAG subjects. The *SGMS2* p.Arg50* variant was present in all family members with skull abnormalities.

We report the first Filipino family with CDL associated with the *SGMS2* p.Arg50* variant. Our study identifies a second CDL family with early-onset glaucoma, suggesting *SGMS2* genetic variation may contribute to glaucoma pathogenesis. Considering the role of *SGMS2* in ceramide, sphingomyelin, and diacylglycerol metabolism, it could contribute to trabecular meshwork dysfunction or retinal ganglion cell degeneration in glaucoma. Of interest, *SGMS2* is included in a loci associated with POAG (rs216197, 3.8e-10, beta= -0.06) and a rare variant burden test (LoF, SKAT-O) is also nominally associated with glaucoma in the UK Biobank (p=0.005). Further work is needed to verify a role for *SGMS2* in glaucoma development. This study expands the known genetic landscape of JOAG and the phenotypic spectrum of *SGMS2*-related disease.

Session Title: Mendelian Phenotypes Poster Session II

PB4897 *SHOX* duplication and biochemical findings of short-chain acyl-CoA dehydrogenase deficiency (SCADD) in a patient with Angelman syndrome.

Authors:

Y. Enchautegui-Colon[1], M. Napoli[1], C. Zimmerman[1], H. Pang[2], A. C. Tsai[1]; [1]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK, [2]Univ. of Oklahoma Hlth.Sci. Ctr., Oklahoma City, OK

Angelman syndrome is a condition associated with severe developmental delay. Patients with Angelman syndrome typically have intellectual disability, ataxic gait and severe speech impairment. Patients also have an apparent happy disposition. We present a 3-year-old boy who was initially evaluated at 11 months old due to feeding difficulties, dysphagia, developmental delays and short stature. He has a history of respiratory failure, bronchiolitis and bradycardic arrest. Prenatal exposures to methamphetamines and marijuana were reported. A chromosomal microarray analysis revealed a 92 kb microduplication at Xp22.33 within pseudoautosomal region 1, classified as likely pathogenic. The Xp22.33 microduplication involves the entire *SHOX* gene. Microduplications at the *SHOX* locus have been reported in patients with autism spectrum disorder and neurodevelopmental conditions with low penetrance. Biochemical testing revealed elevated C4 in two separate acylcarnitine profiles and a small peak of ethylmalonic acid in urine organic acids, raising a concern for short-chain acyl-CoA dehydrogenase deficiency (SCADD). His newborn screen was normal. A molecular panel for elevated C4 was obtained, which revealed the variants c.542G>A (p.Gly181Glu) and c.625G>A (p.Gly209Ser) in *ACADS*, accounting for the biochemical findings. The patient's symptoms and developmental delays were felt not to be completely explained by SCADD or by the Xp22.33 microduplication and whole exome sequencing (WES) was performed. WES did not identify any known disease-causing variants to explain the extent of his features. Patient returned to follow-up at 3 years old, he continued to have developmental delays, had no words and was not walking independently. He also had short stature and excessive weight gain. His physical examination was remarkable for happy disposition, hand flapping and frequent smiling. Patient took steps with assistance and was noted to have a wide based gait. The happy disposition and abnormal gait raised concerns for Angelman syndrome. Methylation study for Angelman syndrome/Prader-Willi Syndrome was performed and showed loss of expression of the maternally derived *UBE3A*, confirming the diagnosis of Angelman syndrome. This case is of great significance as it notes the limitations of WES. It also supports that another underlying diagnosis should be considered in patients with biochemical findings of SCADD who have developmental delays and showcases the importance of physical examination in the diagnostic process. The happy disposition and behavioral phenotype that this patient developed later on provided the clues to make the diagnosis of Angelman syndrome.

Session Title: Mendelian Phenotypes Poster Session III

PB4898 Single nucleotide variations and structural variants affecting the *EYS* promoter cause autosomal recessive retinitis pigmentosa.

Authors:

D. Sharon[1], T. Hayman[1], J. Krishnan[2], D. Panneman[3], S. De Bruijn[3], S. Ovadia[4], S. Khateb[1], J. Nellissery[2], M. English[2], R. Ashery-Padan[4], T. Ben-Yosef[5], S. Roosing[3], F. Cremers[3], E. Banin[1], A. Swaroop[2]; [1]Div. of Ophthalmology, Hadassah Med. Ctr., Faculty of Med., The Hebrew Univ. of Jerusalem, Jerusalem, Israel, [2]Neurobiology, Neurodegeneration and Repair Lab., Natl. Eye Inst., NIH, Bethesda, MD, [3]Dept. of Human Genetics, Radboud Univ. Med. Ctr., Nijmegen, Netherlands, [4]Dept. of Human Molecular Genetics and Biochemistry, Sackler Faculty of Med. and Sagol Sch. of NeuroSci.s, Tel Aviv Univ., Tel Aviv, Israel, [5]Ruth and Bruce Rappaport Faculty of Med., Technion-Israel Inst. of Technology, Haifa, Israel

Purpose: Inherited retinal diseases (IRDs) are a group of heterogeneous diseases caused by variants in over 350 genes. Disease-causing variants can be identified in only 65-70% of cases, even when whole exome or whole genome sequencing are being used. Therefore, a large effort is recently directed to the identification of the remaining pathogenic variants, which led to the identification of deep intronic variants that affect splicing and structural variants affecting at least one exon. Untranslated regions (UTRs), on the other hand, are poorly studied, mainly due to lack of knowledge regarding the effect of variants in these regions on gene expression. The purpose of the current study is to characterize the effect of variants, both single nucleotide and structural, identified in the 5' untranslated region of *EYS* in patients with autosomal recessive retinitis pigmentosa (ARRP). **Methods:** DNA samples were screened for variants using smMIPs (targeted panel of 113 genes underlying RP and Leber congenital amaurosis), the Blueprint IRD panel, Sanger sequencing, whole exome sequencing, and whole genome sequencing. Variants were analyzed and annotated using the Franklin platform. Clinical analysis included electroretinography and retinal imaging. Electrophoretic mobility shift assay (EMSA) was performed using nuclear extracts from bovine retina. **Results:** We identified six Arab-Muslim index cases who harbored a 5' UTR variant (c.-453G>T; hg19, chr6:66,417,033C>A) in *EYS* noncoding exon #1. Three were homozygous and three were compound heterozygotes. In addition, we identified four index cases of various ethnicities who harbored biallelic *EYS* variants, at least one of which was a structural variant affecting the 5' UTR. Clinical phenotype of *EYS* RP patients harboring c.-453G>T is generally less severe than those with biallelic null *EYS* variants. EMSA analysis of c.-453G>T revealed a prominent low molecular weight band that is specific to the reference allele and is completely absent from the mutant allele, indicating that this variant affects binding of transcription factors. *In silico* transcription factor binding analysis revealed two transcription factors (YY-1 and RFX), whose binding to the *EYS* promoter is predicted to be affected by the presence of the c.-453G>T variant. **Conclusions:** Our analysis revealed both single nucleotide and structural variants in the *EYS* promoter as the cause of ARRP. We predict that promoter-affecting variants are responsible for some of the missing heritability in inherited disease, and such variants will be identified more frequently as whole genome sequencing becomes the major tool for mutation analysis.

Session Title: Mendelian Phenotypes Poster Session I

PB4899 Single-cell RNA-sequencing analysis reveals the role of endothelial cells in aneurysm pathogenesis in autosomal recessive cutis laxa type 1B syndrome.

Authors:

W. Espinoza Camejo, E. E. Bramel, L. Restrepo, E. G. MacFarlane; Johns Hopkins Univ., Baltimore, MD

Thoracic aortic aneurysms are localized dilation where the diameter of the blood vessel increases by 50% or more. If left untreated, this condition can lead to dissection or rupture. Autosomal Recessive Cutis Laxa type 1B (ARCL1B) is a connective tissue disorder caused by homozygous loss of function mutation in the *EFEMP2/FBLN4* gene. This disorder is associated with an increased risk of aneurysm in the ascending aorta. To better understand the mechanisms that predispose the ascending aorta to medial weakening and dilation, we examined the *Fbln4*$^{E57K/E57K}$ knock-in mouse model, which carries a homozygous mutation known to cause ARCL1B in humans. We conducted a single-cell RNA-sequencing (scRNA-seq) analysis identifying three major vascular smooth muscle cells (VSMC) subclusters in both control and *Fbln4*$^{E57K/E57K}$ aorta. We identified clusters enriched in the aortic root (VSMC3) and ascending aorta (VSMC1 and VSMC2) using transcripts previously shown to describe a gradient of expression along the length of the aorta. VSMC2, and to a lesser extent VSMC1, inherently expressed higher levels of Angiotensin-converting enzyme *(ACE)*, transcripts promoting proteoglycan accumulation, and those associated with a synthetic VSMC phenotype. All these features were exacerbated in the aortas of *Fbln4*$^{E57K/E57K}$ mice, indicating that VSMC2 may be primed and intrinsically more susceptible to disruptions caused by *Fbln4*$^{E57K/E5K7}$ mutation. We also observed increased expression of *Edn1*, the gene responsible for producing *Endothelin 1*, in endothelial cells (ECs) from *Fbln4*$^{E57K/E57K}$ aortas, suggesting that this ligand may drive some of the phenotypic changes observed in adjacent VSMCs. By validating these results, we can deepen our understanding of the intricate paracrine interactions between a specific subset of VSMCs and ECs, thereby elucidating their pivotal role in the heightened susceptibility to aneurysm formation within the ascending aorta of *Fbln4*$^{E57K/E57K}$ mice.

Session Title: Mendelian Phenotypes Poster Session II

PB4900 Single-cell sequencing analysis of heteroplasmy distribution in mitochondrial retinopathy.

Authors:

N. Mullin, A. P. Voigt, M. J. Flamme-Wiese, X. Liu, M. Riker, K. Varzavand, E. M. Stone, B. A. Tucker, R. F. Mullins; Univ. of Iowa, Iowa City, IA

Variants within the high copy number mitochondrial genome (mtDNA) can disrupt organelle function and lead to severe multi-system disease. The wide range of manifestations observed in mitochondrial disease patients may result in part from varying fractions of abnormal mtDNA molecules in different cells and tissues, a phenomenon termed heteroplasmy. However, the landscape of heteroplasmy across cell types within tissues and its influence on phenotype expression in affected patients remains largely unexplored. Here, we identify non-random, cell type-specific distribution of the most common pathogenic mtDNA variant (m.3243A>G) across a complex tissue using mitochondrial single-cell ATAC sequencing (mt-scATACseq), single-cell RNA sequencing (scRNAseq), and long-read mtDNA sequencing. We profile the transcriptome, chromatin accessibility state, and heteroplasmy in retinal cells of a patient with mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) and of several healthy control donors. We found that the proportion of the m.3243G allele was neither evenly nor randomly distributed across diverse cell types. All neuroectoderm-derived neural cell types were near homoplasmic for the mutant variant (median m.3243G proportion of 1.0). However, a subset of mesoderm-derived cells, namely the vasculature of the choroid and T cells, were near homoplasmic for the wildtype allele (median m.3243G proportion beneath 0.05). Gene expression and chromatin accessibility profiles of cell types with high and low proportions of m.3243G implicate mTOR signaling in the cellular response to heteroplasmy. Using mt-scATACseq data, we observed additional heteroplasmic variants segregating in cells with the m.3243G allele. Linkage of these variants was validated using whole-mtDNA long-read sequencing on MELAS patient samples. Finally, by multimodal single-cell sequencing of MELAS retinal pigment epithelial cells we found that a high proportion of the pathogenic m.3243G variant was associated with dysregulation of genes with core roles for retinal metabolic homeostasis. Together, these findings show the non-random and cell type-specific nature of mitochondrial variant partitioning in human mitochondrial disease and underscore its implications for mitochondrial disease pathogenesis and treatment.

Session Title: Mendelian Phenotypes Poster Session III

PB4901 *SMAD4*-related Juvenile Polyposis - Hereditary Haemorrhagic Telangiectasia has a very high risk of gastrointestinal and pulmonary complications.

Authors:

M. Pearson[1], R. McGowan[2], L. Snadden[3], Z. Miedzybrodzka[4], J. Berg[1]; [1]Univ. of Dundee, Dundee, United Kingdom, [2]West of Scotland Ctr. for Genomic Med., Glasgow, United Kingdom, [3]NHS Grampian, Aberdeen, United Kingdom, [4]Univ. of Aberdeen, Aberdeen, United Kingdom

Background: *SMAD4*, the common-SMAD, is integral to mediating signal transduction for serine threonine kinase receptors, including those in the TGF-β, activin and bone morphogenic protein signalling pathways. Heterozygous germline variants that lead to loss of *SMAD4* function result in Juvenile Polyposis-Hereditary Haemorrhagic Telangiectasia Overlap Syndrome (JP-HHT). JP-HHT is associated with potentially life-threatening complications including gastrointestinal cancers, pulmonary arteriovenous malformations (PAVMs) and ascending aortic aneurysms. We investigated the risk of complications in a cohort of patients with JP-HHT in Scotland.
Methods: A retrospective multi-centre chart review of individuals with *SMAD4* loss of function pathogenic variants identified 21 patients from 11 families in three Scottish health boards.
Results: Colonoscopic screening was offered to 90% (19/21) of patients. Colonic polyps were identified in 84% (16/19) at a median age of 24.5 years (IQR 21-33.8). 42% (8/19) of patients required a colectomy at a median age of 24 years (IQR 20-42.5). Colorectal cancer occurred in 19% (4/21) of patients, diagnosed at a median age of 29.5 years (IQR 24.5-38.5). Gastric screening was performed in 71% (15/21) of patients, with gastric polyps present in 67% (10/15). 50% of those with known gastric polyps required a gastrectomy at a median age of 37 years (IQR 12.7-47). 1 patient was diagnosed with gastric cancer, at age 66 years. Epistaxis was investigated in 86% (18/21) of patients, of whom 78% (14/18) reported its presence, with onset universally in childhood. 62% (13/21) of patients were examined for telangiectasia, with its identification in 23% (3/12) of those examined. PAVM screening was performed in 81% (17/21) of patients and a PAVM identified in 47% (8/17) of those screened. Only 19% (4/21) of patients were screened for a thoracic aortic aneurysm, all of whom had negative screening.
Conclusions: All patients with loss of function pathogenic variants in *SMAD4* are at very high risk of life-threatening gastrointestinal disease, which includes very early onset bowel cancer and a high risk of gastric obstruction caused by non-malignant polyposis. The incidence of PAVMs was at least equivalent to that seen in HHT type 1, if not higher. All patients with LOF variants in *SMAD4* require upper and lower gastrointestinal screening in addition to screening and follow up for HHT.

Genetics, Hosp. Clínico Univ.rio Virgen de la Arrixaca, IMIB-Arrixaca, Murcia, Spain, Murcia, Spain

Snijders Blok-Campeau syndrome (SNIBCPS, OMIM# 618205) is an extremely infrequent disease with only approximately 60 cases reported so far. SNIBCPS belongs to the neurodevelopmental group of disorders. Clinical features of patients with SNIBCPS includes global developmental delay, intellectual disability, speech and language difficulties and behavioral disorders like autism spectrum disorder. In addition, patients with SNIBCPS exhibit typical dysmorphic features including macrocephaly, hypertelorism, sparse eyebrows, broad forehead, prominent nose and pointed chin. The severity of the neurological effects as well as the presence of other features is variable among subjects. SNIBCPS is caused by pathogenic variants in *CHD3 (Chromodomain Helicase DNA Binding Protein 3)* which seems to be involved in chromatin remodeling by deacetylating histones. Here, we report 18 additional patients with clinical features compatible with SNIBCPS from 15 unrelated families with confirmed pathogenic variants in *CHD3*. Patients were analyzed by either Sanger sequencing or by whole exome sequencing. Patients in this study showed different pathogenic variants affecting different functional domains of the protein. Besides, none of the variants described here were reported in control population databases and most computational predictors suggest that they are deleterious. The most common clinical features of the whole cohort of patients are global developmental delay (98%), speech disorder/delay (93%) and intellectual disability (73%). Other frequent features (51-74%) are hypotonia, hypertelorism, abnormality of vision, macrocephaly and prominent forehead, among others. This study expands the number of individuals with confirmed SNIBCPS due to pathogenic or likely pathogenic variants in *CHD3*. Furthermore, we add evidence of the importance of the application of massive paralleled sequencing for neurodevelopmental disorders in which the clinical diagnosis might be a challenge and in which deep phenotyping is extremely useful to accurate manage and follow up the patients.

PB4903 Solving challenging titinopathy cases via multi-omics

Authors:

A. Javed, Y. Zhang, L. Xu, Y. Lei, S. H. S. Chan; The Univ. of Hong Kong, Hong Kong, China

Titinopathy, or skeletal muscle dystrophy due to autosomal recessive mutations in Titin (*TTN*) poses a unique diagnostic challenge due to significant variability in disease manifestation and our incomplete knowledge of the role of various domains within the gene. Many healthy individuals harbor rare and computationally predicted to be damaging variants in *TTN*. This confounds interpretation of *TTN* variants in cardiac and neuromuscular disease patients. Here we report six Titinopathy patients from four unrelated families. In each case, a confirmed diagnosis was reached by co-analyzing familial DNA and proband muscle-biopsy based RNA sequencing data together. This allowed direct window into confirming or ruling out the impact of potential deleterious variants. Comparison with in-house and public muscle transcriptomics datasets brought credence to the outlying isoform usage in each family. The phenotypic diversity amongst these patients is noted which highlights the difficulty of diagnosis. The first family included two siblings presented with early onset elbow and ankle contractures followed by adolescent onset mild limb girdle weakness. They had progressive spine rigidity with stable motor performance and elevated Creatine Kinase (CK). The second family is a girl with infancy onset ankle contractures and delayed walking. The third family is a boy with infancy onset elbow and ankle contractures, severe hypotonia and hyper CK in blood. The fourth family included two siblings with decreased fetal movement during pregnancy, and significant gross motor delay and hypotonia with mild facial weakness during early development. Both siblings had normal CK. All patients in this study had normal echocardiogram suggesting lack of cardiac involvement. Our multi-omics findings link individualized specificity of the patient condition to the specific transcriptomic impact of the observed mutations.

Surgery, Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada, [5]Dept. of Otolaryngology, Dept. of Pediatrics, Emory Univ. Sch. of Med., Atlanta, GA, [6]Children's Hlth.care of Atlanta, Atlanta, GA, [7]Toronto HHT Ctr., St. Michael's Hosp. and Li Ka Shing Knowledge Inst., Toronto, ON, Canada, [8]Div. of Respirology, Dept. of Med., Univ. of Toronto, Toronto, ON, Canada

Vascular malformation syndromes, such as hereditary hemorrhagic telangiectasia (HHT), cause major complications including stroke, epilepsy, and hemorrhage. We recently identified biallelic loss of function of HHT genes (*ENG*, *ACVRL1*, or *SMAD4*) in skin telangiectasia, but a possible role for driver mutations in oncogenes in HHT arteriovenous malformation (AVM) pathogenesis has never been shown. Our objective is to identify the genetic mechanism of AVM genesis in brain and visceral HHT lesions. We sequenced DNA from HHT AVMs, including 3 brain (BAVM), 6 pulmonary (PAVM), 19 hepatic (HAVM), and 1 jaw AVM from HHT patients using a targeted panel of 189 genes implicated in vascular malformations on an Illumina platform. After data preprocessing, potential somatic variants were identified using custom software designed to identify somatic variants in tissue without a normal sample, implemented as part of the Gonomics platform. Sequences were then manually screened in IGV for potential variants. We identified potential second-hit somatic mutations in multiple HHT vascular malformation (VM) samples, including mutations in *ENG* or *ACVRL1* in 7 different HHT HAVMs and a *SMAD4* variant in 1 jaw AVM. We identified individual putative somatic mutations in individual HAVMs from individual patients: one patient harboring two distinct variants in *ENG* (c.1687_87-1delinsTT, p.Glu563* and c.174dupC, p.Asn59Glnfs*5), and another patient harboring three distinct variants in *ACVRL1* (c.881T>A, p.Leu294Gln, c.1277A>G, p.Tyr426Cys, and c.1461G>T, p.Lys487Asn), in addition to the germline mutations in the same genes that we also identified. We are currently validating and establishing the phase of these somatic mutations relative to the germline mutations. We are also further investigating potential oncogenic contributors to the pathogenesis of these lesions. We have identified potential new somatic mutations that may contribute to lesion pathogenesis in HHT AVMs. These novel findings further our understanding of the common genetic etiology underlying both visceral AVMs and skin telangiectasias in HHT and open new lines of investigation into previously unrecognized contributors to HHT pathology.

Session Title: Mendelian Phenotypes Poster Session I

PB4905 *SP7*/osterix neomorphic mutation S309W-zebrafish model recapitulates human high bone turnover disease

Authors:

S. Mumm[1], D. Sepich[1], G. Gottesman[1], W. McAlister[1], M. Whyte[2], L. Solnica-Krezel[1]; [1]Washington Univ. Sch. of Med., St. Louis, MO, [2]Washington Univ. Sch. of Med., St. Louis, MO

SP7 encodes the osteoblast-specific transcription factor osterix, which is critical for osteoblast development and function. In 2020, we reported (Whyte et al. Bone 137:115364) a de novo *SP7* missense mutation (c.926C-G, p.S309W) in a young woman with high bone turnover resembling juvenile Paget's disease (JPD). JPD features rapid bone remodeling throughout the skeleton, presents in infancy or early childhood with fractures and deformity, is characterized by elevated serum alkaline phosphatase (ALP), and is usually caused by recessive mutations in *TNFRSF11B* encoding osteoprotegerin (OPG). She began fracturing her lower extremity long bones during infancy, then developed skull deformity and hearing loss. At age 15, radiographs revealed generalized osteosclerosis, hyperostosis, scoliosis, and craniofacial/dental defects, and DXA showed elevated bone mineral density (Z-score +5.1 at lumbar spine and T-score +3.3 at wrist). Bone turnover markers (serum ALP and urine hydroxyproline) were elevated. Iliac crest biopsy was consistent with rapid skeletal remodeling. She responded to alendronate therapy. Sanger sequencing of the OPG gene was negative, whereas whole exome sequencing identified the *SP7* variant S309W. Independent publication of a second patient with the identical mutation and similar clinical characteristics supports the *SP7* neomorphic variant as causal. Herein, we created a zebrafish model of our patient's allele using CRISPR/cas9, called sp7stl838. The homozygous mutants and heterozygous siblings exhibit frequent scoliosis of caudal vertebra. Initial micro computed tomography analysis of homozygous mutant and WT sib showed altered vertebral morphology, teeth not mounted in bone, and fractures in the caudal (tail) fin. Additionally, the mutant fish have altered growth of the premaxilla, maxilla, and dentary and other bones in the head. Cranial sutures between the frontal plates of the neurocranium ridge-up rather than overlap as in WT. The mid-region of the face centered on the nose, appears to have reduced bone density, while scales (which are dermal bone) have increased bone density. Histologic staining for bone and cartilage shows early excessive mineralization due to overactive sp7. Thus, the zebrafish *sp7* allele recapitulates some of our patient's JPD, with additional features. Our findings confirm c.926C-G, p.S309W as the causal mutation for Type 4 JPD and provide a good model for further study of this *SP7* neomorphic mutation.

PB4906 Spinal muscular atrophy 5q: molecular, clinical, and functional classification in a cohort of Colombian patients.

Authors:

F. Suarez[1,2], **M. Quiroga**[1], F. Ortiz[1,3], S. Castellar[1,3], E. Ruiz[1,3], M. Salcedo[1,3], D. Soto[1], M. Cediel[1], P. Anzola[1], O. Sanchez[1], C. Jaramillo[4]; [1]Inst. Roosevelt, Bogotá D.C., Colombia, [2]Inst. de Genética Humana. Pontificia Univ. Javeriana, Bogotá D.C., Colombia, [3]Univ. Natl. de Colombia, Bogotá D.C., Colombia, [4]Roche, Bogotá D.C., Colombia

Spinal muscular atrophy (SMA) is a genetic disorder that affects the nerve cells that control voluntary muscle movement. It is a rare disease that affects approximately 1 in 10,000 live births. SMA is caused by a mutation in the survival motor neuron 1 gene (SMN1, 5q13.2), resulting in an SMN protein deficiency. This protein is necessary for the survival and function of motor neurons responsible for sending signals from the spinal cord to the muscles throughout the body. SMN2 can partially compensate for the loss of SMN1, but it produces much less functional SMN protein due to a difference in how the gene is spliced. The number of copies of SMN2 that a person has can influence the severity of SMA and the age of onset. Rare diseases require information on functional phenotyping to understand the natural history of the disease. The molecular, clinical, and motor function description of a cohort of 85 Colombian patients with SMA is presented. The cohort is composed of 41 male patients and 44 female patients with a mean age of 13.6 years (Min: 1, Max: 58). The time to diagnosis had a mean of 8.9 years (Min: <1, Max: 53), SMA type 1: 8.3%; type 2A: 35.7%; type 2B 2.4%; type 3: 51%, and type 4: 2.4%. 18.8% of probands had relatives with SMA. 61% of patients had some comorbidity, 10.6% had fractures, and 41.2% required hospitalization related to SMS comorbidities. 40% of the cases received SMA Modifiers (Nusinersen); 98 of the patients had a homozygous deletion of exon 7 in SMN1. Only one case was compound heterozygous (SMN1: c.[835-?_*3+? del]; [724-2A>G]. 90.6% had Hammersmith scale evaluation; 41% of the cases had Motor Function Measurement (MFM); a 6-minute walk test (6MWT) was present in 34% of the patients. Some other motor function scales were applied to patients according to age and SMS type: Vignos, Brooke, CHOP-Intend, and RULM. More than 80% of the cases had multidisciplinary evaluation: rehabilitation medicine, neurology, genetics, pneumology, and pediatrics. Clinical correlation with SMS type and scale scores are discussed.

Session Title: Mendelian Phenotypes Poster Session III

PB4907 Spinocerebellar ataxia 27B: describing the phenotypic spectrum in an expanding founder French-Canadian cohort

C. Ashton[1,2], **F. Villa**[1,3], D. Pellerin[1,4], M. Danzi[5], M-J. Dicaire[1], A-L. Lafontaine[1], M-F. Rioux[6], F. Evoy[6], R. La Piana[1], M. Renaud[7,8], A. Duquette[9,10], S. Zuchner[11], B. Brais[12,10]; [1]McGill Univ., Montreal, QC, Canada, [2]Royal Perth Hosp., Perth, Australia, [3]Montréal Neurological Inst., Montreal, QC, Canada, [4]Univ. Coll. London, London, United Kingdom, [5]Univ. of Miami, Dakota Dunes, SD, [6]Sherbrooke Univ., Sherbrooke, QC, Canada, [7]CHRU de Nancy, Nancy, France, [8]Univ. de Lorraine, Nancy, France, [9]Université de Montréal, Montreal, QC, Canada, [10]Ctr. de Réadaptation Lucie-Bruneau, Montreal, QC, Canada, [11]Univ. of Miami Miller Sch. of Med., Miami, FL, [12]Mc Gill Univ., Montreal, QC, Canada

Introduction: Spinocerebellar ataxia 27B (SCA27B) due to an autosomal dominant intronic GAA repeat expansion in *FGF14* is an increasingly recognised cause of late-onset cerebellar ataxia (LOCA). We performed in-depth clinical phenotyping of an expanding group of French-Canadian cases, including reassessment of the younger generation of three large families to better understand the early clinical manifestations and better define the pathogenic threshold. **Methods**: Clinical records were retrospectively reviewed for all individuals carrying an *FGF14* allele $(GAA)_{\geq 200}$. Individuals with $(GAA)_{200\text{-}250}$ were re-evaluated where possible. Demographics and clinical features, including Scale for the Assessment and Rating of Ataxia (SARA), were reviewed. **Results**: Data of 123 individuals from 52 families were assessed: 94 of 109 individuals with $(GAA)_{\geq 250}$ had sufficient clinical data available - 48 female (51%), median disease duration of 14y (range 1-41). Most (n=73, 78%) reported initial episodic symptoms at median age of 54y (10-87), including dysarthria, diplopia, gait ataxia and vertigo. These could be triggered by alcohol (n=40, 55%), physical exertion (n=36, 49%), as well as other stressors like bright lighting (n=7), emotional stress (n=10), fasting (n=3), caffeine (n=4) and excessive heat (n=3). Thirty-five individuals also suffered from migraine (37%) and three persons reported episodes of speech arrest. Permanent ataxia began at median age of 59y (30-88). Examination features were pancerebellar: axial ataxia (n=80, 85%), appendicular ataxia (n=75, 80%), dysarthria (n=63, 68%). Average SARA scores (n=54) were 8.2 after mean disease duration of 13 years. Only 11 (12%) cases used a wheelchair. Downbeat nystagmus was observed in 45 cases (48%), horizontal nystagmus in 40 (43%), chronic diplopia in 31 (33%). Vibration sensation was impaired in 30 cases (32%) but only seven had EMG proven neuropathy. Brain MRI showed cerebellar atrophy in 31 of 56 cases (55%). Alleles between $(GAA)_{219}$ and $(GAA)_{247}$ were found in 11 individuals: seven with clinical ataxia, allele size $(GAA)_{220\text{-}247}$ (preceded by episodic ataxia in five), one with episodic vertigo and oscillopsia only, $(GAA)_{219}$, and two unaffected on last review (aged 49 and 53, $(GAA)_{224}$ and $(GAA)_{235}$) but with affected family members with pathogenic alleles $(GAA)_{\geq 300}$. **Conclusions**: SCA27B is associated with a prodromal episodic ataxia syndrome, occurring, on average, a decade prior to onset of clinical ataxia. The expansion repeat threshold size for incomplete penetrance of disease will have to be lowered below $(GAA)_{250}$, with familial episodic symptoms associated with expansions as small as $(GAA)_{219}$.

Session Title: Mendelian Phenotypes Poster Session I

PB4908 Splice Mutations and Digital Anomalies Extend the Genotypic and Phenotypic Spectrum of Kim-Gusella Syndrome in PHF21A Patients

Neurologia e Malattia Neurometaboliche, Siena, Italy, [17]Ochsner Clinic Fndn., New Orleans, LA, [18]Univ. Hlth.Network & Mount Sinai Hosp., Toronto, ON, Canada

Kim-Gusella syndrome (KGS) is a rare neurodevelopmental disorder caused by heterozygous mutations in the *PHF21A* gene at 11p11.2. In 2012, *PHF21A* was identified as the causative gene for intellectual disability (ID) and craniofacial anomalies (CFA) through breakpoint mapping of balanced translocations and comparative deletion mapping. This discovery explained these two partial phenotypes observed in Potocki-Shaffer syndrome (PSS), a contiguous gene disorder resulting from the minimal 2.1 Mb interstitial deletion of 11p11.2. PSS also exhibits additional skeletal anomalies, including multiple exostoses caused by *EXT2* and parietal foramina caused by *ALX4*. These three genes in the PSS region at 11p11.2 manifest full spectrum of PSS phenotypes. Subsequent to the identification of *PHF21A* by positional cloning, 14 intragenic mutations in *PHF21A* were reported in KGS patients with additional clinical features, including autism, ADHD, and epilepsy. These mutations consisted of 11 frameshift, two nonsense, and one missense alterations. In our present study, we present 14 unrelated KGS patients with novel variants in *PHF21A*, including six frameshift (resulting from four nucleotide deletions, one nucleotide duplication, and one nucleotide insertion), three nonsense, two missense, and three splice mutations. Notably, the identification of splice variants in *PHF21A* is novel and further supports the loss-of-function mechanism associated with KGS. Most KGS patients exhibited developmental delay, intellectual disability, learning disabilities, and language/speech delays. Additionally, several patients displayed digital anomalies such as clinodactyly, syndactyly, and tapering fingers, confirming previously reported phenotypes, and establishing these digital anomalies as novel features associated with KGS. Our findings expand the genotypic and phenotypic spectrum of KGS and enhance our understanding of the role of *PHF21A* in the pathogenesis and potentially improve diagnostic and therapeutic strategies.

Session Title: Mendelian Phenotypes Poster Session II

PB4909 Splicing response QTLs identify putative osteoarthritis risk genes

Authors:

S. Byun, P. R. Coryell, E. Thulson, N. Kramer, S. D'costa, B. O. Diekman, R. Loeser, D. Phanstiel; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Genome-wide association studies (GWAS) have identified over 100 genomic loci associated with osteoarthritis (OA) risk; however, mechanistic interpretation of these variants within these loci remains an enormous challenge. Differentially spliced transcripts have been observed in OA tissue, which suggests that some OA risk variants could act by altering splicing patterns; however, this possibility has not been extensively explored. Quantitative trait loci (QTL) mapping is a powerful tool to interpret disease-associated variants, but it must be carried out in the correct cell type and disease-related context. We have previously shown that OA risk variants are enriched in chondrocyte regulatory loci and that treating human chondrocytes with fibronectin fragment (FN-f), a matrikine present in OA tissue, stimulates an OA-like phenotype.

The overall objective of our work is to identify genetic variants that alter OA risk by influencing RNA splicing in either resting or stimulated chondrocytes. We performed RNA-seq in primary human chondrocytes isolated from 102 tissue donors treated with either PBS or FN-f. Using LeafCutter, we identified 422 differentially excised introns (affecting 303 genes) in response to FN-f treatment (FDR $P< 0.05$ and PSI > 0.2). Differentially spliced genes were enriched for many OA-relevant GO terms and KEGG pathways, including actin binding, cytoskeleton organization, EGFR, and Hedgehog signaling. Using QTLtools and condition-separated regression modeling, we identified 1137 sQTLs affecting 987 sGenes (FDR $P<0.05$) and 1073 sQTLs affecting 926 sGenes in PBS and FN-f treated cells, respectively. 54 sQTLs were in linkage disequilibrium ($r2 > 0.5$) with an OA risk variant, including NEK4 and ITIH1, which have been previously implicated in OA. This study highlights the relevance of genetic variants and transcript splicing in mediating the response to cartilage matrix damage and offers a valuable resource for further research and therapeutic development in OA.

Ctr., Oxford, United Kingdom, [3]Human Technopole, Milan, United Kingdom, [4]Oxford Univ. Hosp. NHS Fndn. Trust, Oxford, United Kingdom, [5]Weatherall Inst. of Molecular Med., Univ. of Oxford, Oxford, United Kingdom, [6]Chugai, London, United Kingdom, [7]Dept Biochemistry and Cell Biology, Univ. of Vienna, Oxford, United Kingdom

Background
Whole genome sequencing (WGS) is increasingly being used for the diagnosis of patients with rare disease. However, the diagnostic yields of many studies, particularly those conducted in a healthcare setting where patients are referred from a wide range of clinical specialties, are often disappointingly low, at 25-30%. This is in part because although entire genomes are sequenced, analysis is often confined to examining in silico gene panels or coding regions of the genome.
Methods We undertook WGS on a cohort of 122 unrelated rare disease patients and their relatives (300 genomes) who had been pre-screened by gene panel sequencing or high-resolution arrays to exclude known disease genes or chromosomal abnormalities. Patients were recruited from a broad spectrum of clinical specialties. We applied a bioinformatics pipeline that would allow an in-depth interrogation of the genome to provide a comprehensive analysis of all variant types. We combined established bioinformatics tools for phenotypic and genomic analysis with our novel algorithms, SVRare, ALTSPLICE and GREEN-DB, to detect and annotate structural, splice site and non-coding variants.
Results Our diagnostic yield was 43/122 cases (35%), although 47/122 cases (39%) were considered solved when taking novel candidate genes with supporting functional data into account. Structural, splice site and deep intronic variants contributed to 20/47 (43%) of our solved cases. Five genes that are novel, or were novel at time of discovery, were identified (*POLR2A*, *MCM10*, *KMT2E*, *DOCK7*, *SAMD9L*), whilst a further three genes (*DHRS3*, *FOXD3*, *HDLBP*) are putative novel disease genes with evidence of causality. We identified variants of uncertain significance in a further fourteen candidate genes. The phenotypic spectrum associated with *RMND1* variants was expanded to include polymicrogyria. Two patients with secondary findings in *FBN1* and *KCNQ1* were confirmed to have previously unidentified Marfan and long QT syndromes, respectively, and were referred for clinical interventions. Clinical diagnoses were changed, further to WGS, in six patients and treatment adjustments made for eight individuals, which for five patients was considered life-saving.
Conclusions Genome sequencing is increasingly being considered as a first-line genetic test in routine clinical settings and is enabling rapid genetic diagnoses to be provided for many patients. We have demonstrated that structural, splice site and intronic variants make a substantial contribution to diagnostic yield and therefore, that comprehensive analysis of the entire genome is essential to maximise the value of clinical WGS.

Session Title: Mendelian Phenotypes Poster Session I

PB4911 Structural variants are rare sources of molecular diagnosis for secondary findings.

Authors:

M. Walkiewicz[1], E. Karlins[2], M. Sharma[2], S. Byers[1], J. Yan[1], M. Similuk[1], A. Oler[2], D. Veltri[2], R. Ghosh[1], B. Seifert[1], S. M. Holland[1]; [1]NIAID, Bethesda, MD, [2]BCBB/OCICB/NIAID, Bethesda, MD

The contribution of structural variants (SV) to molecular diagnosis of secondary findings (SF) remains largely unaddressed. Several genes (*EPCAM*, *GREM1*, and *HNF1B*) have been excluded due to a technical concern for reliable detection of duplications and deletions which make up a substantial percentage of disease-causing alleles. With the growing utility of genome sequencing in molecular diagnostics and more reliable algorithms to detect SVs, we sought to determine the contribution of SVs to diagnosis of SF.

We called SVs using the GATK-SV pipeline on the Terra platform on 3327 samples with genome sequencing data in subjects recruited for genomic evaluation at the National Institutes of Health. We focused on SVs less than 1% frequency in our cohort and in gnomAD and predicted to overlap coding, UTR, and promoter regions in one of the 78 genes on the SF list: *EPCAM*, *GREM1*, and *HNF1B***.** We utilized ClinGen's dosage sensitivity curation for establishing dose-sensitive gene list. We performed clinical chromosomal microarrays (CMA) for a subset of subjects.

Our analysis identified 18 unique copy number loss calls in 16 genes. Upon further evaluation, 3 calls were technical artifacts due to a very low coverage (*TTN* & *SMAD4*). Of the remaining 15 unique calls (14 genes), 6 occurred in genes with sufficient evidence for haploinsufficiency (*KCNQ1*, *PKP2*, *MAX*, *SMAD3*, *BRCA1*, *VHL*), 2 in genes with little evidence for haploinsufficiency (*ACTA2* & *TNNI3*), 4 in genes with no evidence for dosage sensitivity (*CACNA1S*, *MYH7*, *MYH11*, *TMEM43*0), and 2 in genes with recessive inheritance (*HFE* and *TRDN*; additional variant(s) were not detected). Of note, one copy number loss was detected in *HNF1B*. We also identified 20 unique copy number gain calls, including both whole gene and partial gene duplications, in 16 genes. There is no evidence for triplosensitivity in any of these genes. None of the gains were predicted to result in loss of function except for *TTN*. Interestingly, we identified a possible whole gene gain and a promoter region gain in *GREM1*. Lastly, 17 participants with SV calls by GATK-SV received a CMA: 4 arrays detected the same SV called by our algorithm, 6 arrays were reported as normal, 7 arrays included other findings. Orthogonal confirmations of our findings are pending.

In our cohort, SVs contribute to a small percentage of SF diagnoses. However, with improving algorithms and periodic updates to the SF gene list recommended for reporting the percentage might increase over time. Challenges include orthogonal confirmations as most of these variants were not reported on arrays for our participants, likely due to limited coverage and relatively small size of these variants.

Session Title: Mendelian Phenotypes Poster Session II

PB4912 Study of the cause of death in patients with ATR-X syndrome in Japan

Authors:

T. Wada[1], N. Okamoto[2], K. Kurosawa[3]; [1]Kyoto Univ. Graduate Sch. Med., Kyoto, Japan, [2]Osaka Women s and Children s Hosp., Izumi, Japan, [3]Kanagawa Children s Med Ctr, Yokohama, Japan

BACKGROUND ATR-X syndrome (MIM 301040), caused by loss-of-function variants of *ATRX* gene on X chromosome, is among X-linked intellectual disability syndromes and characterized by male patients, severe intellectual disabilities, alpha-thalassemia, peculiar facies, genital abnormality, skeletal abnormality, and characteristic posture and/or behavior. Since 1995, more than 100 patients have been diagnosed molecular genetically in Japan, and it is estimated that one out of 58,000 to 73,000 of newborn boys has ATR-X syndrome. ATRX gene encode an ATP-dependent chromatin remodeling factors, and ATRX protein binds to guanine-quadruplex, G4, and regulate the expression of genes nearby. (Law MJ. *Cell*, 2010) We reported that 5-aminollevulinic acid as a precursor of protoporphyrin IX and heme, which bind to G4 instead of abnormal ATRX protein and improve expressions of ATRX-targeted genes, could be a treatment for cognitive dysfunction of Atr-x syndrome mice. (Shioda N. *Nature Medicine*, 2018) Now we have been conducting an investigator-initiated clinical trial for ATR-X syndrome patients in Japan since July 2022. Here we report the cause of death of ATR-X patients, because we have few reports about natural history of adult patients or cause of death of ATR-X patients.**PATIENTS and METHOD** 50 ATR-X patients, confirmed molecular genetically, are registered in our ATR-X syndrome database in Japan, including 12 adult patients who are more than 18 years old. We have collected clinical information of these patients from their registered data, clinical records and interviews from their families and/or doctors.**RESULTS** Here we review 10 patients who have passed away. Six died as infants, and the others as adults. In the former group, one died during MRI examination under anesthesia at three years old, one of status epilepticus at one, one of choking on vomit at six, and three of ileus at eight, nine, and 13. In the latter group, one of colon cancer at 61, one of acute renal failure at 46, one of epilepsy or gastro-esophagus regurgitation at 23, and one of myocardial infarction at 37. No cases underwent autopsy. Intriguingly, all patients except two had few complications, and had been living in relatively good health condition. Some infection-like episode triggered their onset, and they got worse rapidly to death.**CONCLUSION** Our data suggests that their health condition can change rapidly after some infectious triggers, even if they seem in relatively good condition as ATR-X syndrome patients, and all adult patients should be examined regularly at least once a year, because some patients were noticed to have renal hypoplasia or heart disease in adults, which were missed in childhood.

Sch., Boston, MA, [5]Broad Inst. of MIT and Harvard, Cambridge, MA, [6]Natl. Human Genome Res. Inst., NIH, Bethesda, MD, [7]Howard Hughes Med. Inst., Chevy Chase, MD, [8]Massachusetts Eye and Ear Infirmary, Boston, MA, [9]NYU Grossman Sch. of Med., New York, NY, [10]Natl. Eye Inst., NIH, Bethesda, MD, [11]Natl. Inst. of BioMed. Imaging and Bioengineering, NIH, Bethesda, MD

Background: Moebius syndrome (MBS) is defined by congenital, neurogenic nonprogressive facial weakness with limited abduction of one or both eyes with absence of ptosis and vertical gaze limitations, with or without additional manifestations such as lower cranial nerve involvement, limb anomalies, pectoralis major hypoplasia (MBS-Poland), other organ dysmorphogenesis, and neurocognitive impairment. While some MBS cases have been attributed to teratogen exposure or maternal homocystinuria, germline genetic etiologies have been posited for others. These include *de novo* changes in *PLXND1* or *REV3L* which were reported in five probands with MBS-like phenotypes (Tomas-Roca et al., 2015). **Objectives**: The Moebius Syndrome Research Consortium was formed to establish a large research-based MBS cohort for whom we performed systemic phenotypic characterization and germline genetic analyses using exome and genome sequencing (ES, GS). **Results:** 153 probands were ascertained after excluding subjects with overlapping congenital facial weakness syndromes. Subsets received deep phenotyping at the NIH Clinical Center (n = 32) and germline ES or GS (n = 70). All probands were sporadic/simplex cases with no known horizontal or vertical transmission, with 17 unaffected offspring and 178 unaffected full siblings across the cohort. Common co-occurring phenotypes included clubfoot (43.1%); intellectual disability (37.7%); major limb anomalies (30.7%); hearing loss (29.6%); autism (17.9%); MBS-Poland (12.4%); and seizures (11.9%). MR imaging revealed hypoplasia or absence of the abducens and facial cranial nerves. Filtering for rare *de novo* or autosomal recessive SNVs, indels, and SVs yielded 180 variants in 113 genes. While none were definitively causal and no convincing recurrent variants were identified, we prioritized 7 candidate genes with *de novo* variants (*USP15, POU2F1, CNTRL, MINDY1, KPNA3, STMN3, PALM*) and 5 candidate genes with biallelic variants (*ZNF407, KCNAB2, ZRANB1, MORC2,* and *PBXIP1).* Putative matches in GeneMatcher were made for 11 candidate genes, but none had MBS phenotypes. We did not identify pathogenic variants in *PLXND1* or *REV3L*, nor a substantial contribution of variants in maternal thrombophilia genes. **Conclusions:** MBS is phenotypically heterogeneous. We did not identify a strong or unifying germline genetic etiology. Alternative genetic etiologies to be explored in future studies include noncoding or somatic variants, as well as oligogenic, polygenic, epigenetic, or complex modes of inheritance. These, alone or in combination with environmental factors, could alter brainstem and organ embryogenesis.

Session Title: Mendelian Phenotypes Poster Session I

PB4914 The genetic architecture and discovery of novel candidate causative genes of visual impairment in consanguineous families from Iran and Pakistan.

Sci., Tehran, Iran, Islamic Republic of, [11]Dept. of Genetic Med., Univ. of Geneva Med. Faculty, Ctr. Médicale Univ.ire, Geneva, Switzerland, [12]Advanced Molecular Genetics and Genomics Disease Res. and Treatment Ctr., Dow Univ. of Hlth.Sci., Karachi, Pakistan

Consanguinity facilitates the discovery of novel genes for autosomal recessive disorders because of the extent of genomic homozygosity. In the children of consanguineous parents, the average homozygosity extends to approximately 253 Mb, which is ten-fold higher than in outbred individuals. Iran and Pakistan, are countries where consanguineous marriages account for up to 39% and 70%, respectively. We have studied 218 consanguineous families (817 patients) from Iran and Pakistan, mostly having more than one affected individual with visual impairment. The most common phenotype was Retinitis pigmentosa, followed by Leber congenital amaurosis and Stargardt disease. Whole exome sequencing was performed on affected individuals and genotyping of potential variants was carried out in all family members (parents, all affected and unaffected siblings). The overall diagnostic yield was 72% (156 families). The most frequent causative genes were *CRB1*, *ABCA4* and *AIPL1* identified in 15, 11 and 9 families, respectively. This includes five families with pathogenic mutations in *RPE65* that can be treated, thanks to the advancements in gene therapy. In the 62 undiagnosed families, we identified several novel candidate genes, including *ACACB*, *NOC4L*, *LIX1* and *MOB1A*. In the case of *ACACB* gene, we identified a homozygous splice variant (c.2295+1G>A) in three affected individuals of a consanguineous family from Pakistan. Through gene matching, we identified another case in which a homozygous missense mutation (c.4469G>A, p.Arg1490His) was observed in five affected individuals of an Iranian Jewish family. The phenotype of all the eight patients was a similar form of Retinitis pigmentosa (RP). In the *NOC4L* gene, we identified homozygosity for a splice variant (c.1235-2A>G) in two individuals with RP. Mouse model for this gene have shown optic disc atrophy. Homozygous missense mutations (c.348C>A, p.Phe116Leu) in *LIX1* in three affected individuals and (c.503C>G, p.Ser168Cys) in *MOB1A* in two affected individuals were identified in two Pakistani consanguineous families. Both genes have been shown to regulate *YAP1* activity which has previously been linked with visual impairment. Additional candidate variants/genes will be presented at the conference. The identification of novel genes for autosomal recessive genetic disorders is accelerated by studying large consanguineous cohorts, this improves the molecular diagnosis and genetic counseling for the affected families, and provides opportunities for precision treatments.

Sch., Bielefeld Univ., Bielefeld, Germany, [11]Ctr. for Pediatric Neurology, Neurorehabilitation, and Epileptology, Schoen-Clinic, Vogtareuth, Rosenheim, Germany, [12]Cologne Ctr. for Genomics (CCG), Univ. of Cologne, Faculty of Med. and Univ. Hosp. Cologne, Cologne, Germany, [13]Berlin Inst. of Hlth.at Charité, Univ.smedizin Berlin, Core Facility Genomics, Berlin, Germany, [14]Max Delbrück Ctr. for Molecular Med. in the Helmholtz Association (MDC), Berlin, Germany, [15]Epilepsy Ctr., Neurological Inst., Cleveland Clinic,, Cleveland, OH, [16]ICM, Paris, France, [17]Ctr. for Molecular Med. Cologne (CMMC), Univ. of Cologne, Faculty of Med. and Univ. Hosp. Cologne, Cologne, Germany, [18]Stanley Ctr. for Psychiatric Res., Broad Inst. of Harvard and M.I.T., Cambridge, MA

Rationale: Understanding the molecular mechanisms involved in the etiology of epileptogenic malformations of cortical development (MCD) is essential to improve the treatment of drug-resistant focal epilepsy. Methods: We aggregated 431 MCD across multiple centers in Europe and the Cleveland Clinic, USA. 224 samples were previously deep (>350x) exome sequenced and 148 samples were deep (>1500x) panel sequenced for 122 candidate genes. Results were pooled with 59 external deep WES samples. All pathology samples were independently reviewed and classified according to the 2022 ILAE consensus classification of focal cortical dysplasia. We tested for somatic variant enrichment with dNdScv, a model that provides quantitative estimates for driver mutations. We used stringent Bonferroni correction after the number of genes captured by the whole-exome screens in each pathology to identify genome-wide significant somatic variant-enriched genes. Gene list enrichment analysis was done with Enrichr. Results: We observed that 122/431 (28.3%) samples had >=1 variant in known causal genes for MCD, and a further 35/431 (8.1%) samples had validated functional cancer driver variants from the Catalogue Of Somatic Mutations In Cancer (COSMIC v98). MTOR was the most commonly affected gene (N=34 samples). Interestingly, multiple variants in shared pathways (e.g., MTOR, TSC2, DEPDC5) co-occurred in 15 samples. Somatic variant enrichment analysis confirmed two genes previously reported to be enriched with somatic variants in individuals with MCD: MTOR in 26.4% of individuals with focal-cortical dysplasia type 2 (FCD II; $P=6.45x10^{-8}$) and SLC35A2 in 30.6% of individuals with mild malformation of cortical development with oligodendroglial hyperplasia in epilepsy (MOGHE; $P=2.22x10^{-9}$). Pathway analyses across all nominal enrichments showed an overrepresentation of the PI3K-Akt signaling (KEGG; $Padj=7.49x10^{-7}$) and autophagy pathways (GO:0016242; $Padj=1.12x10^{-6}$) in FCD II. Conclusions: Few genes contribute to large proportions of specific pathology-defined epilepsies in somatic variant enrichment analyses of MCD. Our study suggests that the remaining unexplained lesional epilepsies are highly heterogeneous. We hypothesize that second-hit somatic variants may potentially occur at pathway-level, pending further confirmation.

PB4916 The p.C759F variant in USH2A is a pathogenic mutation: systematic literature review and meta-analysis of 667 genotypes

Authors:

J. Han[1,2], F. Cancellieri[1,2], I. Perea-Romero[3,4], M. Quinodoz[1,2,5], C. Ayuso[3,4], C. Rivolta[1,2,5]; [1]Inst. of Molecular and Clinical Ophthalmology Basel, Basel, Switzerland, [2]Univ. of Basel, Basel, Switzerland, [3]Univ. Autónoma de Madrid, Madrid, Spain, [4]Inst. de Salud Carlos III, Madrid, Spain, [5]Univ. of Leicester, Leicester, United Kingdom

Background: The p.C759F variant in the Usherin gene (USH2A) has been reported several times in the literature as the molecular cause of recessive retinitis pigmentosa, a form of retinal degeneration. However, its pathogenicity has been questioned once by the publication of two discordant genotypes from a single family. Methods: To elucidate its role as a disease-causing mutation, we performed a meta-analysis on 667 individuals carrying this variant, according to data we collected by reviewing 437 research articles published in the last 22 years. Results: We performed three independent statistical tests and ascertained with a very high degree of confidence that p.C759F is: i) enriched ~11x in patients with respect to healthy individuals (Chi-square = 718, *p*-value = 3.45 x 10-158); ii) enriched ~45x in patients compared to healthy individuals when in trans with a pathogenic mutation in *USH2A*, indicating it is a recessive mutation (Chi-square = 15,681, *p*-value < 5.0 x 10-324); iii) enriched ~2400x in patients with respect to healthy individuals when in homozygosis (Chi-square = 47149, *p*-value < 5 x 10-324). Conclusion: In summary, our results unambiguously confirm that p.C759F is a Mendelian recessive mutation, leading to retinal blindness. Session Title: Mendelian Phenotypes Poster Session I

PB4917 The phenotypic spectrum of the Cornelia de Lange-like “Alazami-Yuan Syndrome”: A case report of the 7th diagnosed patient and review of the literature.

Authors:

A. Pappas[1], K. Kohnen[1], M. Mooney[2], J. Owens[3], W. Zhang[4], A. Shillington[3]; [1]Univ. of Cincinnati, Cincinnati, OH, [2]Univ. of Cincinnati Coll. of Med., Cincinnati, OH, [3]Cincinnati Children's Hosp., Cincinnati, OH, [4]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Alazami-Yuan Syndrome is an autosomal recessive Cornelia de Lange-like syndrome caused by TAF6 loss of function variants. TAF6 encodes a TATA-binding protein associated factor that mediates interactions in early steps of gene transcription. Cornelia de Lange syndrome (CdLS) and Alazami-Yuan Syndrome have significant phenotypic overlap, though no Alazami-Yuan syndrome patient has had enough symptoms to qualify for a clinical diagnosis of classic CdLS. We present a 17-year-old female who had a clinical diagnosis of CdLS in early childhood, but genetic testing later revealed compound heterozygous variants in TAF6 consistent with Alazami-Yuan syndrome.

In addition to CdLS-like features including thick arched eyebrows, long eyelashes, widely spaced teeth, sensorineural hearing loss, growth restriction, and microcephaly, the patient also presented with features not typically seen in CdLS, including premature adrenarche, hair loss, palindromic rheumatism, and a transaminitis. A developmental gene panel revealed a paternally inherited likely pathogenic c.323T>C (p.Ile108Thr) variant and a maternally inherited likely pathogenic c.1974dup (p.Thr659HisfsTer?) variant in TAF6.

This patient represents the 8th reported case of Alazami-Yuan syndrome. She further supports phenotypic overlap between Alazami-Yuan syndrome and CdLS while maintaining that these are two clinically distinct conditions. According to recently developed CdLS clinical scoring systems, all Alazami-Yuan syndrome patients have enough symptoms to merit CdLS testing, but none meet enough criteria for a clinical diagnosis of classic CdLS. This is potentially related to overlapping transcription disruption in both conditions. TAF6 plays a significant role in transcription through stabilization of the TFIID complex, while CdLS’s disruption of cohesins also leads to disrupted transcription. However, cohesion disruption also negatively impacts additional cellular processes such as DNA repair and gene expression. As other CdLS-like genes also have direct roles in gene transcription, we suspect that the “transcriptomopathies” lead to a similar, but more restricted, phenotype than the classical CdLS “cohesinopathies.”

Session Title: Mendelian Phenotypes Poster Session II

PB4918 The use of Chinese version of hyperphagia questionnaire to assess the hyperphagia status of Prader Willi syndrome patients in Taiwan.

Authors:

L-P. Tsai[1], G. Liu[2], S-P. Lin[3], P-C. Chang[4], W-S. Lai[2], P-S. Tsai[4]; [1]Dept. of Pediatrics and Med. Genetic Canter, Taipei Tzu Chi Hosp., Taipei, Taiwan, [2]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan, [3]Dept. of Pediatrics and Med. Res., MacKay Mem. Hosp, Taipei, Taiwan, [4]Sch. of Nursing, Coll. of Nursing, Taipei Med. Univ., Taipei, Taiwan

Background and Purpose The hyperphagia behavior is one of the core symptoms of Prader-Willi syndrome(PWS) patients. Recently, there are many clinical trials aiming the improvement of satiety disorder for PWS. All these clinical trials using a modified hyperphagia questionnaire(HQ) to evaluate the improvement of hyperphagia condition after treatment. In order to understand the hyperphagia status of Taiwan PWS patients and prepare for the coming of satiety treatment, we started the HQ assessment in Taiwan. **Method** Basing on the HQ designed by Elisabeth M. Dykens et al. at year 2007, we translated it into Chinese in the way of back-translation which was approved by a translation committee. Then we enrolled 84 PWS main caregivers with patient age above 4 years for HQ assessment and compared our result with Dykens et al. report to evaluate the difference between these 2 groups. Thirty three caregivers received second assessment 1.5 to 2 month later for reliability evaluation of this questionnaire. **Result** Overall, the Chinese version of HQ showed acceptable test-retest reliability over a 1.5- to 2-month interval with a coefficient of 0.827 for all subjects. In the three dimensions of HQ, behavior, drive and severity, the average scores are 11.85, 10.32 and 4.19, respectively. Compared to the Dykens et al. report with 13.57, 12.29 and 4.61 on the corresponding dimension, our score were all lower with statistic significance. For the subgroup analysis, the study number for patient age 4-10 years, 11-19 years, 20-29 years and above 30 years is 26, 34, 19 and 5, respectively. The score for behavior dimension was higher with age in the trend of 9.96, 11.88, 13.95 and 15.4. The score for hyperphagia drive was also increasing with age in the way from 9.70 to 9.90 to 11.27 and 13.2, which was consistent with clinical observation .However, on the severity dimension, the score from 3.57 to 4.04 to 5.42 and 5.2, revealed lower for patients above 30 years of age. Since only 5 patients more than 30 years in our study, we have to enroll more patients in this age group to confirm the presence of declining severity for older PWS patients. **Conclusion** Our data suggested that this back-translation Chinese version HQ had a good consistency reliability and was available for the clinical evaluation of PWS hyperphagia status. And, the hyperphagia condition in Taiwan PWS patients seemed less severe than Dykens report 10 years ago. Further enrolling the older patients more than 30 years of age is necessary to make sure the idea of presence of declining satiety for older PWS patients.

Mucopolysaccharidosis type IVA (MPS IVA or Morquio Syndrome, MIM #253000) is caused by biallelic pathogenic variants in *GALNS* gene (16q24.3) and characterized by an important skeletal and articular involvement. **Case Report**: The propositus, the 2nd child of non-consanguineous parents, was referred to our institution at 7 years of age, because of frequent falls, abnormal gait, hip, and feet pain, but without intellectual disability. His Apgar score and anthropometric parameters at birth were normal. At 11 years of age, was referred for genetic evaluation by multiple epiphyseal dysplasia and Legg-Calvé-Perthes disease with a height of 138 cm (40th-50th percentile), weight of 30 kg (20th-30th percentile), and head circumference of 54 cm (80th-90th percentile). No facial dysmorphism was noted. A gene panel for skeletal dysplasias (Mendelics, Brazil), revealed a homozygous genotype for the pathogenic *GALNS* variant NM_000512.5(GALNS): c.181C>T or p.(Arg61Trp) [rs145798311], which is associated to attenuated forms of MPS IVA. Later, whole *GALNS* gene sequencing performed in the healthy 15-year-old male brother, and the probably affected 4-year-old female sister (DNA-GEN SC, México), revealed a normal and heterozygous p.(Arg61Trp) *GALNS* genotypes, respectively. We are re-analyzing the family samples to corroborate genotype results. *A posteriori*, evaluation of N-acetylgalactosamine-sulfate sulfatase activity in the *propositus* showed decreased enzymatic activity in dried blood spot samples and leukocytes. Urinary GAGs analysis by metachromatic staining was negative. **Discussion:** The present case illustrates the clinical utility of the DNA sequencing approach to diagnosing atypical phenotypes unsuspected by clinical examination. Our patient does not show the classic dysmorphological and skeletal phenotype of MPS IVA, such as short stature, coarse face, prognathism, short trunk, prominent sternum, inguinal hernia; and evident ophthalmologic, respiratory, cardiac and/or hepatic involvements. According to The International Skeletal Dysplasia Registry database, atypical forms of MPS IVA are often radiographically confused with other skeletal dysplasias, more common Legg- Calvé-Perthes disease, spondylo-epiphyseal dysplasia, and multiple epiphyseal dysplasias, as described herein. **Conclusion:** The diagnosis of MPS IVA, including its atypical forms, must be considered in the clinical approach to bone dysplasias. Molecular diagnosis could be considered a useful tool to achieve a definitive diagnosis in these patients.

Session Title: Mendelian Phenotypes Poster Session I

PB4920 Therapeutic effects of Antisense Oligonucleotide for Treatment of VCP Multisystem Proteinopathy.

Authors:

V. Kimonis[1], P. Pallabi[1], M. Youssef[1], L. Weiss[2], C. Cheng[3], Y. Fazeli[1], A. Shmara[4], M. Carrer[5]; [1]Univ CA Irvine, Irvine, CA, [2]Univ. of California, Irvine, Irvine, CA, [3]UC Irvine, Irvine, CA, [4]UCI, Irvine, CA, [5]Ionis Pharmaceuticals, Inc., Carlsbad, CA

Valosin-containing protein (VCP) disease is an autosomal dominant disease caused by gain-of function pathogenic variants in the *VCP* gene. The disease is associated with inclusion body myopathy with early-onset Paget's disease of the bones, frontotemporal dementia and familial amyotrophic lateral sclerosis, also known as multisystem proteinopathy 1 (MSP1). We hypothesize that regulating VCP hyperactivity to normal levels can reduce the disease pathology. We propose this could be achieved through the reduction of expression in VCP with the use of antisense oligonucleotides (ASOs), a method already approved for spinal muscular atrophy. In this study, we utilized the transgenic mouse model of VCP disease which overexpresses the humanized VCP gene with the severe A232E mutation. After establishing the validity of the mouse model, we screened three ASOs specifically targeting the human VCP gene by administrating ASOs in the mice harboring wildtype VCP transgene weekly for 8 weeks. ASO #1 showed over 50% knockdown of VCP in quadriceps and diaphragms at the mRNA level and a similar knockdown effect at the protein level. At the end-point toxicity analysis, ASO #1 demonstrated a non-significant elevation in organ-to-body weight ratio indicating minimal toxicity. We focused on ASO #1 to continue with a subsequent long-term treatment regimen to test whether VCP ASOs can ameliorate VCP disease pathology for symptomatic mice. We treated VCP A232E mice starting from 4 months of age for 3 months and performed monthly motor tests. Interestingly, the VCP A232E mice showed improvements in the inverted screen tests across 3-month of ASO treatment compared to mice treated with control ASO. We also found reduction at the protein level in quadriceps and diaphragm upon treatment with ASO #1 as compared to control ASO in VCP, and autophagy markers. These results suggest that knockdown of the mutant VCP allele early in asymptomatic mice could be beneficial in preventing progression of the myopathy, and has the potential of improving the clinical features of MSP1 in patients.

Session Title: Mendelian Phenotypes Poster Session II

PB4921 Three KINSSHIP syndrome patients with mosaic and germline *AFF3* variants.

AFF3 at 2q11.2 encodes the nuclear transcriptional activator AF4/FMR2 Family Member 3. AFF3 constitutes super elongation complex like 3, which plays a role in promoting the expression of genes involved in neurogenesis and development. The degron motif in AFF3 with nine highly conserved amino acids is recognized by E3 ubiquitin ligase to induce protein degradation. Recently, six *AFF3* missense variants in this region and two variants featuring deletion including this region were identified and shown to cause KINSSHIP syndrome, named after characteristic clinical features, horseshoe KIdney, Nievergelt/Savarirayan type of mesomelic dysplasia, Seizures, Hypertrichosis, Intellectual disability (ID), and Pulmonary involvement. The variant outside the degron is also reported as causing a developmental delay (DD) and causing skeletal abnormalities. In this study, we identified two novel and one previously reported missense variants in the degron of AFF3 in three unrelated Japanese patients. These variants are not registered in the public control database. Notably, novel two of these three variants exhibited mosaicism in the examined tissues and have not been registered in the Catalogue of Somatic Mutations in Cancer. Although our three affected patients differed in the presence or absence of the typical phenotype and the degree of the phenotype differed among them, all patients consist with KINSSHIP syndrome. This study suggests that mosaic variants also cause KINSSHIP syndrome, showing various phenotypes.

Sch. of Med., Gunma, Japan, [6]Dept. of Pediatrics and Neonatology, Nagoya City Univ. Graduate Sch. of Med. Sci., Nagoya, Japan

Background: Wiedemann-Steiner syndrome (MIM605130: WDSTS)is an autosomal dominant neurodevelopmental disorder caused by pathogenic variants in the *KMT2A* gene. *KMT2A* encodes a histone methyltransferase which regulates chromatin-mediated transcription of multiple genes. WDSTS is characterized by developmental delay (DD), intellectual disability (ID), facial features, hypertrichosis, and additional clinical features. The features associated with WDSTS overlap those of other genetic syndromes and genetic testing is required for accurate diagnosis. In April 2014, the "ID clinic" was established at the Center for Medical Genetics, Shinshu University Hospital. We provide clinical diagnosis, systematic genetic evaluation, and genetic counseling to patients with DD/ID. **Patients:** To date, 281 patients with DD/ID have visited the "ID clinic". ID-multigene panel testing detected heterozygous *KMT2A* variants in three patients (3/281=1%). Two variants (nonsense: 1, missense: 1) have been already known as pathogenic, and the other nonsense variant occurring in the last exon of *KMT2A* is predicted to escape nonsense-mediated mRNA decay and classified as uncertain significance by ClinVar. Comprehensive DNA methylation analysis of this patient's genomic DNA reveals WDSTS-specific episignatures and leads to a definitive diagnosis. All patients presented with mild to moderate ID, short stature, characteristic facial features, and dental anomalies. Two of three patients had hypertrichosis, failure to thrive, and hypotonia in infancy. The patient with a missense variant in the CXXC DNA-binding domain presented with moderate ID and behavior problems. **Conclusion:** Comprehensive DNA methylation analysis is useful for reclassifying a variant of uncertain significance that could lead to an accurate diagnosis. As with previous reports, the patient with a missense variant in the CXXC DNA-binding domain had more severe neurodevelopmental issues.

Session Title: Mendelian Phenotypes Poster Session I

PB4923 *TNNI1* variants disrupt sarcomere contractility resulting in hypo- and hypercontractile muscle disease

Authors:

S. Donkervoort[1], M. van de Locht[2], D. Ronchi[3], J. Reunert[4], C. McLean[5,6], M. Zaki[7], R. Orbach[1], J. de Winter[8], S. Conijn[8], A. Viaene[9], F. Malik[10], N. Acquaye[1], V. Bolduc[1], M. Davis[11], M. Essawi[7], S. Gorokhova[1], R. Bryson-Richardson[6], F. Magri[12], S. Zanotti[12], N. ElBagoury[7], P. Kekenes-Huskey[13], L. Napoli[12], J. Park[14], G. Pietro Comi[3,12], W. Sharaf-Eldin[7], T. Marquardt[4], G. Ravenscroft[11], C. Bönnemann[1], C. Ottenheijm[8], TNNI1 study group; [1]NIH, Bethesda, MD, [2]Amsterdam UMC (location VUmc), Amsterdan, Netherlands, [3]Univ. of Milan, Milan, Italy, [4]Univ. of Münster, Münster, Germany, [5]Alfred Hosp., Melbourne, Australia, [6]Monash Univ., Melbourne, Australia, [7]Natl. Res. Ctr., Cairo, Egypt, [8]Amsterdam UMC (location VUmc), Amsterdam, Netherlands, [9]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [10]Cytokinetics Inc, South San Francisco, CA, [11]QEII Med. Troponin I (TnI) regulates thin filament activation and muscle contraction. Two isoforms, TnI-fast (*TNNI2*) and TnI-slow (*TNNI1*), are predominantly expressed in fast- and slow-twitch myofibers respectively. *TNNI2* variants are a rare cause of arthrogryposis, while *TNNI1* variants have not been conclusively established to cause skeletal myopathy. We identified both recessive loss-of-function *TNNI1* variants, as well as dominant gain-of-function *TNNI1* variants as a cause of muscle disease, each with distinct physiological consequences and disease mechanisms. For the loss-of-function scenario, we report three families with biallelic *TNNI1* variants (F1: p.R14H/c.190-9G>A, F2 and F3: homozygous p.R14C), manifesting with early onset progressive muscle weakness and rod formation on muscle histology. For the gain-of-function scenario, we report two families with a dominantly acting heterozygous *TNNI1* variant (F4: p.R174Q, F5: p.K176del), manifesting with muscle cramping, myalgias, and rod formation in F5. In zebrafish, TnI proteins with either of the missense variants (p.R14H; p.R174Q) incorporate into thin filaments. Molecular dynamics simulations suggest that the loss-of-function p.R14H variant decouples TnI from TnC, which was supported by functional studies showing a reduced force response of sarcomeres to submaximal [Ca^{2+}] in patient's myofibers. This contractile deficit was reversed by a novel slow skeletal muscle troponin activator. In contrast, patient's myofibers with the gain-of-function p.R174Q variant showed an increased force to submaximal [Ca^{2+}], which was reversed by the small-molecule drug *mavacamten.* Our findings demonstrate that *TNNI1* variants cause muscle disease with variant-specific pathomechanisms, manifesting as either a hypo- or a hypercontractile phenotype, suggesting rational therapeutic strategies for each mechanism.

PB4924 Translating the effects of CMT2S variants with human-on-a-chip neuromuscular junction systems.

Authors:

C. Johnson[1], S. Smieszek[1], B. Przychodzen[1], C. Tyner[1], A. Kaden[1], C. Polymeropoulos[1], G. Birznieks[1], W. Hagan[2], L. Lenkiu[2], C. Niccum[2], H. Cannon-Patron[2], R. Brighton[2], X. Guo[3], K. Hawkins[3], N. Akanda[3], J. Hickman[2,3], M. Polymeropoulos[1]; [1]Vanda Pharmaceuticals Inc., Washington, DC, [2]Hesperos, Inc., Orlando, FL, [3]NanoSci. Technology Ctr., Univ. of Central Florida, Orlando, FL

Charcot-Marie-Tooth disease Type 2S (CMT2S) is a rare Charcot-Marie-Tooth disease subtype caused by immunoglobulin mu-binding protein 2 (*IGHMBP2*) variants that result in abnormal RNA processing leading to alpha-motor neuron degeneration. A patient was reported with consequential variants within *IGHMBP2*. Whole genome sequencing revealed a paternally inherited cryptic splice site non-coding variant (c.1235+894 C>A) deep in intron 8, which leads to nonsense-mediated decay resulting in haploinsufficiency. Our objective was to characterize the neuromuscular phenotype of this CMT2S patient by analyzing the morphology and physiology of diseased motoneurons compared to healthy motoneurons, and their subsequent neuromuscular junction (NMJ) differences. CMT2S motor neurons (CMT2S-MNs) were differentiated from an induced pluripotent stem cell (iPSC) cell line generated from the patient's fibroblasts. Patch clamp electrophysiology, phase imaging, and immunocytochemistry experiments were performed to characterize CMT2S-MNs and to identify differences in morphology. To determine NMJ defects, CMT2S-MNs and control iPSCs (WT-MNs) were integrated into a dual-chamber NMJ platform with wild-type (WT) PSC-derived skeletal muscle myofibers. NMJ functional defects were analyzed by NMJ number per chamber, NMJ fidelity, and NMJ fatigue index (FI).

Patch clamp electrophysiological analyses revealed hyperexcitability and spontaneous firing in CMT2S-MNs. Similar characteristics can be found in amyotrophic lateral sclerosis derived motoneurons (ALS-MNs), though ALS-MNs showed hyperexcitability at Day 20, whereas hyperexcitability was seen as early as Day 5 in CMT2S-MNs. Further, analysis of Na+ current normalized by membrane capacitance showed a significant decrease of membrane capacitance and membrane potential in CMT2S-MNs compared to WT-MNs. An NMJ FI functional readout revealed a low FI in CMT2S compared to WTs.

Patient-derived CMT2S-MNs revealed a hyperexcitable phenotype with spontaneous firing, comparable to amyotrophic lateral sclerosis (ALS). However, hyperexcitability in CMT2S-MNs had a much earlier onset as compared to ALS-MNs. These data confirm the observed, clinical phenotype of CMT2S that develops earlier in life than ALS. The hyperexcitability observed in CMT2S-MNs may be caused by the observed reduced resting membrane potential, reduced membrane capacitance, and thus reduced Na+ current density. NMJ FI showed quick fatigue which also correlates with a CMT2S clinical phenotype. We are further analyzing this patient-specific model to continue phenotyping CMT2S caused by *IGHMBP2* variants.

Session Title: Mendelian Phenotypes Poster Session III

PB4925 Trio exome sequencing identifies increased incidence of clonal hematopoiesis of indeterminate potential in Bloom Syndrome probands and carriers

Authors:

I. Lin, A. Wei, T. Gebo, P. Boutros, V. Arboleda, V. Chang; Univ. of California, Los Angeles, Los Angeles, CA

Bloom Syndrome (BSyn) is an autosomal recessive disorder caused by recessive or compound heterozygous variants in BLM. BLM is a RecQ helicase, a family of helicase enzymes that maintain genomic stability. The genomic instability caused by biallelic germline variants in BLM drives the incidence of early-onset cancer, particularly hematologic malignancies, in patients with BSyn. The malignancy risk in BSyn carriers (heterozygous for deleterious BLM variants), remains controversial and understudied. The underlying mechanisms leading to increased cancer risk may involve increased somatic mutation rate, de novo mutations that are not inherited from parents, aberrant epigenetic alterations which can be caused by mutations in DNA methylation (DNAm) genes, or through tissue-specific somatic mutations that drive clonal expansion. For example, in blood, clonal hematopoiesis of indeterminate potential (CHIP) is caused by somatic mutations in leukemia-related "CHIP" genes in individuals without overt evidence of leukemia but associated with increased risk of leukemia.

In this study, we performed exome sequencing on BSyn probands (n=10), BSyn carriers (n=19), control children (n=19) and control adults (n=38). We obtained these 19 age- and sex-matched control trios from the publicly available dbGAP study phs001272.v1.p1 deposited by the Broad Institute Center for Mendelian Genomics. We analyzed the prevalence of CHIP, the presence of somatic variants in DNAm genes, and the occurrence of de novo germline mutations using a multinomial model.

We discovered significantly increased occurrence of low-frequency, putative somatic CHIP variants in both BSyn probands (p-value = 0.0017) and BSyn carriers (p-value = 1.4093E-06) compared to age-matched controls. We also identified an increased occurrence of somatic variants in DNAm genes in BSyn carriers. These findings suggest that the presence of even just one germline pathogenic variant in BLM could be sufficient to increase the risk of clonal hematopoiesis, which may be used as a biomarker of aging, cancer, cardiovascular disease, morbidity and mortality. We find statistically-significant, increased CHIP and somatic DNAm gene variants in BSyn probands and Bsyn carriers compared to age-matched controls. Our findings contribute to growing literature that carriers for genes important in maintaining genomic integrity also have a higher somatic mutation rate and increased cancer risk. Further studies are warranted to confirm these findings in population-scale cohorts and to follow up on the impact of BLM loss-of-function variants on cancer risk.

Session Title: Mendelian Phenotypes Poster Session I

PB4926 Triple molecular diagnosis of Wolf Hirschhorn syndrome,20p duplication syndrome and Frontotemporal dementia and/or amyotrophic lateral sclerosis

Authors:

Y. Ben Moshe, V. Maria Claudia, N. Owen, J. E. Posey; Baylor Coll. of Med., Houston, TX

Background: Wolf Hirschhorn syndrome (WHS) is a chromosomal disorder involving a deletion of the short arm of chromosome 4. Although dual and multiple molecular diagnoses have been reported to occur in at least 5% of individuals for whom exome sequencing (ES) is diagnostic, no individuals with WHS have been reported to have multiple molecular diagnoses unrelated to the WHS genomic rearrangement. Case presentation: A 37-year-old white female with WHS was referred for episodic general mental and functional deterioration. At 3y of age, she had been found to have an unbalanced translocation [der(4)t(4;20)(p16.2;p13)], establishing molecular diagnoses of WHS and 20p duplication syndrome. From 34 to 37 y/o, she had ~6 dementia-like episodes during concurrent infectious illness. Each week-long episode was characterized by disorientation, decline in her ability to manage activities of daily living, and severe sleep disturbances. Between episodes, she would improve but never quite reach her previous baseline level of functioning. Her physical examination did not reveal new neurologic insults. A repeat chromosomal analysis and chromosomal microarray confirmed and refined the breakpoints of her unbalanced translocation der(4)t(4;20)(p16.2;p13). Proband ES showed two pathogenic variants, including a deletion of *NSD2* in the WHS critical region (expected), and a heterozygous variant in *SQSTM1* c.1175C>T(p.Pro392Leu). Notably, both WHS and 20p duplication syndrome have been independently associated with severe developmental delay and intellectual disability, dysmorphic features, as well as other anomalies. Thus, it is challenging to isolate the phenotypic contribution of the 20p13 duplication. The pathogenic variant in *SQSTM1* uncovers a third condition of Paget disease of the bone (OMIM#167250) and Frontotemporal dementia and/or amyotrophic lateral sclerosis (OMIM#616437). A follow-up evaluation revealed that the current mental and functional status of the proband had returned almost to baseline with no clinical signs of myopathy. A recent brain MRI did not show degenerative findings. Alkaline phosphatase level was 82 U/L (ref 40-112). The potential contribution of *SQSTM1* to the proband's episodic neurological decline is unclear, and routine follow-up is warranted to monitor for any neurological or skeletal changes. Conclusions:To the best of our knowledge, there are no other similar individuals with WHS and a second, unrelated molecular diagnosis. This case underscores the potential role of ES in identifying multiple molecular diagnoses, particularly when evolving phenotypes do not fit with the expected disease course of the primary disorder.

Session Title: Mendelian Phenotypes Poster Session II

PB4927 Two additional cases of GM3 synthase deficiency in non-Amish patients

Authors:

J. Muskett[1], J. M. Chambers[1], M. Franchi[2], P. Trapane[3], M. Y. Platt[1]; [1]Quest Diagnostics, Marlborough, MA, [2]UF Hlth.- Jacksonville, Jacksonville, FL, [3]UF Coll. of Med. – Jacksonville, Jacksonville, FL

The *ST3GAL5* gene encodes an enzyme responsible for the formation of ganglioside GM3, which is an important precursor in the production of many biologically important glycosphingolipids. Pathogenic variants in *ST3GAL5* result in low plasma GM3 ganglioside levels, which manifests clinically as global developmental delay, progressive microcephaly, failure to thrive, visual impairment, involuntary movements, and epilepsy. GM3 synthase deficiency was initially described as an autosomal recessive disorder in the Amish population in which there is a founder variant, p.Arg288*, in *ST3GAL5*. With the increase in whole exome sequencing, researchers have recently begun to identify more cases of GM3 synthase deficiency in non-Amish populations, including a recent review that described several families from 3 distinct regions, and included 3 new founder alleles. Our laboratory recently identified 2 cases of this disorder in non-Amish individuals through trio whole exome sequencing. In the first case, the pathogenic homozygous nonsense variant, p.Arg288*, was detected in a patient with Palestinian ancestry. This is the third example in the literature of this variant occurring in a non-Amish family. This patient's clinical features included global developmental delay, microcephaly, encephalomalacia, cortical visual impairment, and an abnormal electroencephalogram (EEG). In the second case, a different pathogenic homozygous nonsense variant, p.Arg334*, was detected in an African American patient. This variant was previously reported in Italian siblings as compound heterozygous with a missense variant. This patient's clinical features included global developmental delay, sensorineural hearing loss, and a skin rash described as ichthyosis. Together, the 2 patients described here illustrate the phenotypic variability of this disorder, while also sharing many core features. Additionally, these cases contribute to the growing body of literature of non-Amish patients with GM synthase deficiency, showing the disorder is present in diverse populations. Finally, it provides additional evidence that p.Arg288* and p.Arg334* are recurrent variants in this gene.

Session Title: Mendelian Phenotypes Poster Session III

PB4928 Two distinct genetic loci contribute to the genetic etiology of a complex syndromic neurodevelopmental disorder.

Authors:

V. Maduro[1], K. Dixon[2,3], S. Huynh[2,4], Y. Shen[3,2], S. Jones[3,2], C. Boerkoel[2,4], M. Malicdan[1]; [1]NIH, Bethesda, MD, [2]Univ. of British Columbia, Vancouver, BC, Canada, [3]BC Cancer Agency, Vancouver, BC, Canada, [4]Women's Hosp. and Hlth.Ctr., Vancouver, BC, Canada

Background: Despite the advancements in molecular and next generation sequencing, establishing a precise diagnosis in complex syndromic disorders remains a significant challenge. This study presents the case of a 17-year-old male who presented with hypotonia, severe failure to thrive, developmental delay, poor brain myelination, cortical visual impairment, feeding difficulties, dysmorphic features and intractable seizures causing hemiparesis. Given the complexity of the phenotype, we hypothesize a digenic etiology to explain the observed manifestations. **Methods:** The patient underwent an extensive clinical and biochemical consultation at the NIH Undiagnosed Diseases Program. To investigate potential genetic causes, we employed targeted sequencing, genome and exome sequencing, as well as long-read sequencing (Oxford Nanopore Technologies, ONT) to identify candidate genes. Sanger sequencing was utilized for validation and disease segregation analysis. Additionally, functional studies were conducted using the patient's primary cells, induced pluripotent stem cells (iPSCs), and neural progenitor cells. **Results:** Genome sequencing identified a de novo missense mutation in *BRAF*, resulting in an Asp638Glu amino acid change. Notably, some phenotypic features overlapped with *BRAF*-associated Noonan syndrome type 7. Further, chromosomal analysis and sequencing show a de novo translocation 46,XY,t(6; 12)(q24.3.1;q12) that occurred within intron 4 of the *SLC2A13* gene, which encodes a membrane channel that localizes in the Golgi apparatus, and intron 6 of the STXBP5-Antisense RNA 1, which encodes a non-coding mRNA. The breakpoints of the translocation were confirmed through ONT and Sanger sequencing. Absolute quantification of gene expression demonstrated amplification of both wild-type and mutant transcripts in iPSC-derived neural progenitor cells from the patient. **Conclusions:** Our findings support a digenic etiology involving two potential disease loci contributing to the complex syndromic manifestation observed in our proband: a de novo translocation disorder that creates a *SLC2A13-STXBP5* fusion transcript, and a likely pathogenic variant in *BRAF*. Our case illustrates the complexity of establishing diagnosis, especially when considering the possibility of a digenic or multigenic inheritance. Advancements in genetic testing technologies, functional characterization of mutations, and collaborative efforts will contribute to improving diagnostic accuracy and enhancing our understanding of the underlying molecular mechanisms of these complex genetic disorders.

Session Title: Mendelian Phenotypes Poster Session I

PB4929 UBA5-related Epilepsy: From Cellular Models to Novel Therapies

Authors:

H. Chen[1], E. Almanza Fuerte[1], M. Wang[1], H. Mefford[2]; [1]St Jude Children s Res. Hosp., Memphis, TN, [2]St. Jude Children`s Res. Hosp., Memphis, TN

UBA5 encodes an E1 activating enzyme in the ubiquitin-fold modifier 1 (UFM1) pathway, regulating ER stress response. Biallelic mutations in *UBA5* cause a rare neurodevelopmental disorder characterized by epilepsy, severe developmental delay and growth failure. In ~75% of patients, one of the pathogenic alleles is a missense variant, p.A371T, that produces a hypomorphic protein, while the other pathogenic allele encodes a nonfunctional protein. Interestingly, there have been at least three healthy adults with homozygous p.A371T variants reported, suggesting that despite the decreased enzymatic activity of the p.A371T allele, the combination of two hypoactive alleles provides enough enzyme activity to prevent disease. This suggests that augmenting the expression of p.A371T may be an effective therapy. To test this, we characterize the cellular phenotypes in engineered and patient-derived cells with disease-causing UBA5 variants and in cells with homozygous p.A371T variants. We then increase the level of the p.A371T protein using CRISPRa-dCas9 or long noncoding antisense RNA modality called SINEUP to rescue cellular defects. We generated U87-MG cell lines with compound heterozygous pathogenic alleles seen in patients (p.A371T/p.R55H and p.A371T/p.F292*). We observed decreased enzymatic activity and conjugation of UFM1 onto substrates. We also noted elevated base-level ER stress, demonstrated by an increase in ER stress proteins and ER swelling. We generated a cell line with homozygous p.A371T allele and demonstrated that it behaves similarly to wildtype, with no cellular defects. To investigate neuronal phenotypes, we engineered cortical organoids from UBA5 patient-derived iPSC. Patient organoids are significantly smaller than those from unaffected controls and exhibit an increase in ER stress markers. Multi-electrode array analyses show aberrant neuronal firing in patient organoids. Moreover, we noted patient organoids showed reduced expression of GABAergic markers, suggesting a reduction in inhibitory neurons compared to controls. We are currently performing single-cell RNAseq experiments to determine neuronal composition and developmental trajectory. Finally, using UBA5-specific SINEUPs or CRISPRa, we can augment the expression of p.A371T allele in both engineered and patient-derived cells, which rescues the aforementioned defects. These findings suggest that augmenting the expression of the hypomorphic allele, p.A371T by SINEUP or CRISPRa can be a potential therapeutic outlet for UBA5 patients. Moreover, these therapeutic modalities may be extended to other neurodevelopmental disorders caused by haploinsufficiency.

Session Title: Mendelian Phenotypes Poster Session II

PB4930 Unbiased plasma proteomics analysis uncovers potential biomarkers for renal disease and pulmonary hypertension in patients with sickle cell disease.

Authors:

Sickle cell disease (SCD) is characterized by red blood cell sickling, vaso-occlusion, hemolytic anemia, damage to multiple organ systems, and, as a result, shortened life expectancy. Sickle cell disease nephropathy (SCDN) and pulmonary hypertension (pHTN) are common and frequently co-occurring complications of SCD; both are associated with accelerated mortality. To identify potential biomarkers for SCDN and pHTN, we performed a mass spectrometry-based proteomic analysis of plasma samples from 189 adult patients from the OMG-SCD cohort. Among 1190 quantified proteins, there were 107 proteins that associated with SCDN (false discovery rate [FDR] $q<0.05$), most prominently β-1,4-GalT1 ($p=1.3x10^{-10}$), cystatin C ($p=4.4x10^{-9}$), and IGFBP6 ($p=1.5x10^{-8}$). No proteins were associated with pHTN by itself ($q>0.05$). However, 42 proteins were associated with the co-occurrence of SCDN and pHTN (SCDN+pHTN; $q<0.05$), the most prominent of which were β-1,4-GalT1 ($p=1.4x10^{-6}$) and PCPE-1 ($p=2.3x10^{-6}$). Of interest, the APOL1 peptides were not associated with SCDN ($p>0.05$). This is consistent with our recent GWAS, showing that SNPs in *APOL1* were not strongly associated with SCDN outcomes. Next, we conducted network analysis to identify modules of co-regulated proteins associated with SCDN and pHTN. Cystatin C was removed prior to network analysis as it can be used to estimate SCDN and is highly correlated with serum creatinine in our cohort ($r=0.72$, $p<0.0001$). One module of co-regulated proteins, termed MEblue, was significantly associated with SCDN ($p=8.0x10^{-6}$) and SCDN+pHTN ($p=1.9x10^{-3}$). Pathway analysis of the 134 proteins in MEblue identified many FDR-significant pathways, including enrichment of glycoproteins, insulin-like growth factor binding, those involved in cell adhesion (such as collagen and basement membrane cellular components), EGF-like calcium binding, and several cadherin family members. Finally, we refined our previously reported renal risk score by including the MEblue module and observed an improved odds ratio: for each one-point increase in the renal risk score, the odds of low eGFR increased 2.195-fold ($p<0.0001$). In a subset of this cohort with longitudinal eGFR measurements (N=67), the odds of rapid renal decline increased with the renal risk score as well. In summary, we identified many proteins associated with SCDN and pHTN, including a network of co-regulated proteins that improves disease prediction and could be utilized as potential biomarkers to facilitate early detection of SCDN and pHTN and help forestall disease progression and early mortality in SCD.

Session Title: Mendelian Phenotypes Poster Session III

PB4931 Uncover Phenotypic Networks through Mutation Carriers at Mendelian Disease Genes: a case Study of Autosomal Dominant Polycystic Kidney Disease (ADPKD)

Authors:

W. Zheng[1], Y. Xie[1], J. Gu[1], G. Zhou[1], S. Somlo[2], H. Zhao[1]; [1]Yale Univ. Sch. of Publ. Hlth., New Haven, CT, [2]Yale Univ Sch Med., New Haven, CT

Although thousands of chromosomal regions and genes have been implicated for thousands of traits, and many statistical methods have been developed to identify traits with shared genetic effects, it is still challenging to infer the phenotypic relationship networks with these methods. Mendelian diseases are disorders where patients for a given disorder often carry rare deleterious genetic mutations in specific genes. Analyzing phenotypes from individuals carrying loss-of-function mutations in Mendelian disease genes offers a new angle to infer relationships among phenotypes. In this project, we focus on Autosomal Dominant Polycystic Kidney Disease (ADPKD), a distinct genetic disorder mainly caused by mutations in the PKD1 and PKD2 genes. We aim to investigate the phenotypic interrelationships among ADPKD rare variant carriers.

We identified rare (MAF<0.01) loss-of-function variants on the PKD1 and PKD2 genes using the whole-exome sequencing data in the UK biobank subjects. We defined carrier and non-carrier groups based on the carrying status of the selected rare variants. We used the hierarchical structure information of ICD-10 codes to explore the phenotypic relationship, and constructed phenotype networks for the two groups. We further compared the intra-group phenotypic similarity scores for carriers and non-carriers and identified phenotypes with significant differences between the two groups.

Our preliminary results show 1) many traits are associated with ADPKD rare variant carrier status. The top significant phenotypes are highly related to kidney and cystic, such as ADPKD, chronic kidney disease, acute renal failure, and so on. Intriguingly, some significantly different phenotypes not directly related to ADPKD-affected organs were also observed, including disorders of the atrial fibrillation and flutter, acute lower respiratory infection and so on. Also, although ADPKD shows significantly different pattern in the two groups, more than 60% carriers do not have ADPKD diagnosis. 2) In comparing the intra-group phenotypic similarity scores of the two groups, a notable difference was found, and it was enhanced when phenotypes were selected by their carrier status and ADPKD patient status, suggesting that specific phenotypes primarily drive these differences. Our study is among the first to integrate genetic data and structured phenotypic data to discover genotype-phenotype relationship of ADPKD in the UK Biobank. These preliminary findings provide new insights into the phenotypic variations among ADPKD variant carriers and lay a foundation for further exploration of this approach to other Mendelian disease genes.

PB4932 Understanding heterogeneity of POLG related disorders for drug discovery

Authors:

y. liu[1], S. Yoo[1], E. Lee[1], Q. Chen[1], S. McGee[2], L. Wang[1], J. Zhu[1]; [1]GeneDx, Stamford, CT, [2]GeneDx, Gaithersburg, MD

POLG encodes the catalytic subunit of mtDNA polymerase that is critical for integrity of the mitochondrial genome. POLG-related conditions are autosomal recessive genetic diseases including a spectrum of severity with clinical features including neurological features, epilepsy, liver dysfunction, and myopathy. Variations in POLG interfere with mtDNA replication and result in mtDNA deletion/depletion. The disease onset and severity are correlated in POLG-related disorders with early onset associated severe diseases. Oxidative phosphorylation (OXPHOS) in mitochondria is essential for all cells. Brain, liver, and muscle cells have the highest dependency on OXPHOS. The molecular pathogenesis of POLG-related disorders is still poorly understood, and there is no efficient treatment for curing the diseases.

Genes transcriptionally co-regulated with POLG in 60 human tissues were significantly overlapped, suggesting common molecular mechanisms in all cells. We then investigated cell type-specific POLG expression and inferred OXPHOS activity in diverse human cells. Across 79 human cell types, brain cells have the lowest OXPHOS activities and are among cells expressing the lowest level of POLG. Furthermore, during development, OXPHOS activities in brain cells increased from fetal to adult. These results indicate that disturbing POLG function or OXPHOS activity in brain cells, especially in early development stage, may have the highest impact on cell function.

It has been suggested that early and late onset of POLG-related diseases are dictated by variations in POLG. However, the same pair of POLG variants (needed for autosomal recessive diseases) occurred in patients with early and late onset diseases, suggesting that pairs of POLG variants are not sufficient to predict POLG-related disease onset and severity. Other genetic and environmental factors may contribute to early or late onset of POLG-related diseases. For variants in calmodulin binding protein were likely associated with early onset of the disease. Similarly, a recent drug screen in zebrafish shows Colfilium Tosylate (CT), a potassium channel blocker, can rescue POLG-related disease phenotypes. We compared gene expression changes in human cells treated with low dose of CT, and identified a set of up-regulated genes which were enriched for genes in multiple stress response pathways, such as HEME deficiency response (Fisher exact test $p=1.9x10^{-10}$). Thus, whole genome sequencing or whole exome sequencing beyond sequencing POLG is necessary to understand heterogeneity of POLG-related disease onset and critical to develop personalized medicine for these patients.

Introduction: Mendelian studies have focused on the impact of single-gene mutations; however, multi-locus pathogenic variants (MPVs) can be a key contributor to phenotypic variability between individuals diagnosed with the same disease. Here, we identified potential MPVs causing intra-familial phenotypic variability in a group of Turkish sibling pairs previously diagnosed with rare neurodevelopmental disorders (NDD), supporting our previous hypothesis that the 'absence of heterozygosity rare deleterious variant burden drives MPV' (PMID: 29790871, 31230720, and 34582790). Method: We reanalyzed exome sequencing (ES) data from 40 affected sibling pairs with shared molecular diagnoses of a wide variety of NDDs recruited from an admixed Turkish population, which exhibited a high level of consanguinity. We detected ROH regions from ES data using BafCalculator and classified them into three size categories (short, medium, and long) based on the previously defined size cut-offs for the Turkish population. Results: In addition to the initial molecular diagnosis, we identified homozygous variants at a second locus, driven by long ROH regions, that are relevant to the phenotypic expansions in one of the siblings in each of four families. In family HOU1842, we revealed additional known variant G61E in *CYP1B1* (OMIM *601771, PMID: 9497261) reported as pathogenic in ClinVar (Variation ID: 7730) in the sibling BAB4134. In pedigree HOU2437, we reported a novel variant R519C in *MFN2* (OMIM *608507), classified as likely pathogenic based on the American College of Medical Genetics and Genomics (ACMG) criteria associated with Charcot-Marie-Tooth disease type 2A2B in BAB6511. In family HOU2280, we identified a novel variant G671E in *ECEL1* (OMIM *605896) classified as likely pathogenic in ACMG associated with Arthrogryposis type-5D in sibling BAB6025. In family HOU4131, we detected a previously reported variant R6C in *PLA2G6* (OMIM *603604, PMID: 33547378) associated with infantile neuroaxonal dystrophy 1 in the sibling BAB11388. It is noteworthy that the siblings with MPVs exhibited significantly larger total size of long ROH regions in all families (Paired t-test, p-value = 6.9e-3). Conclusion: We found MPVs in 10% of families (4/40). Based on our findings, MPVs may exist in families with affected sibling pairs, and ROH can be utilized as an adjuvant tool to uncover an MPV wherein the second locus parsimoniously explains intra-familial phenotypic differences. Overall, this study sheds light on the significance of considering MPVs and the role of ROH in explaining phenotypic variability within families, which includes individuals affected by rare disorders.

Background: Inherited retinal diseases (IRDs) are a group of rare Mendelian disorders that causes degeneration of retinal cells, resulting in progressive vision loss and potential blindness. They are primarily caused by mutations in any of the many genes that are essential for the development, the maintenance, and the normal function of the retina. Pakistan, as the fifth most populous country globally, presents a unique population for genetic studies due to its distinctive features, including a high prevalence of consanguinity and diverse ethnic groups. In this study, we investigated a large cohort from this country, with the aim of understanding the genetic architecture of IRDs in this population.**Methods:** A total of 722 patients were ascertained from three provinces of Pakistan: Khyber Pakhtunkhwa (155 families), Sindh (29 families), and Punjab (28 families). Inclusion criteria for family recruitment was to have at least two affected siblings exhibiting night blindness or progressive vision loss. Genomic DNA was extracted from blood or saliva samples and analyzed using both whole exome sequencing and Sanger sequencing.**Results:** The analyzed cohort comprised 212 indexed cases, each representing a unique family. Of these, 117 (55%) were female and 95 (45%) were male. In terms of inheritance patterns, 201 families (95%) exhibited autosomal recessive, 6 families (3%) showed autosomal dominant, and 5 families (2%) had X-linked inheritance. Overall, the post-analysis diagnostic success rate was 87%. Clinical phenotypes encompassed retinitis pigmentosa (29%), Leber congenital amaurosis (20%), Stargardt (8%), Usher (7%), and other IRDs. Exome sequencing revealed a total of 140 unique variants across 62 different genes, with the most frequently mutated genes being *ABCA4* (10%), *CRB1* (8%), *MYO7A* (6%), and *PDE6B* (5%). Among these unique variants, 60 were unreported in clinical databases. The most common variants observed in the study were: *ABCA4* c.214G>A, p.Gly72Arg (15 alleles from 8 families); *CRB1* c.1459T>C, p.Ser487Pro; (14 alleles from 7 families); *MYO7A* c.4838del, p.Asp1613fs (8 alleles from 4 families); and *PDE6A* c.1444T>C, p.Cys482Arg; c.304C>A, p.Arg102Ser; *PDE6B* c.1921-20_1921-3del; and *PDE6C* c.633G>A, p.Glu=, each present as 6 alleles from three unrelated families. Missense variants were the most frequently observed category of pathogenic variants (42%), followed by indels (25%) and stopgain variants (21%).**Conclusion:** These findings contribute to our understanding of the genetic basis of IRDs in Pakistan and have implications for both diagnosis and future development of therapies.

PB4935 Using long-read sequencing to identify complex damaging variants in familial Parkinson's disease

Authors:

K. Daida[1,2], M. Funayama[2], K. Billingsley[1], L. Malik[1], A. Miano-Burkhardt[1], M. Ishiguro[2], H. Yoshino[2], Y. Li[2], K. Nishioka[2], C. Blauwendraat[1], N. Hattori[2]; [1]NIH, Bethesda, MD, [2]Juntendo Univ. Sch. of Med., Tokyo, Japan

Monogenic Parkinson's disease (PD) accounts for 5~10% of PD. Monogenic PD has autosomal dominant hereditary forms and autosomal recessive (AR) hereditary forms. PRKN and PINK1 are the most common causative genes of ARPD. The significance of biallelic variants of ARPD genes is well established as the cause of ARPD, however, the significance of heterozygous variants is conflicting. For example, in PRKN, the most frequent causative gene in ARPD, the role of heterozygous PRKN variants in PD is controversial; where some reports show an increased risk of carrying a single damaging variant, and others report no effect. There are patients where only one variant is identified although they fit in the typical PRKN phenotype and have young onset PD. We hypothesize that there are unrevealed second damaging variants in ARPD genes, which short-read sequencing and other conventional methods cannot identify, especially in young onset PD cases. To identify the causative variant in ARPD genes from PD subjects, we used targeted resequencing for PD-related genes, multiplex ligation-dependent probe amplification (MLPA), and/or short-read whole exome sequencing (WES). PD subjects only harbor heterozygous PRKN or PINK1 causative variants, without other known causative variants in PD-related genes, were performed long read whole genome sequencing. To confirm the identified variants by long-read sequencing, Sanger sequencing was performed. Long-read sequencing identified large structural variants which MLPA and short-read WES could not determine from ARPD subjects. This study shows that long-read sequencing is a useful tool to identify structural variants in ARPD genes which cannot be identified by conventional short-read sequencing methods. Long-read sequencing may expand the role of the ARPD genes.

PB4936 † Using precision animal models to support the discovery of a new AXIN2-related disorder.

Authors:

L. Burrage[1], D. Lanza[1], P. Marcogliese[2], D. Lu[1], C-W. Hsu[1], N. Aceves[1], M. Gonzalez[1], A. Christiansen[1], T. Rasmussen[1], A. Gaspero[1], J. Seavitt[1], M. Dickinson[1], B. Shayota[3], S. Pachter[4], D-L. Day-Salvatore[5], O. Kanca[1], M. Wangler[1], L. Potocki[6], J. Rosenfeld[1], B. Lee[1], Undiagnosed Diseases Network, Baylor College of Medicine Knockout Mouse Production and Phenotyping Project, Baylor College of Medicine Center for Precision Medicine Models, S. Yamamoto[1], H. Bellen[1], J. Heaney[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Univ. of Manitoba, Winnipeg, MB, Canada, [3]Univ. of Utah Hlth., Salt Lake City, UT, [4]Atlantic Hlth.System, New Brunswick, NJ, [5]Saint Peter's Univ. Hosp., New Brunswick, NJ, [6]Baylor Col Med/TX Child Hosp, Houston, TX

In the BCM Undiagnosed Diseases Network (UDN), ~66% of variants associated with new disorders or phenotypic expansion are *de novo* and heterozygous. Modeling these variants in mice with traditional approaches is challenging if the variant causes a lethal, early-onset phenotype that prevents production of the line. Consequently, time-consuming strategies, such as conditional knock-in approaches, are needed to model these variants in mice. In the BCM Center for Precision Medicine Models, we hypothesized that the generation of low-level germline mosaic founder mice that are viable and fertile with prime editing might be a complementary, more rapid approach for assessing variant pathogenicity. We tested this hypothesis with a *de novo* variant in *AXIN2* [NM_004655.4:c.196G>A (p.Glu66Lys)] identified by the UDN in a patient with phenotypes, such as global developmental delay, microcephaly, ectodermal dysplasia, limb anomalies, bilateral cystic renal dysplasia, eye anomalies, and short palate, that only partially overlap with AXIN2-associated oligodontia-colorectal cancer syndrome (ODCRS). With prime editing, we made a single mosaic (20%) founder with the variant. The founder male was viable and fertile, but no living offspring (N1) had the variant. However, the heterozygous variant was detected in 48% of embryonic day (E)18.5 embryos, a subset of which had tail anomalies (36%), limb anomalies (7%), and small size (21%). Moreover, all heterozygous E18.5 embryos imaged with microCT had a short palate like the patient. Heterozygous p.Glu66Lys embryos did not phenocopy an *Axin2* knockout mouse generated and characterized by BCM KOMP2. Homozygous knockout, E18.5 embryos had a broader range of anomalies and heterozygous knockout adult mice only had abnormal skin coloration. Thus, loss-of-function is unlikely to be the pathogenic mechanism of this variant. In line with this, overexpression of human *AXIN2* p.Glu66Lys variant cDNA in the *Drosophila* wing showed a gain-of-function phenotype compared to reference that also produced different phenotypes than truncations observed in ODCRS. In contrast, the p.Glu66Lys acted as a loss-of-function in the developing eye, likely demonstrating context-specificity of the opposing role of Wnt-signaling in the development of these tissues. Our model organism data and identification of two other patients with similar phenotypes in Clinvar show that p.Glu66Lys is a unique variant in *AXIN2* associated with phenotypic expansion. Our work demonstrates that a prime editing N1 screen may be a useful strategy for quickly testing pathogenicity of heterozygous *de novo* variants that cause severe pediatric phenotypes in mice.

Session Title: Mendelian Phenotypes Poster Session III

PB4937 † Utilizing multiplexed assays of variant effects to solve VOUS and screen for small molecule therapeutics in Alagille syndrome.

Authors:

M. Gilbert[1,2], E. Keefer-Jacques[1], T. Jadhav[1], G-W. Shaw[1], N. Valente[1], G. Matwijec[1], K. M. Loomes[1,2], R. Rajagopalan[1,2], T. J. Hayeck[1,2], N. B. Spinner[1,2]; [1]The Children's Hosp. of Philadelphia, Philadelphia, PA, [2]The Univ. of Pennsylvania, Philadelphia, PA

A major disparity in genomic diagnostics exists between the rate of obtaining sequencing data and the ability to interpret sequence variants, with nearly half of all entries submitted to ClinVar classified as variants of uncertain significance (VOUS). Scalable functional assays are essential for removing this bottleneck. We developed a high-throughput system to classify the disease-causing potential of missense variants in Jagged1 (*JAG1*), an autosomal dominant cause of the multi-system disorder, Alagille syndrome (ALGS). Pathogenic variants in *JAG1*, a Notch signaling ligand, are the primary cause of ALGS. Although functional haploinsufficiency is the established disease mechanism, up to 15% of *JAG1* variants are missense, with only a subset (14%) mechanistically understood. These variants show defects in protein folding, membrane localization, and ability to bind the Notch signaling receptor, NOTCH2. Diagnostic rates vary depending on reporting center and clinical presentation, with VOUS rates as high as 51% for patients with broad cholestatic phenotypes. Additionally, over 400 *JAG1* missense variants are reported in ≤5 individuals in gnomAD, confusing diagnostics. We have developed Multiplexed Assays of Variant Effects (MAVEs) as a scalable, high-throughput assay to allow for the simultaneous study of thousands of *JAG1* variants. We created a library containing every nucleotide permutation across the NOTCH2-binding domain of *JAG1*(exons 1-7). Prior studies of variants in this region show that most result in proteins that fail to reach the cell membrane. Using flow cytometry, we measured the cellular localization of JAG1 as a readout of protein function, sorting our cells into two populations representing membrane (WT-like) or intracellular (mutant-like) expression. Using a pool of >600 synonymous variants included within our library we employed an established variant scoring system to translate raw counts into benign or pathogenic predictions on protein function. Up to 17% of previously uncharacterized variants (373/2144) were scored as having defective cellular localization and validation is in progress using patient samples. Further characterization, such as analysis of NOTCH2 binding ability, is planned to resolve the remaining uncertain variants. Additionally, we show that this assay can be repurposed to characterize mutants for their ability to respond to small molecule treatment. Application of this approach to a disease with a well-characterized genetic etiology efficiently reduces the VOUS burden and provides true diagnostic value while offering a unique setting to test the therapeutic effect of small molecules.

Session Title: Mendelian Phenotypes Poster Session I

PB4938 Variant pathogenicity - support from companion animal genomes

Authors:

L. Lyons; Univ. of Missouri, Columbia, MO

A limiting factor of precision medicine is variants of uncertain significance. Whole genome and whole exome sequencing can be used to rapidly identify candidate variants for maladies and diseases, however, determining the pathogenicity of candidate variants is tedious. For Mendelian disorders, the American College of Medical Genetics and Genomics have developed criteria to assist the interpretation of sequence variants, providing a process and recommendations for the use of specific standard terminology: 'pathogenic', 'likely pathogenic', 'uncertain significance', 'likely benign', and 'benign' to describe variants. Genetic and genomic datasets from diverse animal species have become more extensive, and now include thousands of genomes and millions of variants, particularly as part of variant discovery for diseases and traits. Hence, comparative genetic approaches may be more useful in supporting variant classifications. Commercial genetic testing laboratories for domestic animals are mainly direct - to - consumer and more efforts are being explored to maintain standards, similarly to those established for humans, to interpret sequence variants for diseases and traits. Similar nomenclature for gene names and the unambiguous designation of a variant as set by the Human Genome Variation Society are being employed by domestic cats and other species to help translate animal data to homologous loci and variants in humans. Commonly, reports of variants in domestic cats and other animal species are supported by the same *in silico* approaches, segregation analyses and population datasets as suggested by the established criteria. In addition, variants in animals are usually supported by the conservation of the variant and or amino acid across species, as well as indications if the variant is pathogenic in humans and present in human population datasets. The Online Mendelian Inheritance in Animals curates the variants in animals, other then primates and rodent species. Over 170 variants are associated with diseases and traits is cats, overall, more than 1500 for diverse species. Often, innocuous, and desired aesthetic traits in a cat, such as curly fur, can be in the same gene causing a severe ectodermal dysplasia in humans. The cat research community is reviewing each of the known cat variants to provide interpretations towards pathogenicity following the human standards. Examples of new variants for Duchene muscular dystrophy, Ehlers - Danlos syndrome and dwarfism that have been discovered in the domestic cat will be presented, which may lead to new opportunities in defining undiagnosed patients and variants of uncertain significance.

Session Title: Mendelian Phenotypes Poster Session II

PB4939 Variant specific phenotypes for *SLC6A1*-related disorders.

Authors:

K. Jay[1,2], J. C. Andrews[1,2], R. German[1,2], S. V. Jangam[1,2], K. Pham[1], The National Brain Gene Registry, H. Dierick[1], H. Bellen[1,2], M. Wangler[1,2]; [1]Baylor Coll. of Med., Houston, TX, [2]Jan and Dan Duncan Neurological Res. Inst., Houston, TX

The *solute carrier family 6, member 1 (SLC6A1)* gene encodes the gamma aminobutyric acid (GABA) transporter type 1 (GAT1) protein and contributes to maintaining homeostasis of excitatory and inhibitory neurotransmitters. GAT1 mediates the reuptake of the inhibitory neurotransmitter GABA at the synapse which is essential to protect from seizure activity. *SLC6A1* has recently been implicated in a spectrum of neurological disorders. The *SLC6A1* clinical phenotype presents as a dominant disorder but is pleiotropic and shows variable expressivity of symptoms including developmental delay, epilepsy, intellectual disability, motor dysfunction, and autism spectrum disorder. Seizure types are also highly variable, ranging from absence seizures to myoclonic atonic seizures that are resistant to standard therapeutics. Furthermore, GAT1 is a potential therapeutic target for other forms of epilepsy. In this study, we hypothesize that genotype phenotype correlation underlies the variability of *SLC6A1* disease. We recruited 15 patients through the *SLC6A1 Connect Foundation*, Undiagnosed Diseases Network, and National Brain Gene Registry with rare *de novo* variants in *SLC6A1*. Importantly, seizures were reported in 9/10 patients and the average number of therapeutics attempted was 4.6 per patient. To evaluate variant specific effects *in vivo*, I created patient specific personalized constructs and inserted them into the *Drosophila* genome, effectively replacing the fly homolog with a variant form of the gene. This approach results in genome editing at the endogenous locus and allows us to evaluate dominant heterozygous variants. We quantified variant specific effects in flies using electroretinogram recordings and bang sensitivity assays, which are analogous to seizure activity in humans. The expression of several variants resulted in deficits in “on” and “off” transient signaling and photoreceptor depolarization in electroretinogram recordings. We observed bang sensitivity in only a single variant, suggesting electrophysiological signaling changes can be detected prior to seizure phenotype onset. Our short-term goal is to evaluate phenotypes associated with each variant and correlate this with our patient phenotypes. Our long-term goal is to apply these personalized patient specific models to predict variant response to therapeutics. Identifying therapeutics that will be most effective in suppressing seizure phenotypes by genotype will eliminate several rounds of trial and error for the patients and result in improved outcome for those living with *SLC6A1*-related disorders.

Session Title: Mendelian Phenotypes Poster Session III

PB4940 Variants in *EFCAB7* underlie nonsydromic postaxial polydactyly.

Ctr., New York, NY

Polydactyly is the most common limb malformation that occurs in 1.6-10.6 per one thousand live births, with incidence varying with ancestry. The underlying gene has been identified, for many of the ~100 syndromes that include polydactyly. While for the more common form, nonsydromic polydactyly, eleven candidate genes have been reported. We investigated the underlying genetic cause of autosomal recessive nonsyndromic postaxial polydactyly in four consanguineous Pakistani families. Some family members with postaxial polydactyly also presented with syndactyly, camptodactyly, or clinodactyly. Analysis of the exome sequence data revealed two novel homozygous frameshift deletions in EFCAB7: [c.830delG; p.(Gly277Valfs*5); in three families and [c.1350_1351delGA;p.(Asn451Phefs*2)] in one family. Sanger sequencing confirmed that these variants segregated with postaxial polydactyly, i.e., homozygous in the two to three members with postaxial polydactyly and heterozygous or wild type in the unaffected members. EFCAB7 displays expression in the skeletal muscle and on the cellular level in cilia. IQCE-EFCAB7 and EVC-EVC2 are part of the heterotetramer EvC complex, which is a positive regulator of the Hedgehog pathway, that plays a key role in limb formation. Depletion of either EFCAB7 or IQCE inhibits induction of Glis1, a direct Hedgehog target gene. Variants in IQCE and GLI1 have been shown to cause nonsyndromic postaxial polydactyly, while variants in EVC and EVC2 underlie Ellis van Creveld and Weyers syndromes, which include postaxial polydactyly as a phenotype. This is the first report of the involvement of EFCAB7 in limb anomalies.

PB4941 Variants of uncertain significance: Characterization of a cohort from the Brain Gene Registry

Authors:

A. Sveden[1], J. M. Savatt[2], E. Riggs[3], A. Morgan[4], S. Mahida[5], V. Lanzotti[6], I. Oh[7], A. Gupta[8], H. Hazlett[9], D. Baldridge[10], M. Sahin[1], C. Gurnett[11], J. Constantino[12], P. Payne[7], M. Chopra[5], Brain Gene Registry Consortium; [1]Boston Children's Hosp., Boston, MA, [2]Geisinger, Danville, PA, [3]Geisinger, Huntsville, AL, [4]Geisinger, Kingston, PA, [5]Boston Children s Hosp., Boston, MA, [6]Washington Univ. Sch. Of Med., St. Louis, MO, [7]Washington Univ. in St. Louis, St. Louis, MO, [8]Washington Univ. in St Louis, St. Louis, MO, [9]Univ. of North Carolina, Chapel Hill, NC, [10]Washington Univ. in St. Louis, Saint Louis, MO, [11]Washington Univ. in St Louis, Saint Louis, MO, [12]Children's Hosp. of Atlanta, Atlanta, GA

As the utilization of genetic testing for neurodevelopmental disorders (NDDs) has expanded, the return of variants of uncertain significance (VUS) has increased. VUS can pose emotional challenges for patients and prove difficult to interpret for healthcare providers hoping to tailor care to a genetic diagnosis. VUS in NDDs present particular interpretation difficulties given the broad, and often non-specific, spectrum of neurocognitive manifestations for many monogenic disorders, lack of complete phenotyping in published cohorts and rapid pace of gene discovery. The Brain Gene Registry (BGR) is a consortium of 13 Intellectual and Disability Research Centers (IDDRC's) that was established to address these challenges, creating a repository of paired genotypic and phenotypic data derived from a standardized neurobehavioral battery and the electronic health record. Uniquely, the BGR accepts participants with clinical reports demonstrating VUS in genes implicated in NDDs, in addition to variants classified as pathogenic/likely pathogenic (P/LP) regardless of clinical presentation.

Here, we characterize the first 91 VUS from individuals co-enrolled in the BGR and the Clinical Genome Resource (ClinGen) patient registry, GenomeConnect. Of the 91 VUS, the majority had unknown inheritance (52%). The most common variant type was missense (73%), followed by copy number (9%), intronic non-canonical splice site (7%), truncating (5%), in-frame-indel (3%), and synonymous with potential splicing impact (3%). Variants were primarily identified through exome sequencing (44%) followed by panel testing (29%) and genome sequencing (14%). There were 65 genes represented, of which 35 (38%) had never been evaluated by a ClinGen NDD Gene Curation Expert panel, and 13 (14%) had a Gene-Disease Validity classification of Limited or Moderate. The proportion of Black/African/African American participants in the VUS cohort (11%) was over fivefold that of the Black/African/African American participants in the cohort with P/LP variants (2%).

Our data suggest the importance of family member testing for resolution of inheritance and the need for improved training, tools and assays for interpretation of missense variants. These data also highlight how the underrepresentation of Black/African/African American in genomic studies results in increased uncertain results. Further, we demonstrate the need for more evidence-backed gene curations for NDD-related genes. Expert review of clinically ascertained genotypic and phenotypic data from the BGR will enrich and accelerate the resolution of VUS.

Session Title: Mendelian Phenotypes Poster Session II

PB4942 Vitamin B12-deficient mice lacking the transcobalamin-vitamin B12 receptor, CD320, exhibit modest changes in balance, locomotor activity, peripheral sensation and vision.

Authors:

D. Bernard[1], M. L. Esposito[1], S. P. Bradley[2], D. J. Walsh[1], L. C. Brody[3]; [1]NHGRI, NIH, Bethesda, MD, [2]NIMH, NIH, Bethesda, MD, [3]NHGRI (NIH), Bethesda, MD

Background: Prolonged cobalamin deficiency in humans results in peripheral neuropathy. Cognitive decline has also been associated with deficiency suggesting an impact on CNS function. Previously, we established a mouse model of severe cobalamin deficiency via a targeted deletion of the transcobalamin receptor (encoded by the *Cd320* gene) and dietary restriction of vitamin B12 (1). After 10-12 months on a vitamin B12-deficient diet, Cd320 $^{-/-}$ mice develop severe macrocytic anemia and succumb without exhibiting overt peripheral or CNS neuropathology. We have extended the phenotyping analysis our mouse model of vitamin B12-deficiency through physical and behavioral experiments aimed at testing for subtle neuropathology prior to the onset of anemia. **Methods:** *Cd320* $^{-/-}$ mice and controls were evaluated at 37-51 weeks old (mean of 42.6 weeks) after being continuously fed a vitamin B12-deficient or replete diet starting at 3 weeks old. We subjected these mice to a battery of behavioral (novel object recognition, open field, and balance beam) and physical (hot plate and electroretinogram) assays. All tests were performed prior to the onset of macrocytic anemia. **Results:** *Cd320* mutant mice fed vitamin B12-deficient diet do not differ in their response to novel objects as compared to control isogenic mice. The gene-nutrition interaction in our *Cd320* $^{-/-}$ mice fed a vitamin B12-deficient diet has a negative effect on their ability to traverse a balance beam, as measured by increased falls, perhaps as a result of impaired proprioception. In support of this, *Cd320* $^{-/-}$ mice fed the vitamin B12-deficient diet exhibit a delayed response to peripheral footpad sensations (hot plate assay, $p = 0.03$). Open field testing indicates mild reductions in vertical and horizontal movements. Electroretinogram (ERG) assays, measuring the retinal response to light flashes, indicate that the *Cd320* $^{-/-}$ mice fed vitamin B12-deficient diet have an impaired retinal response ($p < 0.001$). *Cd320* $^{-/-}$ mice fed a replete diet (50µg vitamin B12/kg of diet) do not demonstrate abnormal neuropathology with exceptions in the balance beam assay, where these mice lose balance more frequently than controls ($p < 0.03$), and in the open field testing where they travel less distance and have fewer bout of rearing than controls. **Conclusions:** Dietary vitamin B12 restriction in *Cd320* null mice results in mildly impaired performance in open field, balance beam, and hot plate assays indicating a subtle neuropathology. Furthermore, these mice have reduced ERG responses indicating impaired retinal responses.

Session Title: Mendelian Phenotypes Poster Session III

PB4943 WGS reveals secondary modifiers contribute to parkinsonism in patients with *GBA1* variants.

Authors:

N. Tayebi; NIH/NHGRI, Bethesda, MD

Gaucher disease (GD) is an autosomal recessively inherited disorder resulting from biallelic mutations in *GBA1*, encoding the lysosomal enzyme glucocerebrosidase. In addition, variants in *GBA1* are the most common known genetic risk factor for Parkinson disease (PD), although most patients with GD do not develop PD. Since the frequency of parkinsonism among *GBA1* carriers is low, other genetic or non-genetic factors must work in concert to cause the parkinsonian symptoms in these patients. To identify genetic modifiers leading to or protecting against the development of PD, a cohort of 96 patients (92 GD - with or without PD and four *GBA1* carriers) was evaluated by short-read whole genome sequencing for insertions and deletions (SNP) as well as structural variants (SV). Reads were aligned to hg19 using bwa, while SNPs were called via GATK and SVs by CNVnator. Variants were annotated using ANNOVAR. Of the 96, 28 had both GD and PD (GD/PD), and 26 had a family history of PD. Initially, we focused on eight families with discordant sibling pairs, where one sibling has GD and PD, while the other one has GD alone. We then extended the evaluation to the entire cohort with and without PD. Using minimal differences between the number of patients with GD and GD/PD affected by a specific variant (>25% for sibling pairs and >40% in the rest of the cohort), we detected 41 candidate modifiers. These genes and variants are being explored through functional and pathway analyses. The chromosome 1q21 locus is complicated by the presence of the two pseudogenes, *GBAP1* and *MTX1P1*, and their intergenic region, which both increase the chance of creating complex recombinant alleles. More than twenty different recombinant *GBA1*-associated alleles have been described and generate SV, including deletions, conversions, inversions, and duplications of contiguous genes and pseudogenes, which may function as disease modifiers. Among our cohort, four carried a recombinant allele validated with Sanger sequencing, two Rec*NciI* (1 carrier and 1 GD/PD), one *RecTL*+55bp (GD/PD), and one Rec7 (GD/PD). Two additional cases (1 carrier and 1 GD) with increased copy numbers were identified, which could indicate possible recombination events. We are currently using long-read sequencing to further validate these recombination events and to investigate whether the resulting disruptions may act as modifiers in our GD/PD cases, which could provide insight into why only a subset of patients with GD develop PD.

Session Title: Mendelian Phenotypes Poster Session I

PB4944 Whole exome and mitochondrial genome sequencing identified heterozygous variants in PLOD1, SLC22A5, and SDHD in a Syrian family with a history of sudden unexplained deaths.

Authors:

J. Silas[1], C. Noushad[1], S. Dineshkumar[1], L. Loganathan[2]; [1]Micro Hlth.Lab., Doha, Qatar, [2]Micro Hlth.Lab., Kozhikode, India

Sudden unexplained death (SUD) refers to cases of sudden death where no cardiac or extracardiac underlying cause is identified during autopsy. In less than one-third of SUD cases, standard genetic testing following guidelines can identify a disease-causing mutation. In this study, a consanguineous Syrian couple experienced the loss of two children to SUD. Additionally, the family had a history of five miscarriages, and their third child died on the 14th day after birth due to a cardiac arrest caused by septic shock. Laboratory reports indicated elevated levels of pyruvate, lactate, ammonia, and low blood sugar in the infant, suggesting the presence of a metabolic disease. However, a definitive diagnosis could not be established. Therefore, we conducted whole exome and mitochondrial genome sequencing on samples obtained from the parents with the aim of identifying the carrier status of pathogenic genes responsible for SUD. Here, we report that WES and mitochondrial genome sequencing analysis identified the father and mother as carriers of a heterozygous pathogenic variant in the PLOD1 gene (p.Asp372AlafsTer19), a heterozygous likely-pathogenic variant in the SLC22A5 gene (p.Tyr124Cys), and a heterozygous variant of uncertain significance in the SDHD gene (p.Arg17Gln). The PLOD1, SLC22A5, and SDHD genes have been reported to be associated with SUD. Our data strongly supports the inclusion of WES and mitochondrial sequencing in the evaluation of SUD.

Session Title: Mendelian Phenotypes Poster Session II

PB4945 Whole exome sequence analysis reveals candidate disease genes for lichen sclerosus.

Authors:

K. Lovrenert[1,2], I. Patel[1,2], A. Tomaszewski[3], A. Myers[2], J. Marino[2], F. R. Schumacher[4], J. Eastman[5], M. Drumm[5], C. Farr[6], R. Pope[7], C-H. Wu[1,2]; [1]Dept. of Genetics and Genome Sci., Case Western Reserve Univ. and Univ. Hosp., Cleveland, OH, [2]Dept. of Urology, Case Western Reserve Univ. and Univ. Hosp., Cleveland, OH, [3]Case Western Reserve Univ. Sch. of Med., Univ. Hosp., Cleveland, OH, [4]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ. Sch. of Med., Cleveland, OH, [5]Dept. of Genetics and Genome Sci., Case Western Reserve Univ., Cleveland, OH, [6]Ctr. for Global Hlth.and Diseases, Dept. of Pathology, Case Western Reserve Univ., Cleveland, OH, [7]Urology Inst., Univ. Hosp. Cleveland Med. Ctr., Case Western Reserve Univ., Cleveland, OH

Lichen sclerosus (LS) is a chronic inflammatory mucocutaneous dermatosis most commonly affecting anogenital skin, leading to recalcitrant itching, scarring, sexual dysfunction, and increased risk of local skin malignancy. LS onset can occur at any age in both sexes, but presents a bimodal distribution in incidence, primarily affecting pre-pubertal children and middle-aged adults, and typically affecting more females than males. Accumulating evidence suggests a positive association between LS and autoimmune disease in women, however the exact pathogenesis of LS remains unknown. Here we performed a whole exome sequencing-based gene burden analysis using VAAST2 to profile potential pathogenic variants associated with LS using both a local female cohort of 17 biopsy-proven LS cases and 3 healthy controls and data from the 1000 Genomes Project. We identified candidate variants in 12 genes, all affecting the protein coding regions, with the highest genetic burden among genes regulating HLA class I and II antigens (*HLA-C*, *HLA-DRB5*), those involved in JNK or NF-KappaB signaling (*MAP3K1*, *MAP3K4*), rRNA processing (*KRI1*, *RPL14*), and those associated with tumor suppression (*HNF1A*) and cilium motility (*CFAP251*). Gene ontology analysis of the affected gene set yields “antigen processing and presentation”, “MAP kinase kinase kinase activity”, “MHC protein complex”, and “luminal side of endoplasmic reticulum membrane” as the most significantly enriched terms, while pathway analysis against KEGG and Reactome reveals “interferon-gamma signaling” and “allograft rejection” as top hits. We find that the gene cluster, *HLA-C*/*HLA-DRB5*, is consistently enriched across the most significant ontology and pathway terms. Our results suggest that an enhanced mutational burden in gene sets regulating key immunologic pathways could be associated with LS pathogenesis in women.

PB4946 Whole exome sequencing of families from Senegal reveals known and candidate hearing impairment genes

Authors:

Y. Dia[1], R. Ndiaye Diallo[1], I. Schrauwen[2], T. M. Bharadwaj[2], S. M. Adabey[3], E. T. Abogye[3], K. Popel[3], J. P. D. Diop[1], M. Jonas[3], S. S. Mbacké[1], C. De Kock[3], S. A. Ba[1], P. D. Sarr[1], A. R. G. Sène[1], C. A. T. Ly[1], B. K. Diallo[1], S. M. Leal[2], A. Wonkam[4]; [1]Univ. Cheikh Anta Diop, Dakar, Senegal, [2]Columbia Univ., New York, NY, [3]Univ. of Cape Town, Cape Town, South Africa, [4]Dept. of Genetic Med., JHU, Baltimore, MD

Hearing impairment (HI) remains the most disabling sensory deficit worldwide. Without early diagnosis and treatment, HI impedes language acquisition and cognitive development. 60% of congenital HI have a genetic etiology, of which 70% are non-syndromic. *GJB2* is the major cause of non-syndromic HI (NSHI) in Europeans and Asians. However, its contribution to HI in most sub-Saharan African populations is close to zero. This study aimed to investigate the genetic etiology of HI in Senegal. 157 hearing impaired individuals belonging to 66 families with suspected genetic origin were recruited from 13/14 administrative regions of Senegal. Careful clinical examination was performed, and hearing threshold was assessed by pure tone audiometry or auditory brainstem response. Families segregating autosomal recessive NSHI (ARNSHI) were screened for variants in *GJB2* exon2. Furthermore, Whole Exome Sequencing (WES) was used to identify other HI genes involved in *GJB2*-negative families. Pedigree analysis suggested autosomal recessive inheritance in 48 families. Consanguinity rate was estimated at 70%. Clinically, 59 families exhibited NSHI and 7 families showed SHI. The majority (151/157 patients) displayed prelingual HI. Of the 44 multiplex families segregating ARNSHI, *GJB2* pathogenic variants were identified in 15 families. *GJB2*: c.94C>T was the most frequent variant (11/15 families) and may have a founder effect in Senegal. 51 *GJB2*-negative families underwent WES. We identified variants in 15 known NSHI genes [21/51 families (41.2%)], 5 genes associated with either SHI or NSHI [7/51 families (13.7%)] and 6 SHI genes [6/51 families (11.9%)]. Variants in *CLDN14* and *CIB2* contributed the most to HI [7/51 families (13.7%)]. *CIB2*: c.409C>T p.(Arg137Trp) was the most prevalent variant among *GJB2* negative families and was identified in 3 unrelated consanguineous families with the same ethnic background (Serer). Post lingual HI associated with type 1 diabetes was linked to a variant in *LOXDH1*. *KCNE1,* known to cause Jervell Lange-Nielsen syndrome segregates with profound HI associated with a normal QT interval in a family. Digenic inheritance was suspected for *GJB2/USH2A* in 2 families. We also identified, 3 novel candidate genes associated with NSHI (*OPA3*, *DDX10* and *FST*). Half of the genetic variants identified in this study have not been previously associated with HI (25/50). 10 families were unsolved by WES and will go for Whole Genome Sequencing.This study showed that *GJB2* is a major cause of NSHI in Senegal. WES reveals locus heterogeneity despite a high consanguinity rate, and suggests discovery of novel genes which will foster our understanding of HI biopathology.

PB4947 Whole exome sequencing reveals known and novel variants in two Malians families with neuronal ceroid lipofuscinosis

Authors:

O. Traoré[1], D. COULIBALY[2], Z. Kone[1], S. Bamba[3], A. Maiga[4], A. Yalcouyé[5], A. Toure[1], M. Kotioumbé[1], L. Jeffries[6], J. Weizhen[6], S. Diarra[3], S. Lakhani[6], G. Landoure[7]; [1]Univ. of Sci. Techniques et Technologies of Bamako, USTTB, Bamako, Mali, [2]Ctr. Hosp.ier Univ.ire Mère enfant le Luxambourg, Bamako, Mali, [3]USTTB, Bamako, Mali, [4]Univ. of Sci., Techniques and Technologie, Bamako, Mali, [5]USTTB, Mali, Bamako, Mali, [6]Yale Univ., New Haven, CT, [7]CHU du Point G, Bamako, Mali

Introduction: Neuronal ceroid lipofuscinoses (NCL) are a group of severe neurodegenerative disorders, characterized by accumulation of autofluorescent ceroid lipopigments in cells with a global incidence of 1:100†000. Common clinical features in NCL include retinopathy, motor abnormalities, epilepsy and dementia. To date, eight genes are reported to cause 13 subtypes of NCL. Here, we report the case of two consanguineous Malian families with a novel variant in two genes known to cause NCL. Aim: To clinically characterize patients with NCLs and identify the underlying genetic defects. Methods: After full consent, patients were thoroughly examined by Neurologists. Electroencephalogram (EEG) and brain imaging were performed. DNA was extracted from peripheral blood for whole exome sequencing (WES), in trios. Segregation analysis was done in all available family members. In addition, in silico analysis was done for deleteriousness. Results: Two boys aged 7 and 9 respectively, and their healthy consanguineous parents, were enrolled. Disease started at the age of 5 and 6 by generalized seizure. The average age of onset was 5 years. Clinical examination found psychomotor delay and visual loss, and EEG found an abnormal electrical pattern. Brain imaging showed cortical and subcortical atrophy in both patients. WES identified a known stop gained variant (c.622C>T; p. Arg208Ter) in *TPP1* gene in family 1 and a novel missense variant (c.G784C:p.Asp262His) in *CLN8* gene in family 2. These variants segregate with the phenotypes in the respective families and were shown to be deleterious by several in silico prediction tools, including CADD: 36 and 27, respectively. These genes are known to cause NCL type 1 and type 8, respectively. Functional studies are needed to further assess the pathogenicity of the novel variant in *CLN8* gene, likely using cell and/or frog models. Conclusion: This study reports the first molecularly diagnosed cases of ceroid lipofuscinosis in the Malian population, using WES. It expands the genetic spectrum of NCL and reveals the need of including understudied populations in genetic studies for the global benefit. It also prepares our families for future clinical trials.

Session Title: Mendelian Phenotypes Poster Session II

PB4948 Whole Exome Sequencing Uncovers the Genetic Complexity of Bicuspid Aortic Valve in Families with Early Onset Complications

Ctr., Omaha, NE, [3]Univ. of Leeds, Leeds, United Kingdom, [4]Univ. of Pennsylvania, Philadelphia, PA, [5]Mayo Clinic, Rochester, MN, [6]Univ. of Texas Hlth.Sci. Ctr. at San Antonio, San Antonio, TX, [7]Hoag Mem. Hosp. Presbyterian, Newport Beach, CA, [8]CNR Inst. of Clinical Physiology, Pisa, Italy, [9]Univ. Hosp. Salerno, Salerno, Italy, [10]Univ. Degli Studi Di Salerno, Salerno, Italy, [11]Cleveland Clinic, Cleveland, OH, [12]Baylor Coll. of Med., Houston, TX, [13]Boston Univ., Dover, MA, [14]Univ. of Washington, Seattle, WA

Introduction: Bicuspid aortic valve (BAV), the most common adult congenital heart malformation, causes aortic disease requiring valve replacement and thoracic aortic aneurysms predisposing to acute aortic dissections. The spectrum of BAV ranges from serious valve or aortic complications in childhood to incidentally discovered late onset disease. We hypothesized that BAV cases with early onset complications requiring intervention prior to age 30 (EBAV) may be enriched for rare, highly penetrant, causal genetic variants that predict valve or aortic outcomes.
Methods: We analyzed whole exome sequences of 350 individuals in 215 EBAV families, including 34 trios, using seqr (10.1002/humu.24366). The mean age of probands was 18 years. Individuals with known mutations or syndromes were excluded. We selected high quality, rare ($<1x10^{-4}$ in gnomAD and TOPMed) loss of function, missense, or indel variants with *de novo* or autosomal dominant inheritance. Missense variants and indels were additionally filtered to select variants with REVEL > 0.5, CADD > 20, and damaging by at least 3 of SIFT, Polyphen, Mutation Taster, or FATHMM. We prioritized candidate genes that are implicated in dominant phenotypes and were mutated in at least three EBAV families, with validation by Sanger sequencing.
Results: We identified predicted pathogenic variants of causal genes in 47 families (22%), including genes that cause BAV (9, 4%) or thoracic aortic disease (TAD, 22, 10%), and dominant congenital heart disease genes (24, 11%). The most frequently mutated BAV and TAD genes were FBN2 (5), COL1A2 (4), MIB1 (3), EVC2 (3), and SMAD6 (3). We did not observe any variants in GATA genes or other TGF-beta pathway genes that passed our filters. TTN (9), MYH6 (8), KCNH2 (6) and PKP2 (4) were the most frequently mutated CHD genes. We observed loss of function variants in PKP2 (4), SMAD6 (3), KCNH2 (1), EVC2 (1), and MYH6 (1). MIB1, TTN, and KCNH2 variants segregated in EBAV families.
Conclusion: Our findings highlight the genetic heterogeneity of BAV, even with similar clinical presentations, and implicate alterations of novel candidate genes in the pathogenesis of BAV.

Session Title: Mendelian Phenotypes Poster Session III

PB4949 Whole genome sequencing provides high diagnostic rate and improves patient care for under-served adults with intellectual disability

Authors:

A. Sabo[1], P. Trotter[1], H. Gu[1], S. Dugan[1], M. Gingras[2], D. Murdock[3], B. Yuan[1], K. Glinton[1], S. Pereira[2], R. Gibbs[2]; [1]Baylor Coll. of Med., Houston, TX, [2]Baylor Coll. Med., Houston, TX, [3]The Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

Background: Establishing a genetic diagnosis for individuals with intellectual disability (ID) has numerous benefits for patients and their families. It can provide valuable information about prognosis, guide appropriate therapy and monitoring, and facilitate access to supportive services. Although exome and genome sequencing have become part of routine care for diagnosing pediatric patients, there is a gap in the genetic evaluation of adults with ID, particularly among families who are unable to access these tests due to socioeconomic position, lack of insurance coverage or lack of awareness regarding new testing opportunities.
Methods: Our recruitment strategy involved partnering with service and education providers and clinical sites. We employed whole genome sequencing (WGS) and analysis to identify SNVs, indels, and CNVs, and performed clinical variant interpretation according to ACMG standards. Where WGS analysis identified pathogenic variants, the results were discussed with a board-certified clinical geneticist, prior to further medical follow-up. We formally evaluated clinical utility related to diagnosis, patient clinical management, and familial and psychosocial implications, using the C-GUIDE questionnaire.
Results: We established a molecular diagnosis in 39% (14/36) of individuals. Our results include de novo variants in MED13L, POGZ, BRAF, EHMT1, SATB2, and DNMT3A, homozygous or compound heterozygous variants in TUSC3 and VRK1, and heterozygous variants with unknown inheritance in KANSL1, SATB1, ASH1L, CHD4, AHDC1 and TBL1XR1. Clinicians completed a C-GUIDE questionnaire for nine individuals. The mean score of utility of the genetic testing was 17.1 (SD=3.6; on a scale of -2 - 32, higher scores indicating more utility). When asked whether the genetic testing prompted better care for the patient or their family, clinicians reported it prompted better care or somewhat better care in 78% of cases (7/9). Clinicians also indicated that no psychosocial concern was experienced by the patient or family in eight cases.
Conclusion: Our study indicates that WGS is a valuable diagnostic tool for adult patients with ID who have not received comprehensive sequencing based genetic testing. Furthermore, it demonstrates that WGS has a high level of clinical utility and minimal psychosocial concerns for patients and their families. Research studies like ours, which include assessment of clinical utility, could play a crucial role in evaluating the practical value of genetic testing in cases where medical insurance providers rarely cover the costs of genome sequencing due to perceived limited clinical utility.

Session Title: Mendelian Phenotypes Poster Session I

PB4950 Whole genome sequencing study of consanguineous Pakistani families reveals a set of potentially causative variants in various male infertility phenotypes.

Authors:

A. Akbari[1], M. Khan[2], A. Shah[2], D. Conrad[1]; [1]Oregon Hlth.& Sci. Univ., Portland, OR, [2]Univ. of Malakand, Malakand, Pakistan

Introduction:Last decade witnessed a revolution in studies of human genetic diseases with Mendelian inheritance as a result of emergence and wide use of High-Throughput Sequencing technologies. However, the most widely used method of targeted sequencing has had limited success in discovering large genetic changes due to the intermittent coverage of the genome. In this study, we recruited a set of seven consanguineous families with severe male infertility phenotypes including non-obstructive azoospermia (NOA), oligozoospermia and asthenozoospermia for whole genome sequencing and functional validation assays. Each family includes at least two infertile siblings and, in some cases, a fertile brother which makes for a suitable case study.Methods:Genomic DNA of a total of 26 samples from 7 families were subjected to whole genome sequencing on illumina NovaSeq. The resulting FASTQ files were checked for quality by FASTQC 0.12.0. Raw reads were aligned to the human genome (hg38) using BWA 0.7.17 followed by preprocessing, sorting, marking of duplicate reads, base recalibration and short variant calling by GATK 4.4. In addition, copy number variations were called using Manta 1.6 and smoove 0.2.7. Candidate variants were visualized using IGV 2.16.Results:Three NOA brothers were homozygous for a novel 10 kb deletion in *M1AP* encompassing exon 2 of the canonical transcript whereas their fertile brother was heterozygous. In another family, again three NOA brothers were homozygous for a novel 152 bp deletion downstream to *THORLNC* - A long non-coding RNA whose knock-out mouse has been described as infertile. The unmarried brother is also homozygous for the deletion but we cannot confirm his phenotype. One NOA patient and his oligozoospermic brother were hemizygous for a novel *TKTL1* in-frame deletion. This gene is specifically expressed in spermatogonia but its role in infertility has not been thoroughly explored. In addition, two sets of two asthenozoospermic brothers were homozygous for a rare *SPAG6* and a rare *CCDC9* missense mutation, respectively. Both of these genes have been previously described in asthenozoospermic cases. In total, we managed to discover a potential causative variant in 5 families out of 7 where two of the variants were deletions bigger than 150 bp.Conclusion:This study reaffirms the power of family analysis in revealing the genetic mutations behind Mendelian diseases. Now with whole genome analyses more feasible than ever before, our knowledge about large events affecting disease causing genes both in coding and non-coding regions can be expanded.Keywords:male infertility, whole genome sequencing, CNV analysis, family study

Session Title: Cancer Poster Session I

PB4951 3DIV update for 2021: a comprehensive resource of genome and 3D cancer genome

Authors:

H. Sung, I. Jang, B. Lee, S. Sung; Korea Res. Inst. of BioSci. and Biotechnology, Daejeon, Korea, Republic of

Three-dimensional (3D) genome organization plays a critical role in regulating gene expression during various biological processes and diseases. In cancer, disruptions in the 3D genome structure caused by large-scale genomic rearrangements can lead to abnormal gene expression patterns with oncogenic implications. However, understanding the pathogenicity of the 3D cancer genome has been challenging due to limited tools capable of analyzing disorganized higher-order chromatin structures.
To address this issue, we have updated a comprehensive resource called 3DIV, which is a 3D-genome Interaction Viewer and database. This update aims to expand our understanding of the 3D cancer genome. The key enhancements of 3DIV include:
1. Expanded Data Collection: We have added 401 samples to the database, including 220 cancer cell line/tumor Hi-C data, 153 normal cell line/tissue Hi-C data, and 28 promoter capture Hi-C data. This diverse collection allows researchers to explore both normal and cancer 3D genomes.
2. Interactive Manipulation: Users can now interactively manipulate the 3D cancer genome to simulate the impact of structural variations. This feature enables researchers to investigate how genomic rearrangements affect gene regulation in a dynamic and customizable manner.
3. User-Defined Chromosome Order: We have introduced the ability to reconstruct Hi-C contact maps based on user-defined chromosome order. This feature facilitates the exploration of complex genomic rearrangements and their influence on the 3D genome.
With these updates, 3DIV serves as the most comprehensive resource for studying the gene regulatory effects of the 3D genome in both normal and cancer contexts. Researchers can freely access and utilize 3DIV at http://3div.kr. These advancements in 3DIV empower researchers to gain deeper insights into the intricate relationship between 3D genome organization and gene regulation in cancer and other biological processes.

PB4952 9p21.3 microdeletion cancer susceptibility syndrome: Case series, systematic literature review, and continued clinical challenges.

Authors:

C. Wyman, G. V. George, A. L. Schroeder, D. Korones, C-T. Fong, M. A. Iqbal, A. J. Cox; Univ. of Rochester Med. Ctr., Rochester, NY

Families with germline deletions of 9p21.3 involving the *CDKN2A* gene have been reported previously, and appear to have a cancer susceptibility syndrome overlapping *CDKN2A*-related melanoma-pancreatic cancer and melanoma-neural system tumor syndromes. Clinical similarities to Li Fraumeni syndrome and Neurofibromatosis have also been noted. Additional associated tumor types and cancer risk levels have yet to be well characterized for this multigene deletion, leaving affected families without concrete screening and management recommendations to mitigate cancer risk. Herein, we report two cases of germline 9p21.3 deletion including *CDKN2A*.
In the first case, we describe four generations of a family with a germline 783 kilobase interstitial deletion at 9p21.3. Ten family members presented with various neoplasms including ampullary adenocarcinoma, liposarcoma, astrocytoma, glioma, schwannoma, neurofibroma, sigmoid adenocarcinoma in situ, and melanocytic nevi. In the second case, we describe a pediatric patient with a germline de novo 1.7 megabase interstitial deletion at 9p21.3 who presented with a malignant histiocytic neoplasm. In both cases, following identification of *CDKN2A* gene deletion via next-generation sequencing, we performed confirmatory array comparative genomic hybridization (aCGH) to characterize the extent of the deletion.
These cases demonstrate the association between deletions at 9p21.3 encompassing *CDKN2A* with nerve sheath tumors, gliomas, melanocytic lesions, and sarcomas, and raise additional possible tumor associations including ampullary adenocarcinoma and colorectal cancer. Ultimately, we seek to provide tailored recommendations for clinical screening based on the specific family history of cancer and ages of diagnosis, while also taking into consideration prior groups' broader recommendation for the Li Fraumeni surveillance regimen. We support the ongoing incorporation of *CDKN2A* into hereditary cancer panels given its broad association with various tumor types and clinical similarity to other hereditary cancer predisposition syndromes. While the molecular diagnosis provided an explanation for the cancers in these families, the medical literature concerning germline 9p21.3 multigene deletion remains lacking to inform adequate screening recommendations and more precise characterization of tumor and cancer risks. A systematic review of the literature and characterization of two additional cases is presently underway to further define the phenotypic spectrum of this new cancer susceptibility syndrome.

Session Title: Cancer Poster Session III

PB4953 A cost effective whole genome sequencing method identifies clinically relevant germline variants in patients recruited in a breast cancer clinic.

Authors:

A. Cruickshank[1,2,3], R. Li[1,2], A. Lovato[3], C. Serruya[3], N. Palmour[4], J. St-Cyr[1,2], D. Fleiszer[5,6], Y. Joly[4], S. Meterissian[5,6], I. Ragoussis[1,2], P. Tonin[1,3,7]; [1]Dept. of Human Genetics, McGill Univ., Montreal, QC, Canada, [2]McGill Genome Ctr., McGill Univ., Montreal, QC, Canada, [3]Cancer Res. Program, The Res. Inst. of the McGill Univ. Hlth.Ctr., Montreal, QC, Canada, [4]Ctr. of Genomics and Policy, McGill Univ., Montreal, QC, Canada, [5]Dept. of Surgery, McGill Univ., Montreal, QC, Canada, [6]Dept. of Oncology, McGill Univ., Montreal, QC, Canada, [7]Dept. of Med., McGill Univ., Montreal, QC, Canada

Introduction: Whole genome sequencing (WGS) is increasingly used to capture all possible biologically and clinically relevant germline variants in the human genome from cancer patients. However, the cost, large size, and complexity of this data presents a major challenge when considering implementing WGS technology as part of routine care. To assess the efficacy of integrating WGS in oncological settings, we have investigated WGS data from the germline of at least 100 breast cancer (BC) patients recruited at a local clinic.
Materials and Methods: Consenting participants with a history of invasive BC that were recruited at a Montreal Canada hospital-based breast clinic provided blood samples for WGS and completed questionnaires. Clinical metrics were collected from medical charts. DNA was sequenced at the McGill Genome Centre using the cost effective MGI DNBSEQ-T7 technology. Data was processed using Digital Research Alliance of Canada's high performance computing clusters and the Canadian Centre for Computational Genomics pipelines. Clinically relevant variants harboured by 11 known carriers were investigated, followed by the investigation of variants in 19 clinically actionable BC susceptibility genes (BCSG) according to NCCN guidelines, using ClinVar. Genetic data was aggregated with personal clinical data and family history.
Results: In all, 74% of participants were prioritized for analysis and have completed sequencing. WGS data available from 98 participants exhibited high quality. All SNP/INDEL pathogenic variants were validated in the 11 known carriers. The investigation of 19 BCSG's identified 6 pathogenic/likely pathogenic variants in participants not previously known to be carriers based on clinical reports. A review of clinical data provided information concerning lack of *a priori* BCSG testing for some cases.
Conclusions: Results indicate that WGS can detect variants from prior genetic screens and identify new carriers of actionable variants that for whatever reason where not known to be carriers.

Session Title: Cancer Poster Session I

PB4954 A genome-first approach to characterize *DICER1*pathogenic variant prevalence, penetrance and phenotype in adults from two population-scale cohorts

Authors:

J. Kim[1], J. Haley[2], J. Hatton[1], U. Mirshahi[3], H. Rao[4], D. Smelser[4], G. Urban[4], Geisinger-Regeneron DiscovEHR Collaboration, K. Schultz[5], D. Carey[3], D. Stewart[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]Geisinger, Danville, PA, [3]Geisinger Clinic, Danville, PA, [4]Geisinger Hlth.System, Danville, PA, [5]Children's Minnesota, Minneapolis, MN

DICER1 is an RNaseIII endonuclease essential for processing pre-microRNA into mature, microRNA (miRNA). Loss-of-function germline variants in *DICER1* underlie an autosomal dominant disorder, *DICER1*-related tumor predisposition, with an increased risk of numerous neoplasms, macrocephaly, and thyroid-related disease. The availability of large-scale, exome-sequenced cohorts with linked electronic health records (EHR) from the DiscovEHR study and UK Biobank cohort permits genome-first exploration of phenotype in individuals with a pathogenic germline *DICER1* variant. In this study, we investigated the prevalence of pathogenic germline *DICER1* variants in exomes of 175,503 individuals from the Geisinger DiscovEHR study and 469,787 individuals from the UK Biobank cohort. *DICER1* variants were classified using ClinGen *DICER1* variant curation expert panel (VCEP) criteria; non-carriers were defined as harboring B/LB or canonical *DICER1* varation. For the UK Biobank cohort, we queried for diagnoses using cancer and death registry, and EHR. For the DiscovEHR study, we queried the Geisinger Cancer Registry and EHR for similar diagnoses.We identified 57 individuals (1:8,119) and 77 individuals (1:8,242) with a *DICER1* pathogenic variant in the DiscovEHR study and the UK Biobank cohort, respectively. From *DICER1* heterozygotes, we identified 5 individuals with 6 cancers in DiscovEHR and 12 individuals with 14 cancers in UK Biobank, although this was not significantly enriched compared with non-carriers. Next, to investigate thyroid phenotypes, we analyzed ICD10 codes E01-E07. We found in both cohorts, E01-E07 was significantly enriched in *DICER1* heterozygotes compared to non-carriers. In addition, cumulative incidence showed statistically significant difference in age at diagnosis with thyroid phenotypes in context of DICER1 diagnosed earlier than in non-carriers. Lastly, we applied an agnostic approach and investigated whether any ICD10 code with >10% prevalence in *DICER1* heterozygotes were enriched compared with non-carriers. There were 18 and 6 ICD10 codes enriched in *DICER1* heterozygotes in DiscovEHR and UK Biobank, respectively. However, none of the phenotypes identified in DiscovEHR and UK Biobank overlapped. Of 24 ICD10 codes that were identified, after Bonferroni correction, only Z11 (encounter for screening for infectious and parasitic diseases) and R50 (Fever of other and unknown origin) were statistically significant.Here we provide more refined prevalence, thyroid phenotype penetrance, and additional phenotypes for pathogenic *DICER1* variants in two large cohorts using ClinGen *DICER1* VCEP variant classification guidelines.

Session Title: Cancer Poster Session II

PB4955 A genome-first approach to quantify cancer risk in individuals harboring *CHEK2* pathogenic truncating variants versus pathogenic missense variants in two population-scale cohorts

Authors:

M. Ramos[1], S. Kim[2], J. Kim[1], J. Haley[3], R. Shanker[3], U. Mirshahi[4], B. Graubard[1], H. Katki[1], D. Carey[4], D. Stewart[1], DiscoverEHR; [1]Natl. Cancer Inst., Rockville, MD, [2]Johns Hopkins Med. Inst./NCI, Gaithersburg, MD, [3]Geisinger, Danville, PA, [4]Geisinger Clinic, Danville, PA

Introduction: Pathogenic truncating variants (PTV) in CHEK2 are associated with increased cancer risk; in contrast, pathogenic missense variants (PMV) have more variable effects dependent on whether a critical protein domain is affected. Yet several missense variants in CHEK2 have been associated with increased risk of certain cancers in clinical reports and phenotype-first studies. Using the genome-first approach, we investigated the association of different cancer phenotypes to pathogenic/likely pathogenic (P/LP) variants in individuals who carry PTV and PMV in CHEK2. **Methods:** From the Geisinger (GHS) and UK Biobank (UKBB) cohorts, we investigated cancer phenotypes in individuals over 18 years of age (GHS: n=160,448, UKBB: n=469,802) with germline P/LP variants in CHEK2. Odds ratios measuring the effect of harboring a CHEK2 variant on cancer occurrence for both any cancer and for specific cancers were computed while controlling for current age, sex, smoking, alcohol, and BMI. Bonferroni correction was applied for multiple comparisons ($\alpha<0.05$). Kaplan-Meier survival curves were constructed, and hazard ratios were computed based on the Cox Proportional-Hazards. **Results:** There were 152,662 (GHS) and 305,330 (UKBB) controls and 3,147 (GHS) and 3,226 (UKBB) P/LP heterozygotes. In GHS, 919 (29%) of the P/LP heterozygotes were PTV and 2,227 (70.6%) were PMV. In UKBB, 1,860 (57.5%) were PTV and 1,291 (39.9%) were PMV. The proportion of individuals with P/LP variants who have any type of cancer (GHS: n=864, 27.5%, UKBB: 935, 28.9%) was significantly higher compared with controls (GHS: n=35,053, 22.3%, P-value: <0.0001, UKBB: n=69,840, 22.9%, P-value: <0.0001). From UKBB, the risks of breast, prostate and thyroid cancers were significantly increased in both PTV and PMV. Kidney and bladder cancer, Hodgkin lymphoma, non-Hodgkin lymphoma, myeloid leukemia and acute myeloid leukemia were significantly associated with PTV carriers whereas lymphoid leukemia, chronic lymphocytic leukemia and essential thrombocythemia were significantly associated with PMV. In GHS, risk of breast cancer was significantly increased in both PTV and PMV, while bladder cancer risk significantly increased for PTV and prostate cancer, thyroid cancer, and leukemia risk increased for PMV. There were no differences in overall survival rates and time-to-cancer in between PTV and PMV. Results from the two cohorts largely overlapped. **Conclusions:** The genome-first approach revealed that some of the cancer phenotypes can be different between PTV and PMV carriers which may help inform cancer surveillance and genetic counseling.

Session Title: Cancer Poster Session III

PB4956 A Linear Relationship between the Number of Cancers in the Family History of First-degree Relatives and the Risk of Multiple Primary Cancers

Authors:

S. He[1,2], K. H. Barry[2], B. D. Mitchell[2], S. Chen[2], L. B. Freeman[1], Y. Zhang[2], S. I. Berndt[1]; [1]Natl. Cancer Inst., Bethsda, MD, [2]Univ. of Maryland Sch. of Med., Baltimore, MD

With advances in the early detection and treatment of cancer, the number of cancer survivors has risen over time as well as the incidence of second cancers or multiple primary cancers (MPC) in the same individual. We tested the hypothesis that the number of cancer cases among first-degree relatives is associated with MPC risk in 139,540 participants from the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, a prospective cohort study in the U.S. Cox proportional hazard models were used to calculate hazard ratios (HR) and 95% confidence intervals (95% CI), adjusting for age, sex, self-reported race, smoking, body mass index, and other potential confounders. Overall, reporting a family history of cancer in at least one first-degree relative increased the risk of MPC by 19% (HR=1.19, 95%CI: 1.13-1.25). A positive linear trend was observed between the reported number of cancers among first-degree relatives and MPC risk with HRs (95%CI) of 1.14 (1.07, 1.21), 1.23 (1.14, 1.33), 1.33 (1.18, 1.50), to 1.44 (1.21, 1.70) for 1, 2, 3, and 4+ cancers among relatives, respectively ($P_{trend}=1.31x10^{-13}$). Although the global test for heterogeneity was not significant (P>0.05), small differences in risk were observed based on histology with hazard ratios ranging from 1.12 to 1.97 depending on the cancer subtype. No significant differences were observed by age at first cancer, race, smoking status, or body mass index. Our study demonstrates that family history of cancer among first-degree relatives is associated with an increased risk of developing multiple primary cancers and that the risk increases linearly with the number of cancers reported among first-degree relatives. Although shared environmental factors could contribute to the observed increased risk, our analysis suggests that genetic factors are likely to contribute to the risk of MPC and that the number of cancers among first-degree relatives should be taken into account when assessing the risk of a second cancer.

Session Title: Cancer Poster Session I

PB4957 A novel germline deep intronic BAP1 variant leading to aberrant gene splicing in a patient with familial uveal melanoma

Authors:

M. Abdel-Rahman[1], M. Hussein[2], L. Byrne[2], P. Johansson[3], F. Davidorf[2], N. Hayward[4], C. Cebulla[2]; [1]Ohio State Univ., Columbus, OH, [2]The Ohio State Univ., Columbus, OH, [3]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [4]QIMR Berghofer Med. Res. Inst., Herston, Australia

Objective: The goal of this study was to assess the contribution of germline non-coding genomic variants including 3' UTR, 5' UTR and deep intronic variants to the pathogenesis of BAP1-Tumor Predisposition Syndrome. Methods: A next-generation sequencing gene panel, which included the whole *BAP1* gene (9.7KB) and coding regions of 90 other known cancer genes, was used. Germline DNA from 38 subjects with personal or family histories suggestive of BAP1-TPDS was tested. The effect of the variant on splicing was assessed by RT-PCR. Results: A novel non-coding variant was identified in 1/38 patients. A deep intronic deletion, c.932-57_932-56del, in *BAP1* was detected in a male who presented with uveal melanoma at age 36 yrs. The patient reported a family history of uveal melanoma. Prior exome sequencing identified no pathogenic variants in other known cancer genes. Splicing prediction software did not predict the variant to affect splicing, however, RT-PCR showed whole exon skipping (exon 11). No other family member was available to assess segregation of the variant and the patient was treated by brachytherapy so no tumor tissue was available for assessment of biallelic inactivation. Conclusions: The study provides evidence of the importance of testing for non-coding variants in patients with strong personal or family history of BAP1-TPDS phenotype with no detectable coding variants. A reflex RNA NGS assay to rule out gene rearrangement and deep non-coding variant is highly recommended.

Session Title: Cancer Poster Session II

PB4958 A novel statistical method to identify germline genetic modifiers of driver mutations in cancer.

Authors:

S. Zhao[1], J. Zhou[1], X. He[2]; [1]Dartmouth Coll., Hanover, NH, [2]Univ Chicago, Chicago, IL

Positive selection on somatic mutations is the driving force for cancer progression. Accumulation of multiple driver mutations, which are mutations under positive selection, lead to malignant transformation of a cell. Growing evidence shows that the emergence of a driver mutation in a sample depends on individual-specific factors, in particular, the individual's germline genetic background. A hypothesis for this phenomenon is that germline background provides the context for somatic evolution; for example, germline background may affect an individual's immune system, influencing which driver genes are positively selected. Recently, a number of germline variants have been identified to affect selection on certain driver genes. However, due to the sparsity of somatic mutations and heterogeneous background mutation process across positions and individuals, current statistical tools have limited power in detecting such interactions and are prone to false positives. To address this, we developed a powerful statistical method that models positive selection on driver genes at the individual level, allowing individual-specific factors, such as germline variants, to modify the strength of selection . Our method, DiffDriver, models background mutation rates, accounting for individual-specific mutational processes and tests whether the strength of selection associates with given individual level factors. It further improves the power of detecting these associations by incorporating functional features of mutations, such as effects on proteins, in our model of selection. Through simulations, we show that compared to current methods, it reduces false positives and boosts the power of detecting interactions. We applied our method to identify interactions between germline background and selection of somatic mutations in TCGA. We revealed a number of germline variants and polygenic risk to certain traits that affect the selection of some well-known driver genes. We believe our method will be of critical value to understand selection of somatic mutations on an individual-by-individual basis.

Session Title: Cancer Poster Session III

PB4959 Accounting for heterogeneity in genetic susceptibility by disease subtype identifies eight novel breast cancer risk loci

Authors:

S. Fu[1], D. Dutta[1], X. Li[2], T. Ahearn[1], Z. Li[3], K. Wang[1], J. Jin[4], X. Li[1], K. Michailidou[5], R. Milne[6], P. Kraft[1], J. Simard[7], P. Pharoah[8], M. Schmidt[9], D. Easton[10], N. Chatterjee[11], M. Garcia-Closas[12], K. Yu[1], H. Zhang[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]Harvard T.H. Chan Sch. of Publ. Hlth., Cambridge, MA, [3]Indiana Univ. Sch. of Med., Indianapolis, IN, [4]Univ. of Pennsylvania, Philadelphia, PA, [5]The Cyprus Inst. of Neurology and Genetics, Nicosia, Cyprus, [6]Cancer Council Victoria, Melbourne, Australia, [7]CHU de Québec - Université Laval Res. Ctr., Quebec, QC, Canada, [8]Univ Cambridge, Cambridge, United Kingdom, [9]Netherlands Cancer Inst., Amsterdam, Netherlands, [10]Univ. of Cambridge, Cambridge, United Kingdom, [11]Johns Hopkins Univ., Gaithersburg, MD, [12]Inst. of Cancer Res., London, United Kingdom

Background: Breast cancer is a heterogeneous disease with diverse molecular subtypes, each characterized by distinct clinical presentations, outcomes, and with variation in etiology. Recent studies suggest that many common germline variants are heterogeneously associated with breast cancer subtypes. Although existing methods, such as the two-stage polytomous model, have proven valuable, they encounter limitations in power and computational efficiency, especially when considering interaction effects across tumor markers. Therefore, there is a need to develop more advanced methods that can effectively incorporate tumor subtype information to identify novel breast cancer loci.

Methods: We developed TOPO, a novel, and computationally efficient method to detect variants exhibiting subtype heterogeneity by subtype by leveraging a comprehensive testing procedure with three sub-model structures. Using 106,278 invasive breast cancer cases and 91,477 controls of European ancestry from the Breast Cancer Association Consortium, we conducted a genome-wide association study and defined breast cancer subtypes by estrogen receptor (ER), progesterone receptor (PR), human epidermal growth receptor 2 (HER2), and tumor grade. Covariate adjustments were made for age and top ten genetic principal components. We filtered out variants within ±500kb or in linkage disequilibrium (LD>0.1) with any previously established risk loci, ensuring the novelty of identified variants.

Results: After filtering out 210 known risk loci, we identified eight novel variants (P-value <5*10^(-8)) using the proposed model. The scaled genomic inflation factor was 1.002, indicating negligible inflation in the association analysis. Conditional analyses on previously known variants further confirmed the independence of identified signals. These variants exhibited strong evidence of breast cancer subtype-specific associations across different breast cancer subtypes. For example, rs6677545 had a case-control odds ratio (OR) of 0.97 (95% confidence interval (CI): 0.95-0.99) for luminal-A like subtype (defined as ER positive or PR positive, but HER2 negative) versus an OR of 1.04 (95% CI: 1.01-1.07) for the triple-negative subtype (defined as ER, PR, HER2 all negative).

Conclusion: Utilizing our innovative method that incorporates correlated tumor characteristics, we uncovered eight new breast cancer loci, enhancing our understanding of breast cancer heterogeneity and its varied etiologies. These findings hold promise for developing subtype-specific genetic scores, enabling more precise personalized prevention strategies.

Session Title: Cancer Poster Session I

PB4960 † Additional impact of genetic ancestry over self-reported race/ethnicity to prevalence of *KRAS* mutations and allele-specific subtypes in non-small cell lung cancer

Authors:

X. Wang[1], K. Hou[2], B. Ricciuti[3], J. V. Alessi[3], X. Li[1], F. Pecci[3], R. Dey[1], J. Luo[3], M. M. Awad[3], A. Gusev[3], X. Lin[1], B. E. Johnson[3], D. C. Christiani[1]; [1]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [2]Univ. of California, Los Angeles, Los Angeles, CA, [3]Dana-Farber Cancer Inst., Boston, MA

Background: *KRAS* mutations are the most common oncogenic driver in patients with non-small cell lung cancer (NSCLC). However, the interplay between self-reported race and/or ethnicity (SIRE) and genetically inferred ancestry (GIA) on *KRAS* mutations and allele-specific subtypes is largely unknown. **Methods:** A total of 3918 NSCLC patients from the Chinese OrigiMed (OM) cohort (n=2039) and Boston Lung Cancer Survival (BLCS) cohort (n=1879) were included, all of whom had well-annotated baseline covariates including age at diagnosis, sex, clinical stage, SIRE, cancer histology and smoking status. *KRAS* mutation and its subtypes were determined by targeted NGS panels in each cohort. GIA was inferred from paired germline data for the BLCS. Multivariable and multinomial logistic regressions were employed to assess the associations between SIRE, GIA and *KRAS* mutation outcomes. **Results:** In the entire cohort, 804 (20.5%) patients harbored *KRAS* mutation, with a considerably higher prevalence of 31.5% observed in the BLCS cohort compared to 10.4% in OM cohort. SIRE-Asian patients were associated with a significantly lower rate of *KRAS* mutation (OR = 0.44, 95% CI:0.22 - 0.81, P = 0.01), transversion substitutions (OR = 0.24, 95% CI:0.10 - 0.62, P = 0.003) and $KRAS^{G12C}$ (OR = 0.17, 95% CI:0.04 - 0.72, P = 0.02) compared to SIRE-White patients after adjusting for potential confounders. The association of SIRE and *KRAS* mutation was further modified by sex, with Asian women showing lower risk compared to Asian men, while the opposite trend was observed in SIRE-White patients. Increased European ancestry was associated with a higher risk of *KRAS* mutations (OR per 10% increase = 1.05, 95% CI:1.00 - 1.09, P = 0.03), particularly more transition substitutions (OR per 10% increase = 1.10, 95% CI:1.01 - 1.21, P = 0.03) and $KRAS^{G12D}$ (OR per 10% increase = 1.18, 95% CI:1.04 - 1.34, P = 0.01), and this was more pronounced in patients of increased Northern European ancestry. Furthermore, even among SIRE-White patients, a 10% increase in European ancestry was associated with an additional 6% increase in the likelihood of *KRAS* mutations (OR = 1.06, 95% CI: 1.01 - 1.12, P = 0.03), while a 10% increase in Admixed American ancestry was associated with a 6% decreased likelihood of *KRAS* mutations (OR = 0.94, 95% CI: 0.88 - 0.99, P = 0.04). **Conclusion:** SIRE and GIA both demonstrate associations with *KRAS* driver mutations and allele-specific subtypes of NSCLC. By complementing each other in the understanding of molecular heterogeneity in lung cancer, these factors can contribute to more accurate interventions and clinical decision-making, ultimately benefiting diverse patient populations of NSCLC.

Session Title: Cancer Poster Session II

PB4961 † Advancing Precision Oncology Using Integrated Interpretation of the Germline and Tumor Genomes

Authors:

A. Ghazani[1,2], A. Chittenden[3], R. Isidro[2,1], D. Koeller[3], A. Schwartz[3], M. walker[2], B. Unal[2], C. Hayes[2], M. Manam[2], R. Buehler[3], D. Manning[2], M. Redston[2,1], M. Yurgelun[1,3], H. Rana[3,1], J. Garber[3,1], A. A. Ghazani[1,2]; [1]Harvard Med. Sch., Boston, MA, [2]Brigham and Women's Hosp., Boston, MA, [3]Dana Farber Cancer Inst., Boston, MA

The standard interpretation of germline variants in cancer yields a high number of VUS due to the absence of key supporting data in favor of pathogenicity or benign function of the variants. As the largest category of reported variants, VUS bears well-documented economical, clinical, and psychosocial burden. While many in silico tools assess potential pathogenicity of variants, none exist that systematically incorporates information from tumor in the assessment of germline VUS in cancer. Tumor profiles have long been demonstrated to reveal valuable information about cancer biology, therapeutic efficacy, and tumor progression. Here we present the value of tumor genome profile in revealing key features about the constitutional genome. We have previously demonstrated the utility of tumor data in the reassessment of pathogenic germline variants in selected patients with non-syndromic phenotypes. We have now developed an evidence-based platform called INT2GRATE that allows systematic integration of key tumor parameters to aid interpretation of germline VUS in selected cancer susceptibility genes. INT2GRATE further enables collation and sharing of integrated somatic knowledge associated with germline VUS. INT2GRATE logic utilizes qualifying clinical criteria, tumor-derived genetic information and germline findings separately, in Lynch syndrome, hereditary paraganglioma-pheochromocytoma (PGL/PCC), and von Hippel-Lindau syndrome. INT2GRATE was assessed by retrospective analysis of data of different disease cohorts including patients with somatic variants in DNA mismatch repair genes (n=5018), VHL gene (n=2552); and PGL/PCC genes (n=8049). Somatic tumor profiling was performed by OncoPanel at Brigham and Women's Hospital to evaluate 447 genes. Corresponding germline variants and patient clinical data, when available, were collected from the Dana-Farber Cancer Institute Cancer Genetics database. INT2GRATE effectively identified and excluded approximately 99% of cases due to the absence of key parameters, including cases with non-syndromic tumors or those not consistent with the presentation of constitutional disease. To date, we have identified germline variants in the INT2GRATE POSITIVE category consistent with disease presentation in patients with Lynch syndrome (n=23) and PGL/PCC (n=1). We have also identified VUS in the INT2GRATE NEGATIVE category where the absence of key tumor evidence was consistent with the absence of cancer syndrome or diagnosis related to VHL (n=11) and PGL/PCC (n=18). INT2GRATE provides a platform to comprehensively assess the role of germline VUS using well-established tumor and clinical evidence.

Session Title: Cancer Poster Session III

PB4962 Aggregation of over 600,000 predictors for cancer risk stratification

Authors:

K. Liang[1], Y. Farjoun[2], V. Forgetta[3], Y. Chen[4], S. Yoshiji[1], Y. Ilboudo[5], T. Lu[6], G. Butler-Laporte[7], B. Richards[1]; [1]McGill Univ., Montreal, QC, Canada, [2]Lady Davis Inst., JGH, Montreal, QC, Canada, [3]5 Prime Sci., Montreal, QC, Canada, [4]McGill Univ., Montréal, QC, Canada, [5]Jewish Gen. Hosp., Montreal, QC, Canada, [6]Univ. of Toronto, Toronto, ON, Canada, [7]Univ. of Oxford, Oxford, United Kingdom

Background: Early cancer screening for high-risk individuals is a crucial step in cancer prevention. Genetic predisposition to cancer is currently estimated using a combination of family history and known, rare pathogenic variants. However, it is well known that common variants can have an equally significant contribution to cancer risk. Polygenic risk scores are an easy way to capture common genetic predisposition to cancer; however, it relies on the availability of well-powered GWAS. Therefore, an informative PRS for cancer requires not only high genetic heritability but also sufficiently large sample sizes for a well-powered GWAS. Despite the efforts from many population-level biobanks (e.g., UK Biobank), except for a few common cancers, many cancers still lack sufficient sample sizes for a well-powered GWAS limiting the use of PRS in these cancers.
Aims and Methods: Unlike many cancers, we do have an abundance of different -omic measurements and common traits. We, therefore, set out to determine if it is possible to incorporate these data in the form of polygenic risk scores to improve cancer risk prediction. In total, we collected PRS for 1,091 metabolites, 4,719 proteins, and 616,001 transcript measurements across 49 tissues, and 1,471 non-cancer exposures, and combined them into a single multi-PRS (mPRS) to evaluate their performance across 14 cancers.
Results and conclusion: We found that relative to the cancer PRS, the cancer mPRS can correctly reclassify up to 26% (95% CI: 25 -26%) of controls and 14% (95% CI: 0.03-0.26) of cases relative to the standard cancer PRS based on the net reclassification index. The cancer mPRS provided the most improvement in classification accuracy for chronic lymphoid leukemia (5x increase in AUPRC). For other cancers, minor improvements in classification accuracy were seen, mostly for rarer cancers. No improvement was seen for cancers with large sample sizes (i.e., breast cancer, prostate cancer). We also noted that there can be descent performance for mPRS using only biomarker data and non-cancer traits (AUROC ranging from 0.62 for breast cancer to 0.79 for urinary tract cancer). Overall, it suggests that the most effective way to obtain the best PRS for cancer is through strongly ascertained cohorts with large sample sizes. However, when this is not feasible, it is still possible to construct reasonable mPRS using only readily available biomarker data. Whether this multi-PRS approach can be refined for biomarker discovery or used in developing non-linear PRS remains to be determined.

PB4963 Alterations of super-enhancers in T-cell Prolymphocytic Leukemia.

Authors:

H. Yan, S. Tian, H. Zhang, E. W. Klee, W. Ding; Mayo Clinic, Rochester, MN

T cell prolymphocytic leukemia (T-PLL) is a rare disease, accounting for ~2% of mature lymphocytic leukemia cases in adults. With a rapid clinical course, T-PLL patients show poor response to conventional chemotherapy and immunotherapy. Genetically, T-PLL is characterized by numerous structural variants, including inv(14)(q11q32), t(14;14)(q11;q32) and t(X;14)(q28;q11), as well as recurrent mutations in chromatin regulators. On the other hand, alterations of regulatory regions, in particular enhancers, have been implicated in disease susceptibility and progression. However, the extent of epigenetic changes has not been well defined in T-PLL. We performed ChIP-seqfor histone H3 lysine 27 acetylation (H3K27ac) to identify active enhancers in patients (n=6) and age-matched healthy individuals (n=3). Samples were collected with written consent and approval from the institutional review board at Mayo Clinic. Paired-end reads were mapped to the human reference sequence hg19 using BWA, and peaks were identified by MACS2 and filtered by blacklisted regions. Between 233 and 458 super-enhancers (SEs), i.e., clusters of enhancers, were identified from individual samples using the ROSE algorithm at default parameter setting. These SEs were merged into a list of 819 SE regions. We extracted 109 T-PLL unique SEs, i.e., those present in >=2 T-PLL cases but in none of the normal samples, as well as 40 normal unique SEs, and assigned these SEs to the nearest genes. Pathway analysis with Enrichr package indicated that T-PLL unique SEs are associated with genes enriched in key pathways, such as MAPK signaling, IL-2/STAT5 signaling and T-cell receptor and co-stimulatory signaling, while normal unique SEs are associated with genes enriched in hematopoietic stem cell differentiation, Th17 cell differentiation and regulation of actin cytoskeleton pathways. We further identified 26 and 20 differential SEs with significantly increased and decreased H3K27ac in T-PLL, respectively. The former led to the activation of oncogenes TCL1A and TCL1B in T-PLL. The latter targeted cell surface receptor genes CD84 and CD352 that play key roles in immune response. Our analyses provide insights into the roles of SE alterations in T-PLL.

PB4964 An *MLH1* Gene Mutation in a 27-Year-Old Male: A Case of Somatic Symbiosis

Authors:

T. Demarco, A. Winer, K. Matthijssen, D. Alaeddin, M. Turner, K. Schwarting; Inova Schar Cancer Inst., Fairfax, VA

We present the case of a healthy 27-year-old male with an identified *MLH1* gene mutation. Mutations in the *MLH1* gene are associated with Lynch syndrome and an increased risk for the development of colon cancer and other gastrointestinal malignancies, including pancreatic cancer. This patient had recently lost his father to metastatic pancreatic cancer. A tumor specimen from his father had been sent to an established somatic laboratory for tumor testing utilizing a comprehensive multi-gene panel. This testing was reported in March of 2022 and did not indicate any germline pathogenic or likely pathogenic mutations. However, in January of 2023 following his father's death, an amended report was provided by the somatic testing laboratory to the patient's father's medical oncologist indicating an update to a variant classification. Specifically, a germline variant in the *MLH1* gene known as p.S556T was reclassified as pathogenic, with a variant allele fraction highly suggestive of germline inheritance. The medical oncologist immediately contacted the patient's son, the executor of his father's estate, and recommended genetic counseling and testing based on his father's amended somatic genetic testing report. The patient underwent genetic counseling and testing utilizing a comprehensive multi-gene inherited cancer panel. The results indicated that the patient also carried the *MLH1* mutation that was identified upon his father's somatic testing, thus confirming germline inheritance. The patient was counseled about his cancer risk and referred to an internal multi-disciplinary program to review recommended cancer screening and prevention for Lynch syndrome. For *MLH1* mutation carriers, colorectal cancer screening utilizing high-quality colonoscopy is recommended to commence between the ages of 20-25. While the patient is not currently a candidate for pancreatic cancer screening, this recommendation can be further reviewed in the future. This case illustrates the importance of integrated patient care with ongoing communication amongst various disciplines as part of a comprehensive cancer center. The patient's father's medical oncologist was proactive about contacting his son and counseling him regarding implications of the somatic testing for this patient's personal risk. If this had not been discussed, the patient may have never been made aware of his potential elevated cancer risk. In addition, it further expands the definition of "patient" to include the individual being treated and their family members, who may further benefit from ongoing clinical care and counseling even after the passing of a loved one.

Session Title: Cancer Poster Session III

PB4965 Analysis of cellular heterogeneity in bladder cancer.

Authors:

O. Doumbia[1], O. Samassekou[2,1], H. Berthé[1,3], M. Goita[4], S. Bamba[5], M. Keita[1], G. Landoure[1,6], I. Sissoko[7], A. Kassogué[1,7], A. Diarra[1,8], M. Traoré[1]; [1]Univ. of Sci., Techniques and Technologies of Bamako (USTTB), Bamako, Mali, [2]Sherbrooke Univ (CHUS), Sherbrooke, QC, Canada, [3]Urology Dept. of CHU of Point G, Bamako, Mali, [4]Univ. of Sci. Techniques and Technologies of Bamako (USTTB), Bamako, Mali, [5]USTTB, Bamako, Mali, [6]Neurology Departement of CHU point G, Bamako, Mali, [7]Ctr. Hosp.ier Univ.ire de Kati, Koulikoro, Mali, [8]Urology Dept. of Hosp. " Mère-Enfant le Luxembourg", Bamako, Mali

Background: Bladder cancer is one of the most common cancers and the first cause of death by cancer in urology worldwide and the same epidemiological trend is observed in Mali. The poor prognosis of patients could be due to the presence of aggressive forms associated with genomic instability which can be determined by cell heterogeneity. Cell Heterogeneity defined by genomic changes on cellular basis can better determine clonality and tumor aggressiveness. Cellular telogenomics which explores pan telomeric changes on cell basis might be an approach to determine phenotype differences between cancer cells based on the genomic profile.
Objectif: Determine cell heterogeneity by measuring cell dispersion in normal and cancer cells from urine of bladder cancer patients.
Methodology: We carried out cytological preparation from urine of bladder cancer patients. We did 3D FISH technique of telomeres, 3D microscopy and measured telomere length and number in 100 normal and cancer cells for each patient. To define the heterogeneity index of a cell type from a given sample, we used the similarity measure by calculating the Euclidean distance between cells of the same cell type in the sample. We developed an index score through statistical analysis by defining each cell according to their telomere number and size.
Results: This method allowed us to characterize both genetically and genomically the phenotypes of normal and cancer cells in bladder cancer. We compared the two categories of cells (cancer and normal) in terms of cellular homogeneity. We found that in more than 90% of patients, cancer cells were more heterogeneous, based on telomere length and number, than normal ones. The phenotypic characteristics of cancer cells were mostly their polyploidy state defined by the number of telomeres and the shortness of their telomeres. Moreover, we found that samples presenting a higher proportion of calls having high number and short telomeres were among the most aggressive. Finally, we defined and found that the index of heterogeneity in cancer cells (3.51) were higher than those of normal cells (2.70) with p <0. 0001.
Conclusion: This new method for analyzing telogenomic data opens prospects for more accurately determining characteristics of cancer cells such as clonal evolution, genomic instability, tumor expansion and the process of invasion of the stroma and tissues neighborhood.

PB4966 Analysis of *IDH1*positive enchondroma RNA sequencing shows disruption of the HIF1 pathway in patients with enchondromatoses

Authors:

P. Varela-Calais[1], E. Partan[2], R. Martin[1], D. Drehmer[1], C. Morris[3], G. Gottesman[4], G. Semenza[1], N. Sobreira[1]; [1]McKusick-Nathans Dept. of Genetic Med., Johns Hopkins Med., Baltimore, MD, [2]McKusick-Nathans Dept. of Genetic Med., Baltimore, MD, [3]Mem. Sloan Kettering Cancer Ctr., New York, NY, [4]Ctr. for Metabolic Bone Disease and Molecular Res., Shriners Hosp. for Children, St. Louis, MO

Ollier disease (OD), Maffucci syndrome (MS), and metaphyseal enchondromatosis with D-2-hydroxyglutaric aciduria (MCHGA) are diseases characterized by the presence of multiple enchondromas. Gain-of-function somatic variants at the active sites of *IDH1* and *IDH2* have been identified in individuals with OD, MS and MCHGA. Poll et al. (2022) identified rare candidate causative variants in 6 genes (*HIF1A*, *VHL*, *IDH1*, *IDH2*, *KDM4C*, and *CDKN2A*) related to the HIF-1 pathway. Burden analysis found that germline variants in *HIF1A*, *VHL*, and *IDH1* were all significantly enriched in cases compared to controls. Additionally, RNAseq analysis of patient and control fibroblasts showed a significantly reduced number of differentially expressed HIF-1 related genes in patient samples compared to control samples in response to hypoxia. Here, we compared RNAseq data on *IDH1*-p.Arg132Cys positive enchondroma cell lines from two patients with OD and one with MEHGA to the RNAseq data on three control cartilage cell lines. The cell lines were cultured under normoxia (20% O2) and hypoxia (1% O2 for 24 h). Similarly to what was identified in the fibroblasts, we found that the number of differentially expressed HIF-1 related genes in patient samples compared to control samples in response to hypoxia was significantly reduced. In addition, 26 HIF-1-related genes had more than three-fold increased expression in response to hypoxia in controls; and, of these, 19 had less than three-fold increased expression under hypoxia in patients. *HIF1A* regulation in response to hypoxia occurs primarily on the level of protein stability due to post-translational hydroxylation and proteasomal degradation mediated by *EGLN*s and *VHL*. *HIF1A* is an a-ketoglutarate (a-KG)-dependent oxygenase, and *IDH1* and *IDH2* catalyze conversion of isocitrate to a-KG. Mutant *IDH1* and *IDH2* gain the ability to produce the oncometabolite D-2HG, which competitively inhibits a large family of a-KG-dependent enzymes. D-2HG also stimulates activity of EGLN prolyl 4-hydroxylases, leading to diminished levels of hypoxia-inducible transcription factor. Our RNAseq data on three enchondroma cell lines harboring the *IDH1*-p.Arg132Cys variant suggests that the HIF-1 pathway is downregulated in patients' enchondromas under hypoxia compared to control cartilage. To understand better the role of the HIF-1 pathway in the enchondromas of patients with enchondromatoses, we will measure the HIF-1 transcriptional activity at normoxia and hypoxia in the enchondromas using a cell-based dual-luciferase assay.

Session Title: Cancer Poster Session II

PB4967 Analysis of imprinted genes in cancer cell lines using multi-omics data.

Authors:

J. Krushkal[1], T. Jensen[2], G. Wright[1], Y. Zhao[1]; [1]Natl. Cancer Inst., NIH, Rockville, MD, [2]The Emmes Company, LLC, Rockville, MD

Imprinted genes play important roles during embryonic and postnatal development, and many of them promote cell proliferation and body growth. In normal tissues, the imprinted genes are characterized by parent of origin-specific monoallelic expression, which is tightly controlled via epigenetic mechanisms. Some imprinting patterns are dysregulated in tumors, among a broader array of epigenetic changes in malignant cells. Our earlier study found that response of cancer cell lines to chemotherapy was associated with variation in the copy number, DNA methylation, and overall expression levels of selected imprinted genes. In the current project, we investigated which of the imprinted genes maintained monoallelic expression in cancer cell lines. We developed a computational pipeline to evaluate monoallelic and biallelic expression patterns in cancer cell lines that had available matched RNA-seq expression data, whole exome sequencing information, and copy number data. We analyzed expression patterns at the whole gene and isoform-specific levels for 59,283 autosomal protein-coding genes and ncRNA genes, with a special focus on 94 imprinted genes and 8 non-imprinted control genes. Analysis was performed in 108 cell lines from 9 pediatric and adult tumor histologies using multi-omic data obtained from the DepMap Portal for the Cancer Cell Line Encyclopedia. We will discuss the variation of monoallelic expression patterns of imprinted genes in tumor cells and the potential biological impact of imprinting changes in tumor cells. We will also discuss specific cases of monoallelic expression of non-imprinted genes in cancer cell lines.

División de Genética, Centro de Investigación Biomédica de Occidente (CIBO), Centro Médico Natl. de Occidente (CMNO), IMSS, Guadalajara, Mexico, [8]Doctorado en Genética Humana, CUCS, UdeG. División de Genética, CIBO, IMSS, Guadalajara, Mexico

Introduction: rs2758346 is a single nucleotide variant (SNV) found on chromosome 6, in the SOD2 gene that codes for the enzyme superoxide dismutase 2. This enzyme protects cells from oxidative stress caused by free radicals. The T allele of this SNP seems to be more associated with the risk of developing different diseases. However, there are no association studies with breast cancer. **Objective:** Determine the association of the rs2758346 variant of the SOD2 gene with breast cancer. **Material and methods:** 109 DNA samples from breast cancer patients and 128 from the control group were included in the study. The genotypes of the rs2758346 variant were determined by TaqMan®probes, by real-time PCR assays (qPCR), and were analyzed on a CFX96 thermal cycler, C100 touch, BioRad. **Results:** The wild-type genotype (CC) was observed in 32% (36/105) of the patient group and 34% (46/128) of the control group (OR 0.84, 95%CI 0.49-1.44, p=0.62), the heterozygous genotype (CT) was present in 51% (55/109) of the patient group and 48% (62/128) of the controls, (OR 1.08, 95%CI 0.65-1.8, p=0.85) and TT genotype was present in 17% (19/109) of the patient group and 16% (20/128) of the controls (OR 0.86, 95%CI 0.43-1.17, p=0.81), without showing significant differences between the study groups **Conclusions:** The genotype TT of the rs2758346 variant of the SOD2 gene did not show a risk association for susceptibility to the development of breast cancer in the analyzed sample.

Session Title: Cancer Poster Session I

PB4969 Assessing the expression of Long Interspersed Nuclear Elements (LINEs) via long-read sequencing in diverse human tissues and cell lines

Authors:

K. Rybacki[1], M. Xia[1], J. Xing[2], K. Wang[3]; [1]Univ. of Pennsylvania, Philadelphia, PA, [2]Rutgers, the State Univ. of New Jersey, Piscataway, NJ, [3]CHOP, Philadelphia, PA

Transposable Elements (TEs), such as Long INterspersed Elements (LINEs), are DNA sequences that can replicate themselves within genomes independently of the host cell DNA. LINE activity creates genomic structural variants in human populations and alterations in cancer genomes. Long-read RNA sequencing technologies, including both Oxford Nanopore and PacBio, have generated completely sequenced transcripts and provide the opportunity to examine full-length expressed LINEs. This study focuses on the development of a new bioinformatics pipeline for the identification and quantification of active, full-length LINEs in both healthy tissues, and cancerous and normal cell lines. The pipeline utilized RepeatMasker to identify LINE-1 elements in humans, based on specific criteria such as divergence and length, to focus on young L1 elements with intact retrotransposition machinery. Comparisons of cancerous cell lines with normal cell lines, and healthy human tissue samples revealed higher expression levels of younger, active LINEs in cancer, at intact and fully transcribed L1 loci. Active and inactive L1 elements were analyzed to illustrate the presence and impact of highly mutated and less mutated LINEs across various tissue and cell line types. By employing advanced bioinformatics methodologies on full-length transcriptome data, this study demonstrates the landscape of LINE-1 elements and their contributions in normal and oncogenic cellular processes.

Session Title: Cancer Poster Session II

PB4970 Association of inferred global ancestry with cytogenetic subtypes in pediatric acute lymphoblastic leukemia

Authors:

J. Geris[1], P. Kore[1], M. Leon-Camarena[2], M. Castellanos[3], O. A. Taylor[1], V. Garcia-Morales[1], A. L. Brown[1], P. Sok[1], V. Huynh[4], K. Ludwig[5], L. Klesse[5], S. Pruitt[5], A. Hughs[5], K. Tien[1], K. Heym[6], T. Griffin[1], E. Rodrigo[1], J. C. Bernini[1], M. Gramatges[1], M. E. Scheurer[7], P. J. Lupo[1]; [1]Baylor Coll. of Med., Houston, TX, [2]Univ. of Texas - Austin, Austin, TX, [3]Univ. of California, San Francisco, San Francisco, CA, [4]Children's Hosp. of Orange County, Orange, CA, [5]Univ. of Texas Southwestern, Dallas, TX, [6]Cook Children's Hlth.Care System, Fort Worth, TX, [7]Baylor Coll. Med., Houston, TX

Pediatric acute lymphoblastic leukemia (ALL) is a heterogeneous disease with multiple cytogenetic subtypes, each associated with distinct clinical outcomes. Despite advances in therapies, racial and ethnic disparities in ALL incidence and survival exist. Recent studies have suggested ALL subtypes differ by genetic ancestry, but few efforts have replicated these differences, especially for Latinos. This study leveraged the Reducing Ethnic Disparities in Acute Leukemia (REDIAL) Consortium to examine the association between inferred global genetic ancestry and ALL subtypes. REDIAL includes patients diagnosed with ALL at seven major pediatric cancer centers in the Southwestern U.S. Demographic and clinical characteristics include self-reported race/ethnicity (SRRE), sex, and age at diagnosis. Cytogenetic aberrations were dichotomized as present or absent. Inferred global genetic ancestry proportions, including African (AFR), European (EUR), Amerindian (AMR), and Asian (AS) were estimated with the 1000 Genomes Project Phase 3 reference panels using ADMIXTURE. A K-means clustering algorithm was used to classify children into one of four groups of AFR, EUR, AMR, or AS ancestry. Logistic regression models were used to estimate adjusted odds ratios (aORs) and 95% confidence intervals (CI) accounting for sex and age at diagnosis. Of the 593 ALL patients, 58.9% self-reported as Latino, 31.0% non-Latino white (NLW), 5.7% non-Latino Black (NLB), 3.7% Asian/Pacific Islander (API), and 0.7% Other/Unknown. The mean proportion of genetic ancestry varied by SRRE: Latino, AMR: mean (standard deviation) = 59.2% (11.7); NLW, EUR = 83.1% (3.8); NLB, AFR = 82.9% (12.9); API, AS = 60.7% (17.6). Overall, cytogenetic features associated with favorable outcomes were less frequent among those of AMR ancestry compared with those of EUR ancestry (aOR 0.64, 95% CI 0.42-0.96). Differences were also observed for specific subtypes. For example, *ETV6::RUNX1* (t12;21) was less frequent in patients of AMR ancestry compared with those of EUR ancestry (aOR 0.55, 95% CI 0.33-0.90) or AFR ancestry (0.31, 0.12-0.79). *BCR2::ABL1* was less frequent in patients of AMR ancestry (1.6%) compared with patients of EUR ancestry (3.6%), but this difference was not statistically significant (aOR 0.35, 95% CI 0.09-1.31). Additionally, the prevalence of *KMT2A* gene rearrangements was higher in patients of AS ancestry (4.0%) compared with patients of EUR ancestry (0.7%) but was not significant in our adjusted model (aOR 6.24, 95% CI 0.68-56.85). Our results confirm differences in ALL subtypes by genetic ancestry, which could partially account for outcome disparities among children with ALL.

Session Title: Cancer Poster Session III

PB4971 Association of Microsatellite Instability and gene expression in pathogenesis of Colorectal Carcinoma.

Authors:

M. Kibriya[1], F. Jasmine[1], M. Raza[2], M. Kamal[3], M. Bissonnette[1], H. Ahsan[1]; [1]Univ. of Chicago, Chicago, IL, [2]Jahurul Islam Med. Coll., Kishoregonj, Bangladesh, [3]The Lab., Dhaka, Bangladesh

Background: In sporadic colorectal carcinoma (CRC), several genetic factors play important roles such as genetic mutations, genetic instability, chromosomal instability (CIN) or microsatellite instability (MSI), and DNA methylation. The MSI pathway involves the primary loss of function of DNA repair genes. In a previous study, we demonstrated a difference in DNA methylation pattern in microsatellite stable (MSS) and MSI CRC. In the current study, we explore the similarity and differences in gene expression profile in MSS and MSI at gene level and at pathway level to better understand the CRC pathogenesis and /or potential therapeutic opportunity. **Material & Methods:** Seventy one CRC patients (male = 43, Female=28) with different histological stages (stage 1=12 , stage 2=22 and stage 3=37) were studied. Eighteen of the tumors had MSI and 53 were MSS. From surgically resected colon specimens, paired tissue samples (tumor and adjacent normal) preserved in RNA later were used for genome-wide gene expression studies. **Result:** At gene level, we compared the list of differentially expressed genes (fold change (FC) >=3 and FDR 0.05) in tumor tissue compared to corresponding adjacent normal appearing tissue in patients with MSI (190 genes) and in patients with MSS tumors (129 genes). Of these, 107 genes overlapped and these genes were enriched in many of the pathways known to impact cancer. The list of genes that were differentially expressed in MSI only, showed enrichment in mainly two broad categories of pathways - (a) Inflammation related pathways like *IL 17* signaling pathway, *TNF* signaling pathway, chemokine signaling, *NFkB* signaling, cytokine-cytokine interactions, and (b) metabolism-related pathways including pentose and glucoronate interconversions, ascorbate and aldarate metabolism, steroid hormone biosynthesis, retinol metabolism and drug metabolism. Among them, the genes in Inflammation related pathways were up-regulated and the genes in metabolism related pathways were down-regulated in MSI tumor tissue. For pathway level analysis (taking all the genes in a given pathway into account), Gene set ANOVA also revealed similar results confirming the enrichment findings. For example, the 150 genes involved in *IL 17* signaling pathway were on average up-regulated by 1.19 fold (CI 1.16 - 1.21) in MSI compared to 1.14 fold (CI 1.13 - 1.16) in MSS patients (interaction p= 0.0009). **Conclusion:** We document the association between MSI status and differential gene expression which helps to broaden our understanding of CRC pathogenesis. Furthermore, targeting of several these dysregulated pathways could provide the basis for improved therapies for MSI and MSS CRC.

Session Title: Cancer Poster Session I

PB4972 Association of prostate cancer candidate genes with overall and aggressive prostate cancer in men of African ancestry.

Cancer Inst., Bethesda, MD

Background: There is a growing body of evidence supporting the contributions of germline rare variants to the susceptibility of prostate cancer (PCa), especially aggressive PCa. Here we investigated whether rare germline pathogenic/likely pathogenic/deleterious (P/LD/D) variants and variants of uncertain significance (VUS) in 38 aggressive PCa genes identified mostly from European populations were associated with total and aggressive PCa risk in men of African ancestry. **Methods**: This exome sequencing analysis consists of 7,176 cases and 4,873 controls of African ancestry from North America and Africa. There are 3,283 aggressive cases (tumor stage T3/T4, regional lymph node involvement, metastatic disease, Gleason score ≥ 8.0, PSA ≥ 20 ng/mL or PCa as the underlying cause of death) including 1,074 metastatic cases, and 1,752 non-aggressive cases (Gleason score ≤ 7.0, PSA < 20 ng/mL, and stage ≤ T2). P/LP/D variants were rare (< 1% in controls) and had either a VEP impact score of "high" or a pathogenic or likely pathogenic ClinVar classification. Rare missense variants with a REVEL score > 0.6 were considered as VUS. P/LP/D and VUS variants were assessed separately in gene-based association analysis for total PCa, aggressive PCa, and metastatic PCa. **Results**: Significant associations with total PCa were observed for P/LP/D variants in *BRCA2* (OR=1.86, 95% CI=1.20-2.90, P=0.006), *CHEK2* (OR = 3.22, 95% CI=1.10-9.49, P=0.034), *HOXB13* (OR=2.28, 95% CI=1.34-3.87, P=0.002), and *PALB2* (OR=3.44, 95% CI=1.18-10.1, P=0.024). In the analysis of aggressive vs. non-aggressive cases, the association was significant for *ATM* (OR=2.60, 95% CI=1.13-5.97, P=0.025), *BRCA2* (OR=2.39, 95% CI=1.16-4.95, P=0.018), and *HOXB13* (OR=2.10, 95% CI=1.04-4.27, P=0.039). Similar suggestive associations with metastatic PCa were also observed for *ATM* and *BRCA2* (P < 0.07). In African Americans *PALB2* was strongly associated with aggressive (OR=11.7, 95% CI=1.51-91.2, P=0.019) and metastatic (OR=17.7, 95% CI=1.57-200.3, P=0.02) PCa. There was evidence that VUS of *BRCA2*,*CHEK2*, *MLH1* and *MUTYH* were associated with aggressive and/or metastatic PCa (OR of 1.45-9.01, P of 0.016-0.047).**Conclusion:** The associations of *ATM*, *BRCA2*, and *PALB2* with total PCa and/or aggressive PCa in men of African ancestry are consistent with findings from men of European ancestry. We further confirmed the association of *HOXB13* with risk of total and aggressive PCa which was driven by the known West African ancestry-specific risk variant X285K (rs77179853). These findings further support the importance of these genes in the consideration of screening and active surveillance for high-risk and advanced disease.

Session Title: Cancer Poster Session II

PB4973 Association of stromal transcriptomes with prostate cancer defined by *TMPRSS2:ERG* or *PTEN* molecular subtypes

Authors:

C. Ma[1], Y. Zhou[2], K. H. Stopsack[3,4], T. L. Lotan[5,6], L. A. Mucci[3], **K. L. Penney**[3,7], S. Tyekucheva[2]; [1]Univ. of Massachusetts Amherst, Amherst, MA, [2]Dana-Farber Cancer Inst., Boston, MA, [3]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [4]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [5]Dept. of Pathology, Johns Hopkins Univ., Baltimore, MD, [6]Dept. of Oncology, Johns Hopkins Univ., Baltimore, MD, [7]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA

Background: The *TMPRSS2:ERG* gene fusion and *PTEN* loss are two of the most common somatic molecular alterations in primary prostate cancer. *TMPRSS2:ERG* fusion status has been implicated in the etiology of prostate cancer, while *PTEN* loss has been associated with disease aggressiveness and progression. Prior studies have examined gene expression of tumor with these molecular alterations in prostate cancer. Given the crosstalk between epithelium and stroma, the transcriptome in prostate stroma linked with these subtypes have not been described. In this study, we highlight the whole transcriptome expression associated with ERG gene fusion and PTEN loss in prostate cancer. **Methods:** We performed RNA sequencing after Illumina TruSeq Exome Capture of tumor-adjacent and benign-adjacent macrodissected prostate stromal samples from the Health Professionals Follow-up Study and the Physicians' Health Study. ERG (N=268 prostate cancer cases) and PTEN protein (N=184) were assessed in adjacent tumor tissue using validated immunohistochemistry assays. We performed differential expression analysis comparing stromal gene expression and pathways by tumor ERG gene fusion and PTEN loss status. **Results:** We found 11 genes to be differentially expressed (nominal *P*<0.001) comparing ERG positive vs. negative prostate cancer cases in tumor-adjacent stroma, including *SLCO2B1*, *NDE1*, and *KLHDC1*. Another 12 genes were differentially expressed in benign-adjacent stroma, including *ACAN*, *MIEF2*, and *ZBTB40*. At a pathway level, oxidative phosphorylation, mitochondrial electron transport, and ATP synthesis were differentially enriched in tumor-adjacent stroma comparing ERG positive and negative tumors, and pathways associated with PI3K/Akt/mTOR signaling and E2F targets were differentially enriched in benign-adjacent stroma. Comparing cases with PTEN loss with intact PTEN cases, we identified four genes to be differentially expressed in tumor-adjacent stroma: *FBXL3*, *GABRP*, and *LASP1*, and 34 genes in benign-adjacent stroma, including *DYSF*, *DCLK1*, and *CHD5*. Pathways differentially enriched between PTEN loss and intact PTEN cases included those related to myogenesis, TNFα signaling, angiogenesis, and apoptosis in benign-adjacent stroma. Pathways were not statistically significantly differentially enriched in tumor-adjacent stroma (adjusted *P*>0.2 for all). **Conclusions:** Our study uncovers stroma-specific genes and pathways differentially enriched with ERG gene fusion and PTEN loss, demonstrating that the molecular investigation of the tumor microenvironment can highlight potential new players in prostate cancer etiology and progression.

Background: Breast cancer in Mexico and worldwide represents a health problem. This disease is characterized by a multifactorial origin, so different genetic and environmental factors are attributed to its cause. Some studies in cancer have demonstrated the association of different variants in genes that participate in the process of elimination of free radicals. Among them is the enzyme Cu-Zn cytosolic superoxide dismutase or also called *SOD1* (Cu/Zn-*SOD1*). However, there are no association studies between the rs17880135 variant of the *SOD1* gene and breast cancer. Objective: Determine the association of the rs17880135 (TG) variant of the *SOD1* gene with breast cancer. **Methodology:** 304 DNA samples from breast cancer patients and 118 from the control group were analyzed. Using IDT probes, the genotypes of the rs1788880135 variant were discriminated by qPCR. Amplification and analysis were performed on a CFX96 thermal cycler, C100 touch, BioRad. **Results:** The wild-type genotype (TT) was the most frequent genotype, observed in 85% (258/304) of the patient group and in 93% (110/118) of the control group (OR 0.4, 95%CI 0.18-0.83, p=0.032), which was shown to be a protective factor. However, heterozygous genotype (TG) was present in 15% (46/304) of the patient group and 7% (8/118) of the controls, which when comparing the study groups was observed as a risk factor (OR 2.4, 95%CI 1.12-5.36, p=0.032) for susceptibility to breast cancer development. The GG genotype was not observed in the study groups. **Conclusions:** The heterozygous genotype (TG) of the rs1788880135 variant of the *SOD1* gene is a susceptibility risk factor for the development of breast cancer in the analyzed sample.

Molecular, CIBO, CMNO, IMSS, Guadalajara, Mexico

Background: The SOD2 (Manganese superoxide dismutase, MnSOD) enzyme is involved in the detoxification of the superoxide anion, and is encoded by the *SOD2* gene, and its function is to protect the cell from free radicals generated by oxidative stress. It has an important participation in cell signaling pathways of apoptosis and oxidative stress. The variant rs27758331 C>A is located on chromosome 6 on the *SOD2* gene at position 159684038 of the sense chain, it is characterized by the change of a nucleotide from C to A and has been associated as a risk factor for susceptibility to multiple diseases. However, these studies do not include breast cancer. **Objective**: Determine the association of the rs27758331variant of the *SOD2* gene with breast cancer in a Mexican population. **Material and methods:** The genotype discrimination analysis of the rs27758331 variant of the *SOD2* gene was performed on 180 DNA samples from breast cancer patients and 172 from the control group. The genotype discrimination was determined by TaqMan® probes, by real-time PCR assays (qPCR), and was analyzed on a CFX96 thermal cycler, C100 touch, BioRad. **Results:** The wild-type genotype (CC) was observed in 29% (52/180) of the patient group and in 50% (86/172) of the control group (OR 0.40, 95%CI 0.26-0.63, p=0.00007), showing significant differences between the study groups as a protective factor for susceptibility to breast cancer. The heterozygous genotype (CA) was present in 34% (61/180) of the patient group and 29% (50/172) of the controls, which when comparing the study groups was not significantly different. Nevertheless, the AA genotype was present in 37% (67/180) of the patient group and 21% (32/172) of the controls, which when comparing the study groups was observed as a risk factor (OR 2.4, 95%CI 1.52-3.9, p=0.0003) for susceptibility to breast cancer development. **Conclusions:** The genotype AA of the rs27758331 variant of the *SOD2* gene is a susceptibility risk factor for the development of breast cancer in the analyzed sample.

Molecular, CIBO, CMNO, IMSS, Guadalajara, Mexico, [5]Laboratorio de Inmunofarmacología, Centro Univ.rio de Ciencias Exactas e Ingenierías UdeG, Guadalajara, Mexico

INTRODUCTION: Breast cancer (BC) is a disease caused by the abnormal and uncontrolled growth of cancerous cells in the tissues of the mammary gland. It represents the type of cancer with the highest prevalence among women worldwide, including Mexico, positioning itself as one of the leading causes of death in women in this and all countries of the world. The development of this pathology is influenced by various factors, among which hormonal and genetic factors stand out, and it has been observed that these have a greater weight in the development of the disease. The process of malignization of a cell begins with a series of alterations in the DNA sequence of certain genes, such as the *KRAS* gene. In this gene, high frequencies of mutations (85% in the RAS family) and multiple variants have been reported, including single nucleotide variants (SNV). Worldwide, association studies of variants in the *KRAS* gene with BC are limited. In the Mexican population, the association analysis of the rs8720 variant is nonexistent.

Worldwide, studies of the association of variants in the *KRAS* gene with the pathology are limited. In the Mexican population, the association analysis of the rs8720 variant is nonexistent.**OBJECTIVE:** Determine the association of the rs8720 *KRAS* gene variant with breast cancer (BC). **METHODS:** Genomic DNA samples from 492 healthy women and 377 BC patients were analyzed for the rs8720 T>C variant of the *KRAS* gene using qPCR. **RESULTS:** The genotype CC (38%) of the rs8720 variant was most frequently found in the BC group compared to the control group (23%) showed as risk factors for susceptibility to the development of BC ($p<0.05$). Discrepancies were noted in patients with BC carrying the CC and CT genotypes of the rs8720 variant and the presence of toxicity gastric or hematologic to chemotherapy in BC with stages III-IV furthermore genotype were identified as BC susceptibility risk factors. **CONCLUSIONS:** Variant rs8720 of the *KRAS* gene was associated with risk susceptibility factors for BC in the sample analyzed.

GALLEGOS-ARREOLA[3]; [1]UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, Mexico, [2]Doctorado en Genética Humana, Centro Univ.rio de Ciencias de la Salud (CUCS), Univ. de Guadalajara (UdeG), Guadalara, Mexico, [3]División de Genética, Centro de Investigación Biomédica de Occidente (CIBO), Centro Médico Natl. de Occidente (CMNO), Inst. Mexicano del Seguro Social (IMSS), GUADALAJARA, Mexico, [4]Doctorado en Genética Humana, Centro Univ.rio de Ciencias de la Salud (CUCS), Univ. de Guadalajara (UdeG), Guadalajara, Mexico, [5]Departamento de Biología Molecular y Genómica, Inst. de Genética Humana "Dr. Enrique Corona Rivera", CUCS, UdeG, GUADALAJARA, Mexico, [6]División de Med. Molecular, CIBO, CMNO, IMSS, GUADALAJARA, Mexico

Background: A rs351855 is a single nucleotide variant (SNV) missense which causes a change of substitution of glycine-to-arginine (G/A) at codon 388 (p.Gly388Arg) located in the transmembrane domain of the receptor in the exon 9 (c.1162G/A) in *FGFR4* gene. This variant was reported to increase cancer risk and has been associates with genetic predisposition to multiple types of cancer, included colorectal cancer (CRC). Has been linked to poor prognosis and very poor overall survival for population. **Objective:** Determining the association of *FGFR4* (rs351855) gene variant with colorectal cancer in Mexican population. **Materials and methods:** Genomic DNA samples from 420 healthy controls and 448 CRC patients were analyzed for the rs351855 variant of the *FGFR4* gene using qPCR. **Results:** The wild genotype GG was the most frequent, observed in 46% (205/448) of the CRC patient group and in 59% (246/420) of the control group (OR 0.59, 95%CI [0.45-0.78] p=0.000), which was shown to be a protective factor. However, AA genotype variant was present in 23% (101/448) of the patient group and 6% (24/420) of the controls, which when comparing the study groups was observed as a risk factor (OR 4.8, 95%CI [3 - 7.6] p=0.000) for susceptibility to CRC development. The GA heterozygous genotype didn't find differences between the studied groups, frequencies of 32% (142/448) and 36% (150/420) were detected for the group of patients and the group of controls, respectively (OR 0.83, 95%CI [0.63 - 1.10] p =0.237). **Conclusions:** The AA genotype of the rs351855 variant of the *FGFR4* gene was a susceptibility risk factor for the development of CRC the analyzed sample.

Session Title: Cancer Poster Session I

PB4978 B-allele frequency-based approach to detecting absence of heterozygosity enables detection of low-level mosaic events using optical genome mapping.

Authors:

A. Raksi, W. A. Sherman, M. D. Roytman, A. Hastie, N. Miller; Bionano, San Diego, CA

Introduction: Copy-neutral loss of heterozygosity has been found to be important in several types of cancer and has traditionally been identified using SNP microarray analysis. Previously, a method to detect the absence or loss of heterozygosity (AOH/LOH) using high-resolution optical genome mapping (OGM) results from the Bionano Saphyr® platform was described, based on the B-allele frequency (BAF) observed at label sites overlapping with known SNP positions, which enables the detection of AOH events at low allelic fractions, and performance was evaluated in several samples with known AOH events. Here the analytical evaluation of the method and performance of detecting mosaic AOH events at low aberrant cell fraction (ACF) based on simulated data is described.
Methods: The B-allele frequency of a label is calculated as the ratio of OGM molecules observed with label fluorescence to the total number of molecules aligned to the position. Heterozygous labels are defined as label motif sites that overlap heterozygous SNPs, where a fraction of molecules is observed with a lack of fluorescence at that location. A cohort of samples was simulated to assess performance; 230 AOH/LOH events of sizes ranging from 1 Mbp to 100 Mbp were simulated at various aberrant cell fractions as low as 5% ACF, for a total of 1,350 AOH/LOH events evaluated. Sensitivity and precision were calculated for each size range and cell fraction separately. Simulated samples were analyzed using the Bionano Solve pipeline. BAF values were normalized for the query sample at each SNP position, and AOH regions were called using the NxClinical™ software's SNP-FASST3 algorithm for segmenting and calling events. Additional validation was performed using a cohort of constitutional and cancer samples for which orthogonal testing had been performed and for which cell counts and LOH events were available.
Results: After optimizing parameters used for AOH detection, we demonstrate 92.3% sensitivity and >95% precision for calling AOH events greater than 20 Mbp at 25% aberrant cell fraction. In 15 samples with a total of 37 known AOH events, all events greater than 15 Mbp were called, including a 29 Mbp low level mosaic CN-AOH at 20% aberrant cell fraction.
Conclusion: These results show the analytical performance of an approach for detecting AOH/LOH regions at low allele frequency using optical genome mapping alone and demonstrates the utility of the method to analyzing heterogeneous cancer samples. The software will be made available as part of Bionano Solve 3.8 and VIA™v7.0.

Session Title: Cancer Poster Session II

PB4979 Base resolution deep learning models decipher the regulatory basis of thyroid cancer.

Authors:

A. Singhal, M. Kasowski, A. Kundaje; Stanford Univ., Palo Alto, CA

The initiation and progression of cancer, which has traditionally been seen as a genetic disease, is now increasingly being associated with regulatory abnormalities. Combinatorial binding of transcription factors to complex sequence syntax encoded in cis-regulatory elements mediates the development of normal cell-type specific expression of genes. However, large scale regulatory alterations including transcription factor binding to reprogram the chromatin-accessible landscape of regulatory elements can lead to altered gene function and undesirable cellular transformations that result in the formation of primary and metastatic tumors. The thyroid has been impacted by such regulatory alterations, resulting in cancer growth. Thyroid cancer is the most common cancer of hormone-producing tissue with high metastases frequency, low mutational burden, and a high degree of heritability, making it important to study genetically. To investigate regulatory activity changes in the thyroid, we have developed state-of-the-art base resolution chromatin profiling models to decipher predictive cis-regulatory sequence syntax and to predict the impact of regulatory genetic variants on the strength and shape of chromatin profiles. These models have been developed on a unique thyroid dataset consisting of matched normal, primary tumor, and metastatic tumor for each patient. Many fine-mapped SNPs from genome-wide association studies (GWAS) are in non-coding regions where they are thought to influence gene regulation. We have used our deep learning models to predict regulatory activity and compare transcription factor binding across distinct alleles. Using a prioritized list of SNPs from GWAS loci associated with Thyroid-Stimulating Hormone (TSH), our models predict a set of functional SNPs with a significant difference in the predicted counts and profiles. Our model predicted the upregulation of a transcription factor at *rs16857609*, one such functional SNP previously associated with thyroid cancer and subsequently fine-mapped in a multi-ancestry cohort. This is an expression quantitative trait locus (eQTL) for *DIRC3* and *IGFB5* in thyroid cancer (TCGA). Our deep learning models are the first of their kind to provide base resolution fine-mapping of GWAS hits to quantitative trait loci for a unique thyroid dataset. These models will help address a major gap in the thyroid cancer field by elucidating the role of specific transcription factors and genes in thyroid cancer initiation and progression across heterogeneous clinical cases.

Session Title: Cancer Poster Session III

PB4980 Analysis of the frequency and association of the rs5746094 (T/C) variant of the SOD2 gene in breast cancer

Authors:

P. GARCÍA VERDÍN[1], B. C. Gómez Meda[2], A. F. Garibaldi Rios[3], L. E. Figuera[3], I. A. Carrillo Davila[3], G. M. Zúñiga-González[4], M. P. Gallegos Arreola[5]; [1]Doctorado en Genética Humana, GUADALAJARA, Mexico, [2]2Departamento de Biología Molecular y Genómica, Inst. de Genética Humana "Dr. Enrique Corona Rivera", CUCS, UdeG, Guadalajara, Mexico, [3]Doctorado en Genética Humana, CUCS, UdeG. División de Genética, CIBO, IMSS, Guadalajara, Mexico, [4]Laboratorio de Mutagénesis, División de Med. Molecular, CIBO, CMNO, IMSS, Guadalajara, Mexico, [5]División de Genética, CIBO, IMSS, Guadalajara, Mexico

Introduction: rs5746094 is a single nucleotide variant (SNV) found on chromosome 6, in the SOD2 gene that codes for the enzyme superoxide dismutase 2. This enzyme protects cells from oxidative stress caused by free radicals. The C allele of this SNP seems to be more associated with the risk of developing different diseases. However, there are no association studies with breast cancer. **Objective:** Determine the association of the rs5746094 variant of the SOD2 gene with breast cancer. **Material and methods:** 213 DNA samples from breast cancer patients and 72 from the control group were included in the study. The genotypes of the rs5746094 variant were determined by TaqMan®probes, by real-time PCR assays (qPCR), and were analyzed on a CFX96 thermal cycler, C100 touch, BioRad. **Results:** The wild-type genotype (TT) was the most frequent genotype, observed in 62% (133/213) of the patient group and in 50% (36/72) of the control group (OR 166, 95%CI 0.97-2.84, p=0.085), without showing significant differences between the study groups. However, heterozygous genotype (TC) was present in 16% (34/213) of the patient group and 42% (30/72) of the controls, which when comparing the study groups was observed as a protector factor (OR 0.26, 95%CI 0.14-0.48, p=0.00001). Nevertheless, the CC genotype was present in 22% (46/213) of the patient group and 8% (6/72) of the controls, which when comparing the study groups was observed as a risk factor (OR 3.03, 95%CI 1.25-7.43, p=0.019) for susceptibility to breast cancer development. **Conclusions:** The genotype CC of the rs5746094 variant of the SOD2 gene is a susceptibility risk factor for the development of breast cancer in the analyzed sample.

Session Title: Cancer Poster Session I

PB4981 Breast cancer prevalence and therapeutic complications in carriers of *BRCA1/2* pathogenic variants after *Salpingo-Oophorectomy* risk in *BRCA* gene carriers: A Narrative Review Study

Authors:

A. Ahmadi; Isalmic Azad Univ. Tehran Med. Sci., Tehran, Iran, Islamic Republic of

Introduction: Cancer begins when healthy cells in the breast change and grow out of control and form a lump or sheet of cells called tumors. A tumor can be cancerous or non-cancerous which is also called benign. A tumor is a malignant cancer that can grow and spread to other parts of the body. A benign tumor can grow but has not spread. *Risk Reduction Salpengo Oophorectomy (RRSO)* is the gold standard method of reducing the risk of ovarian cancer, but data on the impact on breast cancer (BC) outcomes are inconsistent. An estimated 43,700 deaths (43,170 women and 530 men) from breast cancer occur in the United States in 2023. Worldwide, breast cancer is the fifth leading cause of death. Women with *BRCA1* or *BRCA2* gene mutations are at risk of breast and ovarian cancer and often undergo surgery to remove both of their ovaries to prevent ovarian cancer. The effect of this operation on breast cancer risk is unclear. The aim of this study was to determine BC mortality rate in *BRCA1/BRCA2* carriers after *RRSO*

Methods: This descriptive study was conducted with narrative review approach in 2023 by searching keywords such as *BRCA*, Breast Cancer, risk - reducing *Salpingo-Oophorectomy, Pathogenic Variants and Prevalence* in valid databases such as Scopus, Science Direct, and Web of Science.

Results: Worldwide, female breast cancer is now outnumbered by lung cancer as the most common cancer. An estimated 2,261,415 new cases of breast cancer were diagnosed in women worldwide in 2020. More women in the United States are diagnosed with breast cancer than any other type of cancer, in addition to skin cancer. It accounts for 1 in 3 new cancers in women annually. The practice is not associated with a reduced risk of breast cancer when considering both *BRCA1* and *BRCA2* carriers together, but it has been linked to a reduced risk of breast cancer when considering the *BRCA2* carrier alone. These findings may have important implications for counselling for women in the clinic.

Conclusion: Carriers of the *BRCA1/2* pathogenic variant increase the risk of breast and ovarian cancer in their lifetime. Women with cancer who have recently been diagnosed with this pathogen may experience psychological distress due to an imminent threat to health.

Session Title: Cancer Poster Session II

PB4982 Cancer predisposition in an Asian population of diverse ancestries

Authors:

S. Chan[1,2], W. Lim[3,4], **J. Ngeow**[1,2]; [1]Natl. Cancer Ctr. Singapore, Singapore, Singapore, [2]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore, [3]SingHlth.Duke-NUS Inst. of Precision Med., Singapore, Singapore, [4]Genome Inst. of Singapore, Agency for Sci., Technology and Res., Singapore, Singapore

Hereditary cancer risk assessment guidelines have primarily been developed based on data from predominantly European-descent populations due to underrepresentation of non-European genomes in human genomics studies. This limits the utility of guidelines in non-European populations, such as Asians, in which genomic variation is less characterized. In this study, we evaluated germline pathogenic variants in cancer predisposition genes from 9,051 genomes of SG10K_Health cohort representing populations of East Asian, South Asian and Austronesian-speaking Southeast Asian ancestries. We found 2.5% (227/9,051) of SG10K_Health at-risk of dominantly inherited cancer predisposition disorders, primarily harboring pathogenic variants (PVs) in breast and ovarian cancer susceptibility genes including *ATM*, *BRCA1*, *BRCA2*, *BRIP1* and *RAD51D*. Hereditary breast and ovarian cancer and Lynch syndrome were the most prevalent cancer syndromes, with an overall prevalence of 1:148 and 1:532 respectively, which are higher than current global estimates. We observed a high carrier burden for recessively inherited bone marrow failure syndromes, particularly Shwachman-Diamond Syndrome (SDS), with 1.2% (109/9,051) of SG10K_Health carrying a *SBDS* PV associated with SDS. We evaluated and found minimal overlap of PVs identified in SG10K_Health with our cancer patient cohort (n=3,537) that underwent clinical multi-gene panel testing. About 12% (25/197) of PVs identified in breast/ovarian cancer patients (n=2,306) were found in SG10K_Health whereas only 4% (2/46) of PVs in colorectal cancer patients (n=251) overlapped and none of the 23 PVs identified in endometrial cancer patients (n=149) were detected in SG10K_Health. Our study highlighted that majority of germline PVs in the cancer cohort are rare and unlikely observed in the general population; cautioning the reliance on population screening data, from European and non-European populations alike, for developing genomic medicine guidelines and making clinical decisions for hereditary cancer risk assessment and management.

Session Title: Cancer Poster Session III

PB4983 Cancer predisposition signaling pathways drive Beckwith-Wiedemann Syndrome Wilms Tumor development

Authors:

S. Nirgude[1], N. Naveh[1], S. Kavari[1], J. Kalish[2]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Children s Hosp. of Philadelphia, Philadelphia, PA

Background: Wilms tumor (WT) exhibits structural and epigenetic changes at chromosome 11p15, which also cause Beckwith-Wiedemann Syndrome (BWS). Children diagnosed with BWS have increased risk for WT. The aim of this study is to identify the molecular signaling signatures in BWS driving these tumors.**Methods**: We performed whole exome sequencing, methylation array analysis, and gene expression analysis on BWS-WT samples. Our data were compared to publicly available nonBWS data. We categorized WT from BWS and nonBWS patients by assessment of 11p15 methylation status and defined 5 groups- control kidney, BWS-nontumor kidney, BWS-WT, normal-11p15 nonBWS-WT, altered-11p15 nonBWS-WT.**Results**: BWS-WT samples showed single nucleotide variants in *BCORL1*, *ASXL1*, *ATM* and *AXL* but absence of recurrent gene mutations associated with sporadic WT. We defined a narrow methylation range stratifying nonBWS-WT samples. BWS-WT and altered-11p15 nonBWS-WT showed enrichment of common and unique molecular signatures based on global differential methylation and gene expression analysis. CTNNB1 overexpression and broad range of interactions were seen in the BWS-WT interactome study.**Conclusion**: While WT predisposition in BWS is well-established, as are 11p15 alterations in nonBWS-WT, this study focused on stratifying tumor genomics by BWS status. Further investigation of our findings may identify novel therapeutic targets in WT oncogenesis.

Session Title: Cancer Poster Session I

PB4984 Cancer risk in Simpson-Golabi-Behmel Syndrome: Case Series and Literature Review.

Authors:

A. Nisbet[1,2], S. D. Klein[1,3], J. B. Kalish[1,3,4,5]; [1]Children's Hosp. of Philadelphia, Div. of Human Genetics, Philadelphia, PA, [2]Perelman Sch. of Med., Philadelphia, PA, [3]Dept. of Pediatrics, Perelman Sch. of Med., Philadelphia, PA, [4]Ctr. for Childhood Cancer Res., Children's Hosp. of Philadelphia, Philadelphia, PA, [5]Dept. of Genetics, Perelman Sch. of Med., Philadelphia, PA

*Introduction:*Simpson-Golabi-Behmel Syndrome (SGBS) is an overgrowth syndrome characterized by macrosomia, craniofacial and gastrointestinal anomalies, intellectual disability, and congenital heart defects. SGBS is caused by variants in *GPC3* or *GPC4* on the X chromosome. Less than 250 cases are reported in the literature. Like other overgrowth syndromes, it has been proposed that patients with SGBS have an increased risk of cancer; but the actual risk is unknown. Current cancer screening guidelines are based on those developed Beckwith-Wiedemann Syndrome. Here, we describe the largest cohort of SGBS to date to define the genotype/phenotype correlation and the spectrum of clinical findings.
*Methods:*We conducted a PubMed literature review for all known cases of SGBS and included nine unreported patients. We calculated the cancer risk and developed a SGBS severity score. 90 out of 323 articles were classified as case reports and phenotyped. Each case was reviewed for data on demographics, genetic information, and comorbidities. The nine unreported cases were also phenotyped. Secondary analyses to further characterize the patients who developed tumors were performed.
*Results:*Based on reviewed data from the literature, organomegaly was reported in 32% of cases with tumors developing in 10.4% of cases. Wilms tumor (WT) and hepatoblastoma (HB) were each reported in 3.9% of cases. Metastatic medulloblastoma and ameloblastoma were also identified. Of the patients that developed cancer, 75% were male, 25% were female, 62% had familial germline mutations, and all cases were due to variants in *GPC3*. Specifically, nonsense and intragenic indels appear to have a greater cancer risk than complete gene duplications/deletions, missense, and frameshift variants. In our unreported cohort, organomegaly and renal anomalies were each reported in 75% of cases and the cancer risk was 12.5%. It appears that patients with more severe clinical presentations were more likely to develop cancer.
*Conclusion:*Using the largest known dataset of patients with SGBS, we define an overall cancer risk of 10-12%, with the risk of WT and HB each approaching 4%. There is an additional risk of non-abdominal tumors around 2%. Based on cancer screening guidelines for syndromic causes of WT and HB in the United States, we recommend screening in SGBS in a similar manner to Beckwith-Wiedemann Syndrome. The higher-than-expected risk of non-abdominal malignancies suggests that additional imaging and surveillance could be considered as well. Additionally, the risk of cancer being highest in nonsense and intragenic indels merits further investigation.

Session Title: Cancer Poster Session II

PB4985 Cancer somatic mutations in miRNA genes affect miRNA biogenesis, miRNA level, isomiRs distribution, and effectiveness of targets regulation.

Authors:

M. Machowska, N. Szostak, P. Kozlowski; Inst. of Bioorganic Chemistry, Polish Academy of Sci., Poznan, Poland

MicroRNAs (miRNAs) play an emerging role in cancer development. miRNAs are small non-coding RNAs that usually downregulate gene expression by binding to 3'UTRs of mRNAs, leading to translation repression or mRNA degradation. Changes in the level of many mature miRNAs and their involvement in carcinogenesis are commonly observed in cancer cells. Moreover, many somatic mutations in miRNA-coding genes have been detected in cancers, however, their effects on miRNA biogenesis, miRNA level, miRNA isoforms (isomiRs) generation, and loss- or gain-of-function effect are mostly unknown.

In the study, we analyzed the effects of somatic mutations identified in miRNA genes in cancer samples from The Cancer Genome Atlas (TCGA). Based on the miRNA-seq data from TCGA, we analyzed the influence of mutations located in all regions of miRNA precursor, including miRNA duplex (seed or non-seed), loop, and flanking regions. First, we focused on mutations located in miRNA duplexes, which effect could be directly observed in miRNA-seq data. It allowed to compare miRNAs derived from the wild-type or mutant allele of the same sample. In most analyzed cases, we observed a significant decrease (or complete loss) of miRNAs derived from the mutated allele in comparison to the wild-type allele. Moreover, for most of the mutated miRNAs expressed on the level sufficient for detailed analysis of isomiRs, we found significant changes in isomiRs distribution between wild-type and mutant allele. Such alterations may result in differences in target recognition (independent from the mutations in seed region that directly affect the target recognition) or may influence the miRNA stability. We observed similar effects of mutations located in the loop or flanking regions. Among the mutated miRNA genes with the mutations having a substantial effect on generated isomiRs were genes playing an important role in cancer, e.g., *MIR142*, *MIR205*, and *MIR342*. Furthermore, we conducted a luciferase assay and showed that mutation-specific isomiRs recognize and regulate different targets. Our results showed that most mutations in miRNA genes have an influence on miRNA gene functioning, either affecting miRNA level, miRNA processing, isomiRs distribution, and/or targets recognition and downregulation.

Session Title: Cancer Poster Session III

PB4986 † Cascade testing with comprehensive multigene panels for hereditary cancer identifies unexpected findings in relatives

Authors:

D. Pineda-Alvarez[1], H. Hampel[2], S. M. Nielsen[1], S. Bristow[1], E. D. Esplin[1], R. L. Nussbaum[1], B. Heald[1]; [1]Invitae, San Francisco, CA, [2]City of Hope Comprehensive Cancer Ctr., Duarte, CA

Background: Studies of relatives undergoing multigene panel testing (MGPT) for a familial pathogenic germline variant (PGV) are limited; one small study found that first-degree relatives (FDRs) undergoing cascade testing via a 30-gene panel had a 4.9% rate of unexpected findings (different PGV(s) than the proband; Caswell-Jin J et al 2019 JNCI). The aim of this study was to see if the above findings could be replicated in a larger cohort of relatives undergoing MGPT for a familial PGV.
Methods: Relatives undergoing clinician-ordered cascade testing for a familial PGV in a cancer predisposition gene at a single commercial laboratory were identified. Analysis was limited to those relatives undergoing a MGPT of ≥47 genes. The PGV(s) identified in the relative were compared to the proband's PGV(s). Demographics, relationship to proband, and cancer history data were pulled from test requisition forms; descriptive statistics, t test, and Fisher's exact test were utilized.
Results: 15,362 relatives of 7,433 probands with ≥1 PGVs underwent cascade testing. Among these relatives, 3,706 (24.1%) had clinician-ordered MGPT. Relatives were primarily female (75.9%), White (74.4%), and FDRs of the proband (73.6%), and 713 (19.2%) reported a personal history of cancer. Unexpected PGVs were identified in 230 (6.2%) relatives. This included 11 (0.3%) who were negative for the familial PGV but positive for a different PGV in the same gene as the proband and 144 (3.9%) who were negative for the familial PGV but positive for a PGV in a different gene than the proband. An additional 75 (2.0%) relatives tested positive for the familial PGV and were positive for an additional PGV in a different gene than the proband. Gender, age at testing, personal cancer history were not associated with an unexpected finding, but being White ($p=0.0253$) or at least a second-degree relative were ($p<0.0001$). Among the 219 relatives with a PGV in a different gene, 45 (20.5%) were in a high-risk gene, 54 (25.7%) in a moderate-risk gene, 18 (8.2%) in a gene associated with rare cancer types, and 102 (46.6%) with a low-risk or carrier finding. Based on the unexpected PGV(s), 79 (36.3%) relatives would potentially have qualified for different or additional cancer screening recommendations than the recommendations based on proband's PGV.
Conclusion: Among relatives undergoing cascade testing via a MGPT, unexpected results were found in 6%. 46% of these results were in high- or moderate-risk genes. Limiting cascade testing to only the familial PGV might result in missed, actionable findings for a subset of relatives.

Session Title: Cancer Poster Session I

PB4987 Cell type-specific effects of common germline variation on gene expression and pancreatic cancer risk.

Authors:

G. Prasad[1,2], T. Truongvo[1], J. Zhong[2], J. Hoskins[2], L. T. Amundadottir[2], E. H. Arda[1]; [1]Lab. of Receptor Biology and Gene Expression, Ctr. for Cancer Res., Natl. Cancer Inst., NIH, Bethesda, MD, [2]Lab. of Translational Genomics, Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Rockville, MD

Pancreatic ductal adenocarcinoma (PDAC) is a highly aggressive and fatal cancer of the exocrine pancreas, which is composed of acinar and duct cells. Uncovering genes that influence PDAC risk is crucial for early detection, prevention, and development of effective therapies. While a few high-risk germline mutations have been identified in protein coding regions of the genome, low-penetrance, common variants identified through Genome Wide Association Studies (GWAS) primarily reside in non-coding regions. This suggests that disease-associated variants contribute to risk by modifying non-coding gene regulatory elements. To identify potential gene targets influenced by such non-coding risk variants, we are employing cell type-resolved expression, chromatin accessibility and methylation quantitative trait loci (eQTL, caQTL and meQTL, respectively) analyses in purified pancreatic acinar and ductal cells. Previous QTL studies in the pancreas have used bulk tissue or tumor samples, potentially masking cell type-specific genetic effects underlying disease risk. In this work, we used a flow cytometry-based method to purify human acinar and duct cells obtained from organ donors. To obtain cell type-specific eQTL, caQTL, and meQTL data, we performed high-throughput genotyping, DNA methylation analysis, RNA sequencing, and ATAC sequencing on purified cells from 100 individuals (100 acinar and 100 duct samples). Initial genetic analyses revealed a diverse ancestry, with the majority of samples being from individuals of European descent. All samples exhibited >10 million mapped (usable) expression reads. Acinar samples were enriched for the expression of pancreatic secretory genes including *CPA1*, *PNLIP*, *PRSS1*, and *CEL*, demonstrating that our cell purification approach successfully separated acinar and duct cells. We performed principal component and hierarchical clustering analyses to identify potentially confounding variables and detect outliers in the expression data. Clustering analysis highlighted distinct cell populations and detected two outlier samples. Factors such as age, gender, BMI, diabetic status, sample source, ethnicity, and RNA quality did not correlate with any sample clusters, though differences in sequencing library preparation methods did. Our study has the potential to identify novel genes and putative regulatory mechanisms underlying PDAC risk with enhanced precision compared to bulk tissue QTL studies. Furthermore, these datasets will serve as valuable resources for annotating non-coding risk loci associated with other pancreatic diseases, including pancreatitis and diabetes.

Session Title: Cancer Poster Session II

PB4988 Characterization of cell free DNA and circulating tumor DNA in a pediatric oncology cohort and implementation into the SickKids Cancer Sequencing (KiCS) precision oncology program.

Authors:

R. Venier, R. Ripsman, R. Khan, A. Huynh, A. Villani, D. Malkin, S. Cohen-Gogo, A. Shlien; The Hosp. for Sick Children, Toronto, ON, Canada

Current survival rates for children and adolescents with newly diagnosed cancer are greater than 80% while survival rates for patients with relapsed, refractory, or metastatic disease are significantly lower. Sensitive methods to monitor disease and identify novel therapeutic targets are key to improving survival for these patients. Studies have shown that cell free (cfDNA) and circulating tumor DNA (ctDNA) analysis from blood, is a promising, non-invasive technique that may improve outcomes for this population. Nonetheless, pediatric cohorts exhibit unique challenges compared to their adult counterparts.

SickKids Cancer Sequencing (KiCS) is a precision oncology program that performs next generation sequencing on samples from pediatric patients with rare or hard-to-cure tumors. We recently described the results of the first 300 KiCS participants (PMID: 36585449), of whom the majority had paired tumor/germline cancer panel testing, whole genome sequencing (WGS) and RNA-sequencing. Thus far, the program has enrolled 594 participants and collected tumor and blood specimens with matched clinical data. Here we describe the implementation of a plasma biobank initiative and cfDNA analysis of a small cohort.

Serial blood samples were collected from patients with cancer at scheduled timepoints, at time of treatment change, or if recurrence was suspected. Blood was separated and banked as plasma and matched cell pellet. cfDNA characteristics were measured using a high sensitivity Bioanalyzer chip. Libraries were generated using a low input kit and WGS (60-80X) was performed. cfDNA data were compared to tumor and germline data from the same patient.

KiCS has banked over 300 plasma samples from more than 100 patients at various timepoints of disease. This pilot study extracted cfDNA from 10 plasma samples. cfDNA fragment size was within the expected ranges for all samples. The concentration of cfDNA in these pediatric samples was comparable to published adult cohorts (average 28.4 ng/ml, median 7.53 ng/ml) though total yield was decreased due to lower collection volumes. Optimization of a low input library preparation method and deep WGS identified expected (tumor-informed) and unique ctDNA variants.

The KiCS program implemented a robust blood collection and cfDNA sequencing workflow within an existing precision oncology program at our institution. We successfully isolated cfDNA from minimal plasma volumes and identified ctDNA variants in patient samples. Further work will focus on optimizing sequencing pipelines. The KiCS program and team are well poised to build upon these data to determine the clinical utility of cfDNA in a large pediatric cancer cohort.

Session Title: Cancer Poster Session III

PB4989 Characterization of cytogenetically cryptic abnormalities in pediatric acute myeloid leukemia by optical genome mapping

Authors:

G. Raca, A. E. Kovach, K. Miller, J. Han, K. Ma, C. Fong, A. Doan, J. Ji, R. Schmidt, D. Bhojwani; Children's Hosp. Los Angeles, Los Angeles, CA

Abnormal gene fusions are predominant oncogenic drivers in pediatric acute myeloid leukemia (AML), and are generated by heterogeneous chromosome rearrangements the majority of which cannot be detected by conventional cytogenetic analysis. RNA-Seq- and panel-based fusion testing are not routinely performed for pediatric AML, and the content of commonly used targeted fusion panels is often biased toward adult cases. To evaluate whether this diagnostic gap can be addressed by optical genome mapping (OGM), a powerful new method for genome-wide high-resolution detection of copy number abnormalities and balanced chromosomal rearrangements, we tested the ability of OGM to identify cytogenetically cryptic fusions in pediatric AML. Retrospective review of 91 pediatric AML cases tested in our laboratory between June 2017 and May 2023 identified 36 cases (39.5%) resolved by karyotype analysis, 12 cases (12.5%) in which the primary driver was a DNA sequence variant, and 29 cases (31.8%) in which the primary genetic subtype remained undetermined after karyotype analysis and clinical molecular testing. Finally, we identified 14 cases (15.3%) in which the CHLA custom sequencing panel (OncoKids®) and/or RNA-Seq fusion assay revealed abnormal fusions which were undetected by karyotype analysis. These included fusions known to be cytogenetically cryptic (*NUP98::NSD1*, n=4; *CBFA2T3::GLIS2*, n=2) as well as fusions typically created by visible translocations that nevertheless remained undetected due to association with either complex or variant chromosome rearrangements (*KMT2A::MLLT10* (n=4), *KMT2A::MLLT3* (n=2), *NUP98-KDM5A* and *KMT2A::AFDN*). To date, OGM is completed in 10/14 fusion positive cases with non-informative karyotype, and could not be performed in 4 cases due to lack of samples (n=2) or poor DNA quality (n=2). OGM analysis successfully revealed all fusions previously detected by OncoKids® and/or RNA-Seq, including *NUP98::NSD1* (n=3), *KMT2A::MLLT10* (n=3), *KMT2A::MLLT3* (n=2) and one case each of *CBFA2T3::GLIS2* and *NUP98::KDM5A.* In 2/29 cases processed to date, which remained unknown after multi-modal clinical testing, OGM revealed *MYB::GATA1* and *ETV6::MNX1* fusions; the analysis is in progress for the remaining 27 unknown cases. OGM also matched the performance of chromosomal microarray (CMA) analysis in detection of copy number variants and revealed the nature and detailed structure of the chromosome rearrangements creating the observed gene fusions. Our preliminary results show potential of OGM to identify clinically significant cryptic fusions in pediatric AML and to thus markedly increase diagnostic yield relative to karyotype analysis.

Session Title: Cancer Poster Session I

PB4990 Characterization of the mutational landscape of metastatic thyroid cancer via targeted next-generation sequencing

Authors:

A. Chung[1], C. Pei-Lung[2], S. Shyang-Rong[1]; [1]Natl. Taiwan Univ. Coll. of Med., Taipei, Taiwan, [2]Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Thyroid cancer patients with distant metastasis contribute to a poor prognosis. Profiling somatic mutations in metastatic thyroid cancer may lay the foundation for cancer treatment and prognosis prediction. We collected samples from 22 thyroid cancer patients with distant metastasis, including 11 cases of papillary thyroid cancer (PTC), 5 cases of follicular thyroid cancer (FTC), 1 case of anaplastic thyroid cancer (ATC), 1 case of medullary thyroid cancer (MTC), 1 case of poorly differentiated thyroid carcinoma (PDTC), and 3 cases of co-existence of two distinct types. We sequenced the tumors from both the primary site and distant metastasis using a 50-gene panel specific to thyroid cancer, which included TERT promoter and noncoding genes GAS8-AS1. Additionally, we used the KAPA hyperPETE lung cancer fusion panel, designed for the detection of 17 fusion genes. We identified hotspot mutations in BRAF and TERT in 12 out of 22 (60%) patients. The frequency of hotspot mutations in BRAF was consistent with previous reports, while the frequency of hotspot mutations in the TERT promoter was higher than previously reported in our cohort, suggesting TERT hotspot mutations may associate with distant metastasis. We observed that hotspot mutations in BRAF and the RAS family were mutually exclusive, and hotspot mutations in BRAF were predominantly found in PTC, whereas hotspot mutations in the RAS family were more prominent in FTC. We compared somatic mutations between the tumor tissue from the primary site and paired distant metastatic sites. We consistently found mutations in BRAF and RAS family genes existing in both the primary and distant metastatic sites, while other mutations were not consistent. Regarding fusion genes, we detected one RNA fusion, PAX8-PPARG fusion, in one case of FTC, which was not detected with any pathogenic variants. In summary, we identified at least one pathogenic somatic event in 20 out of 22 patients (91%). The frequency of hotspot mutations in the TERT promoter was higher than in other reports, suggesting its potential association with distant metastasis. This study provides a comprehensive characterization of metastatic thyroid cancer and its primary and metastatic sites.

Session Title: Cancer Poster Session II

PB4991 Characterization of tumor immune cell infiltration in breast cancer predisposition variant carriers identifies enrichment of tumor-associated macrophages.

Authors:

R. Kelly[1,2], Y. Liu[2], A. R. Harris[1,3], C. Peng[4], Y. J. Heng[5], G. M. Baker[5], D. G. Stover[6,7], R. Tamimi[8], P. Kraft[2,9]; [1]Cancer Prevention Fellowship Program, Natl. Cancer Inst., Rockville, MD, [2]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA, [3]Integrative Tumor Epidemiology Branch, Dept. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., Rockville, MD, [4]Channing Div. of Network Med., Dept. of Med., Brigham & Women's Hosp., Boston, MA, [5]Beth Israel Deaconess Med. Ctr., Harvard Med. Sch., Boston, MA, [6]Div. of Med. Oncology, Stefanie Spielman Comprehensive Breast Ctr., Ohio State Univ. Comprehensive Cancer Ctr., Columbus, OH, [7]Dept. of BioMed. Informatics, Ohio State Univ., Columbus, OH, [8]Dept. of Population Hlth.Sci., Weill Cornell Med., New York, NY, [9]Trans-Div.al Res. Program, Natl. Cancer Inst., Rockville, MD

Despite improvements in overall survival, breast cancer remains a major cause of cancer mortality and incidence is increasing in the United States. Roughly 5% of breast cancer patients have a pathogenic germline genetic variant that is associated with increased risk of breast cancer. Mutations in > 25 genes have been associated with hereditary breast cancer, many of which are involved in genome stability pathways including DNA double-strand break (DSB) repair. In addition to roles in both carcinogenesis and treatment response, the DSB DNA damage response in tumor cells promotes their crosstalk with immune cells in the tumor microenvironment. We hypothesized that DSB repair-related variant carriers may share common characteristics in the immune microenvironment of their tumors that are distinct from non-carriers. Here, we performed transcriptomic analyses of 362 incident breast cancer cases from the Nurses' Health Study (NHS) I and II, including 26 with germline DSB repair-related pathogenic variants in *ATM, BLM, BRCA1, BRCA2, BRIP1, CHEK2, FANCC, FANCM, NBN, RAD50, RAD51C,* and *RECQL*. Gene expression-based cell mixture deconvolution algorithm CIBERSORTx was applied to tumor microarray data to infer the abundance of 22 immune cell types. Immunohistochemical (IHC) staining for four immune cell markers (CD4, CD8, CD20, and CD163) was used to assess immune cell infiltration in a subset of 55 participants. We observed a significant, positive association between carrier status and M1 macrophage infiltration using multivariable linear regression adjusted for age at diagnosis, tumor stage, estrogen receptor, and the top four genetic principal components (change in mean abundance: 0.0195 [0.0091, 0.0299], p = 0.0003). Carriers also showed significantly higher infiltration of CD163+ cells in our subset of participants for whom IHC data was available (Wilcoxon p = 0.0024), suggestive of M2 macrophages. Abundance of these M2 macrophages was highly correlated with that of inferred M1 macrophages (Spearman's rho = 0.5079, p = 7.56E-05), suggesting that carrier status may be associated with increased abundance of both classically and alternatively activated macrophages in their breast tumors. Our results suggest that breast tumors of DSB repair-related pathogenic variant carriers may possess a distinct immune landscape, which may have broader therapeutic implications in this high-risk population.

Session Title: Cancer Poster Session III

PB4992 Characterizing novel fusion proteins in Acute Megakaryoblastic Leukemia (AMKL)

Authors:

A. Perreault, M. Josling; Elon Univ., Elon, NC

Phase separation is the biophysical process of macromolecule condensate formation through interactions between proteins and nucleic acids. Recent literature has suggested that fusion proteins differentially phase separate, causing dysfunctional chromatin organization that can lead to diseases, such as cancer. Importantly, these phase separation-induced chromatin contacts are independent of the canonical proteins necessary for forming chromatin loops, such as CTCF and cohesin. Therefore, gaining a deeper understanding of the structure and function of fusion proteins and how they contribute to impaired gene expression that leads to disease is critical. Using data and tools available on the St. Jude Cloud Genomics Platform, we have identified and characterized fusion proteins found in Acute Megakaryoblastic Leukemia patients. Since intrinsically disordered regions (IDRs) are thought to be the driving force of phase separation capabilities of proteins, IUPRED3 was leveraged to further investigate features of the candidate fusion proteins.

Session Title: Cancer Poster Session I

PB4993 Characterizing selection signatures in coding and noncoding regions of 14,886 cancer genomes

Authors:

M. Zheng[1], S. Xiwei[1,2], Y. Jian[1,2]; [1]Westlake Univ., Hangzhou, China, [2]Westlake Lab. of Life Sci. and Biomedicine, Hangzhou, China

Natural selection plays a crucial role in cancer development, yet the extent of selection within the noncoding cancer genome remains largely unknown. Here, we developed a novel approach that integrates functional impact scores into the dN/dS framework, broadening the identification of selection signals to include not only coding regions but also the entirety of the genome. We applied our method to whole-genome sequencing (WGS) data from 14,886 cancer patients, revealing pervasive signatures of negative selection throughout the genome and co-occurrence of negative and positive selection signals in specific genomic regions. We identified 585 positively selected genes with an FDR < 0.05, of which 81% (474/585) have not been previously reported. Among the 111 known driver genes, 84.7% (94/111) are supported by additional selection signals in noncoding elements of the corresponding genes, suggesting a convergence of functionality between coding and regulatory variants in cancer pathogenesis. Moreover, we discovered a cluster of negatively selected genes enriched in essential and cancer-dependent genes, reflecting the vital roles these genes play in survival and proliferation of cancer cells. Taken together, our findings provide new insights into the role of selection during cancer cell evolution and present an extensive compendium of putative driver genes and noncoding elements with potential therapeutic target applications.

Session Title: Cancer Poster Session II

PB4994 Circulating LINE-1 and MicroRNA Profiles in Plasma Exosomes of Non-Small Cell Lung Cancer Patients Correlate with Histological Subtype, Early Diagnosis, and Clinical Prognosis: Implications for Precision Oncology

Authors:

A. Hassanin[1,2], K. Ramos[1]; [1]Texas A&M Inst. of BioSci.s and Technology, Houston, TX, [2]2Dept. of Animal Wealth Dev., Faculty of Vet. Med., Suez Canal Univ., Ismailia, Egypt

Liquid biopsy can provide insights into a patient's cancer status at successive time points, an essential domain for monitoring temporal tumor burden and early detection of tumor recurrence and treatment resistance. Extracellular vehicles, a new liquid biopsy analyte, are gaining growing interest in thoracic oncology as increased exosome levels have been detected in the body fluids of individuals with lung cancer. In the present study, we evaluated LINE-1 retrotransposon and microRNA profiles in plasma-derived exosomes from patients with non-small cell lung cancer (NSCLC). Both LINE-1 and a panel of eight miRNAs, namely, miR-21-5p, miR-126-3p, miR-210-3p, miR-221-3p, Let-7b-5p, miR-146a-5p, miR-222-3p, and miR-9-5p, were expressed early in NSCLC development in male and female patients with squamous cell lung cancers (SQCLC) and lung adenocarcinomas (LUAD), including metastatic tumors. Patterns of expression correlated closely with clinicopathological characteristics, which combined with ROC curve analyses, established the utility of LINE-1 levels in distinguishing tumor types, as well as the superior diagnostic performance of four miRNAs compared to single miRNA analytes. Ten genes within a discretized LINE-1 oncogenic regulatory network were validated as downstream targets of the eight plasma-derived exosomal miRNAs, confirming postulated mechanisms by which LINE-1 retrotransposons influence the occurrence of NSCLC. We conclude that measurements of the LINE-1 and miRNA load in plasma-derived exosomes from NSCLC patients may serve as precision-based, non-invasive, liquid biopsies for early diagnosis and clinical evaluation of NSCLC.

Session Title: Cancer Poster Session III

PB4995 *Cis*- and *trans*-eQTL TWAS of breast and ovarian cancer identify more than 100 risk genes in the BCAC and OCAC consortia.

Authors:

T. Head[1], F. Dezem[2], J. Plummer[2], A. Todor[1], J. Yang[1], S. Gayther[3], S. Kar[4], J. Schildkraut[1], M. Epstein[1]; [1]Emory Univ., Atlanta, GA, [2]St. Jude Children's Res. Hosp., Memphis, TN, [3]Cedars Sinai Med. Ctr., Los Angeles, CA, [4]Univ. of Cambridge, Cambridge, United Kingdom

Genome-wide association studies (GWAS) have identified numerous common risk variants for breast and ovarian cancer, with most GWAS-derived risk variants lying in non-coding regions of the genome. This has spurred considerable interest in transcriptome-wide association studies (TWAS) that aim to investigate how genetically regulated transcriptional activity plays a role in both the shared and distinct etiologies of these two complex diseases. However, the TWAS methods utilized to date have only considered the regulatory effects of variants located close to the target gene (*cis*-SNPs). With growing evidence for non-trivial distal regulatory effects of common variants (*trans*-SNPs) on gene expression, we performed TWAS of breast and ovarian cancer using a recently proposed Bayesian genome-wide method (BGW-TWAS) that incorporates both *cis*- and *trans*-expression quantitative trait loci (eQTL). We used whole genome sequencing and RNA sequencing data in breast and ovarian tissue from the Genotype-Tissue Expression Project V8 to train genome-wide gene expression imputation models with BGW-TWAS. We then used these imputation models to perform a TWAS on large-scale GWAS summary statistic data from the Breast Cancer and Ovarian Cancer Association Consortia (BCAC and OCAC) to identify genes whose genetically predicted expression levels are associated with risk of breast cancer overall, five breast cancer subtypes (luminal A-like, luminal-B like, luminal B/HER2-negative-like, HER2-enriched-liked, triple-negative), non-mucinous epithelial ovarian cancer, and five ovarian cancer histotypes (high grade serous, low grade serous, mucinous, endometrioid, clear cell). We identified 101 significant genes across breast cancer phenotypes and 8 across ovarian cancer phenotypes. These loci include several novel loci such as *ACAP3* (overall breast cancer risk) whose associations are predominantly driven by *trans*-eQTL effects. These *trans*-driven genes were not identified by a competing TWAS approach that considered *cis*-eQTL only. We replicated several gene associations for breast phenotypes using summary statistics from an independent GWAS of these cancers. We further used genotype and gene expression data in both normal breast and tumor tissue from the Cancer Genome Atlas to explore the robustness of our genome-wide imputation models. Results provide further insight into the complex genetic architecture underlying risk of breast and ovarian cancer subtypes. Efforts to validate top *trans*-eQTL using genome-wide chromatin interaction data are ongoing.

Session Title: Cancer Poster Session I

PB4996 Clinical consequences of a genetic predisposition toward higher benign prostate-specific antigen levels

Authors:

M. Shi[1], J. Shelley[2], K. Schaffer[1], J. Tosoian[1], M. Bagheri[1], J. Witte[3], L. Kachuri[4], J. Mosley[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Vanderbilt Univ. Sch. of Med., Nashville, TN, [3]Stanford Univ., Stanford, CA, [4]Stanford Univ., San Francisco, CA

Background: Prostate-specific antigen (PSA) is a screening biomarker for prostate cancer, and a PSA>4 ng/mL may prompt a diagnostic evaluation to look for cancer. PSA levels are influenced by genetic variation unrelated to prostate cancer risk. We leveraged the VUMC biobank (BioVU) data to investigate whether a genetic predisposition to a higher PSA influences diagnostic assessments and outcomes. **Methods:** We developed a polygenic score (PGS) comprising 111 SNPs associated with PSA levels, but not with prostate cancer risk after accounting for selection bias due to screening. We curated two cohorts of male participants ages 45-70 years without a history of prostate cancer. The "biopsy cohort", comprised 468 men (407 European [EA] and 61 African [AA] ancestry) who underwent a first prostate biopsy for an elevated PSA, was used to test PGS associations with prostate cancer detection on biopsy. The "longitudinal cohort" was used to evaluate incident clinical outcomes associated with the PGS, and comprised 3,110 (2,118 EA and 992 AA) men with a baseline PSA<4 ng/mL undergoing routine PSA screening. Multivariable Cox proportional hazards models were used to test whether the PGS was associated with an incident: 1) PSA value>4 ng/mL, 2) International Classification of Diseases (ICD) code for an elevated PSA, 3) encounter with a urologist, or 4) prostate biopsy. Analyses were stratified by age (45-59 years and 60-70 years). Association estimates were per standard deviation increase in the PGS. **Results:** In the biopsy cohort, prostate cancer was identified on biopsy in 236 men (50%), of which 108 (23%) had a high grade (GG≥2) cancer. The PGS was significantly inversely associated with the outcome of detecting any prostate cancer (OR=0.77 [95% CI, 0.62 - 0.95], p=0.02) and high-grade cancer (OR=0.70 [0.55 - 0.89], p=0.004) on biopsy. In the longitudinal cohort, 2,118 (68%) participants were aged 45-59 years and the median (IQR) baseline PSA level was 1.0 (0.6 - 1.7) ng/mL. Among men 45-59 years, the PGS was associated with a PSA>4 (hazard ratio [HR]=1.35 [95% CI, 1.17-1.57], p=4.5x10-5), a clinical diagnosis of an elevated PSA (HR=1.30 [1.12-1.52], p=8.0x10-4), an evaluation by a urologist (HR=1.34 [1.14-1.57], p=4.8x10-4), and undergoing a prostate biopsy (HR=1.35 [1.11-1.64], p=0.002). Among men 60-70 years, association effect sizes were attenuated and not statistically significant. **Conclusions:** A polygenic predisposition toward higher benign PSA levels was associated with a decreased likelihood of detecting prostate cancer on biopsy, but an increased likelihood of undergoing a diagnostic evaluation including invasive procedures for an elevated PSA among 45-59 years.

Session Title: Cancer Poster Session II

PB4997 Clinical usefulness of multi-gene panel testing in hereditary cancer analysis in Japan

Authors:

M. Yoshida, E. Takamine, M. Egawa, H. Kohbata, M. Komine, S. Takahashi, Y. Ebana; Tokyo Med. and Dental Univ., Tokyo, Japan

Introduction: Multi-gene panel testing (MGPT) is now major genetic testing used in hereditary cancer in the US. However, single gene testing (BRCA1/2, RB1, MEN1, TSC1/2, and RET) is still predominate in Japan partly due to the national universal health insurance that covers around 70% of the medical costs. We thus decided to demonstrate the clinical usefulness of MGPT in hereditary cancer analysis in Japan to see if it would be feasible and acceptable in the Japanese genetic medicine environment. **Method:** Participants were recruited at the genetics department from January 2019 to September 2022 at the TMDU hospital, Kameda General Hospital and Kameda Kyobashi clinic. Those who were suspected of high risk of hereditary cancer by the physicians at the genetics department were eligible regardless of their personal cancer history. Informed consent was obtained prior to the testing. Two different sizes of MGPT were included (47 or 84 genes) in the study and either size was chosen based on the participants' personal and family history. The test fee was paid by the participants since the Japanese universal health insurance does not cover MGPT for hereditary cancer. **Results:** A total of 94 people aged between 0 and 89 participated in the study. Of those, 56 and 38 underwent the 47-gene panel and the 84-gene panel respectively. For the 47-gene panel, 16 participants (28.5%) had positive results. At least one variant of uncertain significance (VUS) was detected in 36 participants (64.2%) and, among them 26 participants (46.4%) had only VUSs for the initial test reports. For the 84-gene panel, seven participants (18.4%) had positive results and 27 (71.1%) participants had at least one VUS, with 25 (65.5%) of which had only VUSs for the initial test reports. In total, seven variants were updated later with four being likely benign or benign from VUS, and two being pathogenic from likely pathogenic. The genes which came back with positive results were ATM, BRCA1, BRCA2, CDH1, MLH1, MSH2, MSH6, PALB2, PTEN, RAD50, RAD51D, RECQL4, TP53, VHL. The turnaround time which included shipping from Japan to San Francisco ranged from 6 to 40 days with a median of 10.5 days. **Discussion:** Our findings demonstrate that MGPT in Japan is as acceptable and useful as in other countries, despite its unique national health insurance constraints. However, the VUS rate was over 64% even with the smaller panel. Therefore, it is important for genetic professionals to explain carefully to clients what VUSs mean and how they are treated.

Session Title: Cancer Poster Session III

PB4998 Clonal dynamics of *TP53* mutations in male germline cells and implications for inheritance

Authors:

R. Sanghvi[1], M. Neville[1], A. Lawson[1], P. Nicola[1], F. Abascal[1], T. Bayzetinova[1], M. Jorgensen[2], R. Rahbari[1]; [1]Wellcome Sanger Inst., Hinxton, United Kingdom, [2]Great Ormond Street Hosp., London, United Kingdom

The origin of heritable genetic variation and disorders lies in mutations that occur in the germline. To understand evolution and disease, it is crucial to comprehend the mechanisms behind germline mutations and the selection pressures that shape them. Inherited cancers play a major role in about 5 to 10 percent of all cancers and exert a devastating toll on the probands, the wider families and future generations. Li-Fraumeni Syndrome (LFS) is an inherited, autosomal-dominant cancer predisposition syndrome caused by a mutated *TP53* gene, leading to a high risk of wide-spectrum of tumours presenting throughout different stages of life.

Approximately 7-20% of germline mutations in *TP53* in individuals with LFS occur *de novo* in the germ cells of the parents, with the remainder following typical patterns of maternal or paternal inheritance. In this study, we analysed whole genome sequences from the nuclear families (parents and offsprings) diagnosed with Li-Fraumeni syndromes. We found 25% of cases are through *de novo* mutation in *TP53*, while the rest were inherited. We identified a median of 83 mutations per LFS child (ranging from 51 to 116) correlating with parental age at birth and in line with the previously published trio studies. Mutational signatures were consistent with previously reported germline signatures i.e. SBS1 and SBS5 (with median contributions of 15% and 85% respectively). Additionally, we investigated the mutational landscape and clonal dynamics of mutant *TP53* in sperm of the fathers (age ranging from 34 to 62 years-old) in the *de novo* LFS subset, using a deep targeted sequencing. In the majority of sperm samples we did not observe any expansion of pathogenic *TP53* except in one father in whom we observed 2.5% of sperm had pathogenic *TP53*, p.V272M.

These findings have important implications for genetic counselling on recurrence risks for families with LFS caused by *de novo* mutations. Understanding the degree of penetrance and cause of *de novo* mutations in *TP53* in germline cells will help develop prevention strategies for cancer predisposition syndromes in offspring.

Session Title: Cancer Poster Session I

PB4999 Clonal hematopoiesis, the aging genome and mantle cell lymphoma.

Authors:

H. Hill[1,2], P. Jain[2], C. Y. Ok[2], S. Vinay[1], M. Wang[2], M. Kimmel[1], K. Chen[2]; [1]Rice Univ., Houston, TX, [2]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Clonal hematopoiesis of indeterminate potential (CHIP) describes clonal expansion of hematopoietic stem cells which contribute to distinct mutations and are found in pre-malignant and malignant states. Hemopoietic cells are found in the blood and bone marrow, but infiltrate all tissues. CHIP is thought to be a process of the aging genome. However, the prevalence of CHIP mutations is linked to cardiovascular disease, myeloproliferative disease and various cancer types independent of age.

Mantle cell lymphoma (MCL) is a rare, incurable type of B-cell lymphoma. MCL occurs frequently in older individuals with a median age of diagnosis of 69 years. Males are disproportionately affected; the male-to-female ratio of MCL diagnosis is approximately 4:1.

We identified seven CHIP related mutations (*TET2*, *DNMT3A*, *GNAS*, *ASXL1*, *JAK2*, *SF3B1*, *PPM1D*) in pre-treatment MCL patient (n=253) samples using targeted NGS sequencing of peripheral blood, bone marrow, lymph node and gastrointestinal biopsies. Clinical, cytogenetic and environmental features were extracted from electronic health records (EHR) for correlative studies.

Of the full cohort, 28.06% (n=71) had one or more CHIP variant: *TET2* (30%, 51 nonsynonymous variants/170 tested), *ASXL1* (11.2%, 19/170), *JAK2* (5.2%, 9/173), *DNMT3A* (3.5%, 6/173), *SF3B1* (1.2%, 3/259), and *GNAS* (1.2%, 2/173). *GNAS* and *JAK2* mutations were found only in peripheral blood and bone marrow, however enrichment of mutations in any sample type was not significant. Three patients had identical CHIP variants observed in more than one sample type. It's unknown if these were germline variants or clonal somatic mutations. CHIP variants were represented in population databases with population allele frequency (PAF) ranging from <1-10%. However, several mutations were identified that weren't in any databases or associated with pathogenicity. Two genes had congruent mutations occurring in more than one MCL patient (*GNAS:* c.602G>A and *JAK2*: c.1849G>T).

We filtered CHIP mutations by PAF in public genome databases and designated them "somatic or of unknown origin". These mutations were associated with age ($p < 0.01$) and progression-free survival (Log-Rank, $p = 0.045$). Patients with these mutations were also more likely to have had prior cancer diagnoses (OR = 3.33, p=0.014). In a Cox regression model, *TP53* mutations and chromosome 13 deletions were also significant in predicting PFS. CHIP mutations were reflected in the AACR Project GENIE database in MCL patients (n=453): *TET2* (4.5%), *DNMT3A* (4.3%), *SF3B1* (2.0%) *and ASXL1*(0.4%). This and other databases will be used for meta-analyses and comparative studies with our patient cohort.

Session Title: Cancer Poster Session II

PB5000 Combatting cisplatin resistance through induced gene expression changes: Trichostatin A as a candidate.

Authors:

B. Waldmann, A. Stark; Univ. of Notre Dame, Notre Dame, IN

One of the main challenges in treating cancer is how cancer cells have an ability to resist treatment. Some cancer cells do this through intrinsic resistance while others develop resistance over time. One particular chemotherapeutic agent, cisplatin, is vulnerable to both acquired and intrinsic resistance. To counter the induced expression changes by the cancer cells, other drugs can be combined with cisplatin to diminish chemoresistance. One such drug: Trichostatin A, has been considered in combination treatment with cisplatin for increased effectiveness. Trichostatin A is a HDAC inhibitor which helps reduce cancer proliferation by causing an increase in accumulation of acetylated histones. One important protein to the proliferation of cancer cells in HIF-1α. HIF-1α is crucial to chemoresistance of several cancer lines (including breast cancer) as it plays a key role in cancer cell survival. Trichostatin A, at a concentration of 100nM, was found to effectively reduce HIF-1α expression in MCF-7 cancer cells. Trichostatin A treatment of MCF-7 cells led to a reduction of expression of 8.9% (16 hours), 26.5% (39 hours), and 41.1% (63 hours). Trichostatin A's ability to reduce the expression of HIF-1α suggests a promising avenue to combat chemoresistance to cisplatin treatment. Further evaluation of additional candidates, time course, and synergistic effects with cisplatin treatment are currently ongoing. The goal is to decrease cancer cell's chemoresistance to cisplatin by using induced gene expression, which may have broad applications to other chemotherapeutic agents.

Session Title: Cancer Poster Session III

PB5001 Common and distinct patterns of acquired uniparental disomy and homozygous deletions between lung squamous cell carcinomas and lung adenocarcinoma,

Authors:

M. Tuna[1], G. B. Mills[2], C. I. Amos[1]; [1]Baylor Coll. of Med., Dan L Duncan Inst. for Clinical and Translational Res., Houston, TX, [2]Oregon Hlth.& Sci. Univ., OHSU Knight Cancer Inst., Portland, OR

Acquired uniparental disomy (aUPD) is a form of allele-based alteration that can lead to homozygosity of existing aberrations. We used data from The Cancer Genome Atlas SNP-based arrays to identify distinct and common aUPD profiles for LUAD and LUSC and their impact on homozygous deletion (HD), overall survival (OS), and recurrence-free survival (RFS). Overall, we found significantly higher aUPD (q = 5.34E-09) in LUSC than in LUAD. A significant portion of HD was due to aUPD in LUSC (24.9%) and LUAD (19.7%). We identified segmental, whole-chromosome arm and whole-chromosome aUPD, in which whole 7p arm aUPD was restricted to LUSC, while whole-chromosome 3 aUPD was observed only in LUAD, and whole-chromosome 21 aUPD was common to both LUSC and LUAD. The most frequent aUPD and HD were observed at *CDKN2A/B* region in both LUAD and LUSC. In LUAD, aUPD and HD at *CDKN2A/B* region were associated with shorter OS ($q < 0.021$ and $q < 0.005$), and RFS ($q < 0.005$ and $q < 0.005$), while heterozygous deletion was not associated with OS and RFS. In contrast, no association was found between aUPD at *CDKN2A/B* region and survival in LUSC. CTL4A expression was significantly lower in samples with aUPD at *CDKN2A/B* regions than in samples without copy number and allele-based changes in LUAD. Immune infiltration correlates with whole-chromosome *q*-arm or whole chromosome aUPD in LUAD. Both LUSC and LUAD have common and distinct patterns of aUPD regions with differing frequencies of occurrence and associations with outcome.

Session Title: Cancer Poster Session I

PB5002 Comparing Breast Cancer Medical History between Participants surveys and Electronic Health Records in All of Us Research Program

Authors:

L. Bastarache[1], E. Venner[2], L. Sulieman[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]HGSC - Baylor Coll. of Med., Houston, TX

About 55-72% and 45-69% women carrying BRCA1 and BRCA2 variants will be diagnosed with breast cancer (BC) by age of 70-80. Electronic health records (EHR) linked to genetic data can be used to measure the penetrance of genetic variants, including BRCA, by computing the percentage of patients with a pathogenic variant and BC diagnosis. However, EHR is an imperfect medical history source, as they are subject to missingness and fragmentation leading to underestimating the true penetrance of a genetic variant.
Surveys offer alternative ways of collecting patients/participants' medical history (PRMH). Prior work showed disagreement between EHR and surveys; patients with a diagnosis record in EHR do not always report that diagnosis in a survey, and vice versa. More research is needed to know 1) how EHR missingness affects penetrance estimate 2) how to use PRMH with EHRs to ascertain diagnosis more accurately.
To address the knowledge gap, we compared BC history (BCH) between EHR and PRMH in BRCA carriers in the All of Us Research Program, a national initiative to collect longitudinal biomedical data from historically underrepresented populations. We assessed EHR BC missingness in female participants who had BRCA mutations by comparing EHR to PRMH. In latest release (CDR-7), we identified female participants with pathogenic/likely pathogenic BRCA variants, extracted EHR BC diagnosis codes, and identified female participants who reported BCH in medical history survey (MHS). CDR-7 had 248135 female participants, 145563 females had genome data, 52% were white. Among those, 709 and 2447 had BRCA1 and BRCA2 variants, with 48.6 as mean age. 50115 females filled MHS (mean age 49.2) where 10418 (20.8%) reported BCH.
In BRCA1 cohort, we found substantial discordance between BCH in MHS and EHR. Of 189 participants who completed MHS, 94 (49.7%) reported BCH. 46 (48.9%) participants reported BCH but lacked EHR BC codes. In BRCA2 cohort, 527 filled MHS and 180 (34.1%) confirmed BCH where 81 participants reported BCH and had BC codes, while 99 (55.0%) confirmed BCH and lacked EHR BC codes. In BRCA1 and BRCA 2, 13 and 32 participants had EHR but didn't report BC in MHS.
Our results show that BC prevalence in participants with BRCA mutations is slightly lower than nationally reported values possibly due to either having PRMH for a subset of participants or lower age at enrollment (<50 years on average). Almost half of participants who reported BCH lacked EHR BC codes. EHR missingness is a major issue that can bias genetics studies if not controlled properly. We showed possible use of genetic variants to quantify EHR missingness. Moreover, PRMH represent valuable source to estimate accurate penetrance.

Session Title: Cancer Poster Session II

PB5003 Comprehensive germline and somatic testing for precision risk-assessment for children with retinoblastoma and their siblings

Med., Inst. of Biomedicine, Univ. of Gothenburg, Gothenburg, Sweden, [13]Dept. of Clinical Genetics and Genomics, Sahlgrenska Univ. Hosp., Gothenburg, Sweden, [14]Dept. of Med. Huddinge, Ctr. for Hematology and Regenerative Med., Karolinska Inst.t, Stockholm, Sweden

Background: Retinoblastoma (Rb) is a rare form of eye cancer that mainly affects children under the age of 5 years. Hereditary Rb is caused by germline disease-causing variants (DCVs) in the tumor suppressor RB1, which is also inactivated in non-hereditary cases. Not all germline DCVs are detected by current genetic tests, so siblings of a proband with Rb without detected germline *RB1* DCVs require intensive ocular surveillance due to residual risk. As part of the prospective nationwide Genomics Medicine Sweden childhood cancer initiative, a universal testing strategy, including germline and tumor DNA whole genome sequencing (WGS), has been offered to all children with solid malignancies at diagnosis and relapse since 2021 to refine diagnosis, individualize treatment and surveillance as well as enable identification of at-risk relatives. This study presents our genetic results for children with Rb.
Methods: Thirteen children between 3 months and 4 years old, diagnosed with Rb (unilateral n=12, bilateral n=1) at St. Erik Eye Hospital in Stockholm, underwent germline WGS (gWGS) between May 1, 2021 and April 30, 2023. The gWGS data were analyzed with an *in silico* childhood cancer predisposition gene panel (n=189), including the *RB1* gene. WGS from fresh frozen tumor tissue (tWGS) was performed on 5 cases, while exome sequencing was performed on 5 other cases for which only formalin-fixed paraffin-embedded tumor samples were available. In the remaining 3 cases, tumor material was not available.
Results: We identified 6 patients with a germline finding in *RB1*. No germline DCV was detected in the other 188 genes. Of the 7 patients without germline *RB1* DCV, 5 had somatic mutations in both alleles of *RB1*. All cases had at least one somatic aberration of a structural type. Cases with two somatic *RB1* mutations without germline DCV were considered sporadic or potentially low-grade mosaic. In total 5 of the 13 cases did not confer risk for siblings, who could therefore avoid intensive surveillance. All findings were discussed at multidisciplinary rounds and reported to the treating physicians. We also offered genetic counseling to the families.
Conclusion: Overall, gWGS, combined with patient-matched tWGS, allows characterization of *RB1* variants, providing precise risk assessment for children with Rb and carrier testing of parents and future offspring. This approach also identifies at-risk siblings within the family and reduces unnecessary surveillance for existing or future siblings in cases where 2 somatic, and no germline, hits in *RB1* are detected. Our results highlight the effectiveness of paired germline-tumor analysis when interpreting germline and somatic variants in Rb.

Session Title: Cancer Poster Session III

PB5004 Computational epigenetic analysis of colorectal cancer identifying Key regulators of genomic and transcriptional dysregulation with chip-seq method.

Authors:

M. HABIBI[1], K. GHDIRA[2]; [1]Faculty of medicine od Tunis (TUNISIA), Ben Arous, Tunisia, [2]Inst. pasteur of tunis, Tunis, Tunisia

Colorectal cancer (CRC) is one of the most prevalent malignant tumors worldwide, characterized by diverse clinical phenotypes and responses to current treatments. The considerable heterogeneity between patients is one of the most important features of CRC. Efforts have been made in recentyears to genetically and phenotypically classify genetically and phenotypically diverse CRC tumorsinto distinct molecular subtypes based on gene expression profiling. Epigenetic dysregulation hasbecome a paradigm of cancer biology that underlies the characteristics of cancer cells. Globalchanges in DNA methylation, chromatin states, and cis-regulatory elements, as well as geneticaberrations in chromatin proteins, characterize more than 50% of human cancers.The identification of precise activators via global mapping of histone modifications contributes tothe cellular reprogramming towards tumor growth and metastasis, making activator dysfunction apromising diagnostic biomarker and potential therapeutic target. A systematic study of chromatinmodifications in cancer and pioneering reports on the molecular mechanisms underlyingtranscriptional addiction have begun to emerge. However, defining the chromatin states thatcharacterize human pathology remains a challenge, partly due to the limited number of cellsavailable from primary tumors. Another critical problem in the study of the epigenetic profiles ofindividual tumors is the use of appropriate research platforms that capture the intrinsic profiles ofcancer cells.In this study, we aim to develop a computational pipeline for epigenetic analysis of genomic andepigenetic events mediating colon cancer and provide clues on the main regulators that orchestrategenomic and transcriptional dysregulation on which cancer cells in colorectal cancer depend. Toachieve this goal, we will identify significant transcription factors relevant to colorectal cancer andexamine the different levels of variation as well as study the variation in copy number and DNAmethylation of these factors. We will also identify potential cis-regulatory non-coding RNAs andnon-coding RNAs that regulate transcription factor activity. Using ATAC-Seq and ChIP-Seqprofiles, we can detect target genes to infer intrinsic associations of target genes based on Bayesiannetworks. We aim to identify potential biomarkers, if possible. The bioinformatics approach ofChIP-Seq will be used to study the interaction between proteins and DNA.

Session Title: Cancer Poster Session I

PB5005 Contribution of Driver Genes in Classical Myeloproliferative Neoplasms (MPNs): Report from developing country

Authors:

M. Rashid[1], R. Ahmed[2], U. Zaidi[1], T. Shamsi[1]; [1]NIBD, Karachi, Pakistan, [2]Univ. of Karachi, Karachi, Pakistan

Background: Classical Myeloproliferative neoplasms (MPNs) are characterized by excessive production of terminally differentiated blood cells that are fully functional. The genetic landscape of MPNs is in large part elucidated. **Materials & Methods:** Total 133 MPNS patients, including 40 polycythaemia vera (PV), 50 essential thrombocythaemia (ET) and 43 primary myelofibrosis (PMF) were investigated for the presence of *CALR* exon 9 by Sanger sequencing and *JAK2*V617F mutations by ARMS-PCR. **Results:** *JAK2*V617F mutation was found significantly (P-value = 0.000) more common in PV (72.5%; 29/40) then in ET (42%; 21/50) and PMF (23.2%; 10/43). Mutations in *CALR* exon 9 were found significantly (P-value = 0.000) more common in ET than PMF with frequencies 38% (19/50) and 20.9% (9/43), respectively whereas absent in PV (0/40). Incidence of *CLAR* mutation in non-*JAK2*V617F mutated ET and PMF combine was 43.5% (27/62), where in ET it was 62% (18/29) and in PMF it was 27.2% (9/33). In PV *JAK2*V617F mutated patients were significantly older than wild type patients and had high platelets count. In ET significantly (P value = 0.009) high platelet count (1272 x 10^9/L mean ±615 SD) and low leukocyte count (8.4 x 10^9/L mean±2.7 SD) (P value = 0.017) were seen in *CALR* mutated ET as compare to wild type. In PMF significantly (P-value = 0.009) high Hb (11 g/dl mean±1.3 SD) and high platelets count (472 x 10^9/L mean ±432 SD) (P value = 0.005) were observed in *CALR* mutated PMF than wild type. **Conclusion:** This study emphasizes on molecular diagnostic approach to adopt in classical MPNs.

Session Title: Cancer Poster Session II

PB5006 Copy Number Variations (CNVs) Contribute to Malignant Tumors Development in Birth Defects Children

Authors:

Y. Liu[1], J. Glessner[2], H. Qu[3], X. Chang[1], H. Qiu[4], T. Wang[1], K. Nguyen[2], F. Mentch[3], X. Wang[2], A. Saeidian[5], D. Watson[3], H. Hakonarson[3]; [1]Children's Hosp. of Philadelphia, Philadelphia, PA, [2]Children s Hosp. of Philadelphia, Philadelphia, PA, [3]Children's Hosp. of Philadelphia, Philadelphia, PA, [4]Children's Hosp. of Philadelphia CHOP, Philadelphia, PA, [5]The children's Hosp. of philadelphia CHOP, Philadelphia, PA

There are two key signatures of pediatric cancers when compared to adults: higher prevalence of germline alterations and heterogeneity in the alteration types. Recent population-based assessments have demonstrated that children with birth defects (BD) are more likely to develop cancer even without chromosomal anomalies; therefore, explorations of genetic alterations in BD children with cancers could provide insights into the underlying mechanisms for pediatric tumor development. In this study, we performed whole genome sequencing (WGS) on blood-derived DNA samples from 1566 individuals without chromosomal anomalies, including 454 BD probands with at least one type of malignant tumor, 767 cancer-free BD children, and 345 healthy individuals, focusing on copy number variations (CNV), one of the most important structural alternations observed in cancer. Roughly half of the BD-cancer children have CNVs that are not identified in BD-only/healthy individuals, and those CNVs are not evenly distributed among the patients. Strong heterogeneity was observed, given that only a few cancer predisposition genes contain CNVs in more than three patients, including deletions in KCND2, SDK1, SP4, and duplications in NEURL1B. Moreover, functional enrichment of genes harboring CNVs show that a large number of patients cluster on the same biological pathways, such as deletions of genes with neurological functions, and duplications of immune response genes. Phenotype clustering uncovered recurrences of patients with sarcoma, such as tumors in bones or soft/connective tissues. A notable observation is that non-coding RNAs, including microRNAs and long non-coding RNAs (lncRNAs), which we identified as gene regulators, show strong signals related to growth and cancer regulations in functional enrichment analysis. In conclusion, we conducted one of the first genomic study to explore the impact of CNVs in cancer developments in children with BD, providing new insights into the underlying biological processes, especially the impact CNVs play in regulating non-coding RNAs.

Session Title: Cancer Poster Session I

PB5008 Deciphering anti-ovarian cancer associated mechanistic regulatory pathways of indigenous Saudi Arabian plants using transcriptomic systems biology and bioinformatics approaches

Authors:

A. Alblihy; KFSC, Riyadh, Saudi Arabia

Ovarian cancer (OC) is the deadliest cancer among women and ranks fourth among all fatal diseases in women. In 2019, the estimated number of new cancer cases was 222,240 and the number of deaths was approximately 14,170. Previous research has suggested that prolonged use of unopposed estrogen and estrogen plus progesterone is associated with an increased risk of OC, particularly in menopausal women. The lack of efficient early detection methods, increased chemotherapy resistance, and the heterogeneity of the disease all contribute to the poor prognosis of most OC cases. Therefore, it is crucial to develop safer and more effective therapeutic strategies to improve the survival rate of women with OC. Sensing these opportunities, the current study integrates bioinformatics and network pharmacology approaches to explore the potential molecular mechanisms of local flora of Saudi Arabia including *Onopordum heteracanthum*, *Acacia ehrenbergiana*, *Osteospermum vaillantii*, *Cyperus rotundus*, *Carissa carandas*, *Carissa spinarum*, and *Camellia sinensis* in ovarian cancer treatment. Initially, the information on active constituents of these local plants and target genes of both liver cancer and plants were retrieved from literature as well as from publicly available databases. Based on the matching results between plant-potential targets and ovarian cancer targets, the protein-protein interaction (PPI) network was constructed using the STRING database and imported into Cytoscape for screening of hub genes based on their degree of connectivity. Later, the interactions network between compounds and overlapping genes was constructed using Cytoscape software to analyze the network pharmacological prospective effects of active compounds on ovarian cancer. Following that, a compound-target protein-pathway network was constructed which uncovered that namely hispidulin, stigmasterol, ascorbic acid, octopamine, cyperene, kaempferol, pungenin, citric acid, d-Tartaric acid, beta-sitosterol, (−)-epicatechin gallate, and (+)-catechin decisively contributed to the cell growth and proliferation by affecting AKT1 and VEGFA proteins. Moreover, the molecular docking and Molecular Dynamic (MD) simulation of 20ns well complemented the binding affinity of the compound and revealed strong stability of predicted compounds at the docked site. This research not only provides a theoretical and experimental basis for more in-depth studies but also offers an efficient method for the rational utilization of active compounds as anti-tumor drugs

Session Title: Cancer Poster Session II

PB5009 Deciphering disease-relevant cell types in prostate, breast, and lung cancers through integration of GWAS and single-nucleus RNA sequencing data.

Authors:

T. Harrison[1], E. Kaplan[2], K. Hou[3], C. M. Vachon[4], R. M. Tamimi[5], B. Pasaniuc[3], S. Lindstroem[1]; [1]Univ. of Washington, Seattle, WA, [2]Wesleyan Univ., Middletown, CT, [3]UCLA, Los Angeles, CA, [4]Mayo Clinic, Rochester, MN, [5]Weill Cornell Med., New York, NY

Hundreds of genetic variants have been identified as associated with prostate, breast, and lung cancers through genome-wide association studies (GWAS). However, the mechanisms by which they confer risk, and the tissues and cell-types involved in disease susceptibility are poorly understood. Single-cell and single-nucleus RNA sequencing (snRNA-seq) data provide potential insights into the tissues, cell types, and cell populations affected by disease-relevant variants. To identify populations of disease-associated nuclei, we utilized existing germline GWAS summary statistics for prostate (up to n=177,526), breast (n=133,384), and lung (n=85,716) cancer, and existing snRNA-seq data from GTEx (a cross-tissue set of 209,126 nuclei in n=8 tissues from a total of n=16 donors across tissues). Specifically, we mapped germline genetic variants to genes and calculated gene-specific z-scores. We then assessed if expression of the 1,000 most strongly associated genes were enriched across individual cell types using the single-cell disease relevance-score (scDRS). We calculated nuclei-level disease associated scores for 13 grouped cell types, and further evaluated 44 individual cell types to better understand which specific cells contributed to cancer associations. Our findings recapitulated known associations of prostate and breast cancer with cell-types, such as the involvement of epithelial cells in cancer risk. Additionally, we identified several genes for which expression was correlated with scDRS scores, but GWAS-based analyses were not statistically significant (p-value > 0.05). We demonstrate that GWAS-derived signatures from prostate, breast, and lung cancer data can be used to identify enrichment of disease-related expression from snRNA-seq data at the individual cell level. Further scDRS may offer unique insights into genes relevant to disease that have not be identified using GWAS statistics alone.

Session Title: Cancer Poster Session III

PB5010 Decoding the Genetic Landscape of Thyroid Cancer: Identifying Critical Single Nucleotide Polymorphisms for Improved Diagnosis and Prevention

Authors:

J. Ke; Dougherty Valley High Sch., San Ramon, CA

In our study, we explored the genetic intricacies of thyroid cancer, a complex endocrine malignancy, with a primary focus on identifying specific single nucleotide polymorphisms (SNPs) associated with the disease. The multifaceted nature of thyroid cancer, marked by a diversity of genetic variations, underscores the importance of research aimed at decoding its genetic architecture. Our investigation began with a focused examination of the NRAS gene region, noted for its documented significance in thyroid cancer pathogenesis. However, recognizing the potential of a broader genetic landscape, our study expanded to encompass the entirety of chromosome 1. We used Genome-Wide Sequencing data from the Sequence Read Archive and constructed robust pipelines to align sequences against chromosome 1 using the Bowtie 2 tool. The subsequent process involved indexing and variant calling. Our stringent protocols resulted in the identification of over 700 statistically significant SNPs within the thyroid cancer cohort. Interestingly, these SNPs were notably absent in the non-cancer cohort. This revelation accentuates possible genetic foundations of thyroid cancer and emphasizes the genetic disparity between cancer-affected and unaffected cohorts. Our findings suggest that the identified SNPs could be useful in developing innovative strategies for early thyroid cancer diagnosis and prevention.

Session Title: Cancer Poster Session I

PB5011 Detection of actionable variants using liquid biopsy samples for therapeutic approach.

Authors:

S. Temel, B. DOGAN, N. Kaya, N. Nalbant, A. Alemdar, L. Aliyeva, S. Ozemri Sag; Bursa Uludag Univ., Bursa, Turkey

Liquid biopsy is used for NGS-based somatic profiling that enables a precision oncology approach and is now showing its advantages over classic tissue biopsy. By bringing NGS into a clinical context, revealing treatable alterations in multiple genes may help clinicians to assess novel options for diagnostic, prognostic and therapeutic strategies. The current study presents analyses of targeted NGS gene panels to detect actionable somatic variants in patients using the GeneReader NGS System. In this study, 203 patients who were admitted to our clinic between 2019 March and 2021 January with different cancer syndromes (mainly lung & colorectal cancer) were screened using liquid biopsy samples with GeneRead QIAact Lung DNA Panel UMI Kit. This panel is designed to enrich specific target regions in selected genes and covers 550 variants across these 19 genes and targets mostly lung cancer-relevant mutations (SNVs, InDels and, CNVs). Targeted sequence analysis was performed via GeneReader NGS System. All detected somatic variants can be further interpreted by QIAGEN Clinical Insight (QCI) analysis and using online tools (My Cancer Genome, cBioPortal, OncoKB, Franklin, HGMD, ClinVAR) and ACMG criteria. This study included 203 patients with a mean age of 64 (149 male and 54 female) 124 were metastatic, 39 were non-metastatic, and 40 were not determined. The most common cancer types in the patient group are patient lung related-cancer (*n*=144), colorectal-related cancer (*n*=26) and other cancer types (*n*=33), respectively. In 203 patients, 65 actionable somatic variants, 3 actionable variants with amplifications, 14 amplifications, and 2 deletions were annotated via QCI. 17/68 heterozygous variants showed over %40 variant allele frequency evaluated. The 3 genes with the most frequent variant changes were *EGFR* (23/68), *ERBB2* (16/68) and *KRAS* (12/68). This study shed light on the importance of liquid biopsy standards for NGS-based testing, mainly the identification of actionable variants impact on the clinical implications. For tumor profiling tissue biopsy is always the gold standard for initial diagnosis but in case of insufficient tissue and follow of treatment response liquid biopsy can be an option.

Session Title: Cancer Poster Session II

PB5012 Detection of large inversions involving the Lynch syndrome gene *PMS2* using Cas9-assisted targeted sequencing.

Authors:

C. Boles[1], T. Huang[2], F. Chen[2]; [1]Sage Sci., Inc., Beverly, MA, [2]Illumina, Inc., Foster City, CA

Deleterious alterations in the *PMS2* mismatch repair gene on chromosome 7 (band p22.1) are associated with two hereditary cancer syndromes, constitutional mismatch repair deficiency (CMMRD), and Lynch syndrome (LS). Genetic tests for *PMS2* alterations are complicated by the presence of 15 *PMS2* pseudogenes scattered across chromosome 7, and a 100kb low copy number repeat (LCR) sequence that covers the 3' portion of the *PMS2* gene (exons 9-15). A second copy of the LCR sequence in inverted orientation is located 700kb toward the centromere, and shares greater than 95% homology with the telomeric copy, including a *PMS2CL* pseudogene. Inversion events between the LCRs have been shown to cause *PMS2* gene activation, but are extremely difficult to detect by next generation sequencing methods due to the great length and sequence homology between the LCRs. We have used Cas9 endonuclease in vitro to selectively excise and electrophoretically purify a 200kb genomic DNA fragment spanning the entire telomeric LCR plus about 50kb of unique flanking sequence on both sides of the LCR - a fragment that encompasses entire unrearranged *PMS2* gene. Purification of the 200kb fragment enables targeted long-read sequencing of the *PMS2* locus without complications from the centromeric LCR or the *PMS2* pseudogenes. To test for inversions involving the LCR regions, a different Cas9 digestion is performed using the same telomere-proximal cleavage site outside of the telomeric LCR, but using a new second cleavage site in unique sequence about 50kb inside of the centromeric LCR. This second Cas9 digestion will also liberate a 200kb product from the inversion allele, but the sequencing reads will map in a very different pattern from the unrearranged allele, with high coverage of the region between the second cleavage site and the border of the centromeric LCR - a region approximately 650kb away from the location of the unrearranged *PMS2* gene. We demonstrate the inversion detection method using Coriell cell lines from the Ashkenazi trio (HG002, HG003, HG004), in which the maternal haplotype inherited by the son carries the *PMS2* inversion.

Session Title: Cancer Poster Session III

PB5013 Developing a Machine Learning model for classifying ctDNA variants.

Authors:

R. Maruzani, A. Fowler, A. Jorgensen, L. Brierley; Univ. of Liverpool, Liverpool, United Kingdom

Circulating tumour DNA (ctDNA) has shown great potential as a minimally invasive biomarker for early diagnosis, personalised treatment, and disease monitoring in cancer patients. All tissues release fragmented cell free DNA (cfDNA) into the bloodstream via a range of mechanisms. Circulating tumour DNA is a subset of cfDNA originating from tumour tissues. Accurate detection of ctDNA variants in next-generation sequencing data is critical in realising the potential of ctDNA analysis as a minimally invasive cancer biomarker. However, ctDNA variants present a challenge for variant calling tools due to the low variant allele frequencies expected in ctDNA NGS data. Additionally, none of the established variant calling algorithms incorporate ctDNA specific features for variant detection, particularly the shorter fragment lengths and our previous work has shown a high level of discordance between variant calling tools. There is a need for computational tools for more accurate detection of true ctDNA variants. Here, we evaluate a range of machine learning algorithms for classifying true positive ctDNA variants from sequencing and PCR artifacts. Models were trained using publicly available ctDNA datasets, with matched tissue samples providing a truth set for low frequency variants. All models were tested using independent datasets. We leverage ctDNA fragment length information and ensemble variant calling as features in training models. Development of ML models for ctDNA variant analysis provide tools to improve detection and prioritisation of cancer mutations.

Session Title: Cancer Poster Session I

PB5014 Diagnostic Challenges: A case of acute promyelocytic leukemia with classical morphology and immunophenotype but cryptic *PML::RARA* rearrangement detected by RT-PCR

Authors:

G. George, M. Elsadawi, B. Zhang, A. G. Evans, **M. A. Iqbal**; Univ. of Rochester Med. Ctr., Rochester, NY

Acute promyelocytic leukemia (APL) is a subtype of acute myeloid leukemia, characterized by the predominance of abnormal promyelocytes and most often the classical t(15;17) (q22;q21) reciprocal translocation, resulting in the fusion of the promyelocytic leukemia (*PML*) and retinoic acid receptor alpha (*RARA*) genes (*PML::RARA*). The diagnosis of APL hinges on the demonstration of the *PML::RARA* fusion, and the classical translocation is present in 98% of cases. Rarely, patients may present with a variant rearrangement or cryptic insertion of *RARA* into *PML*. Combination therapy with all-trans retinoic acid (ATRA) and arsenic trioxide (ATO) is largely curative provided that the diagnosis of APL is established early cytogenetically. Although the incidence of APL in which the classical *PML::RARA* translocation cannot be demonstrated by fluorescence in situ hybridization (FISH) with targeted t(15;17) and RARA breakapart probes is low, it is important to identify these cases by alternate modalities to initiate immediate treatment. Herein, we report a case of APL diagnosed in a 36-year-old male who presented with spontaneous ecchymosis, petechiae, and exertional dyspnea. Laboratory investigations revealed low fibrinogen, prolonged prothrombin time, international normalization ratio, and activated partial thromboplastin time, and elevated D-dimer, indicative of disseminated intravascular coagulation. Peripheral blood examination demonstrated anemia, leukopenia, and thrombocytopenia. Scattered promyelocytes with occasional Auer rods and variable cytoplasmic granules were noted by microscopy. Flow cytometry revealed an abnormal cell population within the CD45-dim gate with high side scatter and classical immunophenotype (expression of CD13, CD33, CD38, CD117, CD123, CD64, and cytoplasmic myeloperoxidase (MPO), while negative for other markers). Although this case appeared characteristic by morphology, it was found to be negative for both the classical translocation by the routine t(15;17) *PML::RARA* probe and APL variants by the breakapart RARA probe. RT-PCR later revealed a cryptic *PML::RARA* fusion. Fortunately, the patient was started on ATRA/ATO early based on the morphological/immunophenotypic findings. This case underscores the importance of performing confirmatory RT-PCR in FISH-negative cases of APL to identify specific *PML:RARA* breakpoints. Moreover, revising the current paradigm to recommend upfront RT-PCR in all APL cases may mitigate the likelihood of missing these cases. A systematic literature review is underway to understand the prevalence, diagnosis, and prognosis of APL with cryptic *PML::RARA* translocations.

Session Title: Cancer Poster Session III

PB5016 Disrupted DNA methylation signals at lung cancer diagnosis differ from smoking-related and pre-diagnostic signals: results based on one hospital-based and four population-based studies in Europe.

Authors:

T. H. Nøst[1,2], I. Urbarova[2], Y-Q. Sun[1,3], X-M. Mai[1], O. Røe[1,4], P. Sætrom[1,3], M. Johansson[5], M. Johansson[6], B-H. Grønberg[1,3], K. Hveem[1,3], M. Chadeau-Hyam[7], T. Sandanger[2]; [1]Norwegian Univ. of Sci. and Technology, Trondheim, Norway, [2]UiT The Arctic Univ. of Norway, Tromsø, Norway, [3]St Olav's Univ. Hosp., Trondheim, Norway, [4]Levanger Hosp., Nord-Trøndelag Hlth.Trust, Levanger, Norway, [5]Umeå Univ., Umeå, Sweden, [6]Intl. Agency for Res. on Cancer, Lyon, France, [7]Imperial Coll. London, London, United Kingdom

Background: Lung cancer (LC) remains the leading cause of cancer deaths worldwide and there is an urgent need to improve LC risk assessment as current screening criteria miss a large proportion of cases and result in a high rate of false positives on low-dose CT screening. Risk markers for LC based on minimally invasive blood-based tests could help refine screening strategies and for clinical nodule management. **Methods:** We evaluated DNA methylation in blood drawn at LC diagnosis or pre-diagnostically in five different cohorts using the Illumina Infinium HumanMethylation450 and EPIC arrays. Diagnostic samples from 127 patients with confirmed LC, and 55 individuals with suspected but confirmed negative LC were obtained in a hospital-based study in the Norwegian Lung Cancer biobank (NLCB). We identified candidate CpG sites differentially methylated in LC cases at diagnosis, and further evaluated candidate CpGs in pre-diagnostic, population-based samples of 820 future LC cases and 829 matched controls (samples drawn up to 21 years before diagnosis). The pre-diagnostic samples were obtained from nested case-control studies within the Norwegian Women and Cancer Study (NOWAC), the Northern Sweden Health and Disease Study (NSHDS), the Trøndelag Health Study (HUNT), and the Italian part of the European Prospective Investigation into Cancer (EPIC) cohort. Logistic regression models formed the basis of the tests and age, sex, chip plate and chip position were covariates in addition to cohort as random effect. Models with adjustment for smoking status was also estimated. **Results:** We identified 15,385 and 49,407 FDR-significant CpG sites for which either hyper- or hypomethylation was observed in all and late-stage LC cases at diagnosis, respectively. We considered 14,981 candidate CpGs identified at the time of diagnosis. Less than 5% were among 18,760 CpGs associated with smoking in past large meta-analyses and the top ranked CpGs were not identified in previous prospective LC studies. Among candidate CpGs, 14 were also FDR-significant in the pre-diagnostic samples. A methylation score is being established for a subset of the candidate CpGs and its discriminative performance for risk prediction of LC is currently being explored both at and prior to diagnosis. **Conclusions:** Specific methylation biomarkers have a strong potential to improve lung cancer risk assessment. Here we present a unique design to identify novel markers with a focus on samples from time of diagnosis and the CpGs identified differ from those identified in previous studies on LC and smoking. At the conference, we will present risk estimates based on a targeted methylation risk prediction model.

Session Title: Cancer Poster Session I

PB5017 Distribution and frequency of BRCA1/BRCA2 variants in Turkish population with BRCA related cancers: A single center experience.

Authors:

A. Ceylan[1,2], G. Güleç Ceylan[1,2], M. Altan[2], B. Cavdarli[2], V. Topcu[2], E. E. Kurt[1,2], M. Zorluer[2], S. F. Yildirim[2], C. Semerci Gündüz[1]; [1]Ankara Yildirim Beyazit Univ., Sch. of Med., Dept. of Med. Genetics, Ankara, Turkey, [2]Ankara City Hosp., Ankara, Turkey

Germline mutations in *BRCA1* and *BRCA2*, play a significant role in cancer pathogenesis and predisposition, particularly in breast, ovarian, and prostate cancers. Identification of recurrent and novel mutations is very substantial to understanding the differences by population and the structure of the genes. The frequency of variation in the Turkish population is not clearly known. Using the Next Generation Sequencing (NGS) and Multiplex Ligation Probe Amplification (MLPA), we analyzed germline variants of *BRCA1* and *BRCA2* genes for the first 2000 individuals who had high pre-test probability or cancer diagnosis from the patients referred to Ankara City Hospital between 2019-2023. We identified 294 variants classified as VUS or LP/P at *BRCA1* and *BRCA2* genes using the NGS method. While 150 out of 294 variants were LP/P; 144 out of 294 variants were VUS. 129 and 165 variations were identified in *BRCA1* and *BRCA2*, respectively. Eleven of them were novel. In addition to single nucleotide variations, copy number changes in *BRCA1* and *BRCA2* genes were also investigated by MLPA method and CNV was detected in 15 patients. Thus, the rate of disease-causing variants *BRCA1* and *BRCA2* genes was calculated as 8.4%. This rate was found to be similar to those reported in the literature. In this study, we aimed to demonstrate the clinical and demographic findings of patients who had *BRCA*-related cancer. It is crucial to identify the known variants in the specific genes and their functional effect for improvement in the targeted therapy protocols.

Session Title: Cancer Poster Session II

PB5018 DNA Methylation Influences the Relationship Between Polysubstance Use and Physical Frailty Among People with Chronic HIV

Authors:

X. Liang[1], A. Justice[2,3], B. Aouizerat[4,5], K. Xu[2,6]; [1]Dept. of Epidemiology and Biostatistics, Coll. of Human Med., Michigan State Univ., East Lansing, MI, [2]VA Connecticut Hlth.care System, West Haven, CT, [3]Yale Univ. Sch. of Med., New Haven VA Connecticut Hlth.care System, New Haven, CT, [4]Bluestone Ctr. for Clinical Res., Coll. of Dentistry, New York Univ., New York, NY, [5]Dept. of Oral and Maxillofacial Surgery, Coll. of Dentistry, New York Univ., New York, NY, [6]Dept. of Psychiatry, Yale Sch. of Med., New Haven, CT

Polysubstance use (PSU) refers to the consumption of more than one substance, either simultaneously or sequentially. Individuals with PSU have an increased risk of physical frailty, especially among people with chronic HIV (PWH), who have systematically elevated inflammatory function. We and others have demonstrated that both substance use and HIV-1 infection are associated with DNA methylation (DNAm), an epigenetic mechanism involved in regulating immunogenomic function. However, the role of DNAm in the relationship between PSU and physical frailty among PWH remains unclear. In this study, we hypothesized that a subset of DNAm CpG sites (CpGs) mediate the relationship between PSU and physical frailty among PWH. We employed the widely recognized Veteran Aging Cohort Study (VACS) 2.0 Index, known as the VACS Index, to evaluate physical frailty. This measurement tool effectively predicts mortality risk and health outcomes in people living with HIV (PWH). By considering various factors such as age, viral load, CD4 count, and coinfections, the VACS Index offers a comprehensive assessment of overall health. Using data from the VACS that included 1,944 DNA samples from PWH, we first performed Epigenome-Wide Association Study (EWAS) on substances of alcohol, tobacco, cannabis, cocaine, stimulants, and opioids separately and jointly. We identified a total of 2,112 CpGs that were associated with at least one substance (False Discovery Rate, FDR<0.05). Among them, 1,708 CpGs were unique for single substances. We then built a model using 2,112 CpGs to predict PSU by applying multi-response Gaussian regression with elastic net regularization method. The model comprising 1,474 CpGs showed the best prediction of PSU. Subsequently, we constructed a methylation risk score (MRS) based on the 1,474 CpGs, which showed excellent prediction for PSU with an Area Under the Curve (AUC) of 83.92%. Finally, we conducted a mediation analysis to quantify the effects of PSU on VACS Index explained by MRS. MRS showed a significant mediation effect of PSU and VACS Index (Indirect Effect IE_{psu}=3.75, p=0.018). Together, our findings provide evidence that DNAm plays a partial mediating role in the linkage of PSU and increased frailty among PWH.

Session Title: Cancer Poster Session III

PB5019 DNA methylation-predicted prenatal smoking exposure and adult lung cancer risk: a nested case-control study

Authors:

M. Ru[1], D. S. Michaud[2], N. Zhao[2], K. T. Kelsey[3], D. C. Koestler[4], L. Jiayun[1], E. A. Platz[1], C. Ladd-Acosta[1]; [1]Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [2]Tufts Univ., Boston, MA, [3]Brown Univ., Providence, RI, [4]Univ. of Kansas, Kansas City, KS

The prenatal period is a critical window for adult disease development, including cancer. Studies show that DNA methylation signatures of prenatal smoking exposure persist into adulthood. Because active smoking alone does not explain all lung cancer, and not all smokers develop lung cancer, it is possible that prenatal smoking exposure may contribute to adult lung cancer risk independent of adult smoking, and possibly act synergistically with adult smoking. A prior study reported null or inverse associations between scores for these methylation signatures and adult lung cancer risk adjusting for methylation-predicted adult smoking. That study did not consider notable trends in maternal smoking prevalence by birth cohort before the 1960s. To address this gap, we examined the association between methylation scores for prenatal smoking exposure and adult lung cancer risk, independent of methylation-predicted adult packyears, and by birth cohort. We conducted a nested case-control study in participants in both CLUE I and II. We included 196 incident lung cancer cases and 196 controls who were incidence density sampled and matched 1:1 on age, sex, race, and smoking status. Cases were ascertained by cancer registry linkage through 2018 and histologically confirmed. Leukocyte DNA methylation was measured using the Illumina MethylationEPIC BeadChip in prediagnostic blood collected in CLUE II in 1989. We calculated 2 methylation prenatal smoking scores detected in (i) older children (19-CpG), (ii) younger adults (15-CpG); and a methylation-predicted adult packyears score. Conditional logistic regression was used to estimate odds ratios (OR) and 95% confidence intervals (CI) adjusting for methylation-predicted adult packyears and principal components for batch effects. We also stratified by birth cohort in quartiles. The 15-CpG score was associated with increased lung cancer risk (OR=1.30 per SD, 95% CI 1.02-1.66, p-trend=0.04), which was driven by the 1930-40 birth cohort (49 pairs, OR=2.76, 95% CI 1.34-5.70, p-trend=0.006). Likewise, the 19-CpG score was associated with increased risk only in the 1930-40 birth cohort (OR=1.89, 95% CI 1.03-3.45, p-trend=0.039). Compared to those <=median on both prenatal scores, participants >median on both scores had higher lung cancer risk (OR=1.92, 95% CI 1.12-3.30), including the 1930-40 birth cohort (OR=4.32, 95% CI 1.19-15.7). This prospective study suggests a positive association between prenatal smoking exposure and adult lung cancer risk, especially in the 1930-40 birth cohort. Studies with multiple birth cohorts are needed to further investigate this association. Funding: AACR-Johnson&Johnson, NCI, NPCR

Session Title: Cancer Poster Session I

PB5020 † Do candidate genes increase clinical utility of hereditary cancer panels? When less is more

Authors:

J. Herrera-Mullar[1], M. Towne[2], C. Horton[1], A. Weaver[1], J. Huang[1], D. Thrush[1], K. Radtke[1], B. Wayburn[1]; [1]Ambry Genetics, Aliso Viejo, CA, [2]Ambry Genetcs, Aliso Viejo, CA

Next generation sequencing has spurred new gene discovery for hereditary cancer predisposition (HCP) and allowed the development of multigene panel tests (MGPT). While the inclusion of more genes on HCP-MGPT increases diagnostic yield compared to single gene testing, data is lacking on how including new candidate genes on HCP-MGPT impacts diagnostic yield and variant of uncertain significance (VUS) rates. We assessed the frequency of variant classifications by gene-disease validity (GDV) scoring categories of genes on HCP-MGPT.
Reported variants in genes on HCP-MGPTs offered at a commercial laboratory from 2014-2021 were retrospectively reviewed. The frequency of pathogenic (P), likely pathogenic (LP) variants, and VUS were recorded and categorized according to four different GDV categories: uncharacterized (genes with limited/disputed GDV), moderate, strong, and definitive based on evaluation of published clinical and experimental evidence in accordance with ClinGen GDV guidelines. Frequencies were determined by reviewing cases with a reported relevant variant (>240,000 cases). Genes uncharacterized for HCP but characterized for an autosomal recessive disorder were excluded from this analysis (*FANCC, RAD50, MRE11, XRCC2, BLM, NBN*). Genes with moderate or limited GDV for HCP at the start of the time frame (n=20) were reviewed for changes to GDV category. Variants were classified in accordance with ACMG guidelines.
Of >240,000 cases reported, the frequency of P/LP variants was 31.5%, 19.9%, 11.0%, and 0% among genes in the definitive, strong, moderate, and limited/disputed categories, respectively. VUS rates were inversely proportional to positive rate and increased as GDV scores decreased (68.5%, 80.1%, 89.0%, 100% for the definitive, strong, moderate, and uncharacterized categories, respectively). Among 20 genes with moderate/limited GDV at time of addition to MGPT, only 1 (5%) became characterized to a definitive GDV. Instead, the majority (55%) were downgraded to limited or disputed, and the remainder were unchanged limited (25%) or moderate (15%).
Rates of clinically actionable variants (P/LP) are correlated with higher GDV scores, and the rate of VUS is inversely related to GDV scores. Most genes with limited or moderate GDV at the time of panel addition were downgraded to limited/disputed categories or remained uncharacterized. The inclusion of newer candidate genes on HCP-MGPT did not affect the diagnostic yield, but substantially increased the VUS rate on HCP-MGPT. These results emphasize the importance of standardized GDV scoring to inform variant classification and gene inclusion criteria on MGPT to optimize clinical utility.

Session Title: Cancer Poster Session II

PB5021 Drug-target Mendelian randomization revealed significant association of genetically proxied metformin use with increased prostate cancer risk

Authors:

X. Shu[1], X. Sun[1], J. Ping[2], J. Long[2], X. Guo[2], Q. Cai[2], X-O. Shu[2]; [1]Mem. Sloan Kettering Cancer Ctr., New York, NY, [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Background: Previous observational studies have assessed the association between metformin use and incidence of prostate cancer in general populations or diabetic patients, but findings remained mixed.**Methods:** This study used drug-target Mendelian randomization (MR) approach to evaluate potential causal relationship between metformin use and the risk of developing prostate cancer. *Cis*-expression quantitative trait loci (*cis*-eQTL) variants in the gene targets of metformin were identified in the Genotype-Tissue Expression (GTEx) project and eQTLGen. A MR analysis was conducted to filter eQTL variants that also affected blood HbA1c levels using UK Biobank data. Summary statistics for prostate cancer were obtained from the Prostate Cancer Association Group to Investigate Cancer Associated Alterations in the Genome (PRACTICAL) consortium (79,148 cases and 61,106 controls). We also obtained male-specific summary-level data for type 2 diabetes, body mass index (BMI), total testosterone, bioavailable testosterone, estradiol, and sex hormone binding globulin (SHBG) from corresponding international consortia or UK Biobank. Inverse-variance weighted (IVW) regression, weighted median, MR-Egger regression, MR-PRESSO, multivariable MR, and colocalization test, were performed.**Results:** Genetically proxied metformin use (1 SD of target-associated HbA1c reduction, equivalent to 6.75 mmol/mol, 1.09%) was associated with higher risk of prostate cancer (odds ratio [OR]: 1.55, 95% CI:1.23-1.96, $P = 3.00\times10^{-3}$). Two metformin targets, mitochondrial complex I (MCI) (OR: 1.48, 95% CI:1.07-2.03, $P = 0.016$) and gamma-secretase complex (GSC) (OR: 2.58, 95% CI:1.47-4.55, $P = 0.001$), showed robust associations with prostate cancer risk. We further observed that the MCI and GSC-specific effects were partially mediated through BMI and total testosterone levels, with a mediated proportion of 16.4% and 34.3%, respectively. MR and colocalization suggested that expressions of *NDUFA13* (MCI-related gene) in testis and BMI, *APH1A* (GSC-related gene) in hippocampus and total testosterone levels may be influenced by shared genetic factors in the corresponding loci, respectively.**Conclusion:** Genetically proxied metformin use was associated with increased prostate cancer risk. Repurposing metformin for chemoprevention of prostate cancer is not supported by our findings.

Session Title: Cancer Poster Session III

PB5022 Educational attainment and variation of blood DNA methylation among survivors of childhood cancer: A bidirectional causal inference using polygenic scores

Authors:

Q. Dong[1], C. Chen[2], N. Song[3], H. Mulder[4], J. Easton[1], E. Walker[4], G. Neale[4], G. Kang[5], G. T. Armstrong[4], K. K. Ness[4], M. M. Hudson[4], I-C. Huang[4], Z. Wang[1]; [1]St. Jude Children s Res. Hosp., Memphis, TN, [2]Shanghai Jiaotong Univ., Shanghai, China, [3]Chungbuk Natl. Univ., Cheongju, Korea, Republic of, [4]St. Jude Children's Res. Hosp., Memphis, TN, [5]St. Jude Children's Res. Hosp., Memphis, TN

BACKGROUND: We previously identified a DNA methylation (DNAm) signature encompassing a total of 88 DNAm sites for educational attainment (Edu) among survivors of childhood cancer (CCS). We now evaluate bidirectional causal inferences with polygenic scores (PGS). **METHODS:** Study participants comprised 1,618 CCS (median age at DNAm=33.9 years) of European ancestry from the St. Jude Lifetime Cohort Study with pre-existing whole-genome sequencing (WGS) and DNAm profiling (Illumina EPIC BeadChip) data. PGS was calculated as the sum of the trait (Edu or DNAm) measurement increasing alleles. Bidirectional causal inference was analyzed using either Edu-associated genetic variants to derive the PGS (forward: Edu as an exposure and DNAm as an outcome) or methylation quantitative trait loci (meQTL) to derive the PGS (backward: DNAm as an exposure and Edu as an outcome). **RESULTS:** For forward analysis, we started with 1,271 independent Edu-associated SNPs established in general population studies and excluded SNPs not associated with Edu in CCS (i.e., P>0.05), resulting in 105 SNPs for an Edu-PGS. A substantial reduction in SNPs was expected, considering previous evidence of heterogeneous effects across different populations. A total of 88 DNAm sites were tested, and we set statistical significance to be 5.7×10^{-4} (i.e., 0.05/88). We found that Edu-PGS was only significantly associated with DNAm of cg03028088 ($P=5.30\times10^{-6}$). Further analysis using Mendelian Randomization (MR) with one-sample (two-stage least-squares) showed similar results ($P=2.1\times10^{-6}$). Sensitivity analyses excluding SNPs from PGS showed consistent results indicating that horizontal pleiotropy is not a major concern. For backward analysis, we searched SNPs within 1Mb-window centered around cg03028088, evaluated the associations between SNP dosages and the DNAm of cg03028088, and identified 214 significant meQTLs ($P_{FDR}<0.05$). After excluding correlated SNPs ($r^2<0.1$), 14 remained and were used to construct a cg03028088-PGS. We found a nominally significant association between cg03028088-PGS and Edu ($P=7.2\times10^{-3}$), which failed multiple testing, and further one-sample MR analysis confirmed the non-significance (P=0.27). cg03028088 was mapped to *ARID5B*, a gene implicated in inflammation, immune response, and carcinogenesis. Further MR analysis with two-sample methods (inverse variance weighted and MR-Egger) is underway. **CONCLUSION:** We found that DNAm of cg03028088 (*ARID5B*) was associated with Edu as an exposure. Future analyses will evaluate whether cg03028088 is predictive of adverse health outcomes among CCS and assess whether other Edu-associated DNAm sites may influence Edu.

Session Title: Cancer Poster Session I

PB5023 Elucidating the clonal evolutionary dynamics of hypermutated tumours using single-cell whole-genome sequencing

Authors:

M. Kalyva[1,2], F. Gibson[3], F. Muyas[1], C. Sauer[1], J. Espejo Valle-Inclan[1], S. Bhosle[3], S. Barthorpe[3], C. Herranz-Ors[3], H. Francies[3], G. Picco[3], M. Garnett[3], I. Cortes-Ciriano[1]; [1]EMBL-EBI, Hinxton, Cambridge, United Kingdom, [2]Univ. of Cambridge, Cambridge, United Kingdom, [3]Wellcome Trust Sanger Inst., Hinxton, Cambridge, United Kingdom

Immune checkpoint blockade (ICB) has revolutionized the cancer treatment landscape. Yet, durable responses are only observed in a subset of patients. The highest response rates to ICB have been observed in mismatch repair-deficient (MMRD) tumors, which are caused by the inactivation of the MMR pathway. Tumors with MMRD are characterized by a high burden of neoantigens. However, only ~50% of MMRD tumors respond to ICB. Previous clinical and preclinical studies of MMRD tumors indicate that the clonality rather than the burden of mutations determines the variable responses to ICB observed in the clinic. Given that the clonality of mutations is determined by the evolutionary dynamics and patterns of intra-tumour heterogeneity, it is paramount to elucidate the evolutionary trajectories of MMRD tumors to understand the variable immunogenicity of MMRD tumors. Prior genomics analysis of MMRD tumor evolution used bulk whole-genome sequencing (WGS), which is limited to infer the clonal structure and dynamics of tumors due to the impossibility to assign mutations to subclones and limited sensitivity for mutation detection.

Here, to study the evolution of MMRD tumors, we performed single-cell WGS on ~200 single cells from eight patient-derived colorectal MMRD organoids. Mutational burden, though variable across models, was comparable across single cells from the same tumor. Phylogenetic analysis uncovered multiple clones per tumor, with most pathogenic mutations mapping to the trunk of the phylogenetic tree, demonstrating that these mutations are shared across all cancer cells. Notably, few copy number aberrations were observed, indicating that tumor heterogeneity is driven by point mutations and indels. Furthermore, we developed a phylodynamic analysis software, called ClonalSim, to analyze the growth dynamics of tumors using the phylogenetic trees constructed for each tumor, and to infer the fitness of cancer cells and the timing of clonal expansions.

In sum, we present a novel experimental and computational framework that has allowed us to study the patterns of genetic heterogeneity and clonal dynamics underpinning the evolution of MMRD colorectal cancer at single-cell resolution. This framework is broadly applicable to study genetic heterogeneity and clonal evolution in other malignancies and cancer types.

PB5024 Elucidation Of Tumor Clonal Diversity in An AML Drug Resistance Model Using A High Throughput Single Cell Genome Amplification Method.

Authors:

S. Velivela, J. Dahl, J. West, J. Zawistowski; BioSkryb Genomics, Durham, NC

Introduction: Genomic plasticity within tumors contributes to the cellular heterogeneity, which can drive treatment resistance. However, detection of rare, treatment-resistant progenitors is extremely difficult using either conventional bulk population analysis or when analyzing a few individual cells. The goal of our study was to develop a high-throughput automated workflow that can detect intrinsic and acquired mechanisms of resistance to quizartinib, an FLT-3 inhibitor, in an acute myeloid leukemia (AML) cell line, MOLM-13. Methods: A "continual" drug dosage resistance model was created by 2-month duration of 2nM quizartinib, replenished every 3 days with fresh media, while a "dose-escalation" model was created by increasing the quizartinib dose weekly by 100 pM increments up to 2 nM. The single-cell whole genome amplification was performed using ResolveDNA (BioSkryb Genomics) with digital cell dispensing (HP D100), digital liquid dispensing (HP D300), and automated library preparation (Agilent Bravo). 184 resistant and 184 parental cells were sequenced by lowpass sequencing (Illumina NextSeq2000). 1,104 were processed at 272plex for whole exome sequencing. Bioinformatics analysis was performed using BaseJumper (BioSkryb Genomics). Results: The degree of genomic plasticity observed in the parental and two drug dosage models is significant, finding both loss (5p) and gain (19q) of chromosomal regions as a direct result of the drug regime. Copy number variation (CNV) within these groups shows dynamic genomic rearrangements within a single drug treatment model. Specifically, in the continual dosage model CNV analysis clusters into two predominant models with genomic rearrangements in the pathway for drug resistance of FLT-3 and or downstream MAPK activation circumventing the primary drug target. Principal component analysis (PCA) of single cells reveals 6,444 genomic variants that stratify the treatment groups, including a *FLT3* N841K secondary mutation predominant in the resistant population but identified at low frequency in the parental population. Conclusions: Detection of a *FLT3* secondary mutation in the treatment-naïve cell population demonstrates the diversity within treatment naïve cells and highlights the role of natural selection during drug treatment driving resistance. Similarly, the distinct mechanisms of acquired therapy resistance between models shed light on the marked genomic plasticity resulting from varying modes of selection pressure.

PB5025 Enhanced Breast Cancer Subtyping Integrating Complete Gene Expression Profiles and Genetic Ancestry

Authors:

J. Stepanian-Rozo[1], J. Zabaleta[2], J. Duitama[1]; [1]Univ. de los Andes, Bogota, Colombia, [2]Stanley S. Scott Cancer Ctr., LSU Hlth.Sci. and Louisiana Cancer Res. Consortium Ctr., New Orleans, LA

Breast cancer (BC) is the first leading cause of death in women around the world. Accurate subtyping of BC based on gene expression is crucial for optimizing treatment strategies, and ancestry has shown to be a modulator in gene expression. This study aims to improve BC subtyping by integrating comprehensive gene expression profiles and ancestry information.We acquired and analyzed a dataset of 406 RNA-Seq samples sequenced from patients with diverse ancestries, geographical origins, and ethnicities, combining 318 publicly available samples with 88 new samples.RNA-Seq from breast tumor data were used to genotype 10,397 SNPs and predict ancestries using the software ADMIXTURE, and combining the RNA-seq genotype calls with calls from the 1000 genomes project. We ran the genefu R package for predicting PAM50 subtypes, and recreated the results using the supervised machine learning algorithms random forest (RF) and support vector machine (SVM), achieving accuracy rates of 0.95 and 0.92, respectively.We integrated ancestry prediction to supervised machine learning experiments resulting in less favorable metrics, achieving accuracy values of 0.86 and 0.85 for RF and SVM, respectively. Additionally, we observed discrepancies between the assigned PAM50 subtypes, the gene expression patterns, and ancestry prediction.To overcome possible biases in the genefu predictions, we investigated the clusters obtained following an unsupervised machine learning strategy, based on the K-means algorithm. The results suggest novel gene expression-based subgroups within breast cancer tumors, where a part of the variance is explained by ancestry.In conclusion, this study highlights the importance of integrating gene expression profiles and ancestry information in BC clustering, contributing to understanding BC heterogeneity. The findings presented lay the groundwork for improved treatment decision-making in BC management.

Session Title: Cancer Poster Session I

PB5026 Enhancer Analysis Identifies *PAK6* and *CHST14* as Regulatory Targets of Endometrial Cancer Risk Variation at the 15q15.1 Locus

Authors:

D. Glubb[1], B. Naumann[1], C. Chapman[1], J. Gertz[2], T. O'Mara[1]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Univ. of Utah, Salt Lake City, UT

The largest published endometrial cancer GWAS identified a credible set of 47 risk variants at the 15q15.1 risk locus, all of which are located in non-coding regions. Based on previous observations of enrichment in endometrial cancer enhancer/promoter chromatin loops, we hypothesised that the causal risk variant(s) mediates its effect through regulation of gene expression. To identify credible risk variants that regulate gene expression through enhancer activity at the 15q15.1 locus, we focused on eight credible risk variants located in five putative enhancers marked by H3K27Ac in Ishikawa endometrial cancer cells. We used matching H3K27Ac chromatin looping data to identify 17 genes whose promoters physically interact with the putative enhancers and prioritised 13 genes that had robust expression. Using CRISPR interference to inhibit the putative enhancers, we confirmed enhancer activity for four genes (*CHST14, GPR176*, *KNSTRN*, and *PAK6*). We further investigated *CHST14* and *PAK6*, as both genes have function related to sex hormones, such as estrogen and testosterone, which are endometrial cancer risk factors. Reporter gene assays showed that the presence of risk alleles in one of the enhancers targeting *CHST14* and *PAK6* increased their promoter activity by ~2-fold compared to the alternate alleles. Knockdown experiments in Ishikawa cells suggested that *CHST14* plays a critical role in colony formation, while PAK6 knockdown had no consistent cellular effects. Lastly, we used RNA-seq to explore the effects of *CHST14* and *PAK6* knockdown on gene expression and identify other phenotypes or pathways impacted by these genes. In summary, we identified credible risk variants at the 15q15.1 locus that regulate *CHST14* and *PAK6* expression through enhancer activity, providing insight into their potential contribution to endometrial cancer development.

PB5027 Enhancing risk stratification of Acute Myeloid Leukemia with next generation cytogenomics

Authors:

S. Eacker[1], A. Muratov[1], M. Malig[1], B. Nelson[1], M. Wood[1], M. VanDyke[1], K. Langford[1], L. Beppu[2], O. Sala-Torra[2], M. Fang[2], C. Yeung[2], S. Sullivan[1], I. Liachko[1], J. Radich[2]; [1]Phase Genomics, Inc., Seattle, WA, [2]Fred Hutchinson Cancer Ctr., Seattle, WA

Cytogenetic diagnostics including karyotyping, FISH, and chromosome microarray are regularly applied in cases of suspected leukemia, including Acute Myeloid Leukemia (AML). Each of these three tests can identify non-overlapping sets of chromosome aberrations known to have prognostic or diagnostic value. Because each test addresses different classes of prognostic variants, all three tests are often performed in series or in parallel, adding time and expense to the diagnostic process. Here we describe OncoTerra, a platform based on proximity ligation sequencing (PLS), that can be used to identify variants commonly assayed by karyotyping, FISH, and array in a single assay. OncoTerra uses a specialized library preparation chemistry that requires no specialized equipment. Following Illumina sequencing, data is analyzed on a secure cloud platform. In a pilot study of 48 AML patient samples, OncoTerra identified variants previously observed by cytogenetics and additional variants that previously identified. These variants were composed of translocations, inversions, and copy number variants either too small or too complicated to be accurately identified by cytogenetics. We identified a novel recurrent inv(9)(p13) that likely escapes resolution by karyotyping and involves two paralogous genes making it difficult to detect by WGS. OncoTerra's resolution differentiates canonical and non-canonical inv(16), a variant for essential for patient risk stratification. Importantly, additional variants identified by OncoTerra changed risk categories for a significant fraction of patients based on ELN 2022 standards. These findings support deployment of OncoTerra as a time- and cost-effective, high-resolution cytogenomic solution to improve patient care.

Session Title: Cancer Poster Session III

PB5028 Equitable machine learning counteracts ancestral bias in precision medicine, improving outcomes for all

Authors:

K. Graim, **L. A. Smith**, J. A. Cahill; Univ. of Florida, Gainesville, FL

Gold standard genomic datasets severely underrepresent non-European populations, leading to inequities and a limited understanding of human disease. Therapeutics and outcomes remain hidden because we lack insights that we could gain from analyzing ancestry-unbiased genomic data. To address this significant gap, we present PhyloFrame, the first-ever machine learning method for equitable genomic precision medicine. PhyloFrame creates equitable transcriptomic signatures of disease and corrects for ancestral bias by leveraging two big-data resources (global population variation data and functional interaction networks) with disease-relevant genomic data. Application of PhyloFrame to cancer shows marked improvements in predictive power across all ancestries, less model overfitting, and a higher likelihood of identifying known cancer-related genes. Our ability to provide accurate predictions for underrepresented groups is substantially increased. These results demonstrate how AI can mitigate ancestral bias in training data and contribute to equitable representation in medical research.

Session Title: Cancer Poster Session I

PB5029 Establishing a single-cell eQTL dataset of lung tissues from Asian women never-smokers to elucidate cell-type specific genetic regulation

Authors:

T. Luong[1], E. Long[1], J. Yin[1], J. Shin[2], A. Kane[1], A. Golden[1], Y. Chang[2], J. Shi[1], J. Lee[3], E. Kim[2], J. Choi[1]; [1]Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Bethesda, MD, [2]Dept. of Internal Med., Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of, [3]Dept. of Thoracic and Cardiovascular Surgery, Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of

Expression quantitative trait loci (eQTL) studies have been powerful in linking GWAS variants to potential target genes, providing genetic mechanisms underlying common diseases such as cancers. However, the current eQTL resources lack ancestral diversity and are primarily based on bulk tissues. Emerging single-cell eQTL (sc-eQTL) approaches can detect context-specific gene regulation but are mainly of blood samples or cultured cells and still representing European populations. This limits our abilities to test GWAS variants in cancer-relevant cell types as well as in diverse populations. One of the most common cancers and the leading cause of cancer-related death worldwide is lung cancer, and GWAS has identified multiple loci in diverse populations including East Asians. To generate a resource to characterize lung cancer GWAS loci we are building a lung sc-eQTL dataset of Asian population while addressing common challenges of tissue sc-eQTL. Namely, processing fresh tissue in a population scale is logistically challenging and costly, and epithelial cells (including cell types of lung cancer origin) are vulnerable to the dissociation and freezing/thawing process. To address these issues, we incorporated sample multiplexing and cell type balancing of cryopreserved tissues. We collected fresh tumor-adjacent normal lung tissues from 128 never-smoking Korean women and dissociated them before cryopreservation. We then performed single-cell RNA sequencing (scRNA-seq) using 10x Chromium Single Cell 3' v3.1 chemistry with multiplexing of 6 samples/batch. To enrich for epithelial cells, we utilized flow cytometry with surface markers of four major lung cell types (epithelial: EpCAM+/CD45-, immune: EpCAM-/CD45+, endothelial and stromal: EpCAM-/CD45-) before 10X library preparation. Concurrently, we performed DNA genotyping and imputation using matched blood samples. Following scRNA-seq (~36,000 reads/cell) we performed a genotype-based sample demultiplexing using Demuxlet. By integrating Demuxlet and Scrublet we identified ~88% of the detected cells as singlets. After applying QC measures to filter empty droplets and low-quality cells we obtained 435,739 cells or 3,404 cells/patient. After clustering, an initial label transfer using Azimuth and Human Lung Cell Atlas reference data identified ~50% of our cells in epithelial groups. We will further perform eQTL analyses for individual cell types and integrate the results with lung cancer GWAS data to identify susceptibility genes in population and cell-type specific manner. Our approach presents a disease-customized and cost-effective method of building sc-eQTL dataset for solid tissues.

Session Title: Cancer Poster Session II

PB5030 Establishing the effect of reproductive factors on breast cancer risk: a multivariable Mendelian randomization analysis.

Authors:

C. Prince[1,2], L. D. Howe[1,2], G. C. Sharp[3,1,2], A. Fraser[1,2], B. Lloyd-Lewis[4], R. C. Richmond[1,2]; [1]MRC Integrative Epidemiology Unit, Univ. of Bristol, Bristol, United Kingdom, [2]Population Hlth.Sci., Bristol Med. Sch., Univ. of Bristol, Bristol, United Kingdom, [3]Sch. of Psychology, Univ. of Exeter, Exeter, United Kingdom, [4]Sch. of Cellular and Molecular Med., Univ. of Bristol, Bristol, United Kingdom

Background: Childbirth is thought to be associated with breast cancer risk due to the changes that occur to the mammary tissue during pregnancy and lactation. Previous studies have identified an early age at first full-term birth is a protective factor against later life breast cancer, whereas nulliparity or a late age at birth and thought to increase risk. However, there may be an increase in risk of breast cancer immediately post pregnancy due to the breast remodelling, which creates a inflammatory and wound healing-like environment. While there has been some investigation of causality in this setting, it is unclear how reproductive traits affect the risk of breast cancer independently from other reproductive and menstrual factors, given that the traits are often highly correlated. **Methods**: We used genetic data from UK Biobank and the Breast Cancer Association Consortium for four reproductive factors; age at first live birth, age at last live birth, number of live births and ever having children, and 3 breast cancer outcomes; overall, oestrogen-receptor positive and oestrogen-receptor negative breast cancer. We applied univariable and multivariable mendelian randomization, to account for genetic correlation and potential confounding, to estimate the causal effects of the reproductive factors on breast cancer. **Findings**: We found limited evidence for an effect of earlier age at first birth on overall (Odds ratio (OR):1.00; 95% confidence interval: 0.85,1.18, per standard deviation (SD) increase) and oestrogen-receptor positive breast cancer risk (OR:1.04; 0.89,1.20, per SD increase), however some evidence that an earlier age increases risk of oestrogen-receptor negative breast cancer (OR:0.76; 0.61,0.95, per SD increase). Furthermore, we identified limited evidence that age at last live birth, number of live births or ever having children impacts breast cancer risk. **Conclusion**: Our findings contrast with previous observational research regarding age at first live birth and highlights the importance of considering a lifecourse approach and the inter-relationships between reproductive factors when assessing risk on breast cancer.

Session Title: Cancer Poster Session III

PB5031 ETCHING: Ultra-fast Prediction of Somatic Structural Variations and Fusion Genes

Authors:

J-W. Nam; Hanyang Univ., Seoul, Korea, Republic of

Variant callers typically produce massive numbers of false positives for structural variations, such as cancer-relevant copy-number alterations and fusion genes resulting from genome rearrangements. Here we describe an ultrafast and accurate detector of somatic structural variations that reduces read-mapping costs by filtering out reads matched to pan-genome k-mer sets. The detector, which we named ETCHING (for efficient detection of chromosomal rearrangements and fusion genes), reduces the number of false positives by leveraging machine-learning classifiers trained with six breakend-related features (clipped-read count, split-reads count, supporting paired-end read count, average mapping quality, depth difference and total length of clipped bases). When benchmarked against six callers on reference cell-free DNA, validated biomarkers of structural variants, matched tumour and normal whole genomes, and tumour-only targeted sequencing datasets, ETCHING was 11-fold faster than the second-fastest structural-variant caller at comparable performance and memory use. The speed and accuracy of ETCHING may aid large-scale genome projects and facilitate practical implementations in precision medicine.

Session Title: Cancer Poster Session I

PB5032 Evaluating analytical validity of diverse cancer mutation calling pipelines of whole exome sequencing data

Authors:

P-M. Chien[1,2], T-H. Yuan[2], Y-B. Wang[2], J-H. Huang[2], J. Hsu[1]; [1]Graduate Inst. of Med. Genomics and Proteomics,Natl. Taiwan Univ., Taipei, Taiwan, [2]AI Labs, Taipei, Taiwan

Identification of somatic mutations from tumor tissue samples holds substantial clinical consequences for making informed medical decisions. Therefore, evaluating the performance of various tool combinations within somatic variant calling pipelines has become an important issue when employing whole exome sequencing (WES) analysis in clinical settings. In the study, we utilized 9 set of WES reads data of tumor samples released by the Sequencing and Quality Control Phase 2 (SEQC2) project to benchmark the analytical validity of somatic mutation calling workflows. The SEQC2 project, conducted in collaboration with the U.S. Food and Drug Administration (FDA), aims to assess the performance and accuracy of various genomic sequencing technologies and analysis pipelines for clinical applications.We explored the benchmarking approach to compare various combinations of aligner and caller tools. Included aligning tools BWA, Bowtie2, Dragen-Aligner, DRAGMAP, and HISAT2. For the caller, we included Mutect2, TNscope, Dragen-Caller, and DeepVariant. Among these tools, Dragen-Aligner and Dragne-Caller combination showed the best performance with mean F1-score of 0.9659 in SNV detection ,while the combination of BWA and Mutect2 showed the highest mean F1-score of 0.9485 among the open-source software combinations. Notably, results showed that the variant callers exerted a significant influence compared with the impact of the aligners. Furthermore, in true positive set, all variant callers except DeepVariant share the same detect limitation of variant allele frequency (VAF) at 0.0063 whereas the benchmark lowest VAF is at 0.0058. Among several cancer-related indicators, we identified varying concordance results in some tools. For example, TNscope exhibited a tendency to underestimate tumor mutation burden and missed drug-resistance variants such as FLT3(c.G1879A:p.A627T) and MAP2K1(c.G199A:p.D67N). To conclude, our investigation provides a valuable and inclusive guide for clinical genomic researchers on tumor mutation identification, accomplished through an in-depth performance comparison among diverse tool combinations.

Session Title: Cancer Poster Session II

PB5033 Evaluating the Two-Hit Hypothesis: Analyzing differences between germline and somatic cancer-associated mutational patterns in tumor suppressor genes

Authors:

S. Lulla[1], D. I. Ritter[1], C. Kesserwan[2], S. E. Plon[1]; [1]Baylor Coll. of Med., Houston, TX, [2]NYU Sch. of Med., New York, NY

Background: The 'two-hit' hypothesis of cancer predisposition requires two inactivating events in *trans* for complete loss of tumor suppressor gene (TSG) function and consequent tumorigenesis. Both events can be somatic but inheriting one germline loss of function (LoF) variant increases cancer risk. However, *DICER1*-associated tumors display one LoF variant (somatic or germline) in *trans* with one missense variant (exclusively somatic). We are comprehensively analyzing TSG germline and somatic mutational data to assess concordance of germline and somatic mutational patterns consistent with the two-hit hypothesis.
Methods: We identified 44 TSGs associated with autosomal dominant cancer predisposition. For these, we extracted Pathogenic/Likely Pathogenic (P/LP) germline variants from ClinVar and developed a weighted score by translating nominal classifications to numeric values to include conflicting variants with a high proportion of P/LP submissions. Somatic variants curated as Oncogenic/Likely oncogenic (O/LO) were extracted from cBioPortal (213 non-redundant studies). We harmonized variant nomenclature between germline and somatic data using the ClinGen Allele Registry. For each TSG, we also evaluated the proportion and germline classification of somatic O/LO variants that overlap with any ClinVar variant.
Results: From 44 TSGs, we identified $3.2x10^4$ P/LP variants out of $1.7x10^5$ germline variants in ClinVar (median=323; IQR=122-733 P/LP variants per TSG). By applying our weighted score, we retained an additional 4 (IQR=1-13; range=0-43) conflicting variants per TSG with primarily P/LP assertions. O/LO somatic variants from cBioPortal totaled $1.7x10^4$ (median=198; IQR=94-435 per TSG), of which $5.1x10^3$ variants (median=69; IQR=20-130 variants per TSG) were in ClinVar as germline variants. Of these, 82.6% (IQR=71.3-91.3%) intersecting variants per TSG were included in our P/LP set with other germline classifications ranging from Benign to variant of uncertain significance.
Conclusion: Although germline and somatic variants are interpreted using different criteria, we find that both classifications are highly concordant for the shared variants. However, approximately 90% of the 45,277 unique cancer variants in these large databases are exclusive to either germline or somatic data. We are further assessing consistency with the two-hit hypothesis by comparing the distribution of annotated variants by mutation type, mutational spectrum, and location within TSGs to inform genetic mechanisms of tumorigenesis and contribute to improved classification of hereditary and somatic cancer variants.

Session Title: Cancer Poster Session III

PB5034 Evaluation of germline variants in retinoblastoma using non-negative matrix factorization

Authors:

L. Chapman Hannah[1], J. Kim[2], D. Stewart[2], Z. Boukouvalas[3]; [1]NIH, Rockville, MD, [2]Natl. Cancer Inst., Rockville, MD, [3]American Univ., Washington, DC

Approximately 8-10% of children with cancer harbor rare, pathogenic or likely pathogenic (P/LP) germline variants in known tumor-predisposition genes. Common variants have smaller effect sizes and collectively may affect risk. Most children with brain tumors, however, do not harbor known risk variants. To identify additional risk alleles, we used non-negative matrix factorization (NMF), a feature-reduction algorithm commonly used in somatic mutation analysis, to evaluate rare germline variants in a set of retinoblastoma samples (Rb) from the Pediatric Cancer Genome Project (PCGP) and the St. Jude LIFE (SJLIFE) Study. NMF is an unsupervised method that reduces high dimensional feature spaces to a latent feature space.

In this pilot study, variants from chromosomes 13 (harboring known tumor-predisposition genes RB1 and BRCA2) were evaluated. Whole genome sequencing (WGS) data from 145 Rb patients and 364 non-cancer controls from PCGP and SJLIFE were downloaded from St. Jude Cloud. Single nucleotide variants (SNVs) and indels from WGS were called using an ensemble-based pipeline (GEMSCAN) and then filtered based on a set of quality metrics. In the following study NMF was used to identify a latent set of features (variants) within chromosomes 13, and as a result we are able to evaluate underlying groups within the data. The NMF model was generated with the R package RcppML (v0.3.7) using 2 features to capture the most variance in the lowest feature space. We hypothesized that distinct clusters of cases and controls can be identified within chromosome 13.

The analysis included 7,631 rare coding germline variants from chromosome 13 for NMF analysis. In this study, NMF is used to extract sets of germline variants from a high dimensional feature space from cases and controls. The highest ranking features within the coefficient matrix (H) were evaluated. The variants within RB1 that had NMF coefficient weights greater than zero had a higher frequency in cases versus controls (P-value:0.02857). NMF clustering identified 4 RB1 variants all found in Rb cases, including 2 pathogenic variants: NC_000013.11:g.48379594C>T and NC_000013.11:g.48362859C>T. The results of these studies could help identify putative germline variants that collectively contribute to cancer risk.

Session Title: Cancer Poster Session I

PB5035 Evaluation of hereditary predispositions to hematologic malignancy in stem cell transplant: A case series

Authors:

N. Deuitch[1], J. Davis[2], K. Craft[3], L. Cunningham[4], P. Liu[1]; [1]Natl. Human Genome Res. Inst., Bethesda, MD, [2]Natl. Inst. of Allergy and Infectious Disease, Bethesda, MD, [3]Natl. Human Genome Inst., Bethesda, MD, [4]Natl. Cancer Inst., Bethesda, MD

Hereditary predispositions to hematologic malignancy (HHMs) are present in ~10-20% of hematologic malignancies. Allogeneic hematopoietic stem cell transplantation (HSCT) is the gold standard of treatment in hematologic malignancies (HMs). However, HHMs can complicate the transplant process. One such HHM, familial platelet disorder with associated myeloid malignancies (FPDMM) caused by germline RUNX1 pathogenic variants, is characterized by thrombocytopenia, platelet functional defects and predisposition to HM. Identifying these conditions is imperative for diagnosis, management, and treatment of affected individuals and family members. Here we present three families with RUNX1-FPDMM, who underwent HSCT each highlighting unique issues with HHMs. Case 1: A 59 yo Hispanic male was referred for HSCT for myelodysplastic syndrome (MDS). He had been transplanted 20 years prior for MDS, using his brother as the donor. In the interim his brother had also developed MDS and had died. Somatic NGS revealed homozygous loss of *RUNX1*, and fibroblast testing confirmed a heterozygous germline deletion. Cascade screening indicated the brother was an obligate carrier of the *RUNX1* deletion and raising suspicion for donor derived malignancy. Unfortunately, no acceptable donor could be identified, and this patient ultimately died. Case 2: A 42 yo Hispanic male was referred for HSCT for acute myeloid leukemia (AML), which had progressed from MDS. Somatic NGS testing revealed pathogenic variants in *RUNX1*, *RAD50* and *BCOR*. Fibroblast sequencing confirmed that the *RUNX1* and *RAD50* variants were germline, and cascade testing was initiated as a part of donor identification. While there was limited evidence for impact of the *RAD50* variant on transplant outcomes, a familial donor was identified who was negative for both variants. The patient is now 2.5 years post-transplant and doing well. Case 3: A 33 yo White male was identified to have a duplication of exons 3-7 of RUNX1 on NGS panel testing for a longstanding history of thrombocytopenia and family history of AML. Baseline bone marrow biopsy revealed increased myeloblasts and anemia, raising concern for evolving HM. Given the family history and diagnosis of RUNX1-FPD, the patient was referred for HSCT. A matched unrelated was used. The patient is now one-year post-transplant and doing well. The cases highlight the importance of identifying HHMs and issues including evaluation of VUSs, detection of CNVs, racial disparities in donor availability, sample type, and timing of transplant and genetic testing.

Session Title: Cancer Poster Session II

PB5036 † Evolutionary routes of oesophageal adenocarcinoma genomes following whole genome doubling.

Authors:

G. Contino[1,2,3], M. Yap[1], F. Swirsky[1]; [1]Inst. of Cancer and Genomic Sci., Univ. of Birmingham, Edgbaston, United Kingdom, [2]Univ. Hosp. of Birmingham Univ., Birmingham, United Kingdom, [3]Von Hugel Inst., Univ. of Cambrdige, Cambrdige, United Kingdom

Background: Oesophageal Adenocarcinoma (OAC) is the 5th most common cancer related cause of death in the UK and is characterized by a dismal 5-year survival of less than 20%. Whole genome sequencing studies including Pan-cancer analysis highlighted that OAC is driven by large scale loses, gains and rearrangements of the DNA that result in Chromosomal Instability (CIN) and aneuploidy (i.e. change in chromosomal number). A critical event in the evolution of OAC genomes is whole genome doubling (WGD), an endoreduplication of the genetic material that occurs in about 30-50% of OAC genomes. WGD occurs at the early stages of Barrett's dysplasia giving rise to molecularly distinct genomic asset that evolves into invasive adenocarcinoma. We developed *in vitro* models to trace the evolution of OAC genomes after WGD and identify mechanisms of dependency and maintenance of WGD. We validated the findings in a large series of whole genome sequences (WGS) from OAC patients and patient-derived organoids(n=651patients). **Methods**: We selected a non-dysplastic cell line of Barrett's oesophagus (CP-A) and a diploid oesophageal cancer cell line (OACM5.1). Isogenic WGD models were isolated and FACS sorted according to DNA content and grown and clonal cultures. WGD clones were verified with Flow cytometry, metaphase count and centromeric FISH. Corresponding CRISPR/Cas9 TP53 knock out (TP53KO) models were generated for CP-A. DNA and RNA from each clone were collected longitudinally and characterised with single cell shallow genome sequencing, long read sequencing and RNAseq. In addition, we characterised a large cohort (496 patients) of whole genome sequences and RNAseq of Oesophageal cancers with a custom bioinformatic pipeline.**Results**: We isolated multiple clones of WGD isogenic models of CP-A and OACM5.1. WGD is a rare event occurring in <1% of live OAC cells. Single Cell Karyoseq analysis confirmed the acquisition of genomic instability after WGD. TP53 mutation dramatically increases chromosomal instability and accelerates the acquisition of arm wide chromosomal alterations. We estimated the absolute copy-number and presence of WGD in WGS from the OCCAMS consortium (UK, 496 patients), the 100k genome project of Genomics England (UK, 120 patients) and tumour derived organoids (35 patients). We identified three subgroups of patients (diploid, WGD-derived aneuploidy, non-WGD derived aneuploidy) with specific transcriptional profiles. **Conclusions**: Our data identify transcriptomic changes and recurrent patterns of genomic evolution associated with WGD that have implication for patient stratification and treatment.

Session Title: Cancer Poster Session III

PB5037 Ewing sarcoma with two fusion transcripts involving *EWSR1*, *AP1B1*, and *ERG* genes: Further evidence of *EWSR1::ERG* fusions arising from complex genomic mechanisms.

Authors:

N. Uddin, A. L. Sengupta, M. Nagel, J. Y. Park; UT Southwestern Med Ctr. at Dallas, Dallas, TX

The molecular hallmark of Ewing Sarcoma (ES) is *EWSR1* gene rearrangement resulting in its fusion with various partner genes. *EWSR1::ERG* fusion is the second most common rearrangement in ES (~ 5% of the cases). A few sequencing studies have demonstrated complex genomic rearrangements result in *EWSR1::ERG* fusion. Here we present a patient with *EWSR1::ERG* fusion positive ES that was found to have two fusion transcripts involving *EWSR1*, *AP1B1*, and *ERG* genes. The patient is a 17-year-old male who presented with a posterior right flank subcutaneous cystic mass, which was subsequently excised (measuring 22.0 x 11.0 x 8.0 cm). No metastatic disease was found on further evaluation. The histopathological examination of the tumor showed a small round cell tumor, diffusely and strongly positive for CD99 (membranous) and NKX2.2 (nuclear) by immunohistochemistry. Fluorescent in situ hybridization (FISH) performed on formalin fixed paraffin embedded (FFPE) tumor was negative for *EWSR1* rearrangement. RNA sequencing of the FFPE tumor tissue using a clinically validated, targeted anchored multiplex next-generation sequencing (NGS) panel showed two fusion transcripts *EWSR1*:NM_013986.3(Exon 8)::*ERG*:NM_001136154.1(Exon 12) and *AP1B1*:NM_001127.3(Exon 1)::*ERG*:NM_001136154.1(Exon 4). Targeted reverse transcription polymerase chain reaction (RT-PCR) confirmed the NGS results.
The *EWSR1::ERG* fusion was consistent with the diagnosis of ES. The *AP1B1::ERG* is a novel fusion transcript. It likely represents a secondary fusion event in context of *EWSR1::ERG* fusion, in this case. Due to opposite orientation of *ESWR1 (22q12.2)* and *ERG (21q22.2)* on their respective loci, fusion between these two genes was thought to occur by complex genomic rearrangements involving inversions and multiple chromosomal breaks, instead of simple reciprocal translocation. Few NGS studies of ES with *EWSR1::ERG* fusion have shown complex rearrangement mechanisms, including chromothripsis or chromoplexy resulting in *EWSR1::ERG* fusion, confirming this hypothesis. Our case also illustrates a complex rearrangement mechanism resulting in *EWSR1::ERG* and *AP1B1::ERG* fusions. *AP1B1* is near to *EWSR1* on *22q12.2* locus (about 27 kb downstream / telomeric), and is oriented opposite to *EWSR1*, in the same orientation as *ERG*. Therefore *AP1B1::ERG* fusion, in addition to *EWSR1::ERG* fusion is indicative of further rearrangements of *22q12.2* locus and *ERG* gene, possibly involving multiple chromosomal breaks and inversions. Some studies have shown higher chances of relapse in ES patients with complex genomic rearrangements. Our patient is currently undergoing treatment for ES.

Session Title: Cancer Poster Session I

PB5038 Examination of modifiable risk factors and risk of mosaic chromosomal alterations in the UK Biobank

Authors:

C. Young[1], A. Hubbard[2], P. Saint-Maurice[1], S. Khan[3], C. Matthews[1], S. Moore[1], E. Loftfield[4], M. Machiela[4]; [1]NCI-DCEG, Rockville, MD, [2]NCI, Montgomery Village, MD, [3]Natl. Cancer Inst., Bethesda, MD, [4]Natl. Cancer Inst., Rockville, MD

Observational studies suggest modifiable exposures such as sleep, physical activity and alcohol use could impact cancer risk, but biologic mechanisms underlying these associations are poorly characterized. Mosaic chromosomal alterations (mCAs), a type of clonal hematopoiesis in which a detectable fraction of circulating leukocytes harbor large structural changes to chromosomes, present an opportunity to examine the association between modifiable risk factors and clonal expansion in the hematopoietic compartment. We utilized raw intensity and phase information from blood-derived DNA genotyping array data of 485,028 participants free of hematologic malignancies in the UK Biobank (UKBB) to detect mCAs. Modifiable risk factors were self-reported at baseline. Multivariable logistic regression models adjusted for age, sex, smoking, and ancestry were used to evaluate the association between modifiable exposures and risk of detectable mCAs.
In total, 11,826 autosomal mCAs, 15,499 loss of the X chromosome (mLOX) and 43,044 loss of the Y chromosome (mLOY) events were detected. For sleep patterns, we observed evidence for a reduced risk of mLOY in individuals getting >9 hours of sleep compared to individuals getting 7-9 hours of sleep, but limited evidence for associations with autosomal mCAs and mLOX. For physical activity, we noted an association between high levels of vigorous activity (e.g., >2 hours daily) and increased mLOY, but no evidence for associations with autosomal mCAs or mLOX. For alcohol use, multiple lines of evidence indicated potential associations between alcohol intake on increased autosomal mosaicism, mLOX and mLOY. These observations provide initial evidence suggesting possible associations of modifiable risk factors with mCAs. As mCAs are intermediate markers of hematologic cancer risk, mCAs could highlight selective mechanisms relevant to clonal expansion as a potential mechanism by which modifiable exposures contribute to cancer risk.

Session Title: Cancer Poster Session II

PB5039 Expanding the spectrum of germline pathogenic variants among Mexican patients with colorectal cancer

Authors:

D. Aguilar[1], R. Ortiz López[2], A. Rojas-Martínez[2]; [1]Hosp. Zambrano Hellion Tec Salud, San Pedro Garza García, Mexico, [2]Escuela de Med. y Ciencias Médicas del Tecnológico de Monterrey, Monterrey, Mexico

Backorpund:Colorectal cancer (CRC) is the third most common cancer in the worl and tha second leading cause of death due to cancer. 5-10% of CRC are explained by hereditary predisposition syndromes. The most frequent being Lynch syndrome (LS) followed by Familial Adenomatous polyposis (FAP). The purpose of this study is to describe the spectrum of germline pathogenic variants identified among Mexican CRC patients using Next-generation sequencing.Methods: 81 patients with early-onsent and/or family history of CRC were enrolled. All the patients signed the informed consent. NGS was performed using cancer sequencing panel (Illumina) wich targeted a set of 94 genes known to play a role in cancer predisposing. Bioinformatics data analysis was carried out using Pediatric Cancer Sequencing Pathogenicity Information exchange (PeCanPIE). Variant were annotated according to nomenclature recommendations from Human Genome Variation Society and further classified according to the 5 tier ACMG class system.Results: Mean age of CRC diagnosis was 44 years old, 39 (48.15%) were woman and 42 (51.85%) were man. 32 (39.5%) had family history of CRC, 15 fulfilled Amsterdam II criteria and 74 (91.4%) the Bethesda criteria. We identified 28 pathogenic/likely pathogenic variants in 27 individuals, in 11 Lynch Syndrome was molecular confirmed. 17 PV variants were identified in genes typically and not-tipically associated with CRC: ATM(2), CHEK2 (3), MUTYH (3), STK11 (1), BRCA (1), FANCA (1), MEN1 (1), PPMD1 (1), PRF1 (2), RUNX1 (1) and TP53(1). We identified 7 novel variants potentially pathogenic according to in silico and clinical data. Conclusions: NGS technology allow the discover of pathogenic in genes not typically associated with CRC as well as novel variants potentially pathogenic. The better understanding of genes involved in hereditary CRC could be used to identify new biomarkers as well as design target therapies. Fanconi Anemia pathway genes emerges as new candidate genes associated with hereditary CRC, previous evidence supports these observations.

Session Title: Cancer Poster Session III

PB5040 Exploring the non-invasive potential of miRNA 145 and miRNA 363 in Prostate Cancer

Authors:

A. Manoj, M. Ahmad; King George's Med. Univ., Lucknow, India

Owing to the misdiagnosis and over-treatment of prostate cancer, due to its indolent growth and false-positive errors produced by diagnostic ways like PSA level, DRE, and biopsy. Consequently, there is an urgent need for reliable diagnostic and detection technologies to diagnose aggressive prostate cancer non-invasively by exploring the potential of circulating microRNAs. Efficient and reliable markers within the body fluids can help in personalized treatment decisions for monitoring disease and survival. MicroRNA (miRNA) are highly conserved small non-coding RNA that modulate genes involved in numerous biological processes and form part of complex networks that play a significant role in prostate cancer initiation and progression. In keeping this view, we have designed our study to investigate biomarker potential miRNA 145 and miRNA 363 in prostate cancer. We determined the comparative expression of miRNA 145 in benign prostatic hyperplasia (BPH) and prostate cancer blood samples by Real Time-PCR and performed the Receiver Operating Characteristics (ROC) curve analysis. Further, we explored target genes of miRNA using In-Silico tools like TargetScan, miRDB, and miRWalk3.0 and performed gene and pathway enrichment analysis using DAVID 6.8. Our observation suggests a significant tumor-suppressive role of miRNA 145 and the oncogenic role of miRNA 363 in prostate cancer compared to BPH. Computational analysis reveals that miRNA 145 and miRNA 363, both target genes like e2f3, nras, pten, foxo1 etc., play a significant role in prostate cancer survival and progression. Finally, ROC curve analysis predicts that miRNA 145 (AUC 0.822***) and 363 (AUC 0.852***) have good biomarker potential for distinguishing BPH from prostate cancer. Collectively these results reveal that miRNA 145 and miRNA 363 expression may act as a non-invasive biomarker for effective diagnosis of Prostate Cancer. For future suggestions, the target genes evaluation may provide therapeutic targets for better treatment and management of prostate cancer.

Mexicano del Seguro Social, Mexico City, Mexico

Introduction. Neuroendocrine neoplasms (NENs) are heterogeneous tumors with variable clinical behaviors. Given that NENs are frequently inherited, genetic tests are key for early diagnosis, tailored clinical management, and counseling. Yet, platforms for genetic diagnosis are not widely available and current data on disease drivers do not accurately represent all human populations. *Aims.* To report preliminary data on the repertoire and frequency of germline defects underlying NENs in a prospective cohort of Mexican Mestizos. *Methods.* Adult individuals with diagnosis of bronchopulmonary, gastrointestinal, pancreatic, pituitary, and thymic NENs, medullary thyroid carcinoma, primary hyperparathyroidism, and paragangliomas or pheochromocytomas, including sporadic, familial, isolated, and syndromic presentations were recruited from two reference hospitals in Mexico City. Under informed consent, DNA samples from blood were obtained. The study started in August 2022 and is designed as a prospective 15-year cohort. A next generation sequencing (NGS) panel was designed and optimized *ad hoc*. Variants with frequency <0.1% in public databases were classified in accordance with the American College of Medical Genetics and Genomics and Association for Molecular Pathology guidelines, using *in silico* analyses, ClinVar reports, and experimental and clinical data from the literature. *Results.* As of April 2023, 79 individuals (69.2% women) with mean age at recruitment of 50.4±17.6 years had been included. Disease presentation was sporadic in 44.6% of cases; among those with familial presentation, 21.6% were from kindreds with cancer predisposition. The presentation was multiple endocrine neoplasia type 1 in 20.3% of participants, the rest were distributed among 18 other phenotypes. Two individuals underwent testing in external laboratories, one with a commercial NGS panel and one via Sanger sequencing. Forty-five DNA samples were sequenced by means of our custom NGS panel, obtaining ~300x depth of sequencing of target regions. Likely germline drivers of NENs were identified in 17 samples (36.2%), including four cases in which the genetic defects were not expected from the phenotypes. The affected genes were: *AIP*, *CDKN1B*, *DNMT3A*, *MEN1*, *NF1*, *PIK3CA*, *RET*, *SDHA*, *SDHC*, *SDHD*, and *VHL*. Likely population-specific variants were identified among both tumor drivers and benign variants. *Conclusions.* Germline drivers of NENs were found in one-third of individuals from a genetically diverse population that is underrepresented in international studies. Our data support the idea that genetic drivers underlying phenotypes of NENs might differ among populations.

Session Title: Cancer Poster Session II

PB5042 Exploring the Potential: Evaluating the Celemics WES panel for NGS-based Comprehensive Cancer Analysis and Precision Medicine

Authors:

H. Jang, H. Seo, J. Jeong, H. Kim; Celemics Inc., Seoul, Korea, Republic of

Whole exome sequencing (WES) has emerged as a powerful tool for comprehensive genomic analysis, enabling researchers to study genetic variations associated with various diseases, including cancer. In this study, our aim was to present the performance of the Celemics Whole Exome Sequencing (WES) panel, which is the most comprehensive WES panel covering all target regions of major WES panels available in the market. With a target size of 37.1 Mb, the panel does not compromise performance in terms of coverage and uniformity, enabling highly efficient and cost-effective sequencing of the human whole exome, along with complete in-house bioinformatics solutions provided by Celemics Analysis Service (CAS). Featuring these distinctive characteristics, we evaluated the WES panel using OncoSpan FFPE (Cat. ID: HD832, Horizon Discovery, USA) reference material. OncoSpan FFPE is a well-characterized, cell line-derived reference standard containing over 380 variants in 152 cancer-associated genes. The results of the Celemics WES panel showed exceptional sequencing performance, successfully detecting all relevant known variants in the reference sample, even in hard-to-capture regions such as GC-rich and homologous regions. The outstanding sensitivity and specificity, as well as the superior on-target ratio, indicate that the Celemics WES panel can not only be used for research and molecular diagnostics in the field of oncology but also for discovering cancer-associated novel SNPs or conducting comprehensive exome analysis, bringing NGS one step closer to robust clinical diagnostics and precision medicine.

Session Title: Cancer Poster Session III

PB5043 Frequency of 50 bp Ins-del and rs4817415 variant of SOD1 gene and their association with vitiligo patients

Authors:

B. Gómez Meda[1], G. M. Zúñiga-González[2], L. D. Bañuelos-Díaz[3], M. P. Oceguera-Angel[3], A. Galindo-Gómez[3], M. G. María G. Sánchez-Parada[4], B. M. G. Torres-Mendoza[2], J. I. Delgado-Saucedo[5], M. G. Márquez-Rosales[2], A. L. Zamora-Perez[1], M. P. Gallegos-Arreola[2]; [1]Univ. de Guadalajara, Centro Univ.rio de Ciencias de la Salud, Guadalajara, Mexico, [2]Inst. Mexicano del Seguro Social, Centro de Investigación Biomédica de Occidente, Guadalajara, Mexico, [3]DermaMed Clinic, Guadalajara, Mexico, [4]Univ. de Guadalajara, Centro Univ.rio de Tonalá, Guadalajara, Mexico, [5]Univ. de Guadalajara, Centro Univ.rio de Ciencias Exactas e Ingenierías, Guadalajara, Mexico

Vitiligo is a common, systemic, idiopathic, autoimmune disease affecting skin, hair and mucous membranes. Among the causal factors of the disease, oxidative stress plays an important role, which also involves the imbalance of cellular homeostasis, causing damage to the cell and to the integrity of the genetic material, as well as to multiple processes of cell survival and risk of carcinogenesis. Therefore, the aim of the present study was to analyze the frequency of SOD1 gene variants (50 bp Ins/Del and rs4817415 in patients with a previous diagnosis of vitiligo and in a control group. Blood samples were collected from patients with a clinical diagnosis of vitiligo, adults of both sexes, who underwent analysis of gene variants by real-time-PCR, and were compared with a reference group without the disease. The population analyzed were young people aged 29 to 37 years with a higher percentage of women. The population was found in HWE. The 50 bp Ins/Del and rs4817415 variants showed no significant difference between groups ($p>0.05$). In conclusion, the 50 bp Ins/Del and rs4817415 variants of the SOD1 gene showed no association in patients with vitiligo in the sample analyzed.

Session Title: Cancer Poster Session I

PB5044 Frequency of pathogenic and likely pathogenic variants in genes associated with an increased risk for cancer in patients undergoing population based carrier screening.

Authors:

E. Cooper, L. Petrarca; LabCorp, Philadelphia, PA

INTRODUCTION: Carrier screening is used to identify individuals at risk for having children with autosomal recessive or X-linked genetic disorders. In some instances, carrier testing may reveal unintended findings, including identifying individuals who have an increased risk to develop cancer. The objective of this study was to investigate the frequency at which individuals test positive on carrier screening for pathogenic and likely pathogenic variants in genes associated with a risk for malignancies. These types of results highlight the need for appropriate pre and posttest counseling. METHODS: Carrier screens (n=1581), collected from July to November 2021, were analyzed to identify carriers of 4 conditions (6 genes) associated with cancer predisposition: Ataxia-telangiectasia (ATM), Bloom syndrome (BLM), Fanconi anemia (FANCL, BRIP1, FANCC), and Nijmegen breakage syndrome (NBN). All patients had the same carrier screening panel drawn which included over 500 genes. RESULTS: Out of the 1581 carrier screens, we identified 20 patients (1.3%) who were carriers for one or more genes associated with cancer predisposition. The number of carriers for each gene is as follows: ATM (8), BLM (3), FANCL (3), BRIP1 (2), FANCC (2), NBN (2). CONCLUSIONS: These data suggest that approximately 1.3% of individuals who undergo a carrier screening panel of this size will be positive for a variant that may increase their risk to develop cancer. These findings are outside the original intention of carrier screening which is to identify reproductive risks. Additionally, they underscore the need for appropriate pre-test counseling that includes a discussion of the possibility of identifying a variant associated with an increased risk for malignancy. Post-test counseling regarding these results is critical, not only to review reproductive risks, but also to review potential implications for one’s own healthcare.

Session Title: Cancer Poster Session II

PB5045 Frequency of the rs8720 variant of the KRAS gene in patients with colorectal cancer from a Mexican population

Authors:

M. Rentería-Ramírez[1], J. I. Cruz-Sanchez[2], C. A. Ronquillo-Carreón[2], A. F. Garibaldi-Ríos[1], G. M. Zúñiga-González[3], L. E. Figuera[1], B. C. Gómez-Meda[1], J. I. Delgado-Saucedo[4], M. P. Gallegos-Arreola[1]; [1]División de Genética, Centro de Investigación Biomédica de Occidente (CIBO), Centro Médico Natl. de Occidente (CMNO), Inst. Mexicano del Seguro Social (IMSS), Guadalajara, Jalisco, México., Guadalajara, Mexico, [2]Inst. Mexicano del Seguro Social, Guadalajara, Mexico, [3]División de Med. Molecular, CIBO, CMNO, IMSS. Guadalajara, Jalisco, México., Guadalajara, Mexico, [4]Laboratorio de Inmunofarmacología, Centro Univ.rio de Ciencias Exactas e Ingenierías UdeG, Guadalajara, Jalisco, México., Guadalajara, Mexico

Background: Colorectal cancer (CRC) is considered a public health problem, as it is one of the most common malignant neoplasms in developed countries and Mexico is no exception. CRC represents the third most common malignant neoplasm in the world and the second cause of death. Different studies have evaluated the association of variants in the KRAS gene with various diseases. In this sense, the rs8720 T>C variant in the KRAS gene (identified in Kirsten rat sarcoma virus) has been associated with risk susceptibility to cancer. However, in patients with CRC from the Mexican population, this association is unknown.**Objective:** To evaluate the association of the rs8720 T>C variant of the KRAS gene in patients with colorectal cancer from Western Mexico.**Methodology:** 386 CRC genomic DNA samples were included and 311 for the control group. Genomic DNA samples from both study groups were analyzed to verify the amount of DNA by spectrophotometry. Using the real-time Polymerase Chain Reaction (PCR) method, the alleles and genotypes of the rs8720 variant of the KRAS gene were identified in the study groups.**Results:** the CC genotype (variant) was observed in 38% (146/346) of the patient group and 26% (82/311) of the control group (OR 1.69, 95%CI 1.22-2.35, p=0.001) showed as a risk factor, TT wild-type genotype was present in 23% (89/386) of the patient group and 24% (74/311) of the controls (OR 0.95, 95%CI 0.67-1.36, p=0.889), without showing significant differences between the study groups; and the heterozygous genotype (TC) was present in 43% (151/346) of the patient group and 52% (155/311) of the controls, (OR 0.64, 95%CI 0.47-0.87, p=0.005) was observed as a protective factor for the association to development to CRC in the sample analyzed.**Conclusions:** The variant rs8720 of the KRAS genes was associated as a risk factor for susceptibility to the development of CRC in the analyzed sample.

Session Title: Cancer Poster Session III

PB5046 Functional annotation and gene mapping of gastric cancer

Authors:

J. Lee, S. Moon, K. Jung, H. Kimma, S. Jee; Yonsei Univ., Seoul, Korea, Republic of

Background: Gastric cancer (GC) is the fifth most frequently diagnosed malignancy and the third leading cause of cancer mortality worldwide. However, the exact etiology of gastric cancer is not clear. **Method:** A large-scale genome-wide scan was performed in gastric cases and controls from KCPS-II cohort. To explore the roles of gene mapping in gastric cancer, a genome-wide association study of the gastric cancer GWAS re-evaluated by the FUMA. **Results:** A total of 65 independent significant single nucleotide polymorphisms (SNPs) and 42 lead SNPs were identified in 39 genomic risk loci. Out of these identified genomic risk loci, 67 candidate causal genes were screened by positional mapping. We identified 26 genes via positional mapping and expression quantitative trait locus (eQTL mapping). In gene-based analysis, THEM6 gene had the lowest P-value (P-value=2.47x10-11), followed by TRIM46 gene (P-value=1.34 x 10-10) and THBS3 gene (P-value=2.59 x 10-10). Among prioritized genes, a gene set consisting with THEM6, PSCA showed strong enrichment related to chr8q24 which was previously reported cancer-related loci. Furthermore, a gene set including THBS3 gene showed strong enrichment related to BREAST_CANCER_1Q21_AMPLICON pathway. Functional annotation of these prioritized genes revealed that chr1q22 and chr8q24 positional pathway was implicated in the onset of gastric cancer. Overall, our findings suggested novel candidate gene and demonstrated that the several pathway has a crucial role in the risk of gastric cancer.

Session Title: Cancer Poster Session I

PB5047 Functional characterization of non-coding *CDKN2B* single nucleotide variants identified in high-risk melanoma families.

Authors:

A. Dennis[1], R. C. Hennessey[1], J. W. H. Wong[2], J. A. Barbour[2], R. Chari[3], K. Jones[1,4], W. Luo[1], M. R. Sargen[1], M. A. Tucker[1], A. M. Goldstein[1], X. R. Yang[1], K. M. Brown[1]; [1]Natl. Cancer Inst., Rockville, MD, [2]The Univ. of Hong Kong, Hong Kong SAR, China, [3]Natl. Cancer Inst., Frederick, MD, [4]Natl. Cancer Inst., Bethesda, MD

Melanoma is a common cancer in which approximately 10% of cases are familial. Of these familial cases, roughly 20-40% are explained by variation in the high-penetrance susceptibility gene *CDKN2A* (which encodes tumor suppressors p14 and p16) and another ~10% by other susceptibility genes. While the remaining families are unexplained by protein-coding variants in known high-penetrance genes, some nonetheless show genetic linkage to the 9p21 locus, which harbors *CDKN2A* and another tumor-suppressor gene, *CDKN2B* (which encodes p15). To examine the apparent predisposition to melanoma in these families, we conducted whole-exome sequencing. Sequencing germline DNA of high-risk melanoma families from the United States identified two families (one with 7 and one with 3 sequenced melanoma patients) harboring distinct cosegregating rare genetic variants clustered closely together at the 9p21 locus, along with a third rare variant found in a melanoma case from an American case-control study. These single nucleotide variants (SNVs) are all within 10 base pairs of each other and are located within the first intron of *CDKN2B*. Notably, these SNVs are found within consensus binding sites for CCCTC-Binding factor (CTCF), which modulates chromatin interactions necessary for gene expression. Consistent with a potential role for altered CTCF binding, ChIP-seq (chromatin immunoprecipitation with sequencing) in fibroblasts from one family showed significant loss of CTCF binding on the familial variant allele, coupled with a slight decrease in the number of interactions across the region where the variant was located. We hypothesized that these *CDKN2B* SNVs may influence melanoma risk because of their ability to disrupt CTCF binding, impacting chromatin interactions necessary for the expression of *CDKN2A* and/or *CDKN2B*. To test this hypothesis, we performed CRISPR-Cas9-based genome editing of immortalized human melanocytes. We created multiple melanocyte clones missing a 107 bp region around this CTCF binding region and also edited in each of these three variants using separate homology vectors with the Lig4 inhibitor SCR7 to promote homology-directed repair. We are presently performing variant characterization (comparing these to wild-type clones), including assessing their effects on expression of nearby genes and determining whether they function via *CDKN2A*, *CDKN2B*, or both. We are also evaluating phenotypic consequences of these variants, including melanocyte proliferation and region-specific chromatin interactions. These results have the potential to shed light on the mechanistic underpinnings of non-coding variants linked to familial melanoma cancers.

Session Title: Cancer Poster Session II

PB5048 Functional copy number alterations as diagnostic and prognostic biomarkers in neuroendocrine tumors.

Authors:

H. Vaughn[1], H. Major[2], E. Kadera[2], K. Keck[3], T. Dunham[2], Q. Qian[2], B. Brown[4], L. Borbon[3], A. Scott[3], A. Belizzi[5], T. Braun[1], P. Breheny[6], D. Quelle[7], J. Howe[3], B. Darbro[2]; [1]Univ. of Iowa Interdisciplinary Graduate Program in Genetics, Iowa City, IA, [2]Stead Family Dept. of Pediatrics, Iowa City, IA, [3]Univ. of Iowa Hlth.care Dept. of Surgery, Iowa City, IA, [4]Univ. of Iowa Dept. of BioMed. Engineering, Iowa City, IA, [5]Univ. of Iowa Dept. of Pathology, Iowa City, IA, [6]Univ. of Iowa Dept. of Biostatistics, Iowa City, IA, [7]Univ. of Iowa Dept. of Pharmacology and NeuroSci., Iowa City, IA

Neuroendocrine tumors (NETs) can arise in multiple organs throughout the body. Sixty percent of NET patients have advanced metastatic liver disease before they are diagnosed, often leading to exploratory procedures to determine primary tumor site. Functional copy number alterations (fCNAs) are DNA copy number changes with concordant differential gene expression. Given that fCNAs are less likely to be bystander genetic lesions, we hypothesized that they could be used as diagnostic (site of origin) and prognostic (event free survival) NET biomarkers. To identify candidate fCNAs, we integrated chromosomal microarray (CMA) and RNA-seq differential gene expression data from 31 pancreatic (pNET) and 33 small bowel neuroendocrine tumors (sbNET) as well as 47 early disease progression (<24 months) and 17 late disease progression (>24 months) patients. Candidate fCNAs that could accurately differentiate these groups were then replicated using fluorescence in situ hybridization (FISH) on formalin-fixed, paraffin-embedded (FFPE) tissues in a larger cohort of 86 pNETs, 114 sbNETs, 75 early disease progression, and 100 late disease progression samples. Logistic regression analysis was performed to determine the predictive ability of these biomarkers as well as the assay performance metrics of sensitivity, specificity, and area under the curve. Our results indicate that fCNAs at chromosomal loci 4p16.3, 5q32, 7q31.2, 9p21.3, 17q12, 18q21.2, and 19q12 may be used as diagnostic and prognostic NET biomarkers and can be utilized in clinical testing to aid in determination of primary tumor site for patients with metastatic liver disease of pNET or sbNET origin and may for the basis for risk stratified therapies in the future.

PB5049 Gene co-expression networks capture potential biomarkers of UTUC.

Authors:

T. Fu, Y. Lin, Y. Yang, N. Xiang, L. Du, G. Liao, J. Huang, B. Liao; West China Hosp., Sichuan Univ., Chengdu, China

Background Upper tract urothelial carcinoma (UTUC) accounts for 5%-10% of all urothelial malignancies. And the incidence of UTUC in China is much higher than that in European and American countries, accounting for about 31%. Approximately two-thirds of patients have invasive disease at diagnosis. However, little research has been done on UTUCs. **Patients and methods** To better understand the pathogenesis of UTUC and provide reference for its diagnosis and treatment, we conducted a Weighted Correlation Network Analysis (WGCNA) involving the RNA sequencing data of 27 UTUC patients. Multiple linear regression models were used to explore the association between gene modules and clinical indicators. We then imported related modules into Cytoscape 3.7.1. to screen hub genes. Additionally, we performed RNA differential expression analysis, exon mutation analysis, and looked at mutations in hub genes. Enrichment analysis was then conducted based on differentially expressed genes to discover potential pathways regulating UTUC. Finally, bladder cancer data in TCGA public database was used to verify the hub genes. **Results** We classified the genes into 31 modules by unsupervised clustering, with 4 modules (FDR<0.05) significantly associated with tumor infiltration. Then 9 potential biomarkers, including *MSRB3, HSPB2, SCRG1, SYNPO2, FXYD1, PLXNA4, CD163, IFFO1,* and *FPR3,* were discovered by importing these 4 modules into Cytoscape software. Differential expression analysis showed that except for the *FPR3* gene, the remaining 8 genes were underexpressed in UTUC. This has also been verified in public databases. Meanwhile, SNP mutation occurred in *MSRB3, SYNPO2,* and *PLXNA4* genes. Functional enrichment analysis revealed that differentially expressed genes regulate UTUC through pathways such as cell adhesion, transmembrane receptor protein kinase activity, cGMP-PKG signaling pathway, p53 signaling pathway, and cardiomyocyte adrenergic signaling pathway. **Conclusion** Although these 9 genes are new and significant genes in UTUC, they have been proved in public databases. Our results not only promote our understanding of the relationship between the transcriptome and clinical data in UTUC but will also guide the development of targeted molecular therapy for UTUC.

Session Title: Cancer Poster Session I

PB5050 Gene expression analysis of *miRNA 146b* and *miRNA 181b* in Papillary Thyroid Carcinoma

Authors:

R. Khan; Inst. of BioMed. & Genetic Engineering (IBGE) Islamabad Pakistan, Islamabad, Pakistan

Background: Thyroid cancer is considered the most common cancer and is the most recurrent malignancy of the endocrine system. The most frequent type is papillary thyroid cancer (PTC), contributing more than 80% globally with noticeable prevalence in females of Asia, America and Iceland. Genetic insights into molecular pathogenesis of PTC, have been getting a shape of rich library of useful information. The genetic elements known as MicroRNAs (miRNAs) are endogenous non-coding RNAs operating as post-transcriptional regulators involved in development, proliferation and differentiation. They are gaining fame as druggable biomarkers for clinical management of neoplasms. The momentous stackeholding of miRNA family by virtue of gene expression variations in the cancer microenvironment has been witnessed in the thyroid cancer onset, amplification and apoptosis. The growing body of knowledge highlights the modifiable play at the miRNA level harbors potential in lessening the perpetuation of the disease with safe handlers. The genetic information leads to a big highway which can replace the unified yardstick to tailor PTC with the more targeted personalized disease treatment by monitoring the disease risk and aggression modalities. **Objectives:** The study aims to speculate the characteristic involvement of expression level changes in the *miRNA-146b* and *miRNA-181b* as tangible biomarkers for PTC. **Methodology:** The present study was conducted on the PTC in Pakistan, a genetically less explored South Asian country. Specimen of the cancer tissue and healthy normal samples adjacent to the cancer part were collected from the PTC and nodular goiter patients undergoing thyroidectomy. The anthropometric and clinical parameters relevant to each patient were recorded after informed consent. Total RNA was isolated and first strand cDNA was synthesized from all the samples. Gene expression profile for *miRNA-146b* and *miRNA-181b* was done by quantitative Real-Time PCR. Relative gene expression was identified as fold change by utilizing essential gene expression levels. **Results:** The statistically significant changes in the relative expression of *miRNA-146b*; 5 to 20 folds and *miRNA-181b*; 4-60 folds were observed in PTC tissues in comparison to nodular goiter and healthy tissue specimens. **Conclusion:** The boosted gene expression of the *miRNA-146b* and *miRNA-181b* manifests the plausible misregulations in deployment of these molecular musketeers as foes in PTC. This forged maladaptation of the *miRNA-146b* and *miRNA-181b* in cancer microenvironment may warrant analytically, therapeutically and genetically surmountable miRNA targets for PTC clinical management prevention.

Session Title: Cancer Poster Session II

PB5051 Generalizability of PRS313 for breast cancer risk amongst non-Europeans in a Los Angeles biobank

Authors:

H. Shang[1], Y. Ding[2], V. Venkateswaran[2], K. Boulier[2], P. Boodaghi Malidarreh[3], J. Luber[3], B. Pasaniuc[2]; [1]Univ. of California Los Angeles, Los Angeles, CA, [2]UCLA, Los Angeles, CA, [3]Univ. of Texas Arlington, Arlington, TX

Polygenic risk scores (PRS) summarize the combined effect of common risk variants and are associated with breast cancer risk in patients without identifiable monogenic risk factors. One of the most well-validated PRSs in breast cancer to date is PRS313, which was developed from a Northern European biobank but has shown attenuated performance in non-European ancestries. We further investigate the generalizability of the PRS313 for American women of European (EA), African (AFR), Asian (EAA), and Latinx (HL) ancestry within one institution with a singular EHR system, genotyping platform, and quality control process. We found that the PRS313 achieved overlapping Areas under the ROC Curve (AUCs) in females of Lantix (AUC, 0.68; 95 CI, 0.65-0.71) and European ancestry (AUC, 0.70; 95 CI, 0.69-0.71) but lower AUCs for the AFR and EAA populations (AFR: AUC, 0.61; 95 CI, 0.56-0.65; EAA: AUC, 0.64; 95 CI, 0.60-0.680). While PRS313 is associated with Hormone Positive (HR+) disease in European Americans (OR, 1.42; 95 CI, 1.16-1.64), for Latinx females, it may be instead associated with Human Epidermal Growth Factor Receptor 2 (HER2+) disease (OR, 2.52; 95 CI, 1.35-4.70) although due to small numbers, additional studies are needed. In summary, we found that PRS313 was significantly associated with breast cancer but with attenuated accuracy in women of African and Asian descent within a singular health system in Los Angeles. Our work further highlights the need for additional validation in diverse cohorts prior to clinical implementation of polygenic risk scores.

Session Title: Cancer Poster Session III

PB5052 Generation of a functional genomics assay for the clinical re-classification of *PMS2* missense variants of undetermined significance.

Authors:

J. Plowman, E. Matoy, I. Scavuzzo, M. Belshan, H. Feser Stessman; Creighton Univ., Omaha, NE

Lynch syndrome (LS) is the most common hereditary cancer affecting an estimated 1 in 279 people. LS is caused by germline heterozygous mutations in mismatch repair (MMR) genes. While not directly cancer-causing, mutations in LS genes increase the number of somatic mutations over time, increasing cancer risk. *PMS2* is the most frequently mutated LS gene. However, the pathogenicity or functional effect of most missense *PMS2* variants is unknown leaving most classified as variants of uncertain significance (VOUSs). There is a great need to re-classify *PMS2* VOUSs for improved clinical diagnostics and management. We hypothesize that a portion of *PMS2* missense VOUSs will have decreased MMR activity, which will increase cancer risk over time. Our recent identification of a suspected hereditary cancer family carrying a missense variant in *PMS2* (p.Gly29Ala; MAF: 0.000440 across all races) had conflicting interpretations of pathogenicity in ClinVar, prompting the need for an *in vitro* assay by which *PMS2* variants could be functionally assessed in a high-throughput way. CRISPR/Cas9 engineering was used to knockout *PMS2* expression in the HAP1 haploid cell line (MMR proficient) by targeting exon 7 of the canonical transcript. Western blotting for *PMS2* showed full knockout in ~40% of the individual clones. MMR function-quantified by cell viability after 72 hours of 6-thioguanine (6-TG) treatment-showed that two independent *PMS2* KO lines were significantly more resistant to 6-TG compared to the wild-type HAP1 parent line ($p<0.0001$; Tukey's test) indicating reduced MMR activity. Full-length, wild-type (WT) human *PMS2* was cloned into the pCW57.1 Gateway vector and packaged into lentiviral particles. The *PMS2* KO lines were infected, selected with G418, and treated with doxycycline to induce WT *PMS2* expression. Induced WT *PMS2* expression rescued 6-TG sensitivity ($p<0.0001$; Tukey's test) in *PMS2* KO cell lines. Using site-directed mutagenesis on the pCW57.1-WT *PMS2* plasmid, we generated one benign and pathogenic-confirmed in ClinVar-missense variant as well as the p.Gly29Ala variant (VOUS) identified locally in 4 confirmed carriers of a suspected hereditary cancer family. Individual variants were again packaged into lentiviral particles and used to infect *PMS2* KO lines. While the known pathogenic variant conferred significantly decreased MMR sensitivity ($p<0.0001$; Tukey's test), the VOUS was not significantly different from WT *PMS2* suggesting a benign classification. In summary, we present a novel *in vitro* MMR assay for the high-throughput classification of human *PMS2* missense variants that can contribute to the re-classification of VOUSs identified in human patients.

Session Title: Cancer Poster Session I

PB5053 Genetic pathways of temozolomide resistance in glioblastoma.

Authors:

T. Carter[1], R. Valenzuela[1], S. Yerukala Sathipati[2], R. Medina-Flores[1]; [1]Marshfield Clinic, Marshfield, WI, [2]Marshfield Clinic Res. Inst., Marshfield, WI

Glioblastoma (GBM) tumors frequently reoccur despite aggressive surgical resection and temozolomide (TMZ) chemo-radiation, and the acquisition of TMZ resistance remains a barrier to extending survival in GBM. To discover genetic pathways involved in TMZ resistance, bioinformatics analysis was conducted to identify gene interactions predictive of GBM patient survival, considering that patients with shorter survival are more likely to be highly TMZ-resistant cases. Network-based stratification, a bioinformatics approach that has been used previously to identify gene subnetworks in cancer subtypes that are predictive of overall survival, was applied to the somatic variant data of 221 GBM patients who had undergone TMZ chemo-radiation following surgery, as provided in The Cancer Genome Atlas. Differentially mutated genes (DMGs) in each subtype were determined using the Statistical Analysis of Microarrays method, and the over-representation of these genes in biological pathways was assessed by Gene Ontology (GO) term enrichment analysis. Four GBM subtypes were identified, with a median overall survival of 12.8, 16.3, 15.6, and 18.3 months for subtypes 1 (n = 17), 2 (n = 54), 3 (n = 79), and 4 (n = 71), respectively (P = 0.032; log-rank test). The difference in overall survival between subtype 4 and subtypes 1 (P = 0.031) and 3 (P = 0.021) remained significant independent of other factors associated with GBM survival, including age, type of surgery, and radiation treatment, in Cox proportional hazards regression. Subsequently, the discovery of genetic pathways was focused on subtypes 3 and 4, that had a significantly different median overall survival but a similar proportion of subjects with *MGMT* promoter methylation (51.1% and 45.9%, respectively), which is correlated with increased overall survival in GBM. The top 10 GO terms ($P < 0.00001$) were related to mitotic DNA damage checkpoint signaling and telomere formation and maintenance for the 507 DMGs in subtype 3 and to intrinsic apoptotic signaling and DNA damage checkpoint signaling for the 86 DMGs in subtype 4. To validate the presence of somatic variation in the DMGs of subtypes 3 and 4 within other GBM cases, an independent sample of 37 GBM tumors from patients who had been treated with TMZ was exome sequenced. Somatic variants in 39 DMGs from subtype 3 and four DMGs from subtype 4 were detected in 25 and four of the tumors, respectively. In conclusion, DNA damage checkpoint signaling, apoptosis, and telomere regulation are potentially involved in TMZ resistance. The targeting of genes in these pathways could hold promise for developing new strategies to improve TMZ treatment efficacy and overall survival in GBM.

Session Title: Cancer Poster Session II

PB5054 Genetic profiling of human hepatocellular carcinoma by using advanced techniques

Authors:

R. Issa; Inst. of genetic engineering, Cairo, Egypt

In Egypt, Hepatocellular Carcinoma is a major health problem in which the most common cancer- related causes of morbidity and death, account for the fourth most common cancer compared to the sixth most common worldwide.Maintaining genomic integrity, preventing viral infection, and eliminating tumorigenesis are all dependent on cellular responses to DNA damage. Several genes are responsible for cellular responses and repairing DNA damage including TP53 and ATMTP53, also famous as “the guardian of the genome”, is a tumor suppressor gene that plays a key role in organizing cellular responses to various types of stresses by preserving genome safety and preventing the proliferation of mutated cells The ATM plays a critical mechanism as a central role in the repair of Double-strand DNA breaks (DSB). The DSB may be induced by many environmental factors, including HCV. DSB represent the greatest risk for causing genomic instability Circulating tumor DNA, a portion of the cfDNA, can be liberated into peripheral blood from the primary and metastatic tumor cells, which carries a recent image of tumor status and donates important value for molecular studies in a variety of cancers, including HCC In the present study, cfDNA samples of Egyptian HCC patients were sequenced by Ion Torrent NGS to identify the novel and existing variants in TP53 and ATM genes.MethodsClinicopathological data and 5 ml of whole blood were obtained from each 21 primary HCC patients. After extraction of cell-free DNA (cfDNA), the library construction was prepared and sequenced using Next Generation Sequencing (NGS) techniques.ResultsThe age of the studied HCC patients ranged from 48 to 80 years (Mean ± SD = 62.19 ± 9.08), thirteen (61.9%) patients were more than 60 years at diagnosis.Eighteen patients (85.70%) were males while only three patients (14.30%) were females. The Hepatitis C infection was reported in 18 patients (85.71%), and one case had co-infection (HCV and HBV). Four patients (19.05%) had a positive family history for cancers. Medical history was reported by 17 patients in the form of bilharziasis in 13 (61.90%) patients, diabetes in 7 (3.33%) patients and Hypertension in 3 (14.29%) patients.The distribution of somatic mutations in TP53 gene were: missense mutations (50%), intron mutations (21.88%), splicing mutations (9.38%), and 5′ UTR (9.39%), synonymous mutations (3.12%), INDEL (3.12%), and copy number variations (3.12%).On the other hand, the somatic mutations in ATM gene were distributed to be non-synonymous mutations (46.30%), synonymous mutations (22.22%), intron mutations (11.11%), copy number variations (1.85%), and other mutations (18.52%).

Session Title: Cancer Poster Session III

PB5055 Genetic re-assessment of *BRCA*-negative families in the Lynch Legacy Hereditary Cancer Biobank.

Authors:

H. Feser Stessman, J. Plowman, E. Matoy, C. Watson; Creighton Univ., Omaha, NE

Breast cancer remains the most common cancer diagnosed among women and is a leading cause of cancer-related deaths across all races and ethnicities. Approximately 20% of breast cancer cases are attributed to increased family risk; yet variation in *BRCA1/2* can only explain 20-25% of these cases. Until recently, single gene (i.e., *BRCA1/2*) and even single variant testing were common in at-risk family members with little additional follow-up sequencing. For many *BRCA* mutation negative (BRCAX) families, genetic risk remains ill-defined. We performed targeted sequencing of 28 high-risk familial hereditary breast and ovarian cancer (HBOC) genes using a custom molecular inversion probe (MIPs) panel in 246 human samples representing both cancer positive (n=174) and negative (n=72) individuals from 135 BRCAX HBOC families recruited from 1973-2014 by Dr. Henry Lynch. MIP probes were designed to span all RefSeq coding exons plus 10 base pairs of flanking introns to capture both coding and splice variation. Sequencing identified 391 high-quality variants which were annotated using the Ensembl Variant Effect Predictor (VEP) tool and further ranked based on their predicted clinical impact. All annotated pathogenic and variants of undetermined significance (VOUSs) were Sanger validated highlighting a SNV false positive rate <1%. Known pathogenic breast cancer variants in *CHEK2* (p.Thr410MetfsTer15 found in six unrelated families and p.Ser471Phe found in two families) were identified representing ~6% families in the study. While BRCAX was an inclusion criterion for this study, we still identified a pathogenic *BRCA2* variant (p.Met192ValfsTer13) in one family. A portion of BRCAX families could be explained by other hereditary cancer syndromes that increase HBOC risk including Li-Fraumeni Syndrome (gene: *TP53*) and Lynch Syndrome (gene: *MSH6*). Interestingly, these families carried additional VOUSs that may further modify the phenotypes of affected family members. Ten families carried more than one VOUS suggesting the presence of complex multi-variant families; a single VOUS variant was identified in 17 families. Overall, 8.1% of BRCAX HBOC families in our study may be explained by other known pathogenic variants; VOUSs could contribute up to an additional 18.5% of families which will require further functional testing. We conclude that our MIP approach is an inexpensive and scalable multigene screening tool that can be used to genetically re-evaluate suspected HBOC families. Further, genetic mining of historic hereditary cancer biobanks may still have great value in clinically re-defining VOUSs and in discovering novel genetic modifiers of disease.

Session Title: Cancer Poster Session I

PB5056 Genetic study in African ancestry populations identifies 16 novel loci associated with lung cancer risk.

Authors:

M. Betti[1], J. N. Hellwege[1], J. Jaworski[1], S. Zhao[1], J. Rao[2], B. Ryan[3], A. G. Schwartz[4], J. K. Wiencke[5], M. A. Bruce[6], S. Chanock[3], M. C. Aldrich[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Univ. of Minnesota, Minneapolis, MN, [3]Natl. Cancer Inst., Rockville, MD, [4]Karmanos Cancer Inst., Detroit, MI, [5]Univ. of California, San Francisco, San Francisco, CA, [6]Univ. of Houston, Houston, TX

Introduction: The heritability of lung cancer is well established, yet prior lung cancer studies have been largely focused on populations of European descent, leaving the genetics of lung cancer in African ancestry persons poorly understood. We performed a genome-wide (GWAS) and transcriptome-wide association study (TWAS) across nearly 7,000 African ancestry individuals, representing the largest lung cancer genetics study performed to date in persons of African ancestry.

Methods: We analyzed data from 6,998 individuals of African ancestry (2,540 cases and 4,458 controls) collected from eight studies across the US. Imputed SNPs were evaluated for an association with lung cancer risk, adjusting for age, sex, smoking status, smoking pack-years, enrollment site, and the first three principal components. Linkage disequilibrium score regression (LDSC) was used to estimate the total narrow-sense heritability (h^2) of lung cancer captured by the GWAS, leveraging a novel linkage disequilibrium (LD) panel constructed using whole genome sequencing data from an independent set of 600 African ancestry individuals. Finally, TWAS was performed using models of genetically predicted expression with SNP covariance matrices of both African and European LD patterns. Significant associations were tested for causality using Mendelian randomization.

Results: We identified 34 loci associated with lung cancer ($p < 1 \times 10^{-6}$), including 11 which were genome-wide significant ($p < 5 \times 10^{-8}$). Of these loci, 18 have been previously associated with lung cancer, while the remaining 16 are novel. Of particular note are novel loci 5q22.1 (closest gene *CAMK4*), 7p22.2 (*SDK1*), 10q11.22 (*ARGHAP22*), 12q14.3 (*LINC02389*), 18q12.1 (*B4GALT6*), and 18q22.1 (*AC007631.1*), all of which were genome-wide significant. The captured h^2 was estimated to be 0.23 (0.10 SE). TWAS identified 8 gene-tissue pairs of suggested significance ($p < 1.85 \times 10^{-6}$) using African ancestry-based covariance matrices, 5 of which were predicted to be causal, and 76 using European ancestry matrices, 21 of which were predicted to be causal. With the TWAS results in lung tissue performed with both African and European ancestry covariance matrices, we also performed gene set enrichment and found a positive enrichment of genes associated with notable metabolic pathways and negative enrichment of genes associated with DNA repair pathways, suggesting potential biological mechanisms mediated by genetically regulated gene expression.

Conclusion: This study suggests novel loci for lung cancer in African ancestry individuals and provokes further studies to identify the genetic underpinnings in diverse ancestry individuals.

Session Title: Cancer Poster Session II

PB5057 Genetic susceptibility to nonalcoholic fatty liver disease and risk for pancreatic cancer: Mendelian randomization

Authors:

S. King[1], S. Veliginti[2], S. Antwi[2], Pancreatic Cancer Cohort Consortium (PanScan), Pancreatic Cancer Case Control Consortium (PanC4); [1]Mayo Clinic Graduate Sch. of BioMed. Sci., Jacksonville, FL, [2]Mayo Clinic, Jacksonville, FL

Background: There are conflicting data on whether nonalcoholic fatty liver disease (NAFLD) is associated with susceptibility to pancreatic cancer. Using Mendelian randomization (MR), we investigated the relationship between genetic predisposition to NAFLD and risk for pancreatic cancer. **Methods**: Data from genome-wide association studies within the Pancreatic Cancer Cohort Consortium (PanScan; cases n=5090, controls n=8733) and the Pancreatic Cancer Case Control Consortium (PanC4; cases n=4,163, controls n=3,792) were analyzed. We used data on 68 genetic variants with four different MR methods (inverse variance weighting [IVW], MR-Egger, simple median, and penalized weighted median) separately to predict genetic heritability of NAFLD. We then assessed the relationship between each of the four MR methods and pancreatic cancer risk using logistic regression to calculate odds ratios (ORs) and 95% confidence intervals (CIs), adjusting for pancreatic cancer risk factors, including obesity and diabetes. **Results**: No association was found between genetically predicted NAFLD and pancreatic cancer risk in the PanScan or PanC4 samples (e.g., PanScan, IVW OR=1.04, 95% CI: 0.88-1.22, MR-Egger OR=0.89, 95% CI: 0.65-1.21; PanC4, IVW OR=1.07, 95% CI: 0.90-1.27, MR-Egger OR=0.93, 95% CI: 0.67-1.28). None of the four MR methods indicated an association between genetically predicted NAFLD and pancreatic cancer risk in either sample. **Conclusion**: Genetic predisposition to NAFLD is not associated with pancreatic cancer risk. Given the close relationship between NAFLD and metabolic conditions, it is plausible that any association between NAFLD and pancreatic cancer might reflect host metabolic perturbations (e.g., obesity, diabetes, or metabolic syndrome) and does not necessarily reflect a causal relationship between NAFLD and pancreatic cancer.

Session Title: Cancer Poster Session III

PB5058 Genetic Testing for Hereditary Cancer Syndromes in Algerian population: Recurrent Germline Pathogenic Variants, Ethical and Social Issues

Authors:

F. Cherbal[1], C. Mehemmai[1], L-L. Saada[1], M. Nehar[1], F. Gouaref[2], K. Bentabak[2], F. Khider[1], A-L. Boumehdi[1], H. Mahfouf[3], F. Zebboudj[4], M. Oukkal[5], M. Maaoui[6], W. Batna 2 Chahid Mostefa Ben Boulaid, Batna, Algeria, [8]Radiation Oncology Services and Lab. for Cancer Res., Anticancer Ctr. of Blida, Blida, Algeria

Background:The effects of genetic counselling and testing for hereditary cancers in Algerian population are largely unknown. To date, the Algerian population is composed of native Berber descent with Sub-Saharan, European and Middle East elements. Genetic testing studies are of interest in admixed populations as most of genetic testing studies have been conducted in individuals of European ancestries. In Algeria, like in most of emerging countries, there is a limited access in clinical genetic services mainly due to the costs, the availability of genetic testing and the lack of public insurance for coverage of genetic services. Here, we report preliminary results of multi-center studies of the effects of genetic counselling and testing on hereditary cancer syndromes in Algerian patients. **Methods**: Since 2008, we conducted three research projects on genetic testing and counselling for hereditary cancer syndromes. We used PCR-Sanger sequencing and multi-gene hereditary cancer panel (Color Genomics) for testing *BRCA1/2* genes in 314 hereditary breast and ovarian cancer patients . We also tested *APC* gene and *MMR* genes in 54 severe familial adenomatous polyposis and 72-suspected Lynch syndrome patients in a national cohort and relatives at risk, respectively. **Results**: We detected six recurrent germline pathogenic variants in *BRCA1* gene: c.83_84del, c.181 T>G, c.798_799del, c.2125_2126insA, Del exon 7 and Del exon 15 and one recurrent germline pathogenic variant in *BRCA2* gene: c1310_1313del. In addition, we detected two recurrent germline pathogenic variants in *APC* gene: c.3927_3931del and c.4728dup and two recurrent germline pathogenic variants in *MLH1* gene: c.1546C>T and *MSH2* gene: c.942+3A>T, respectively. Our results showed that patients with limited background knowledge about genetics expressed positive attitudes towards genetic studies and genetic testing, with the possibility of preventing hereditary cancers in theirs siblings as main advantage. These patients also expressed a strong need for the protection of genetic information. Interestingly, the identification of recurrent germline pathogenic variants in *BRCA1/2* genes in Algerian population by our laboratory have already set up some need and demand from the Algerian patients living abroad. We have got request from these patients for genetic testing of specific or recurrent germline pathogenic variants in *BRCA* genes in their family relatives who are still living in Algeria. **Conclusions**: Continued efforts should be made by our national health care system to allow the access to affordable genetic counseling and testing for Algerian hereditary cancer syndromes' patients and their families.

Session Title: Cancer Poster Session I

PB5059 Genome-wide analysis to assess whether heavy alcohol intake modifies the association between SNPs and pancreatic cancer risk.

Authors:

Z. Ni[1], P. Kundu[2], D. McKean[1], W. Wheeler[3], The Pancreatic Cancer Case Control Consortium, The Pancreatic Cancer Cohort Consortium, L. T. Amundadottir[4], R. Z. Stolzenberg-Solomon[4], A. P. Klein[1,5,6]; [1]Dept. of Oncology, Sidney Kimmel Comprehensive Cancer Ctr., Johns Hopkins Sch. of Med., Baltimore, MD, [2]Dept. of Biostatistics, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [3]Information Management Services, Inc., Silver Spring, MD, [4]Div. of Cancer Epidemiology and Genetics, Natl. Cancer Inst., NIH, Bethesda, MD, [5]Dept. of Epidemiology, Johns Hopkins Bloomberg Sch. of Publ. Hlth., Baltimore, MD, [6]Dept. of Pathology, Sol Goldman Pancreatic Cancer Res. Ctr., Johns Hopkins Sch. of Med., Baltimore, MD

Background: Pancreatic cancer is a leading cause of cancer-related death globally. Risk factors for pancreatic adenocarcinoma, the most common subtype of pancreatic cancer, include common genetic variants and potentially heavy alcohol use. Objective: To assess whether heavy drinking modifies the association between genetic variants (SNPs) and pancreatic cancer risk. Methods: We conducted genome-wide single nucleotide polymorphism (SNP) by heavy alcohol use (greater than three drinks per day) interaction analysis for pancreatic ductal adenocarcinoma in European ancestry populations. The study population included prior genome-wide association studies (GWAS) conducted by the Pancreatic Cancer Cohort and Case-Control Consortia, PanScan I-III GWAS and PANC4 GWAS. The analysis was stratified by study design (case-control and cohort) due to differences in assessment of alcohol intake. There were 3,707 cases and 4,167 controls from the case-control and 1,199 cases and 4,813 controls from the cohort studies. Analyses were conducted using logistic regression with unconstrained maximum likelihood estimation, followed by fixed effect meta-analyses to combine results across GWAS phases. Results: In the case-control studies, a novel region of association on 10p11.22, lead SNP rs7898449 (odds ratio for the interaction $OR_{interaction}$=0.44, 95%CI 0.33-0.57, $P_{interaction} = 2.1x10^{-9}$) was identified. Among the non-heavy drinking participants, each copy of the minor allele A was associated with an increased pancreatic adenocarcinoma risk (OR = 1.16, 95%CI 1.05 - 1.29) compared to the major allele G. In contrast, among heavy drinkers, each copy of the minor allele A was associated with decreased pancreatic adenocarcinoma risk (OR = 0.51, 95%CI 0.37 -0.69) compared to the major allele. This region contains an eQTL for the *NRP1* gene. Of the 20 genomic regions with genome-wide significant evidence of association to pancreatic cancer in our prior studies, we observed that alcohol use potentially modifies the association between genomic variation near *LINC*00673, rs11655237 on 17q25.1 (P = 0.03) and *ABO*, rs505922 (P = 0.04) on 9p34.2 in the case-control studies. Due to the smaller size, there was limited power to detect association in the cohort subset. Conclusion:We identified a novel genomic region that may be associated with pancreatic adenocarcinoma risk in conjunction with heavy alcohol use. This region is located near an eQTL for the NRP1 mRNA, which plays an important role in pancreatic cancer progression. Future studies are needed to confirm the association and better understand how alcohol use may modify pancreatic adenocarcinoma risk.

Session Title: Cancer Poster Session II

PB5060 Genome-wide association study of transient myeloid leukemia in children with Down syndrome

Authors:

Y. Li[1], N. Elliott[2], P. Vyas[2], I. Roberts[2], A. de Smith[1]; [1]Univ. of Southern California, Los Angeles, CA, [2]NIHR Oxford BioMed. Ctr., Oxford, United Kingdom

Background: Children with Down syndrome (DS) have a remarkably high risk, ~150-fold, of developing myeloid leukemia (ML-DS). ML-DS is preceded by a transient preleukemia in newborns with DS that is characterized by increased blast cells and somatic mutations in the ChrX gene *GATA1* that result in a shorter protein isoform (*GATA1s*). In this study, we aimed to investigate the role of genetic variation in the development of *GATA1s* mutations in DS, with the central hypothesis: heritable variation influences the in utero generation of somatic *GATA1s* mutations in neonates with DS.
Methods: The study comprised 436 newborns with DS from the Oxford Down Syndrome Cohort Study, in which targeted deep sequencing of *GATA1* exons 2 and 3 had been previously performed. Whole genome sequencing (WGS) was performed at the Broad Institute and funded by the NIH Gabriella Miller Kids First and INCLUDE projects. Following quality control of WGS data, 425 DS newborns were included in a genome-wide association study (GWAS) of somatic *GATA1s* mutations. Association tests included *GATA1s* mutation as either a binary trait (105 *GATA1s*-positive cases, 320 *GATA1s*-wildtype controls), or continuous trait with variant allele frequencies (VAF) ranging from 0% to 89%. Biological sex, gestational age, and ten principal components were adjusted in the logistic model and the linear model with logit-transformed frequency, respectively. We also assessed genetic variation in the *GATA1* gene itself, on ChrX, in males and females separately.
Results: In the GWAS of *GATA1s* mutation VAF, we identified one genome-wide significant hit, a low frequency variant rs115118904 (p=3.3x10^{-8}, MAF=0.055), in a genomic region at chr2p16.3 previously associated with body mass index. The top signal comprising common variants was located at chr15q26.2, with lead SNP rs2584234 (p=1.5x10^{-7}; allele freq.=0.28) which has previously been associated with lung function. In the GWAS treating *GATA1s* as a binary trait, this SNP was associated with a 2.3-fold increased risk of developing a mutation. In targeted association testing of variants in *GATA1*, we found a distinctive result between males and females with several nominally significant SNPs only in males, including lead variant rs5906709 (p=0.021) that was previously associated with blood cell traits.
Discussion: We performed the first GWAS of transient leukemia in DS, identifying putative risk variants that may influence the development of *GATA1s* mutations in DS neonates, albeit these require validation. Ongoing analyses include examination of variants on the trisomic Chr21, and the pursuit of independent DS cohorts to increase our study sample size.

Session Title: Cancer Poster Session III

PB5061 † Genomic alterations in lung cancer among never-smokers: An ancestry and sex-stratified analysis.

Authors:

A. Schroeder, S. Chatterjee, J. Cadley, C. Falcon, M. Mehine, C. Bandlamudi, Y. Kemel, A. Chatterjee, M. Ladanyi, D. Solit, M. Berger, Z. Stadler, M. Kris, D. Jones, A. Schoenfeld, C. Rudin, K. Offit, S. Mukherjee; Mem. Sloan Kettering Cancer Ctr., New York, NY

Although most lung cancer cases are linked to cigarette smoking, an estimated 10-25% of lung cancer cases occur in never smokers. Lung cancer in never-smokers (LCINS) presents unique molecular characteristics compared to its smoker-induced counterparts. LCINS incidence, mortality, and outcomes vary widely across race/ethnicity. Our study aims to comprehensively assess genomic alterations in LCINS stratified by sex and ancestry to identify clinically actionable alterations and gain insight into targeted therapeutics. We analyzed 6,355 patients with lung cancer who underwent germline and somatic tumor sequencing for 505 genes by MSK IMPACT between 2015 and 2021. Smoking history data was derived using a unique self-reported smoking behavior questionnaire or from electronic health records using machine learning methods. Somatic mutation data was analyzed for recurrent driver mutations, structural alterations, and mutational signatures. In total, 46 genes with recurrent driver mutations observed in >20 cases were tested for sex and ancestry-specific differences. Pathogenicity assessment for germline variants in 90 cancer predisposition genes was performed using ACMG guidelines. In total, 1364 (21.5%) lung cancer patients in our cohort had no smoking history nor a smoking mutational signature. The majority of patients had lung adenocarcinoma (88%) and 70% were female. The prevalence of LCINS varied by ancestry with the highest prevalence in Asian (343/606; 57%), followed by African (75/230; 33%), Ashkenazi Jewish (270/1149; 23%), and European (575/3782;15%). Patients of African ancestry had a significantly earlier age at diagnosis compared to others (58 vs 63 years, p=<.001). Patients of Asian ancestry had higher rates of chromosomal instability as measured by fraction genome alteration (FGA) compared to others (mean FGA 0.21 vs 0.17; p=.005). As previously reported, *EGFR* mutations predominated in never smokers with the highest frequency observed in Asian patients (69.5%) followed by African ancestry patients (56%). In addition to *EGFR, RBM10* mutations were found to be enriched in patients of Asian ancestry compared to others (p<.001). Germline pathogenic variants in DNA damage repair pathway genes were observed in 7% of patients. The prevalence of germline pathogenic variants in *BRCA1* and *BRCA2* was significantly higher in never-smokers compared to ever-smokers (p-value <0.01). Our study suggests that the variation in somatic and germlin*e* mutation frequency is significantly distinct in different ancestry groups. We are currently exploring germline-somatic interactions to elucidate their impact on clinical management and outcomes.

Session Title: Cancer Poster Session I

PB5062 Genomic landscaping of Oral Cancer using Liquid Biopsy: search for an elusive target

Authors:

R. Rawal, D. Yadav; Gujarat Univ., Ahmedabad, India

Oral cancer is a prevalent and potentially life-threatening disease, necessitating the development of robust diagnostic and prognostic tools. Traditional tissue biopsies for molecular profiling have limitations in terms of invasiveness and limited sampling. The emergence of liquid biopsy, a non-invasive approach that analyzes biomarkers in body fluids , including blood, saliva, offers promising opportunities for comprehensive multi-omic profiling in oral cancer. The purpose of the present study was to use bioinformatics to discover concurrent gene signatures from tissue and liquid biopsy sample and define their potential mechanisms in OC.The Gene Expression Omnibus (GEO) database was used to acquire data for OSCC(involving either buccal mucosa or Tongue). Differentially expressed genes (DEGs) in the control and case groups were determined using GeneSpring analysis. Protein-protein interaction (PPI) network and functional enrichment were built for DEGs. Intrinsic disorder property of hub genes were evaluated using PONDR®. qPCR of four selected hub genes (STAT1, MMP9, CXCL8 and ISG15) was carried out in 100 OSCC tissues along with their adjacent normal tissue and exosomal transcripts derived from serum samples. The expression profile of tissue derived transcript correlated well with exosomal transcripts. These genetic alterations in oral cancer, providing insights into dysregulated signaling pathways in oral cancer pathogenesis. The integration of multi-omic data enabled the identification of novel molecular subtypes and the elucidation of complex molecular networks underlying oral cancer. The identified biomarkers hold promise for early detection, risk stratification, treatment selection, and monitoring of therapeutic response in oral cancer patients. In conclusion, the application of liquid biopsy-based genomic profiling in oral cancer has facilitated a deeper understanding of the molecular heterogeneity and complexity of the disease. This approach holds great potential for advancing precision medicine in oral cancer, ultimately leading to improved patient outcomes and personalized therapeutic strategies. Further research and validation studies are warranted to translate these findings into clinical practice.

Session Title: Cancer Poster Session II

PB5063 Genomic profiling of group of Egyptian retinoblastoma patients

Authors:

O. Eid[1], A. Mohamed[2], H. El-Bassyouni[3], I. Fadel[1], R. Mahrous[1], K. Refaat[1], S. Hussein[1], Retinoblastoma group at 57357; [1]Natl. Res. Ctr., Egypt, Giza, Egypt, [2]Natl. Res. Ctr., Cairo, Egypt, [3]Natl. Res. Ctr., Cairo, Cairo, Egypt

Background: Retinoblastoma is a malignant tumor of the retina. About 50% of patients are predisposed to retinoblastoma by a germline *RB1* pathogenic variant. However, retinoblastoma patients can have non-*RB1* germline pathogenic variant in other cancer-associated genes that promote tumorigenesis. Identification of such genetic alterations is essential and may guide the treatment strategy. **Aim:** The aim of the work was to profile germline "hot spot" genomic variants in group of Egyptian retinoblastoma patients. **Results:** Blood sample from forty three retinoblastoma patients were investigated by MLPA and MLPA negative cases by either aCGH or panel NGS for the most common genes involved in retinoblastoma. 20.9% showed *RB1* deletion, abnormal methylation status, or both by MLPA. Moreover, seven case were investigated by aCGH. aCGH analysis detected CNVs that implicated in carcinogenesis, such as CNVs involving 8p11.22, 14p11, 22q11.2. Furthermore, panel NGS analysis was performed using AmpliSeq Custom DNA panel utilizing a list of genes that are available at cancer genetics web. Pathogenic mutations in *RB1* were detected in 10 cases out of 23 cases 43.47%. 10 cases had likely pathogenic mutations in the *RB1*. While, no mutations were detected in 3 cases. **Conclusion:** Our results might contribute to deepen our understanding of the genetic predisposition of this malignancy as well as it might provide valuable tumor biomarker. Further functional validation of our findings is now required.

Session Title: Cancer Poster Session III

PB5064 Genomic, clinical, and pathologic features of *CHEK2* breast cancer

Inst. of City of Hope, Duarte, CA, [7]Dept. of Lab. Med. and Pathology, Mayo Clinic, Rochester, MN, [8]Dept. of Pathology and Lab. Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [9]Univ. of Kansas Cancer Ctr., Kansas City, KS, [10]Corporal Michael Crescenz VA Med. Ctr., Philadelphia, PA, [11]Dept. of Genetics, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Background: The DNA damage response gene Checkpoint Kinase 2 (*CHEK2*) has been established as a moderate penetrance gene in breast cancer (BC) development. *CHEK2*+ BC is typically estrogen receptor positive (ER+); however, studies have suggested worse outcomes for *CHEK2*+ BC patients. We thus sought to understand genomic and pathological features of *CHEK2*+ compared to germline mutation negative BCs. **Patients and Methods:** We determined the association of likely pathogenic/pathogenic (LP/P) and low-risk *CHEK2* variants with BC in the Penn Medicine BioBank (PMBB). We then compared clinicopathological characteristics of *CHEK2*+ BC to BC from PMBB patients with no cancer risk gene variants upon whole exome sequencing (WES). Finally, we conducted genomic analyses using WES of breast tumor/normal pairs from 60 *CHEK2*+ patients. **Results:** Among the 22,056 women who underwent WES, a significant but moderate association between LP/P *CHEK2* variants and BC was found (OR: 2.1, 95% CI 1.2-3.7, p = 0.01), while that for low-risk missense *CHEK2* variants and BC was not significant. *CHEK2*+ BCs (n = 99 BC/82 people) were majority ER+ (78%), low/intermediate grade (54%), and diagnosed as Stage II and under (n = 87%). Compared to 1013 PMBB mutation negative BC patients, the *CHEK2*+ cohort had a significantly younger age of diagnosis (median 45 vs 55, p < 0.01) but no differences in invasive hormone receptor profile, histology, grade, tumor stage at diagnosis, distant metastasis rates, and deaths. In the WES cohort, 62% of patients (37/60) had the *c.1100delC* variant, 11 had other LP/P variants, and 12 had low-risk missense variants. Allele-specific loss of heterozygosity was found in 56% of all LP/P and 42% of low-risk missense carriers (p = 0.52), with 19% and 17% each losing the mutant allele, respectively. *TP53* variants were found in 31% of *CHEK2* LP/P carriers, similar to ER+ BC (23%) but lower than TNBC (86%) and germline *BRCA1/2* carriers (67%) from The Cancer Genome Atlas (TCGA). All LP/P, *c.1100delC* only, and low-risk missense *CHEK2* subsets had similar homologous recombination deficiency (HRD) scores, tumor mutational burden, microsatellite instability, and *BRCA* signature (Signature 3). LP/P *CHEK2* HRD scores were lower (mean: 24, 95% CI: 21-28), while Signature 3 (mean: 0.05, 95% CI: 0.03-0.07) was similar compared to the mutation negative ER+, HER2-, or TNBC groups (n = 639) in TCGA. **Conclusions:** These results indicate that *CHEK2*+ BC is similar clinically and genomically to sporadic ER+ BC without evidence to suggest PARP inhibition response. Genomic and pathological features do not suggest an etiology for increased aggressiveness of *CHEK2*+ BC, consistent with outcomes in our clinical cohort.

Session Title: Cancer Poster Session I

PB5065 Germline DNA repair pathway deficiency and clonal TP53/KRAS alterations in pancreatic cancer driving target therapy.

Authors:

S. Innamorato[1,2], E. Pasquinelli[1,2], V. Serio[1,2], L. Adamo[1,2], M. Lista[1,2], L. Loberti[1,2,3], E. Antolini[1,2], G. Castello[1,2], J. Covarelli[1,2], D. Maffeo[1,2], C. Fallerini[1,2], P. Pancreatic cancer remains one of the most lethal malignancies, with a dismal prognosis and mortality/incidence ratio of 94%. In a fraction of patients BRACA germline variants have been identified but PARP inhibitor clinical trials failed in these patients. Here we want to address the full spectrum of germline variants and interpret the results within the framework of clonal mutations. A cohort of 87 pancreatic cancers who underwent accurate pedigree reconstruction and genetic counselling were enrolled. A virtual panel of 230 cancer driver genes were investigated by exome analysis for germline variant identification, while Next Generation Sequencing (NGS) cell-free DNA (cfDNA) analysis focused on 77 clonal cancer drivers. Germline variants in DNA repair genes (DRGs) were identified in 53% of cases. The homologous recombination (HR) genes (*BRCA1/2*, *PALB2*, *CHEK2*, *ATM*, *SLX4*, *RECQL4*) were found to be the most frequently mutated (46%), followed by base Excision repair (BER) genes (*MUTYH*, *NTHL1*) (14%), mismatch repair (MMR) genes (*MSH2*, *MSH3*, *MSH6*) (11%) and Fanconi anemia (FA) genes (*FAN1*, *SLX4*, *FANCM*) (11%), which were always paired with a second germline mutation in another DRGs. Clinical worsening was marked by paired *TP53* and *KRAS* variants (6 of 19 cases tested). Our results indicated that while a fraction of patients remain target elusive (35%), another fraction (11%) could be treated by immunotherapy with checkpoint inhibitors, and a larger fraction of cases (57%) can be potentially treated by PARP inhibitors: all those within HR or FA deficiency. However, clonal assessment needs to be evaluated as well, as recently KRAS-tumors became druggable by covalent and non-covalent inhibitors. Not addressing clonal evolution could be the primary reason for PARP inhibitor failure in BRACA patients and combo therapy could be envisaged after clonal characterisation by NGS.

Session Title: Cancer Poster Session II

PB5066 Germline genetic analysis of Lynch syndrome using 110K samples from patients with 23 cancer types and controls

Authors:

K. Mizukami[1], U. Yoshiaki[1], M. Endo[1], Y. Iwasaki[1], Y. Kamatani[2], M. Hirata[3,2], K. Shiraisihi[4], T. Kohno[4], I. Imoto[5], K. Matsuda[2], H. Nakagawa[1], Y. Murakami[2], Y. Momozawa[1]; [1]RIKEN, Yokohama, Japan, [2]The Univ. of Tokyo, Tokyo, Japan, [3]Natl. Cancer Ctr. Hosp., Tokyo, Japan, [4]Natl. Cancer Ctr. Res. Inst., Tokyo, Japan, [5]Aichi Cancer Ctr., Nagoya, Japan

Lynch syndrome is a rare familial cancer syndrome caused by pathogenic variants (PV) in the mismatch repair genes: *MLH1*, *MSH2*, *MSH6*, or *PMS2*. Although PVs in these genes are known to be associated with various types of cancers, the current estimated risk of developing the cancers was based mainly on studies with potential selection bias. In this study, we conducted a large-scale case-control analysis to evaluate the risk of developing cancers in individuals with PVs in the four genes and identify their clinical and demographic characteristics. Using targeted sequencing, we analyzed the coding regions of the four genes in over 75,000 patients with 23 cancer types and over 35,000 individuals without cancers in the same population, both of which were sourced from a multi-institutional hospital-based registry, BioBank Japan. Variants predicted to loss of function based on changes in amino acid sequence or registered as pathogenic and likely pathogenic in ClinVar were collectively referred to as PV. We compared the PV frequencies between cases and controls and documented the demographic and clinical characteristics of patients with PVs. In this study, we defined associated genes if they had a high or moderate risk ($OR \geq 1.5$) of development ($p < .05$). We identified a total of 229 PVs across the four genes. The highest carrier frequency of PVs in one of the four genes was observed in endometrial cancer (5.0%), followed by colorectal cancer (1.0%), among cancers with over 100 patients. PVs were associated with the development of several cancers, including colorectal and endometrial cancers. The type of associated cancer and the risk varied depending on the four genes. PVs in *MSH2* had the broadest spectrum of associated cancer types: endometrial (OR 53.6), bladder (26.6), colorectal (16.2), gastric (5.8), and prostate (5.3) cancers. The frequency of patients with PVs was higher in patients with multiple associated cancers. Compared to patients without PVs, the diagnosed ages were significantly younger in patients with PVs in terms of colorectal (*MLH1*, *MSH2*, and *MSH6*), endometrial (*MLH1* and *MSH2*), gastric (*MLH1*), and prostate (*MSH2*) cancers. Family histories of endometrial and colorectal cancers were more frequently observed not only among the same cancer patients with PVs but also among other associated cancer patients with PVs. In conclusion, this study precisely defined the risk of developing cancers caused by PVs in the mismatch repair genes and characterized patients with PVs.

Session Title: Cancer Poster Session III

PB5067 Germline mutations in *RAD51C* and *RAD51D* genes observed in cancer patients in Singapore

Authors:

S-T. Li[1], N. Ishak[1], S. Chan[1], S. Chong[1], Z. Zhang[2], J. Chiang[2], J. Ngeow[2,3]; [1]Natl. Cancer Ctr. Singapore, Singapore, None, Singapore, [2]Natl. Cancer Ctr. Singapore, Singapore, Singapore, [3]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Background: *RAD51C* and *RAD51D* play crucial roles in homologous recombination-mediated DNA repair. Germline pathogenic variants in *RAD51C* and *RAD51D* genes have been known to associate with increased risk of developing breast and ovarian cancer. However, the prevalence and clinical significance of germline mutations in *RAD51C* and *RAD51D* among cancer patients in Singapore has not been fully explored. **Methods:** We performed a review on cancer patients who were seen at the Cancer Genetics Service, National Cancer Centre Singapore, from 2015 to May 2023. Patients who underwent germline genetic testing using multi-gene panel including *RAD51C and RAD51D* were reviewed. Patient demographics, clinical characteristics as well as their family history of cancers, were collected and analysed. **Results:** A total of 3121 cancer patients, representing various cancer types, who underwent germline genetic testing were included in our analysis. Germline pathogenic variants (PV) in *RAD51C* and *RAD51D* were identified in 19 (0.6%) and 17 (0.5%) unrelated cancer patients, respectively. The prevalence of germline PVs in *RAD51C* and *RAD51D* genes was 1.9% and 1.2% among 642 ovarian cancer patients, respectively, and 0.6% and 0.4% among 1746 breast cancer patients, respectively. The median age at ovarian diagnosis was 57.5 years for patients with *RAD51C* PVs and 48 years for those with RAD*51D* PVs. Similarly, the median age at breast cancer diagnosis was 49 years for patients with *RAD51C* PVs and 46 years for those with *RAD51D* PVs. Majority of patients harbouring germline PVs in *RAD51C* and *RAD51D* genes presented with a family history of cancer. Specifically, 57.9% of patients with *RAD51C* PVs and 41.2% of patients with *RAD51D* PVs had a family history of breast and/or ovarian cancer. Several recurrent PVs were identified in patients of Chinese ethnicity, including c.394dup (p.Thr132Asnfs*23) (5/19), c.905-2A>C (5/19) and c.571+5G>A (4/19) in *RAD51C* genes and c.270_271dup (p.Lys91Ilefs*13) (14/17) in *RAD51D* gene. **Conclusion:** Our findings provide insights into the prevalence, cancer spectrum and recurrent variants in *RAD51C* and *RAD51D* genes among cancer patients in Singapore.

PB5068 Germline Panel As Standard Method for Investigating Hereditary Breast and Ovarian Cancer Syndrome in Brazilian Supplementary Health System

Authors:

J. FARIA[1], L. Marco[2], L. bastos-rodrigues[2], J. Assumpção[3], F. Soardi[4], L. Matos[2], G. Cunha[5], A. Ribas[6]; [1]UNIVERSIDADE FEDERAL DE MINAS GERAIS, BELO HORIZONTE, Brazil, [2]Univ.e Federal de Minas Gerais, Belo Horizonte, Brazil, [3]Geneticenter Centro de Genética, BELO HORIZONTE, Brazil, [4]Laboratório Lustosa, BELO HORIZONTE, Brazil, [5]Cetus Oncologia, BELO HORIZONTE, Brazil, [6]Hosp. Felício Rocho, BELO HORIZONTE, Brazil

The Brazilian private health system currently follows the medical literature in which it estimates the prevalence of 10% of pathogenic and/or probably pathogenic variants in women with breast cancer, recommending germline testing in stages through New Generation Sequencing of Genes and Multiplex Ligation-dependent Probe Amplification of the BRCA1 and BRCA2 genes and, in case of inconclusive results, performing a germ panel. Recent studies published worldwide suggest an approximate prevalence of between 10 and 20% of pathogenic and probably germline pathogenic variants in individuals with cancer. Two recent Brazilian studies showed an approximate prevalence of 18% of pathogenic and probably pathogenic variants in individuals at risk of hereditary cancer. The present study evaluated 701 individuals between 2021 and 2022 with Hereditary Breast and Ovary Cancer Syndrome criteria and performed a single test through germ panel, identifying a prevalence of 19.74% of pathogenic and probably pathogenic variants. The results suggest that the standard use of the germ panel results in a 90% gain in the sensitivity of identifying pathogenic and probably pathogenic germline variants and a 67% reduction in the cost and time of investigation.

Session Title: Cancer Poster Session II

PB5069 Germline Testing for Lynch Syndrome:Are we there yet?

Authors:

S. Agnihotri, A. A. Mehta, S. Nathany, H. H. Diwan, D. D. Kumar; Rajiv Gandhi Cancer Inst. And research centre, New Delhi, India

Introduction: Of the genetic cancer risk syndromes, Lynch syndrome is the most prevalent, accounting for 3-5% of all colorectal cancers (CRC) and endometrial malignancies (EC). Finding these individuals facilitates family screening, future surveillance planning, therapeutic optimization, and prognosis prediction. The most practical, economical, and effective screening technique is now being used to screen patients with MSI or MMR deficiencies for other genetic abnormalities. **Objective: T**o assess the MMR/MSI prevalence across all tumor types and the take-up of Lynch syndrome germline testing in India. **Methods:** The adoption of germline Lynch syndrome testing from 2021 to 2015, as well as the MMR and MSI status across all malignancies, were evaluated in this single-center cross-sectional investigation. The state of mismatch repair was assessed by analyzing the somatic tumor using either immunohistochemistry (IHC) for MLH1, PMS2, MSH2 & MSH6 (on Ventana platform) or MSI by fragment length analysis with a Promega kit (SeqStudio/Applied Biosystems).
Peripheral blood was used for the germline test, which looked for single nucleotide variants and indels in the four MMR genes (MLH1, PMS2, MSH2, and MSH6) using a tailored DNA panel and Next-generation sequencing (Ion Torrent).**Results:** Out of 1447 cases showed, a total of 288 (19.9%) showed MMR deficiency (dMMR)/MSI.In 77 of 288 patients (26.7%), a germline lynch test was performed. MLH1 gene mutations were found in 51 of 77 (66.2%) cases analyzed, with a frequency of 60.8%. 60 of 288 cases (20.8%) had insurance coverage but did not undertake germline testing (p=0.0005). A germline mutation was found in 42/61 CRCs tested (68.9%), with the MLH1 gene being most frequently implicated (66.7%) (p 0.0001). **Discussion:** Guidelines recommend germline testing after assessing all CRCs and, more recently, all ECs f r dMMR/MSI to identify Lynch syndrome patients better. When compared to an Australian study that discovered a referral rate of 11% in dMMR CRCs, the current study's referral rate for genetic testing for Lynch syndrome was 26.7%.2In the US, non-Hispanic whites had the highest referral rate (21.2%), while the Hispanic patients 10.9%. **Conclusion:** Genetic testing aids in the early detection of recurrence and the screening of relatives. According to our observations, socioeconomic limitations contribute to India's limited penetration of germline testing. By providing proper counseling, doctors and molecular pathologists can address this unmet need and assist in eliminating the accompanying societal stigma.

Session Title: Cancer Poster Session III

PB5070 Germline whole genome sequencing of children with Down syndrome identifies novel variants associated with risk of acute lymphoblastic leukemia.

Authors:

M. Richard[1], Y. Yu[2], J. J. Junco[1], C-J. Hsu[1], A. J. de Smith[3], T. C. Rosser[4], E. J. Leslie[4], M. Devidas[5], E. A. Raetz[6], M. L. Loh[7], S. P. Hunger[8], J. M. Espinosa[9], J. J. Yang[5], S. L. Sherman[4], C. D. Huff[2], K. Rabin[1], P. J. Lupo[1]; [1]Baylor Coll. of Med., Houston, TX, [2]UT MD Anderson Cancer Ctr., Houston, TX, [3]Univ. of Southern California, San Gabriel, CA, [4]Emory Univ., Atlanta, GA, [5]St Jude Children's Res. Hosp., Memphis, TN, [6]New York Univ., New York, NY, [7]Seattle Children's Hosp., the Ben Town Ctr. for Childhood Cancer Res., Univ. of Washington, Seattle, WA, [8]Children's Hosp. of Philadelphia, Philadelphia, PA, [9]Linda Crnic Inst. for Down Syndrome, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Background: Children with Down syndrome (DS) have a 10-fold greater risk for acute lymphoblastic leukemia (ALL), primarily B cell precursor ALL, than children without DS. We previously reported ALL susceptibility variants identified by array-based genotyping among children with DS. Here, we leverage whole genome sequencing (WGS) to expand identification of common variants associated with the excess risk of ALL in DS. **Methods**: We performed Illumina 30X germline WGS of 379 individuals with DS-ALL enrolled on Children's Oncology Group trials and 1504 individuals without ALL from DS research cohorts. Variants were detected following Gabriella Miller Kids First best practices, with quality control and ancestry estimation. We conducted autosomal, non-chr21 genome-wide association studies (GWAS) adjusted for sex and top principal components using 1) PLINK for ancestry-specific GWAS followed by trans-ancestry meta-analysis, and 2) GENESIS mixed models for pooled GWAS including all individuals. **Results**: In meta-analysis and pooled analysis, we identified known and novel loci significantly associated with DS-ALL (P<5x10^{-8}). Variants in the *IKZF1* locus were the top known association with DS-ALL, yet each analysis identified different top variants*:* rs58923657 in European ancestry individuals (odds ratio [OR]: 2.08, P =1.1x10^{-10}), rs17133807 in trans-ancestry meta-analysis (OR=1.90, P=7.3x10^{-12}), and rs28462675 in pooled analysis (OR=1.11, P=1.1x10^{-13}). These variants map to similar enhancer regions and transcription factor binding sites (including *PAX5*, *IKZF2*) in ENCODE B-lymphoblastoid cell lines. We validated the *CDKN2A* association (rs3731249, OR=1.23, P=1.5x10^{-9}) and report a novel locus on chr4q13.1 (rs17290452, OR=1.17, P=2.4x10^{-8}), a region also previously associated with susceptibility to *ETV6::RUNX1*+ B-ALL. Our pooled analysis identified multiple novel loci, including 22 significant variants mapping to *PCBP2* (top variant rs1361910621, OR=2.24, P=2.1x10^{-16}), a poly(rC)-binding protein that may function as an oncogenic splicing factor. This *PCBP2* region has strong support for regulatory potential in B cells and has recently been characterized as a novel tumor suppressor in hematologic malignancies. **Conclusions**: Leveraging WGS data on individuals with DS, we validated enhanced genetic penetrance at known ALL predisposition loci among individuals with DS-ALL and identified a novel locus at *PCBP2*. Expansion of these findings is underway by integrating additional germline samples, identifying trisomic variants on chromosome 21, and performing functional validation of identified loci.

Session Title: Cancer Poster Session I

PB5071 Germline-phased de novo assembly of K562 cancer genome from HiFi and HiC data imparts complete cancer genomic rearrangements at single-nucleotide resolution.

Authors:

Y. Guo[1,2], H. Cheng[1,2], H. Li[1,2], C-Z. Zhang[1]; [1]Dana Farber Cancer Inst., Boston, MA, [2]Harvard Med. Sch., Boston, MA

Long-read sequencing has enabled the first complete assembly of a human genome and is rapidly transforming the analysis of human genetic variation. *De novo* long-read assembly is especially powerful for resolving complex structural variation and large segmental duplications, both of which occur frequently as somatic alterations in cancer genomes. However, the presence of whole-chromosome and large segmental duplications in aneuploid cancer genomes poses critical problems for the current assembly algorithms that are designed for haploid or diploid genome assembly. Due to this technical challenge, both the utility and the feasibility of *de novo* cancer genome assembly are unknown.

Here we took these cancer genome characteristics into account and presented the *de novo* assembly of the K-562 genome that preserves the germline phasing, allelic copy number and chromosome structures of this widely used cancer cell line. The assembly was constructed from PacBio HiFi long reads and Hi-C short reads. It was based on the phased assembly generated by a diploid genome assembler (hifiasm) and further refined by haplotype-specific Hi-C contacts and DNA copy number. We resolved previously unknown translocations, even with complex ones such as foldback. We discussed technical challenges due to large DNA deletions (loss-of-heterozygosity) and duplications in aneuploid genomes and described strategies to overcome these challenges in *de novo* assembly. The assembly of the K-562 genome provides a more complete and accurate reference than ever before for the interpretation and correlation of functional genomic and epigenomic data of this widely used cell line. This study further establishes a framework for analyzing cancer genomes by long-read sequencing and *de novo* assembly.

Session Title: Cancer Poster Session II

PB5072 Haplotype-resolved multi-modal analysis of cancer genomes using Oxford Nanopore sequencing.

Authors:

P. Rescheneder[1], S. Mckenzie[2], S. Aganezov[3], P. James[4], S. Juul[5]; [1]Oxford Nanopore Technologies, Oxford, United Kingdom, [2]Oxford Nanopore Technologies, Spokane, WA, [3]Oxford Nanopore Technologies, Inc., Reading, MA, [4]Oxford Nanopore, Oxford, United Kingdom, [5]Oxford Nanopore Technologies, New York, NY

Cancer is a complex and dynamic disease driven by somatic genomic and epigenomic alterations that accumulate over time. These changes give rise to heterogeneous collections of cells or clones, each with distinct (epi)genomic profiles within a single tumour. Accurate characterisation of these changes is crucial for understanding the mechanisms driving the disease, identifying potential therapeutic targets, and personalising treatment strategies. Due to the technological constraints of short-read and array-based approaches, cancer research has historically had a strong focus on detecting small genomic changes like SNPs and small indels (SNVs) as well as the broad characterisation of large-scale copy number changes (CNVs), mostly ignoring other important variant classes and epigenetic modifications. Here we demonstrate how Oxford Nanopore native long-read sequencing enables the direct detection of not only SNVs, but also break point-resolved simple and complex structural variants (SVs and CNVs), identification of DNA modifications like 5-methylcytosine (5mC) and 5-hydroxy-methylcytosine (5hmC), and haplotype phasing of all variant types from a single tumour-normal dataset. We use well characterised cancer cell lines and in-silico benchmarking datasets to assess somatic SNV, and SV calling performance using different sequencing depths, and also demonstrate how Nanopore long reads enable haplotype and clone specific CNV calling. Finally, we use twelve matched tumour-normal pairs from four different tissues to showcase a comprehensive tumour-normal analysis using Nanopore sequencing. This includes the characterisation of complex patterns of somatic SVs in the different cancer samples, the identification of 5mC methylation patterns (e.g. in promotor regions) that are unique to certain tissues, exploring characteristic differences in 5hmC levels between tumour and normal samples as well as the detection of microsatellite instability and other hall marks of cancer.

Session Title: Cancer Poster Session III

PB5073 Hematopoietic cell transplantation for inborn errors of immunity in the context of Lynch syndrome

Authors:

E. Damskey[1], M. Similuk[1], R. Gore Moses[1], J. Yan[1], S. Byers[1], B. Beers[1], H. Orellana[1], M. Kamen[1], M. Setzer[1], R. Ghosh[1], G. Uzel[1], D. Dimitrova[2], J. Kanakry[2], D. Hickstein[2], L. Notarangelo[1], S. Holland[1], M. Walkiewicz[1]; [1]NIH/NIAID, Bethesda, MD, [2]NIH/NCI, Bethesda, MD

Background Allogeneic hematopoietic cell transplantation (HCT) can potentially provide long-term curative treatment for patients with severe immune disorders. Late effects from HCT include increased risk of secondary solid tumors due to genotoxic stress from HCT. Concurrently, relatively common cancer predispositions such as Lynch syndrome lead to an increased cancer risk due to defective DNA repair mechanisms. The extent to which familial malignancy risk may be exacerbated by HCT is largely unknown. We seek to add to this sparse literature by reporting on three cases of HCT recipients with both an immune disorder and Lynch syndrome.
Methods We performed exome and/or genome sequencing on study participants with known or suspected inborn errors of immunity from 2017-2023. We analyzed the data for primary findings related to clinical presentation as well as secondary findings. Cases Patient 1: 40yo Non-Hispanic Caucasian female presented with myelodysplastic syndrome. Exome sequencing identified a previously known heterozygous pathogenic *GATA2* variant (p.Arg398Trp), as well as a heterozygous pathogenic *MSH2* variant (p.Gln337LysfsTer20). The patient underwent HCT with a HLA-matched unrelated donor and is >3 years post-HCT without malignancy detected by high-risk Lynch syndrome screening. Patient 2: 35yo Hispanic Caucasian female with a history of granulomatous lymphoproliferation, sinopulmonary infections, and B-cell non-Hodgkin lymphoma, followed by T-cell lymphoma 9 years later, prompting HCT using an HLA-matched unrelated donor and reduced intensity conditioning (RIC). She died 339 days post-transplant due to progressive lymphoma despite successful engraftment. Exome analysis identified two mosaic *TET2* variants [pathogenic, p.Ser280PhefsTer14; and variant of uncertain significance (VUS), p.His1881Tyr], associated with a lymphoproliferative immunodeficiency. Additionally, a likely pathogenic heterozygous *PMS2* variant (p.Ser46Ile) was identified. Patient 3: 5yo Non-Hispanic Caucasian female with a history of immune thrombocytopenia, neutropenia, and alopecia. Genome sequencing identified a homozygous VUS in *RASGRP1* (p.Leu413Pro), which is consistent with her clinical presentation, as well as a heterozygous pathogenic variant in *MLH1* (p.Leu404ValfsTer12). The patient is currently preparing for RIC HCT. Conclusion These three cases add to the sparse literature on allogeneic HCT in the setting of Lynch syndrome. Longitudinal studies in larger cohorts would clarify risks. Identifying cancer predisposition in a critical minority of HCT patients may inform donor selection, conditioning, and post-HCT risk management.

Nenni, 20, 52100, Arezzo, Italy, [7]Oncology, Ospedale La Misericordia, Grosseto, Italy, [8]Dept. of Urology, IRCCS Humanitas Res. Hosp., Rozzano, Italy, [9]Dept. of BioMed. Sci., Humanitas Univ., Pieve Emanuele, Italy

Bladder cancer is the 10th most commonly diagnosed cancer worldwide. Environmental risk factors such as tobacco smoking and occupational exposure to aromatic amines are well known. A not negligible percentage of superficial bladder cancers recur and show resistance to intravesical treatments (IMC or BCG) evolving into a muscle-invasive disease associated with high mortality. Radical cystectomy with or without neoadjuvant cisplatin-based chemotherapy or immunotherapy is the standard of care but morbidity and mortality remain high. Therefore, there is an unmet clinical need for improving the rate of care and quality of life. Markers that can indicate the rate of response and guide chemo- and/or surgical therapy are missing. Thus, the combination of tumor micro-environment analysis and genetic profiling could lead to new risk stratification for those patients and guide personalized treatment. Genetic predisposition has been thought to be less relevant than in other types of cancer due to little impact from family history and lack of clinically significant genetic changes. Therefore, genetic testing is not currently recommended. We wanted to explore the impact of germline predisposition in a cohort of 21 patients with bladder cancer at different stages. A virtual panel of 230 cancer driver genes from exome sequencing was used. A pathogenic germline variant was identified in 33% of patients, while uncertain significance variants were identified in 33% of patients. DNA repair genes were the most affected genes and included the Homologous recombination genes (*BRCA1/2, ATM, RECQL4*), followed by mismatch repair genes (*MLH1, PMS2, MSH3*). Our results challenge the current recommendation on genetic testing for bladder cancer. Furthermore, they suggest the possible use of PARPi or could predict response to immunotherapy with checkpoint inhibitors. The prognosis of patients with bladder cancer who are unexposed to environmental risk factors is generally poor. Bladder cancer tends to present earlier, be more aggressive and show higher resistance to chemotherapy. Thus, the knowledge of genetic profiling in this subset of patients may represent an improvement in the management of bladder cancer offering specific treatments and exploring new drugs such as PARPi.

Session Title: Cancer Poster Session II

PB5075 Higher breast cancer polygenic risk scores (PRS) are associated with less aggressive tumors and longer survival.

Authors:

D. Kurant, S. Groha, A. Gusev; Dana-Farber Cancer Inst., Boston, MA

Background: Identifying patients who are most likely to respond to treatments is a fundamental goal of precision oncology. Germline Polygenic Risk Scores (PRS) are an estimate of an individual's genetic risk for a trait/disease, but the influence of PRS on clinical outcomes in patients with cancer is largely unstudied. Here we quantified the association between germline PRS and somatic features in 2,058 patients with breast cancer treated at a tertiary cancer center.

Methods: Patients were biopsied as part of routine clinical care, sequenced on a targeted panel of 400-500 known cancer genes, and had common germline polymorphisms imputed based on off-target reads. Over 200 PRS from public GWAS were evaluated for association with survival across multiple anchor points. Patients were restricted to European ancestry and a PRS was computed for each patient for common traits including cancer risk and non-cancer phenotypes. The association between PRS and survival was assessed by a Cox proportional hazards model with sex, age, ancestry, and technical factors as covariates. Survival time was evaluated from diagnosis, biopsy, and first palliative intent therapy. All participants provided informed consent for research.

Results: An ER-positive breast cancer PRS was significantly associated with longer survival with a Hazard Ratio (HR) of 0.89 per standard deviation of PRS ($p = 1.50x10^{-4}$, FDR 0.03). 4 additional (partially correlated) breast cancer-related PRS were nominally significant and exhibited similar HRs. While the strongest association was seen from the time of biopsy, nominally significant ($p<0.01$) associations between the PRS and survival were also observed starting from diagnosis date or the date of first palliative-intent therapy.

We hypothesized that increased germline risk may lead to less aggressive tumors in patients who develop breast cancer and evaluated associations with somatic features. Higher breast cancer PRS was significantly associated with fewer TP53 mutations (OR=0.85, $p=8.7x10^{-5}$). The breast cancer PRS was also nominally associated with subclonal TP53 mutations after restricting to mutation carriers (OR = 1.22, p=0.032). The PRS association with survival remained nominally significant when including TP53 status as a covariate (HR = 0.93, p = 8.85x10-3). Statistical power was insufficient for an interaction analysis.

Conclusions: We demonstrate that higher germline risk correlates with longer survival in a large cohort of breast cancer patients. We hypothesize that higher germline risk may result in the development of less aggressive tumors and lead to better clinical outcomes.

Session Title: Cancer Poster Session III

PB5076 High-throughput DNA methylation profiling in the ovarian cancer susceptibility genes promoters: assessment across a wide spectrum of blood- and tissue-derived samples from patients and healthy individuals.

Authors:

M. Suszynska[1], A. Mostowska[2], J. Dabrowska[2], M. Ratajska[3,4], P. P. Jagodzinski[2], P. Kozlowski[1]; [1]Inst. of Bioorganic Chemistry Polish Academy of Sci., Poznan, Poland, [2]Poznan Univ. of Med. Sci., Poznan, Poland, [3]Med. Univ. of Gdansk, Gdansk, Poland, [4]Dunedin Sch. of Med. Univ. of Otago, Dunedin, New Zealand

Hypermethylation of promoter CpG islands is a generally recognized epigenetic mechanism responsible for gene silencing, constituting, apart from mutations, an alternative mechanism of gene inactivation in cancers. Such epimutations (EM) are somatic events in tumors; however, constitutional EM may occur in some normal tissues (e.g., blood), usually as a secondary event (i.e., with an associated genetic variant) or in a mosaic state, contributing to increased cancer risk.

To investigate the incidence of EM in ovarian cancer (OC) susceptibility genes, we developed a deep bisulfite sequencing assay targeting the promoter regions of 8 OC high- to moderate-risk genes (*BRCA1*, *BRCA2*, *BRIP1*, *RAD51C*, *RAD51D*, *ATM*, *NBN*, and *CHEK2*) and the *HOXA11* gene, which hypermethylation has already been identified as a potential biomarker in several cancers. The amplicon library was prepared from blood-derived DNA samples of OC patients (n=~100) and sex- and age-matched controls (CTRL; n=~100) using a two-step PCR process, and the library was then profiled by next-generation sequencing. Over 1000 individual DNA molecules per region and sample were analyzed to precisely determine the DNA methylation level. To better characterize the methylation profile of selected genes, we extended the analysis with external datasets generated with CpG genotyping arrays deposited at the GEO, UCSC Xena, and GTEx portals, collecting in total an additional ~1800 blood- and tumor/tissue-derived DNA samples from both OC patients and healthy CTRL. Promoter methylation levels of analyzed genes were minimal (except for *HOXA11*) in both blood- and tissue-derived samples. Comparing the mean DNA methylation between OC patients and CTRL revealed no relevant differences in blood-derived samples; however, a significant difference was observed for *HOXA11* in tumor-/tissue-derived samples. In addition, numerous EM with >20% methylation level in *BRCA1* and *RAD51C* was observed in tumors compared to normal tissue. Also, examples of EM with methylation level <20% occurred in *BRIP1* and *RAD51D*; however, these differences may not be representative due to the smaller CTRL size group. In summary, our data improve the understanding of the role of epigenetic silencing in OC, pointing to the particular importance of *HOXA11*, *BRCA1*, and *RAD51C* somatic EM in oncogenesis, while indicating that constitutional EM in OC susceptibility genes are very rare. In addition, the developed assay represents a highly sensitive, cost-effective, and high-throughput tool for precise multisample, multigene DNA methylation analysis, which could become the gold standard in OC cancer research and diagnostics.

Gunter[14], S. B. Gruber[15], A. I. Phipps[1], S. L. Schmit[2], U. Peters[1]; [1]Fred Hutchinson Cancer Ctr., Seattle, WA, [2]Cleveland Clinic, Cleveland, OH, [3]The Univ. of Melbourne, Parkville, Australia, [4]Univ. of Toronto, Toronto, ON, Canada, [5]Albert Einstein Coll. of Med., New York, NY, [6]American Cancer Society, Atlanta, GA, [7]German Cancer Res. Ctr., Heidelberg, Germany, [8]Univ. of Utah, Salt Lake City, UT, [9]Univ. of Pittsburgh, Pittsburgh, PA, [10]Umeå Univ., Umeå, Sweden, [11]Harvard Med. Sch., Boston, MA, [12]Brigham & Women's Hosp., Boston, MA, [13]Mem. Univ. Newfoundland, St John's, NL, Canada, [14]Intl. Agency for Res. on Cancer, Lyon, France, [15]City of Hope Natl. Med. Ctr., Duarte, CA

Background: Germline genetic factors central to immunity, such as human leukocyte antigen (HLA) variants, have been associated with tumor immune microenvironment features and response to immune checkpoint inhibitors. HLA heterozygote advantage, where heterozygosity may be related to presentation of cancer neoantigens in more diverse contexts for T cell recognition, may have differential effects by colorectal cancer (CRC) molecular subtype. Methods: Utilizing the resources of the Genetic Epidemiology of Colorectal Cancer Consortium (GECCO) and the Colon Cancer Family Registry (CCFR), classical HLA alleles were imputed from genome-wide array datasets through SNP2HLA. Eleven observational studies including up to 7,241 cases with molecular subtypes for microsatellite instability (MSI), CpG island methylator phenotype (CIMP), and somatic mutations in *BRAF* and *KRAS* genes, and 10,510 controls were analyzed, all of European descent. Associations between HLA class I and class II heterozygosity and risk of developing CRC stratified by molecular subtypes were assessed using case-only logistic regression and multinomial regression adjusted for age, sex, GWAS panel, and the first five principal components of ancestry. Results: A higher number of homozygotes for class II HLA alleles was associated with a higher odds of developing *BRAF*-mutated tumors [Odds ratio (OR) 3 homozygotes vs. heterozygotes = 1.61, 95% confidence interval (CI) (1.08, 2.38)] but not *BRAF*-wildtype tumors [1.06, 95% CI (0.85, 1.32); P heterogeneity = 0.084]. No other overall measure of class I or class II heterozygosity was associated with a meaningful difference in trend; however, some specific HLA allele differences where heterozygote was the reference group were significant for HLA-C by MSI status [MSI-high OR = 0.87, 95% CI (0.69, 1.10); MSI-low/MSS OR = 1.11, 95% CI (0.99, 1.23); P heterogeneity 0.044] and HLA-DRB1 by *BRAF* status [*BRAF*-mutated OR = 1.30, 95% CI (1.04, 1.64); *BRAF*-wildtype OR = 0.97, 95% CI (0.86, 1.09); P heterogeneity 0.025]. Conclusions: HLA heterozygosity association with CRC risk may vary by CRC tumor molecular subtype, where less heterozygosity may be associated with higher risk for *BRAF*-mutated tumors.

Session Title: Cancer Poster Session II

PB5078 Identification of *331G.A* Polymorphism of *PR*gene and *397T.C* and *351A.G* of the *ER alpha*gene as genetic predisposition markers for breast cancer management in yaoundé general hospital.

Authors:

N. NGUEDIA KAZE; Covenant Univ., Ota city, Nigeria

Background : 30% of breast cancer patients in Cameroon usually die a year after diagnosis, since cancer is an accumulation of molecular changes in gene, the *+331 G.A* polymorphism of *PR* gene and *397T.C* and *351A.G* polymorphisms of ER Alpha gene have been investigated as etiological factors. **Methods :** 16 cases diagnosed positive for breast cancer at the Yaoundé general hospital were recruited through the patient file consulting for the case control study. Blood samples were collected from them and 22 healthy women recruited using a questionnaire and a inform concern was signed by each of them. *+331 G.A* polymorphism in the *PgR* gene was identified using NIaIV endonuclease and direct molecular haplotyping was used to determine the relationship between the 2 polymorphisms in the *ER* Alpha gene, *397T.C* and *351A.G* using PvUII and Xbal endonucleases by PCR-RFLP. The data were analyzed using SPSS v20. **Results**: We got a mean age of 53+/-11,08 in our cancerous group with the predominance of invasive ductal carcinoma. We obtained an Odds Ratio of 1.067 with 95% Confidence Interval of 0.940-1.211 and P value of 0.421, making a non-significant association of *331G.A RP* mutation with breast cancer. In addition, we identified the mutant *CG* haplotype allele of the *ER* alpha gene with a predominance in the cancer group exclusively with a frequency of 56.25% with an OR of 2.022 with a 95% CI 0.432 - 9.461 with a p-value of 0,3, not significantly associated with breast cancer. **Conclusion**: Based on our study findings, the specific genetic markers investigated, did not show a significant association with the risk of breast cancer development in our study population.

Session Title: Cancer Poster Session III

PB5079 Identification of a robust microRNA signature for estimating survival time in patients with hepatocellular carcinoma.

Authors:

S. Yerukala Sathipati[1], N. Aimalla[2], M-J. Tsai[3], R. Sharma[2], S. Shukla[1]; [1]Marshfield Clinic Res. Inst., Marshfield, WI, [2]Marshfield Clinic Hlth.System, Marshfield, WI, [3]Hinda and Arthur Marcus Inst. for Aging Res. at Hebrew Senior Life, Boston, MA

Hepatocellular carcinoma (HCC) is one of the most commonly diagnosed liver malignancy and leading cause of cancer-associated mortality worldwide. Most HCCs are resistant to systematic treatments, including surgery, radiation, immune and chemotherapies. Due to the ongoing advancements in the genetic field, identifying microRNA (miRNA) markers in HCC may unravel the disease mechanism and help estimate survival outcome in patients with HCC. Accordingly, we aimed to identify a survival-associated miRNA signature that estimate survival time in patients with HCC. We extracted the miRNA expression profiles of 373 patients with HCC from The Cancer Genome Atlas Database and developed a machine learning-based survival estimation method called HCC Survival Time (HST). The HST method was designed using optimal feature selection algorithm incorporated with support vector regression. HST selected a robust miRNA signature consisting of 32 miRNAs and obtained a mean R and MAE of 0.87±0.02 and 0.73 year, respectively between actual and estimated survival time of patients with HCC. The miRNAs of the identified signature has four diagnostic miRNAs, including hsa-miR-1301-3p, hsa-miR-17-5p, hsa-miR-34a-3p, and hsa-miR-200a-3p, and prognostic miRNAs, including hsa-miR-146a-3p, hsa-miR-200a-3p, hsa-miR-652-3p, hsa-miR-34a-3p, hsa-miR-132-5p, hsa-miR-1301-3p, and hsa-miR-374b-3p, of HCC. The Kyoto Encyclopedia of Genes and Genomes pathway analysis and miRNA-disease association results revealed that identified miRNA signature enriched in hepatitis B pathway. We conclude that survival associated miRNA signature can estimate the prognosis in patients with HCC and further exploration of these miRNAs would help determine mechanism for therapeutic interventions.

PB5080 Identification of Aurora A as a Novel Oncogene in Hepatocellular Carcinoma and targeting it with CRISPR/Cas9 system

Authors:

m. el-hefnawy, N. Samir, b. soliman, R. Hassan; Natl. research center, cairo, Egypt

Hepatocellular carcinoma (HCC) is one of the most lethal cancers worldwide. There are still challenges for HCC treatments, especially high resistance of the cancer cells to chemotherapy and/or target therapy. The clustered regularly interspaced short palindromic repeats (CRISPR/Cas9) system has demonstrated considerable advantages over other nuclease-based genome editing tools due to its high accuracy, efficiency, and strong specificity. The aim of the present study was to identify the hub genes and underlying pathways of HCC via bioinformatics analyses and using CRISPR/Cas9 system for treatment HCC. The differentially expressed genes (DEGs) were analyzed for functional enrichment pathways and protein-protein interaction (PPI) network was constructed. We knocked out (KO) AURKA(Aurora A) gene using CRISPR-Cas9 system to evaluate its effect on tumor proliferation, migration and apoptosis in HCC. We report that AURKA was highly expressed in liver cancer, showing its promise to be developed further into an anti-cancer agent. We identified differentially expressed genes (DEGs) based on four Gene Expression Omnibus(GEO) datasets. A protein-protein interaction (PPI) network was established to identify the central nodes associated with HCC. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analysis of the central nodes were conducted in online tool Database for Annotation, Visualization and Integrated Discovery (DAVID) and using the Cytoscape software to find the 14 top hub genes. This hub genes are : CDK1, CCNA2, CCNB2 ,CCNB1, CDC20, UBE2C, BUB1B, CDKN3, CDC6, AURKA, BIRC5, MAD2L1, MELK, CKS2. AURKA was targeted for Knock out by CRISPR/Cas9 system. We designed AURKA gene specific single guide RNA (sgRNA) with CRISPR/Cas9 system and studied in vitro effects on tumor properties of HepG2. We cloned the sgRNA into pCAG-eCas9 CRISPR vector then transfected into cell culture by lipofectamine transfecting agent. The expression of AURKA was investigated in transfected cell culture by real time PCR and Western blot then using many assays for screening the effect on the tumor proliferation, apoptosis and migration: cell cycle assay, MTT assay, wound healing assay, apoptosis assay. The study identified several genes and the signaling pathways that were associated with tumorigenesis using bioinformatics analyses, which could be potential targets for the diagnosis and treatment of HCC. AURKA was overexpressed in HCC tissues and inhibition the apoptosis process and increasing the cell cycle and cell migration. The study provides evidence that CRISPR/Cas9-mediated AURKA knockout suppresses HCC cell proliferation and migration.

PB5081 † Identification of circulating epigenetic biomarkers for lesion burden in familial Cerebral Cavernous Malformation by whole-genome methylome profiling.

Authors:

S. Weinsheimer[1], J. Nelson[2], M. C. Mabray[3], B. L. Hart[3], L. Morrison[4], C. E. McCulloch[5], H. Kim[6]; [1]Dept. of Anesthesia and Perioperative Care, Ctr. for Cerebrovascular Res., Inst. for Human Genetics, Univ. of California San Francisco, San Francisco, CA, [2]Dept. of Anesthesia and Perioperative Care, Ctr. for Cerebrovascular Res., Univ. of California San Francisco, San Francisco, CA, [3]Dept. of Radiology, Univ. of New Mexico, Albuquerque, NM, [4]Dept. of Neurology, Univ. of New Mexico, Albuquerque, NM, [5]Dept. of Epidemiology and Biostatistics, Univ. of California San Francisco, San Francisco, CA, [6]Dept. of Anesthesia and Perioperative Care, Ctr. for Cerebrovascular Res., Epidemiology and Biostatistics, Inst. for Human Genetics, Univ. of California San Francisco, San Francisco, CA

Background: Individuals with familial Cerebral Cavernous Malformation (fCCM) present with multiple lesions that can grow in number and size over time which may cause hemorrhagic strokes. Lesion burden is highly variable, suggesting environmental or genetic disease modifiers. Comprehensive DNA methylome profiling has revealed biomarkers for cardiovascular disease and cancer, and may be a useful tool to identify disease monitoring biomarkers for CCM and novel therapeutic targets to stabilize CCM lesions. We hypothesized that the methylome differs between fCCM cases with greater lesion burden compared to cases with lower lesion burden.
Methods: We selected 10 individuals enrolled in the Brain Vascular Malformation Consortium CCM study at the University of New Mexico as representative cases with *CCM1* Q455X genetic mutation and extreme CCM lesion burden (n=5, range 51-619, mean age 47.5y and n=5, range 3-5, mean age 42.0y). Genomic DNA from whole blood was profiled for genome-wide methylation using Whole Genome Bisulfite Sequencing services at Psomagen (~20x coverage). Differentially Methylated Regions (DMR) were identified by comparing the average methylation ratio in fCCM cases with high vs. low lesion count by *t*-test. DMRs with a delta average methylation ratio between the two groups ≥|0.2| and P≤1x10-06 were flagged as both statistically significant and having a large effect size.
Results: Methylome profiles differed between fCCM cases with high vs. low lesion burden with 259 significant DMRs (53% hypermethylated in high lesion burden) mapping within or nearby genes. Ten DMRs mapped to CpG islands for the following genes: *RNA45S5*, *EHBP1L1*, *LBX2-AS1*, *AATK*, *SOX11*, *CDH18*, *NFIC*, *SEMA5B* and *NKX6-2*. DMRs with the largest differences (≥|0.5|) mapped to the promoter *LRRC14B*, 3' untranslated region *EHBP1L1*, exonic region *UACA*, downstream *DDX12P* and *METTL2B*, and intronic regions of the following genes: *MYPN*, *IGFBP7*, *CCSER1*, *CNOT4*, *MAST4*, *ADGRL2*, *ADGRB1*, *OTUD7A*, *KRT72*, *NDUFAF5*, *ADK*, *LMTK2*, *ZC3H6*, *ADCY2*, *SH3RF3* and *PLBD1*. Interestingly, two DMRs associated with lesion burden map to *RASGRF2* and *IGF1R*, which both function in the RAS and MAPK signaling pathways important to CCM pathogenesis.
Conclusions: We performed the first whole-genome methylome profiling of individuals with fCCM and identified several differentially methylated genomic regions associated with lesion burden. DNA methylation modifications of novel genes may serve as a new layer of biological regulation that contributes to CCM pathogenesis. Further studies are needed to validate these findings in a larger fCCM cohort and investigate the role these epigenetic biomarkers have in CCM disease.

Session Title: Cancer Poster Session III

PB5082 Identification of Novel Biomarkers in African American Prostate Cancer (Pca) Samples

Authors:

H. Wei[1], N. Palanisamy[2]; [1]Beckman Coulter Life Sci., Indianapolis, IN, [2]Henry Ford Hlth., Detroit, MI

Identification of novel biomarkers in African American prostate cancer samples Abstract:Introduction: Prostate cancer (PCa) is the most frequent cancer in men in the Western world. In addition, population-based studies demonstrate that African Americans (AA) in the United States have an increased risk of developing prostate cancer and a 4.4% risk of death compared with a 2.4% risk of death in Caucasians. Fusion genes, formed by joining parts of two different genes, are one of the fundamental drivers contributing to the development of PCa. In this study, we aimed to utilize this knowledge and RNA-seq to identify transcriptomic signatures for PCa in AA.Method: We used PCa AA FFPE (N=5) and fresh frozen (N=12) samples in this proof of principle study. First, FFPE RNA was extracted from a single 10 µm curl input using FormaPure XL RNA (Beckman Coulter Life Sciences, Indiana, U.S.). Then, FFPE RNA with DV200 >= 30% and RNA from fresh frozen samples was used for library preparation and sequencing. After sequencing, the raw reads in fastq files were processed using the Trim Galorescript to remove adapter sequences and low-complexity regions. Next, STAR software mapped the trimmed reads to the human genome GRCh38. Finally, the differentially expressed genes (DEGs) between the in-house PCa AA cohort (n=17) and The Cancer Genome Atlas (TCGA) PRAD cohorts were identified using DESeq2. Gene lists were compared using the Venny online tool.Results: We first examined the FFPE RNA yield from 5 PCa AA samples to ensure optimal quality for RNA-Seq workflow. We observed that sufficient yield was obtained from all samples and exceeded the 600 ng required for RNA sequencing. We also assessed the RNA integrity, andfound that the DV200 was above 30% for all of the extracted samples. The average unique reads across all FFPE-derived PCa AA samples were 68 million. Using the TCGA PRAD dataset, we identified 3936 downregulated and 9696 updated genes in PCa AA groups. Commonly regulated protein-coding genes (mRNA) and lncRNA-coding genes (long non-coding genes) were detected in PCa AA and TCGA PCa AA groups. Functional enrichment analysis of the differentially expressed genes revealed a link between top biological processes and associated pathways to the PCa AA group.Conclusion:Our study suggests that these genes might be involved in different networks that lead to uniquely aggressive PCabehavior in AA samples, potentially serving as biomarkers for the racial disparity in PCa progression. This proof of principle study also demonstrates the successful use of FFPE RNA for NGS analysis in cancer research

Session Title: Cancer Poster Session I

PB5083 Identification of sex specific molecular features in glioblastoma

Authors:

Y. Huang[1], Y. Shan[1], W. Zhang[1], C. Printzis[2], L. Pesce[2], B. Stranger[2], R. Huang[1]; [1]Univ. of Minnesota, Minneapolis, MN, [2]Northwestern Univ., Chicago, IL

Glioblastoma (GBM) is a lethal disease with limited treatment options available. Sex differences in GBM are well-documented in clinical settings, with males having twice the risk of developing the disease and increased mortality compared to female counterparts. To investigate the molecular basis of sex differences in GBM, we characterized the somatic genetic alterations in *IDH1* wild-type GBM samples from the GENIE project (n=4530). We also analyzed transcriptomic sex differences in a collection of three independent GBM datasets (n=346) and validated them in three additional independent studies. The impact of differentially expressed genes were assessed through Gene Set Enrichment Analysis (GSEA) on approximately 5000 gene sets to interpret their biological relevance. Given the well-recognized heterogeneity of GBM, we also integrated three single-cell RNA (scRNA) sequencing datasets to decipher the sex differences in cellular composition between male and female tumors. We identified 91 genes exhibiting sex-biased mutation patterns in GENIE GBM samples, including the Androgen Receptor (AR) signaling pathway. The effects of sex on gene expression are modest and primarily driven by the X chromosome (14 out of 16 differentially expressed genes were on the X chromosome). These genes are associated with escape from X-chromosome inactivation (e.g., *KDM5C*, *KDM6A*) and are also sex-differentially expressed (DE) in the healthy human brain according to Genotype-Tissue Expression (GTEx) data. GSEA results suggest increased activity in cell proliferation and neuronal signaling in male GBM samples, whereas females show enrichment in glycoprotein/lipid metabolism and inflammatory response. By deconvoluting the cell-type composition, we identified a higher percentage of pericytes in the male GBM tumor microenvironment compared to those in females, which is consistent with recent spatial-omic discoveries in GBM. By integrating scRNA sequencing data, we found that both differentially expressed genes and pathways show cell-type-specific enrichment. For example, the female-biased gene *GBGT1* is exclusively expressed in the myeloid lineage, while male-biased neuronal pathways are enriched in cancer stem cells. Integrating with the inference of cell trajectories, we observed that male tumors harbor more unconnected, invasive malignant cells than females, which might explain the poor prognosis in male GBM patients. In summary, our results provide a comprehensive multi-level characterization of sex differences in GBM tumors, and these findings will provide novel insights into GBM disease progression and development of new therapy.

Session Title: Cancer Poster Session II

PB5084 Identifying functionally methylated regions in breast cancer

Authors:

H. Xu, V. George; Augusta Univ., Augusta, GA

DNA methylation is an important genomic modification involved in the regulation of gene expression, cell differentiation and developmental processes. Abnormal methylation has been implicated in human diseases such as various forms of cancers. There has been great interest in identifying genes with differentially methylated regions (DMRs) between different biological conditions. With the high-throughput technologies, large-volumes of methylation data at genomic level have been generated. This also poses challenges in data management, analysis, and interpretation. Taking advantage of the high-quality genomic data, various strategies are employed for detecting functional differentially methylated regions (fDMRs) by integrating both methylation data and gene expression data. One such approach is based on unified Bayesian hierarchical modeling. We model DNA methylation and gene expression in a hierarchical way, based on the assumption that fDMRs will show changes in methylation levels, which then lead to changes in gene expression. The evidence of differential methylation will be used as prior information to update the evidence of differential gene expression. Integrating methylation and gene expression data will help address some of the challenges in DMR identification methods and more effectively identify fDMRs, which can help elucidate the genetic mechanisms of complex human diseases. We applied our method to breast cancer data from the Cancer Genome Atlas and identified 6 fDMRs with FDR < 0.05.

Session Title: Cancer Poster Session III

PB5085 Impact of bioinformatics pipelines and prediction tools on the detection of breast cancer susceptibility variants: application to the GENESIS case-control study.

Authors:

F. Lesueur[1], S. Murat El Houdigui[1], E. Girard[1], P. Apostolou[2], S. Eon-Marchais[1], M-G. Dondon[1], J. Beauvallet[1], D. Le Gal[1], R. Olaso[3], C. Baulard[3], M-T. Bihoreau[3], A. Boland-Augé[3], GENESIS study collaborators, J-F. Deleuze[3], D. Stoppa-Lyonnet[4], N. Andrieu[1], N. Servant[1]; [1]Inst. Curie, Inserm U900, Mines ParisTech, Paris, France, [2]Human Molecular Genetics Lab., INRaSTES, Natl. Ctr. for Scientific Res. Demokritos, Athens, Greece, [3]Université Paris-Saclay, CEA, Ctr. Natl. de Recherche en Génomique Humaine, Evry, France, [4]Service de Génétique, Inst. Curie, Université de Paris, Inserm, U830, Paris, France

Epidemiological studies make increasing use of massively-parallel sequencing to identify rare alleles involved in susceptibility to complex traits like cancer. To analyze sequencing data, bioinformatics pipelines perform a chain of data-processing tasks that use tools to annotate and filter variants. Gene-based burden testing is then performed by comparing the aggregate burden of rare, protein-altering variants in each gene between case and control subjects. Here we assessed how the choice of tools for annotating, filtering and interpreting variants affect the results of a case-control study on breast cancer. We examined the consequence of these choices in the GENESIS study where sequencing data for 113 genes were available for 1207 women with familial breast and 1199 controls.
We first compared number and types of variants detected by the original pipeline (Girard et al. 2019, PMID:30303537) and by an upgraded pipeline that uses more recent tools for alignment of bam files (BWA aln was replaced with BWA-MEM), variant calling (the use of the three callers GATK Preprocess, GATK Unified Genotyper and Freebayes was replaced with GATK Haplotype Caller) and annotation (Annovar was replaced with SnpEff and SnpSift). This new pipeline detected less variants (3568 vs 4023) but a higher proportion of loss-of-function variants (LoF) than did the previous one (17.5% vs 9.2%). Especially, the new pipeline was more efficient to detect splice site variants. A total of 3081 variants (68%) were detected by both pipelines of which 43% LoF and 73% missense variants (MV). Despite these differences, analyses aggregating all LoF and MV with CADD score ≥20 confirmed the association of *ATM*, *CHEK2* and *PALB2* with breast cancer, with similar risk estimates (in 2023: OR_{ATM}=2.0 (1.4-3.1), OR_{CHEK2}=2.8 (1.8-4.6), OR_{PALB2}=3.8 (1.8-8.7); in 2019: OR_{ATM}=1.9 (1.3-2.9), OR_{CHEK2}=3.0 (1.9-5.0), OR_{PALB2}=3.5 (1.7-7.5)).
We also assessed the influence of nine ensemble methods other than CADD built on different training and test sets, namely BayesDel, BayesDel no AF, ClinPred, DANN, META-LR, META-SVM, PON-P2, REVEL and VEST4, and found that the number of filtered variants varied from 14% to 66% according to the scoring method. Consequently, additional genes were associated with breast cancer when using some alternative methods.
Hence, sequencing data processing influence the number of variants included in the analyses. Notably, results are impacted by the choice of the prediction models employed for interpretation of deleteriousness of MV. Even if there is no effect on risk estimates, this may impact the list of variants to further investigate in a clinical context.

Session Title: Cancer Poster Session I

PB5086 Impact of panel size on minimum residual disease (MRD) assay performance.

Authors:

C. J. Battey, A. Acevedo, M. LaBella, S. Ganesh, E. Buser, N. Xu, R. Patel, K. Haug, K. Trettin, J. Jasper, J. Risinger, G. Gould, D. Muzzey; Myriad Genetics, Inc., Salt Lake City, UT

Background: Sequencing circulating tumor DNA is a promising method for monitoring cancer treatment response and detecting recurrence, but sensitivity at the low tumor fractions typical of early-stage, post-treatment, and early recurrent tumors is limited by the small number of variants targeted in commercially available assays. Methods: We developed a tumor-informed minimum residual disease (MRD) assay using tumor-normal whole-genome sequencing (WGS) followed by interrogation of select somatic variants in cell-free DNA (cfDNA). We describe theoretical limits on panel designability as a function of tumor purity and sequencing depth using simulations and a discovery cohort of 31 patient samples. cfDNA assay performance was tested by creating serial dilutions of patient plasma before somatic enrichment and sequencing. Simulations and *in-silico* downsampling of target sites were used to test sensitivity as a function of panel size. A bioinformatics pipeline incorporating somatic calling, copy number inference, error assessment, and tumor-fraction estimation was developed to analyze results. Results: Across a range of tissues, tumor-normal WGS identified from hundreds to tens of thousands of somatic variants to inform an MRD capture panel. 97% of samples tested returned at least 300 high-confidence somatic variants, and targeted sequencing demonstrated over 95% positive predictive value in somatic variant calls. In cfDNA dilution experiments, we observed >99% sensitivity at a tumor fraction of 0.01%. Expanding the panel size from 16 to 300 target variants increased sensitivity at 0.005% tumor fraction from approximately 20% to >95%. Our tumor fraction model returned accurate quantification down to the parts per hundred thousand (0.001%) range, even when only a single tumor molecule could be observed at each target site. Conclusions: Increasing the number of targeted variants in an MRD assay increases sensitivity at low tumor fractions, and WGS-driven panel design ensures a sufficient number of interrogated variants while minimizing the failure rate due to panel designability. High sensitivity MRD has the potential to enable earlier recurrence detection while also giving researchers and clinicians new tools for monitoring patient treatment responses.

Session Title: Cancer Poster Session II

PB5087 Impact of sex, age, and ancestry on Apolipoprotein E (*APOE*) risk for Alzheimer's disease (AD): a pooled case-control of Alzheimer's Disease Genetics Consortium (ADGC).

Authors:

O. Garcia Rodriguez[1], L. Wang[1,2], J. Young[1], Alzheimer's Disease Genetics Consortium (ADGC), M. A. Pericak-Vance[1], E. Martin[1], K. Brian[1]; [1]Hussman Inst. for Human Genomics, Univ. of Miami, Miami, FL, [2]Dept. of Publ. Hlth.Sci., Univ. of Miami, Miami, FL

Background/Significance: Previous studies have reported that non-Hispanic white (NHW) females carrying the *APOE ε*2 or ε4 allele differ in risk of developing Alzheimer's disease (AD) when compared to men. However, several studies also indicated that the risk for developing AD may be similar for males and females in carriers of *APOE ε4* but may differ by age. We aimed to comprehensively evaluate the association between sex, age, ancestry, and *APOE* with AD in multiple cohorts. **Materials/Methods:** A pooled case-control study was conducted for 50 independent datasets (n = 42,295 individuals with ages ≥ 55 years) from the Alzheimer's Disease Genetics Consortium (ADGC). Logistic, linear, and Cox regression models were used to study the associations between disease status and independent variables age, sex, self-reported race (as a proxy of ancestry), and *APOE* genotype. A *p-value* less than 0.05 was considered statistically significant. **Results:** Ancestry-specific analyses showed when comparing subjects with *APOE* ε3/ε4 (vs. ε3/ε3), East-Asian (EA) females (*OR*, 5.00; 95% CI: 4.09-6.12) and males (*OR*, 4.20: 3.26-5.42) had strongest *ORs*; whilst the weakest risk difference was for South-Asian (SA) men (*OR*, 1.23: 0.66-2.29). Nevertheless, men and women with *APOE* ε3/ε4 showed no significant difference in the risk of developing AD after accounting for age among ancestries. Age group-specific analyses showed that NHW females (*OR*, 4.66: 4.12-5.27 vs. males: *OR*, 3.99: 3.46-4.60) and African American (AA) females (*OR*, 4.27: 3.09-5.91 vs. AA men: *OR*, 1.98: 1.23-3.16) with *APOE* ε3/ε4 presented a higher risk of developing AD between ages 66-75; whereas EA and SA exhibited this pattern at 55-64. In Hispanics, the relationship was reversed, with males aged 55-65 years carrying *APOE* ε3/ε4 (*OR*, 3.42: 1.22-9.60: vs. females: *OR*, 2.30: 1.18-4.50) having a stronger association with AD risk than females. Nonetheless, these differences were not statistically significant. Case-only and survival analyses also established that NHW, AA, and EA female carriers of APOE ε3/ε4 had an earlier age at the onset of AD than their male counterparts. When comparing *APOE* ε2/ε2 and ε2/ε3 carriers vs. ε3/ε3 carriers, NHW women (*OR*, 0.64: 0.55-0.74) and men (*OR*, 0.50: 0.44-0.57) presented the lowest *ORs* for risk of AD among all ancestries. No differences were found when stratified by age for *APOE* ε2 and AD. Nonetheless, NHW females had later age of onset for AD than NHW males. **Conclusions:** Our findings suggest sex differences by age and ethnicity in the risk for developing AD and age of onset for AD in carriers of *APOE* ε2 and ε4. However, additional local ancestry analyses for APOE are warranted to confirm these findings.

Session Title: Cancer Poster Session III

PB5088 Improving Diagnostic Yields of Cancer Predisposing Variants in Diverse Populations

Authors:

K-l. Huang, A. Elmas, R. Vaza; Icahn Sch. of Med. at Mount Sinai, New York, NY

Cancer risk differs across ancestries. According to the data provided by NCI SEER, cancer incidence per 100,000 individuals is 438 in Whites, 433 in Blacks, 289 in Asian/Pacific Islanders, 320 in American Indian/Alaskan Natives, and 327 in Hispanics from 2011-15. Although factors such as healthcare access or diet may account for some of these disparities, it is likely that a significant proportion of these differences can be attributed to genetic factors unique to each ancestry. In this study, we undertook a comprehensive analysis of the ethnically diverse Mount Sinai BioMe cohort, which includes over thirty-thousand cases with quality-controlled whole-exome sequencing (WES) data. By integrating WES data with electronic health records (EHR), we identified over five-thousand cases or individuals with a family history of cancer. The distribution of known pathogenic variants varies among different types of cancer, and also among different population groups that reflect potential bias in existing databases. Notably, by incorporating protein-truncating variants (PTVs) in ACMG and cancer susceptibility genes, we enhanced the detection rates across genetically-defined populations. Importantly, we developed a rare variant polygenic risk score (rvPRS), which can effectively identify high-risk individuals across varied ancestry groups. Consequently, our study highlights the potential of using a rare variant PRS to more equitably identify high-risk individuals across diverse populations.

Session Title: Cancer Poster Session I

PB5089 In vitro effect of curcumin in combination with chemotherapy drugs in Ph+ acute lymphoblastic leukemia cells

Authors:

U. Santana, U. Santana-Bejarano; Univ. de Guadalajara, Guadalajara, Mexico

Philadelphia chromosome-positive acute lymphoblastic leukemia (Ph+ ALL), is characterized by the t(9;22)(q34q11) that generates the BCR-ABL protein with uncontrolled tyrosine kinase activity. Recently, a connection between BCR-ABL signaling with NF-κB activation mediated by CK2 has been hypothesized. Approximately 95% of patients with Ph+ ALL have the BCR-ABLp190 isoform, which causes aggressive leukemia with a high rate of chemotherapy resistance. Therefore, the use of compounds that could improve the efficacy of chemotherapy drugs is of particular interest. Curcumin is an active chemical in turmeric with antineoplastic potential; it regulates protein-kinases by modulating downstream molecular pathways. The present study evaluated the effect of curcumin in combination with the chemotherapeutic drugs vincristine, imatinib and daunorubicin in the human OP-1 cell line. Several doses of the chemotherapy drugs were examined, and the effects were evaluated following 12, 24 and 48 h of exposure. The interaction between the chemotherapy drugs and curcumin was determined by the dose-effect curve, which generated a combination index (CI); these data were represented in isobolograms. In addition, the individual effect of each drug was compared with its effect in combination with curcumin on cell viability, apoptosis degree, NF-κB activation and gene expression changes. The present study observed that curcumin potentiates the efficacy of vincristine and imatinib, generating an additive/synergistic effect in a dose- and time-dependent manner. These combinations significantly increased the apoptosis degree, decreased the activation of NF-κB and the expression of its regulated genes. Conversely treatment with daunorubicin + curcumin combination produced an antagonistic/additive effect in a dose-dependent manner, and this combination significantly increased the apoptosis degree. However, this effect seems not to be associated with NF-κB activity, as no significant changes were observed in its activation or in the expression of the genes that it regulates. The results of the present study demonstrate that curcumin may be used as an adjuvant agent for chemotherapy in patients with Ph+ ALL.

Session Title: Cancer Poster Session II

PB5090 Initial sequencing and analyses of a new broadly-consented tumor cell line for development of a Genome in a Bottle Tumor/Normal Benchmark

Authors:

J. Wagner[1], G. Rosen[2], J. McDaniel[1], A. Liss[3], J. Zook[1]; [1]Natl. Inst. of Standards and Technology, Gaithersburg, MD, [2]Drexel Univ., Philadelphia, PA, [3]Massachusetts Gen. Hosp., Boston, MA

Here, we describe initial analyses on PCR-Free Illumina WGS and Hi-C sequencing with the goal of developing the first tumor/normal benchmark from the Genome in a Bottle (GIAB) consortium. This effort builds on the widely-used GIAB germline variant benchmarks for seven normal DNA reference materials. We performed sequencing on new cell lines from a broadly-consented pancreatic ductal adenocarcinoma patient and we plan to perform an array of PacBio HiFi, ONT ultralong and duplex, Bionano, and Bioskryb single cell WGS from a large batch of the tumor cell line, along with other technologies in the future.

Using Hi-C for copy number and structural variant analysis, preliminary results identified substantial aneuploidy common in pancreatic tumors, with ~17 large inversions and translocations and 16 chromosomes with extensive loss of heterozygosity due to missing >30% of one copy. Many of these large events appeared to occur in all cells, but some deletions and duplications occur in only a fraction of the cells. The tumor contains the common G12V mutation in KRAS, and interestingly the ~2 Mbp region containing this mutation is likely triplicated.

To assess sources of error in variant calls, we aligned the Illumina PCR-Free data at coverages of ~150x on normal and ~180x on the tumor to GRCh38 then ran Lancet, Mutect2, Strelka2, DRAGEN, and NeuSomatic. We compared Mutect2 calls to Strelka2 using default filtering and found that after excluding difficult regions using the GIAB stratifications more than 90% of SNVs and small indels agree. We categorized disagreements to find that many occur because of systematic sequencing errors, alignment errors, low frequency, and proximity to germline variants. Examining discordant SNVs in difficult regions, most are erroneous somatic variants in regions with loss of heterozygosity that also have mapping errors due to segmental duplications, sequences missing from GRCh38, and/or tandem repeats. After excluding difficult regions, we also found that somatic SNVs fell in 4 primary classes: ~5000 in most cells in diploid regions, ~2000 in most cells in haploid regions, ~800 in only some cells in diploid regions, and ~500 in only some cells in haploid regions.

GIAB is forming an open working group to develop the first authoritative benchmarks from publicly available, broadly-consented tumor-normal cell lines and long read sequencing data will be made public as soon as possible after it is generated.

Session Title: Cancer Poster Session III

PB5091 Insights into the Development of *BAP1* Mutant Uveal Melanomas Following Spontaneous Differentiation of iPSCs into a Self-Formed Ectodermal Multi-Zone primitive eye structure

Authors:

P. Begani, A. Z. Eriksen, T. A. Blenkinsop, A. M. Bowcock; Icahn Sch. of Med. at Mount Sinai, New York, NY

Uveal melanoma (UM) arises from neural crest of the eye and has a mortality rate of 80%. Almost all UMs harbor oncogenic mutations in *GNAQ*, *GNA11* or *CYSLTR2*. However, these do not affect their metastatic competency which is defined by a classic gene expression profile. Class 1 tumors (low risk) usually harbor mutations in *SF3B1* or *EIF1AX*. 84% of Class 2 tumors (high risk) harbor inactivating mutations in BRCA1-Associated Protein 1 (*BAP1*) gene, along with loss of the chromosome 3 homolog harboring WT *BAP1*. *BAP1* encodes a ubiquitin carboxy-terminal hydrolase that regulates multiple cellular processes including chromatin modification, DNA repair and cell cycle control. *BAP1* is also mutated in several other highly aggressive cancers. Cell based studies have shown that loss of *BAP1* function in UM cells leads to a stem-like phenotype. However, the role of *BAP1* in tumorigenesis and metastasis remains largely unknown. We hypothesized that understanding the consequences of *BAP1* loss in development would provide insights into its role in the development of UM and other cancers. We used human iPSCs and induced them to differentiate to form a primordium of four concentric zones termed Self-formed Ectodermal Multi-Zone (SEAM). The SEAM mimics whole eye development and cells within each zone are indicative of lineage. SEAMs were stained for several lineage and ocular markers. *BAP1* localized to Zone 2, which is the developmental analog of neural crest cells. Zone 2 also developed dense melanin pigmentation at around Day 20 of differentiation. Next, using the CRISPR-Cas9 based system, we successfully generated iPSCs with downregulated *BAP1* which were then also differentiated into ocular SEAMs. RNA-sequencing revealed significant alterations in various pathways as a consequence of *BAP1* knockdown. These included melanogenesis, morphogenesis (WNT signaling), ECM assembly and degradation, chromatin modeling and DNA repair. *BAP1* downregulation also led to reduced melanin pigmentation in Zone 2 as well as to decreased BAP1 deubiquitinase activity, consistent with a role for *BAP1* in melanogenesis. Intersection of differentially expressed transcripts from SEAM *BAP1* knockdown with those of primary tumors with *BAP1* loss of function mutations revealed shared altered pathways of cell cycle control, translation regulation, ECM assembly and degradation and EMT. Hence, ocular SEAMs can provide insights into eye development, neural crest differentiation and potentially tumorigenesis and metastasis.

Session Title: Cancer Poster Session I

PB5092 Integrating multiomics data to identify African ancestry-informative markers acting as eQTLs in breast cancer

Authors:

S. Boudeau; Temple Univ., Philadelphia, PA

Ancestry-informative markers (AIMs) are SNPs that are found at relatively higher frequencies in a specific population and can be used to estimate genetic ancestry. Genetic ancestry is becoming more commonly used in biomedical research investigating the genetic basis of diseases. For many cancers, the literature suggests that African ancestry is associated with poor response to treatment, poorer prognosis, and poorer survival. More specifically, African American women with breast cancer are more likely to have more aggressive subtypes of the disease and diagnosed with a later stage of the disease at an earlier age compared to their European American counterparts. Some of this disparity remains after accounting for socioeconomic factors, suggesting a genetic basis for the health disparities observed in many cancers. To evaluate the genetic basis of cancer health disparities in populations of African ancestry, we identified a set of 46,787 African ancestry informative markers (AIMs) using 1000 Genomes Project data from African and European populations. These AIMs were functionally annotated and investigated for potential associations with cancer in the literature, using tools such as VEP, SIFT, and Polyphen. Using multiomics data (RNAseq, genotype, methylation, copy number variation) from The Cancer Genome Atlas and an integrative eQTL modeling approach, we are investigating which of these AIMs act as expression quantitative trait loci in breast cancer. Of the 47K SNPs identified, 0.6% percent was found to be in the coding regions of the genome and AIMS located on chromosomes 8, 10, 11, 15, 18, and 19 were found to be associated with different cancers in the literature including breast and colorectal cancers. Approximately 5K of the AIMs were found in the TCGA breast cancer data and preliminary results identified cis-eqtls in 4 different genes including SERINC2 and ZSCAN23, and trans-eqtls in about 8 genes including CLCN3 and DEDD. These eQTL AIMs are being evaluated for potential association with ancestry-specific differential survival and response to treatment in breast cancer.

Session Title: Cancer Poster Session II

PB5093 Integration of label-free, interpretable image features with spatial molecular profiles from spatial transcriptomics

Authors:

J. Hu[1], Y. Yang[2], J. Huang[1]; [1]Emory Univ., Atlanta, GA, [2]Emory, Decatur, GA

Recent advances in Spatial Transcriptomics (ST) have enabled gene expression profiling while preserving spatial information in tissues. Data from such technologies are typically complemented by histology images of the same tissue section, which are invaluable for examining cellular morphology. The combined gene expression and histological features allow researchers to study the progression of diseases comprehensively. Existing methods for ST data analysis usually employ well-trained deep neural networks to extract features from histology images. Due to the “black box” nature of these methods, these deep features suffer from a lack of biological meanings and are difficult to be integrated with molecular measurements. Novel methods that can extract interpretable, meaningful and robust morphological features are demanded in ST studies.To solve this limitation, we developed a novel approach for Interpretable Morphological features from Unsupervised Segmentation (IMUS). IMUS is fully unsupervised and label-free. Features extracted from IMUS have high interpretability. IMUS starts from unsupervised segmentation. Each cluster from the segmentation is separated as a binary mask, and summary statistics are calculated as features to quantify the pattern in the masks. Next, object detection is performed within each mask, and features for the detected objects are measured. Many features may not be biologically meaningful, e.g., the ones that capture the blurriness of the image. Therefore, IMUS utilized a novel metric to quantify the structural similarity between image features and molecular measurements so that image features with less biological interpretability can be dropped.We have systematically compared IMUS with other popular methods, and IMUS has higher accuracy in segmentation using pathologists’ annotation as ground truth. We also demonstrate that features from IMUS can be integrated with spatial gene expression and identify spatial regions that cannot be revealed when gene expression and histology image is analyzed separately. The interpretability of IMUS’s features also helps to decipher the function of different tissue regions.IMUS is a novel statistical tool to maximumly mine the rich pathology information in ST data. IMUS can be easily applied to studies where training samples are not available and bypass cumbersome labelling steps.

Hlth.Genomics, Univ. of Virginia, Charlottesville, VA, [13]Dept. of Epidemiology, Univ. of Washington Sch. of Publ. Hlth., Seattle, WA

Genomic-wide association studies (GWAS) have identified numerous genetic risk variants associated with various types of cancer. To enhance our understanding of the genetic basis of cancer susceptibility, candidate target genes for the risk variants identified in GWAS have been extensively studied through expression quantitative trait locus (eQTL) analysis. However, the investigation of target proteins for most of GWAS-identified risk variants remains unexplored. In this study, we comprehensively examined previously reported cancer risk variants, and performed additional fine-mapping analyses using summary statistics data from European-ancestry populations from six cancer types: breast (N=247,173), ovary (N=63,347), prostate (N=140,306), colorectum (N=125,478), lung (N=85,716), and pancreas (N=21,536)]. We identified a total of 712 independent risk-related signals for these six cancer types. To identify candidate proteins associated with these risk variants, we conducted a meta-analysis for the results of plasma protein quantitative trait locus (pQTL) analysis from two European-ancestry population studies (N=42,772; PMID: 35501419 and PMID: 34857953). Integrating the findings from these six cancer types, we discovered 259 pQTL associations at a Bonferroni corrected p-value threshold of < 0.05, involving 207 unique proteins associated with 162 risk variants. Among these, 34 proteins were shared by at least two cancer types. Importantly, more than 70% of these 207 proteins had not been previously reported in eQTL analysis or transcriptome-wide association studies in these cancers. Furthermore, over 40% of these proteins were supported by additional evidence based on the analysis of epigenetic data in cancer-related cells and colocalization with GWAS risk signals. Enrichment analyses of these 207 proteins highlighted the prominent involvement of well-established cancer signaling pathways, such as acute-phase responses, IL-6, Natural Killer cell wound healing, and STAT3 signaling pathways. Our study identified a significant number of novel putative susceptibility proteins associated with cancer risk. By shedding light on intricate pathways of genetic variants, target proteins, and signaling pathways related to cancer risk, our findings provide new insights and potential avenues for prevention and therapeutic interventions of these common cancers.

Session Title: Cancer Poster Session I

PB5095 Integrative analysis of RNA-Seq and microarray data for identification of molecular networks and potential biomarkers associated with adverse effects of UVB exposure on the Skin.

Authors:

Y. Jang[1,2], J. Lee[1], J. Han[1], C. Lee[2], H-W. Na[3], Y. Hong[3], H-J. Kim[3], Y. Seo[1]; [1]Dongguk Univ., Goyang-si, Korea, Republic of, [2]The Jackson Lab. for Genomic Med., Farmington, CT, [3]AMOREPACIFIC, Yongin, Korea, Republic of

Ultraviolet B (UVB) from sunlight represents a major environmental factor, which causes toxic effects resulting in structural and functional cutaneous abnormalities of most living organisms. In humans, UVB irradiation acts as a tumor initiator by producing irreversible mutagenic damage. Although numerous studies have indicated the biological mechanisms between UVB exposure and cutaneous manifestations, they have typically originated in a single study, performed under limited conditions. To address this gap, we crawled all publicly accessible expression data on various skin cell types, including skin biopsy data, keratinocytes and fibroblasts exposed to UVB, and we analyzed the biological networks to identify the molecular mechanisms. We identified the three candidate biomarkers (*IL1B*, *CCL2*, and *LIF*) and predicted the inflammatory response and carcinogenesis as major UVB-induced signaling alterations. Furthermore, we confirmed that these three candidate biomarkers contribute to the survival probability of patients with cutaneous melanoma, the most aggressive and lethal form of skin cancer, and that UVB radiation is the main risk factor. Our finding will aid to understand the UVB-induced dermal toxicity and the accompanying molecular mechanisms.

Coll. of Wisconsin, Milwaukee, WI, [10]Univ. of Wisconsin-Madison, Madison, WI, [11]Univ. of Pennsylvania Sch. of Med., Philadelphia, PA, [12]Natera and Latin American Sch. of Oncology, Sierra Madre, CA, [13]Fred Hutchinson Cancer Ctr., Seattle, WA

Background: Due to the complex interplay between genetic (G) and known reproductive, anthropometric and behavioral ("environmental") (E) risk factors, there is substantial interindividual variability in the risk of developing breast cancer. Previous gene-environment (GE) interaction studies of rare pathogenic variants in breast-cancer predisposition genes have been limited in sample size and the number of interactions assessed.
Methods: We assessed multiplicative and additive GE interactions between five breast cancer predisposition genes (*ATM*, *BRCA1*, *BRCA2*, *CHEK2*, and *PALB2*) and 14 established risk factors (age at menarche, parous, number of births, age at first full-term pregnancy, breastfeeding duration, age at natural menopause, height, pre-and post-menopausal body mass index (BMI), use of menopausal hormone treatment, use of oral contraceptives, history of benign breast disease, smoking and alcohol consumption) in a sample of women drawn from the Cancer Risk Estimates Related to Susceptibility (CARRIERS) Consortium and the UK Biobank, with 28,745 breast cancer cases and 102,997 controls. We assessed both multiplicative and additive interactions using multivariable logistic regression models, adjusting for age at recruitment and study site. Analyses were further stratified by estrogen receptor (ER) status. We used meta-analysis to pool results and assess the heterogeneity of interaction effects between CARRIERS and UK Biobank.
Results: No interaction was significant after adjusting for multiple comparisons ($P<1.2 \times 10^{-4}$) and 28 interactions showed nominal significance at $P<0.05$. Among these, twelve were significant for overall breast cancer, and ten and six were significant for ER+ and ER- breast cancer, respectively. The strongest suggestion of multiplicative interaction was observed for nulliparity and BRCA2 (interaction OR = 3.10, 95% CI: 1.36 - 7.08, P = 7.29 × 10-3), suggesting that those with a pathogenic/likely pathogenic (P/LP) variant in BRCA2 who are nulliparous might have a particularly high risk of breast cancer. For age at first birth and ATM, we observed negative multiplicative (interaction OR = 0.71, 95% CI: 0.54 - 0.93, P = 0.01) and additive interactions (RERI = -0.55, 95% CI: -0.98 - -0.12, P = 0.01), suggesting that the risk increase associated with an older age at first full-term pregnancy is attenuated among women with a P/LP variant in ATM.
Conclusions: The associations between P/LP variants in known predisposition genes and breast cancer may be modified by reproductive factors. Larger studies encompassing diverse populations are needed to confirm these findings.

Session Title: Cancer Poster Session III

PB5097 Interlaboratory assessment of NIST test materials for lentiviral vector copy number and integration site measurements

Authors:

H-J. He[1], Z. He[1], A. Whale[2], C. Foy[2], A. Li[3], B. Schroeder[3], E. Stelloo[4], H. Feitsma[4], G. Dijksteel[4], L. Turner[5], Y. Fan[5], B. Dropulic[6], O. Slessareva[6], J. Kandell[7], U. Lakshmipathy[7], P. Welch[8], S. X. Senderovich[9], D. Steenmans[10], M. Raimo[10], W. Vogels[10], Y. Ding[11], M. Sheldon[11], S. Ahmed-Seghir[12], S. Miller[1], S. Lund[1], S. Maragh[1], J. Zook[1], J. Elliott[1], S. Lin-Gibson[1], K. Cole[1]; [1]Natl. Inst. of Satndards and Technology, Gaithersburg, MD, [2]Molecular and Cell Biology, Natl. Measurement Lab., LGC, Teddington, United Kingdom, [3]Mission Bio, South San Francisco, CA, [4]Cergentis, Utrecht, Netherlands, [5]Azenta, South Plainfield, NJ, [6]Caring Cross, Gaithersburg, MD, [7]Thermo Fisher Scientific, San Diego, CA, [8]Castle Creek Biosci, Exton, PA, [9]GSK, Stevengage, United Kingdom, [10]Glycostem Therapeutics, AB Oss, Netherlands, [11]Sampled, Piscataway, NJ, [12]Genomic Vision, Bagneux, France

Lentiviral vectors (LV) have emerged as powerful tools for stable gene delivery for both cell and gene therapies. As an effective measure to reduce the genotoxic and tumorigenic potential caused by uncontrolled integration, the US Food and Drug Administration recommends the integrated lentiviral vector copy number (VCN) shall be less than 5 copies per cell. Reference or control materials are essential for accurately measuring VCN, a critical quality attribute to the safety and efficacy of gene modified cellular products. We conducted an interlaboratory assessment to determine the utility and suitability of NIST test materials to serve as reference materials or controls for the VCN measurements. The test materials comprise of five human genomic DNAs extracted from clonal cell lines with N=1 (VCN1), N=2 (VCN2), N=3 (VCN3), and N=4 (VCN4) copies of the integrated provirus and the parental Jurkat cell line (VCN0), or fixed cell samples from these clonal cell lines. A total of twelve laboratories from four countries participated in this study, composed of two National Metrology laboratories and ten companies. Quantitative real-time PCR (qPCR; four laboratories), digital PCR (dPCR; seven laboratories using droplet, two of them also using chamber dPCR), Next Generation Sequencing (NGS; targeted amplicon NGS, targeted locus amplification NGS, and single cell NGS), and molecular combing methods were used to make VCN measurements. All laboratories were able to identify the five blinded VCN samples by either qPCR, dPCR or NGS assay. In all cases no integrated LV was identified in the VCN0 sample. Using qPCR and dPCR, VCN1-3 samples were identified correctly within 10.2% of the expected VCN. Greater variability in the estimates for the VCN4 sample between the laboratories using both qPCR and dPCR. All three NGS methods reported correct copies and positions of integration upon aligning on the same reference genome build. Interestingly, one integration site in the VCN4 sample reported by all three methods was different from the site originally published, but was confirmed to be correct by additional whole genome sequencing analyses. The consensus integration sites were achieved after the optimization of assays and bioinformatics pipelines. The cell-based test material was also used to evaluate the assay performance of a new direct visualization technology called molecular combing. This interlaboratory assessment supports the utility and suitability of the NIST VCN test materials in the analytical parameters of different VCN measurement methods to ensure quality assurance.

Session Title: Cancer Poster Session I

PB5098 Interplay of germline risk loci, somatic variants, and structural alterations in the development of pancreatic cancer

Authors:

J. Levine, L. Ali, K. McKenna, S. Finkelstein, V. Timmaraju; Interpace Dx, Pittsburg, PA

Germline variants can predispose an individual to an increased risk of pancreatic cancer, a disease with the 2nd highest mortality rate in the US. However, with a low incidence of occurrence compared to its mortality rate, understanding the germline mutations' role in concert with acquiring somatic mutations is critical to early detection and diagnosis, allowing intervention. To address this, we developed a hybrid capture-based next-generation sequencing method to detect: germline mutations in key risk loci, somatic single nucleotide variants, insertion-deletions in cognized PC oncogenes, and tumor suppressor genes, genome-wide copy number analysis, and repeat expansion alterations. We compared precancerous pancreatic cysts (n=66) and pancreatic cancer (n=22) to elucidate the presence of variants in pancreatic cancer germline risk loci and acquired somatic alterations. Most notably, we discovered a change in heterozygosity of the *TP53_P72R* germline variant, which, when combined with a TP53 oncogenic mutation, co-occurred with multiple structural variants in both cohorts. These results further support germline mutation screening to be combined with somatic variant detection for early diagnosis and accurate risk assessment for both the primary patient and first-degree relatives.

Session Title: Cancer Poster Session II

PB5099 Interrogating immuno-oncological interactions in the tumor microenvironment

Authors:

C-Y. Chen, B. Patterson, N. Fernandez, S. Kaushal, L. Colbert, J. He; Vizgen, Cambridge, MA

Single-cell RNA sequencing is a powerful tool for assessing cancer heterogeneity. However, single-cell RNA-seq inevitably destroys the spatial information within tumor microenvironments, preventing the study of the complex tumor niche interactome during disease progression. The Vizgen MERSCOPE® Platform is built on Multiplexed Error-Robust Fluorescence in situ Hybridization (MERFISH) technology and enables direct molecular and cell atlasing in intact tissue with subcellular resolution. Here, we used MERSCOPE to probe immuno-oncological interactions in patient-derived cancer tissues. Using a custom 500-gene panel designed to assess immune cell states, canonical cancer signaling pathways and immune-oncological interactions occurring within the tumor microenvironment, we spatially profiled the gene expression of >1 million cells across human lung cancer samples. The MERFISH data showed strong correlation when compared with block-matched RNA-seq data, demonstrating the high accuracy of our data capture. To map the cell types and characterize their molecular signatures within the tumor microenvironments, we employed a deep learning-based segmentation algorithm, and resolved distinct gene expression patterns and spatial locations in fibroblasts, endothelial cells, and multiple cancer cell populations within the 3-dimensional tissue context of the tumor tissue. The expression of CXCL9, CXCL10, and CXCL11 were used to identify immune hubs and neighboring cell types which can provide key spatial insights into potential immuno-oncological interactions occurring across these lung cancer samples. We quantified the overlap of various cell types in immune neighborhoods and found that macrophages and CD4+ T cells spatially overlap with immune hubs, while B cells and monocytes have low spatial overlap with the hubs; these differences suggest a proximal-to-distal polarization of the tumor interactome. Lastly, we identified three major cancer clusters with distinct spatial distributions and relationships with epithelial cells, which may provide further insights into tumorigenesis and metastasis. These findings demonstrate how the MERSCOPE Platform is a powerful research tool providing insights into the complex immuno-oncological microenvironments in tumor samples.

Session Title: Cancer Poster Session III

PB5100 Intersecting predisposition germline variants from TCGA with the *All of Us* Research Program reveals the importance of diverse cancer datasets.

Authors:

B. Bates, K. Bates, S. Boris, M. Davis, M. Bailey; Brigham Young Univ., Provo, UT

The last two decades of cancer research have benefited tremendously from the advent of next-generation sequence technologies. The Cancer Genome Atlas (TCGA) has led the way in this genomics revolution by molecularly characterizing 10,000 tumors from 33 different cancer types. Among the biomarkers discovered by TCGA are cancer predisposition mutations, or germline mutations that contribute to cancer development. Despite this large effort, TCGA is a case set, which is heavily biased toward cancer selection and is primarily composed of participants of European genetic ancestry. Consequently, while many predisposition germline variants have been identified in TCGA, their impact on diverse populations remains understudied. The All of Us Research Program provides an excellent dataset for validating the effect of the predisposition variants from TCGA in a cohort that is both more diverse and unbiased by cancer selection. Using the All of Us Controlled Tier Dataset v6, which contains 70,666 people with both whole-genome sequences and insurance billing code data, we investigated the connection between predisposing germline variants and cancer occurrence across 6 genetic ancestries: European (EUR), African (AFR), Admixed American (AMR), East Asian (EAS), South Asian (SAS), and Middle Eastern (MID). We identified 22,372 patients with billing codes suggesting a cancer-related phenotype (15,925 EUR, 3166 AFR, 2639 AMR, 362 EAS, 189 SAS, and 91 MID), making the All of Us Research Program a meaningful cancer dataset. We validated established predisposition variants in EUR participants, showing that the presence of predisposition variants was associated with higher frequency of cancer occurrence ($p < 0.001$, relative risk = 1.12). However, this result did not replicate in any other genetic ancestry. Additionally, the presence of predisposition variants did not correlate to earlier age at onset in any genetic ancestry. Further analyses establish the relationship between predisposition variants and other clinically available data. By embracing diversity and harnessing the power of comprehensive datasets, we illuminate the interplay between genetics, ancestry, and cancer risk.

Session Title: Cancer Poster Session I

PB5101 Intra-tumor heterogeneity of HPV integration and its association with focal genomic instability in oropharyngeal cancer.

Authors:

N. Sasa[1], H. Eguchi[1], H. Tanaka[1], T. Fukusumi[1], M. Suzuki[1], Y. Takenaka[1], Y. Okada[2,3,4,5], H. Inohara[1]; [1]Osaka Univ. Graduate Sch. of Med., Suita, Japan, [2]Osaka Univ. Graduate Sch. of Med., Osaka, Japan, [3]Graduate Sch. of Med., The Univ. of Tokyo, Tokyo, Japan, [4]RIKEN Ctr. for Integrative Med. Sci., Yokohama, Japan, [5]Immunology Frontier Res. Ctr. (WPI-IFReC), Osaka Univ., Suita, Japan

Human papillomavirus (HPV) integration has been considered as one of the driver factors for cancer progression, but its pattern and role in carcinogenesis is still unclear. Whole genome sequencing data of 14 Japanese HPV16+ OPSCC and 13 HPV+ OPSCC from Pan-Cancer Analysis of Whole Genomes were used to identify integrations and somatic mutations. A total of 254 integration breakpoints (BPs) in 20 of the 27 tumors (74.1%) were detected. We estimated the cancer cell fraction of integration BPs and found that HPV integration also shows intra-tumor heterogeneity, indicating that nearly half of the integration events occurred after carcinogenesis. Clonal BPs were more likely to occur in the *E1* ($P = 0.036$), confirming that the disruption of the *E1* gene may result in abnormal negative regulation of the *E6/E7* oncogenes and promote OPSCC carcinogenesis. Subclonal BPs were less likely to occur in the *E6* ($P = 0.045$), suggesting that the *E6* may also play an important role in the process of cancer evolution after carcinogenesis. Four states of the HPV genome were identified: (1) episomal-only (7/27, 25.9%), (2) integrated-only (4/27, 14.8%), (3) clonally-mixed (episomal + clonally integrated) (11/27, 40.7%), and (4) subclonally-mixed (episomal + subclonally integrated) (5/27, 18.5%). Since nearly half of these cancers have developed with just episomal copies of HPV, integration itself is not essential for carcinogenesis and can occur during and after carcinogenesis. Interestingly, the *E6/E7* were conserved in all four cancers with integrated-only HPV, while the *E2* and *E1* were disrupted or deleted. This confirms that the constitutive expression of *E6/E7* is essential for the carcinogenesis of HPV+ OPSCC. These results suggest that some integrations may be drivers of carcinogenesis with disruption of *E1/E2*, as in these four cancers, and others may arise randomly due to genomic instability, as in the cancers with the *E6/E7* deleted integrants. The number of BPs of structural variations (SVs) occurred in the overlapping 100 kb regions flanking integration BPs (ITG regions) was positively correlated with the number of integration BPs (Spearman's rank correlation $\rho = 0.78$; Permutation test $P = 9.9 \times 10^{-5}$). The genomic instability that causes clonal integrations during carcinogenesis is considered to cause clonal SVs, mainly large duplications, and subclonal integrations and SVs such as large deletions. Clonal SVs, mainly large duplications, were also observed in the regions where only subclonal integrations occurred, suggesting that large duplications occur before integrations.

Session Title: Cancer Poster Session II

PB5102 Investigating cell-type specific regulation of *IRF4* via a lung cancer risk-associated pleiotropic variant

Authors:

J. Yin[1], A. Kane[1], E. Long[2], J. Feng[1], C. Gräwe[3], H. Patel[1], J. Byun[4], C. Amos[4], K. Brown[1], J. Xia[5], M. Vermeulen[3], J. Choi[1]; [1]Natl. Cancer Inst./NIH, Bethesda, MD, [2]Chinese Academy of Med. Sci. and Peking Union Med. Coll., Beijing, China, [3]Radboud Inst. for Molecular Life Sci., Oncode Inst., Radboud Univ., Nijmegen, Netherlands, [4]Baylor Coll. of Med., Houston, TX, [5]5Dept. of BioMed. Sci., Creighton Univ., Omaha, NE

A cross-ancestry genome-wide association study (GWAS) in European, East Asian and African populations have identified a locus associated with lung cancer risk at 6p25.3 tagged by rs12203592. Subsequent eQTL colocalization followed by cell-based DNA damage assays identified *IRF4* as a plausible susceptibility gene in this locus. rs12203592 was previously associated with other traits, including pigmentation traits, melanoma and other skin cancers, blood molecular traits, and smoking cessation. Importantly, GTEx and primary melanocyte eQTL (n = 106) data indicated that rs12203592 is an eQTL in multiple tissue types but in opposite allelic directions. Namely, the lung cancer risk-associated T allele is correlated with higher *IRF4* expression in lung and whole blood tissues but lower expression in skin tissues and melanocytes. Pairwise cross-tissue eQTL colocalization identified rs12203592 as the common causal variant of *IRF4* eQTLs between lung tissue and melanocyte, skin, and whole blood (colocalization posterior probability > 0.8 for all three). rs12203592 was previously shown to drive an allelic enhancer function in melanocyte and blood cell lines, and the pigmentation trait-associated C allele binds TFAP2A together with a lineage-specific regulator. To further characterize the context-specific role of rs12203592 in *IRF4* gene expression we first identified allele-specific binding proteins by mass spectrometry using the nuclear extracts from three cancer cell lines representing lung, melanocyte, or lymphocyte lineage. Among them, the NF-kB family proteins were prioritized as potential regulators of *IRF4* expression through rs12203592-T risk allele in A549 lung cell line. We further confirmed the allele-dependent binding of rs12203592 to NF-kB2 recombinant protein using electromobility shift assays, as well as antibody-supershift using A549 nuclear extract. Next, we performed expression-genotype interaction analyses using GTEx and melanocyte eQTL data. Consistent with the previous report of NF-kB pathways regulating *IRF4* in blood cell types, most of the *NF-κB* family members displayed a correlation with *IRF4* expression in lung, skin, blood, and melanocyte. However, their interaction with rs12203592 was mainly observed in lung tissues ($P < 0.025$ for *NF-kB2*, *RELB*, and *cREL*). To validate our observation and demonstrate the molecular interaction between NF-kB and *IRF4* through rs12203592, we are performing chromatin immunoprecipitation under stimulation of NF-kB proteins in lung cells. In summary, we identified NF-kB pathway proteins as potential transcriptional regulators of *IRF4* expression via rs12203592 in a context-specific manner.

Session Title: Cancer Poster Session III

PB5103 Investigating the relationship between sleep-wake characteristics and risk of colorectal cancer: A Mendelian Randomization approach.

Authors:

K. Santiago[1], T. Rogne[1], N. S. Redeker[2], X. Llor[3], A. Dewan[1]; [1]Yale Sch. of Publ. Hlth., New Haven, CT, [2]Sch. of Nursing, Univ. of Connecticut, Storrs, CT, [3]Yale Sch. of Med., New Haven, CT

Colorectal cancer is the third most diagnosed malignancy and the estimated second leading cause of cancer-related death in the United States. There are several well established modifiable risk factors for colorectal cancer (CRC), however, few studies have examined whether sleep-wake characteristics are associated with CRC. In observational studies, long sleep duration has been associated with an increased risk of CRC, while evidence suggests an inverse association of morning chronotype (i.e., individuals known as early risers) with CRC. To further investigate these relationships, we conducted Mendelian Randomization (MR) analyses to assess the effect of insomnia, chronotype, short sleep duration, and long sleep duration on CRC risk. A total of 536 independent SNPs associated with insomnia at the genome-wide significance level ($P < 5 \times 10\text{-}8$) were used as instrumental variables from a genome-wide meta-analysis of 2,365,010 individuals. For chronotype, a total of 148 SNPs from 403,195 adults of European ancestry from the UK Biobank were used as instrumental variables. Lastly, a total of 25 SNPs associated with short sleep duration and 8 SNPs associated with long sleep duration from 446,118 UK Biobank participants of European ancestry served as instrumental variables. Summary-level data on colorectal cancer was obtained from FinnGen (5,458 cases) and a meta-analysis of CRC from subjects of both European and Asian ancestry (100, 204 cases). In the meta-analysis of the two sources, genetic liability to short sleep duration (<7 hours) was associated with an increased risk of colorectal cancer (OR 4.62, 95% CI: 3.42-5.82). Consistent with extant literature, morning chronotype was associated with a decreased risk of CRC (OR 0.92, 95% CI: 0.82-1.03). In sex-specific analyses, genetic liability for insomnia in females was associated with a significantly increased risk for CRC (OR 1.62, 95%CI: 1.06-2.18), while the genetic effect of insomnia in men did not result in a significantly increased risk (OR 1.49, 95%CI: 0.98-1.99). Evidence from these MR analyses support the findings that morning chronotype reduces risk of CRC and support the hypothesis that chrono-disruption, in this case short sleep duration, significantly increases CRC risk. Given these preliminary results, future directions include multivariable MR analyses to adjust for potential confounding and an exploration of mediating pathways such as that of the metabolome. This study highlights the importance of designing interventions that promote healthy sleep behaviors such as limiting screen time and promoting a regular sleep schedule to reduce the risk of CRC.

Session Title: Cancer Poster Session I

PB5104 Investigating vitreous cytokines in posterior uveal melanoma in relation to tumor occurrence, size parameters, and gene expression profiling-based prognostication.

Authors:

Y. Demirci[1], L. Tang[1], C. Ozgonul[2], S. Weber[3], J. Sundstrom[3], H. Demirci[2]; [1]Univ. of Pittsburgh, Pittsburgh, PA, [2]Univ. of Michigan, Ann Arbor, MI, [3]Penn State Univ., Hershey, PA

Uveal melanoma (UM) is a rare but aggressive cancer with a high rate of metastasis. Metastatic risk prediction in UM is currently done by using clinical information, and when available, tumor biopsy-based information. While tumor biopsy-based molecular analysis (i.e., chromosomal aberration, driver mutation, or gene expression profiling) is known to improve UM prognostication, a search is underway for a liquid biopsy-based approach (e.g., ocular fluid-based molecular analysis) that can overcome the limitations of direct tumor biopsy. Vitreous humor fills the posterior eye cavity, and its composition can reflect the state of posterior eye layers. Given that UMs predominantly occur in posterior eye segment (>90% in choroid), vitreous is expected to be enriched in tumor-derived molecules because of its proximity to these posterior tumors. Molecular analysis of the vitreous may thus provide useful insights into UM biology and inform new clinical interventions. Inflammatory tumor microenvironment (TME) is associated with poor prognosis in UM, and cytokines constitute key soluble factors/molecules of the TME. In this study, we aimed to gain further insights into the TME in UM arising from the choroid (CM) by examining the vitreous cytokines in 32 eyes, including 18 with CM (prior to plaque radiotherapy or following enucleation) and 14 without CM. We employed a 42-plex cytometric bead immunoassay to measure vitreous cytokines and used median fluorescence intensity values as relative quantification of cytokine abundance. We used Wilcoxon rank sum test to compare vitreous cytokine levels between CM and non-CM groups and across different prognostic categories within the CM group (classified as having high or low metastatic risk using tumor biopsy-based gene expression profiling (GEP)). We used Spearman's rank correlation to assess the relation between vitreous cytokine levels and tumor size parameters. We identified twenty-six vitreous cytokines significantly upregulated in CM-bearing eyes compared to CM-free eyes. Within the CM group, we detected six differentially expressed vitreous cytokines in eyes with GEP Class 2 (high risk) vs. Class 1 (low risk) tumors. Principal component analysis of these six vitreous cytokines suggested a potential separation between the CM subgroups representing different tumor GEP-based prognostic categories. The vitreous levels of these six plus multiple other cytokines showed correlations with the tumor size. In summary, we identified several UM-relevant vitreous cytokines, which may serve as new therapeutic targets or biofluid-based prognostic biomarkers upon further validation in larger and longitudinal studies.

Session Title: Cancer Poster Session II

PB5105 Investigation of cancer related genes in patients with Ollier disease and Maffucci syndrome

Authors:

I. Babler-Madrid[1], R. Paulo Martin[2], E. Wohler[3], N. Sobreira[4]; [1]Johns Hopkins Univ., Orlando, FL, [2]Johns Hopkins Med., Towson, MD, [3]Johns Hopkins Univ., Baltimore, MD, [4]Johns Hopkins Univ, Crownsville, MD

Ollier disease (OD) and Maffucci syndrome (MS) are newly recognized cancer susceptibility syndromes. Our recent work shows that ~50% of patients with these syndromes develop a malignancy. Most commonly chondrosarcomas (~30%), gliomas (~10%), and, in patients with MS, vascular malignancies (~7%). Additional shared clinical features include enchondromas with resulting bone deformities, and other skeletal abnormalities. In addition, patients with MS have vascular overgrowth anomalies. Here we present an analysis based on a burden test using a multisample VCF file containing whole genome sequencing (WGS) data from 639 samples (73 cases and 566 controls), and whole exome sequencing (WES) data from 1855 samples (55 cases and 1800 controls). FASTQ files were aligned to the reference genome (GRCh38) with the Burrows-Wheeler Alignment (BWA 0.5.10) resulting in SAM/BAM output. GATK best practices were applied in order to obtain the multisample VCF file. First, variants were filtered based on the gene symbols of 1202 genes described in the GeneDx oncology panels and COSMIC (cancer gene census). Only single nucleotide variants (SNVs) were analyzed, and the final multisample VCF was annotated with ANNOVAR. SNVs were filtered based on RefSeq and gnomAD annotations to include functional (missense, nonsense, stop-loss, and splicing variants) rare (MAF $\leq$ 0.01) SNVs. A contingency 2x2 table containing the sum of individuals presenting at least one functional rare SNV was built for each gene mutated in at least 5 cases. 135 genes were mutated in 5 or more cases. Out of the 135 genes, three were statistically significant based on a Fisher's exact test where $p<0.05$ was considered statistically significant. The variants in these three genes will be further evaluated based on their gnomAD frequency, familial segregation, variant type, in silico prediction, ClinVar and HGMD classification, and ACMG classification to determine if any of these genes should be further investigated functionally. Additionally, the strongest candidate genes will be further investigated in unrelated cohorts of patients with isolated gliomas, chondrosarcomas, osteosarcomas and Ewing's sarcoma to determine if they are also involved in these malignancies.

Session Title: Cancer Poster Session III

PB5106 Investigation of the effect of FCRL gene family expression levels on prognosis in chronic lymphocytic leukemia patients.

Authors:

K. Gündüz[1], E. Coskunpinar[1], S. Erdem[2], M. Yenerel[2]; [1]Univ. of Hlth.Sci., Istanbul, Turkey, [2]Istanbul Univ., Istanbul, Turkey

Background: Chronic lymphocytic leukemia (CLL) is a malignancy of CD5+ B cells characterized by the accumulation of small, mature-appearing neoplastic lymphocytes in the blood, bone marrow, and secondary lymphoid tissues, resulting in lymphocytosis, leukemia cell infiltration in the bone marrow, lymphadenopathy, and splenomegaly. Although the disease shows a heterogeneous clinical course, some of the diagnosed patients are asymptomatic and live for many years without progression, while some show rapid progression even in the early stages. Therefore, it is crucial to predict the prognosis of the disease at the time of diagnosis to identify high-risk patients. *FCRL*, called the Fc receptor-like protein family, encodes type 1 transmembrane proteins with tyrosine-based signaling properties expressed by B cells. It is thought that *FCRL* family members may function to regulate innate and adaptive humoral immunity by positively and/or negatively affecting B-cell signaling. **Aim:** To reveal candidate biomarkers that may be effective in predicting the prognosis of the disease by examining immunophenotypic markers, chromosomal abnormalities, and the expression levels of *FCRL* gene family members (*FCRL1*, *FCRL2*, *FCRL3*, *FCRL4*, *FCRL5*) in CLL patients. **Methods:** 48 patients diagnosed with CLL between November 2021 and June 2023 were included in our study. Immunophenotypic parameters by flow cytometry and chromosomal abnormalities by FISH method (del13q14, del11q22, trisomy12, del17p13, del14q32 and del6q23) were analyzed from the peripheral blood samples. *FCRL* gene family members (*FCRL1*, *FCRL2*, *FCRL3*, *FCRL4*, *FCRL5*) and *ZAP70* gene expression levels were determined by qRT-PCR using RNA samples isolated from whole blood. **Results:** It was determined that there was a difference between the two groups in the fold regulation rates of *FCRL2* and *FCRL5* genes, but there was no statistical significance between the groups (respectively; FR-*FCRL2*= 2.23, p-*FCRL2*= 0.196498; FR-*FCRL5*= 2.41, p-*FCRL5* = 0.156453). When the expression of these genes in normal tissues is examined, it is known that they are mostly expressed in lymph nodes and both genes play a role in the cell surface signaling receptor pathway. **Conclusion:** It is thought that *FCRL2* and *FCRL5* genes, which are in the cell surface signal receptor pathway, can be considered as good prognostic markers in CLL.

Session Title: Cancer Poster Session I

PB5107 Karyotype prediction in pediatric acute leukemias using long-read sequencing.

Authors:

J. Lin, T. Alexander, C. Jones, J. Wang; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Throughout the past few decades, the 5-year survival rate for pediatric cancers in high-income countries (HICs) has greatly increased in comparison to that of low-to-middle-income countries (LMICs). This disparity can be attributed to advances in cancer detection and treatment more readily available in HICs. Acute lymphoblastic leukemia (ALL) accounts for most pediatric cancers and diagnosis-dependent risk stratification greatly affects clinical prognosis. While short-read sequencing technologies have proven useful in diagnosing genomic subtypes of pediatric leukemias, long-read sequencing (specifically, Oxford Nanopore Technologies) has the benefits of relative affordability, flexible implementation, and better detection of genomic structural variations. Therefore, Nanopore sequencing may be a viable diagnostic resource in LMICs to subtype ALL. Our previous work demonstrated that gene expression profiles derived from whole transcriptomic sequencing (using Nanopore RNA-Seq) can be used to classify major lineages of leukemia (B-ALL vs T-ALL vs AML) and clinically relevant genomic subtypes of B-ALL such as *ETV6-RUNX1* and *BCR-ABL1*. Building on these efforts, we show there is the potential to additionally infer aneuploid subtypes. From a cohort of 137 ALL samples, we show that Nanopore RNA-seq shows signals consistent with known karyotypes. Our results show minor allele frequency (MAF) distributions with qualitative peak shifts correlated with chromosomal copy number variation. Additionally, gene expression distributions on a chromosome level show elevations and decreases consistent with copy number gains and losses, respectively. Using features derived from MAF distributions and gene expression levels per chromosome, we tested various classification models (from python's scikit-learn machine learning library) to predict chromosomal copy number in our cohort. Initial results show a best overall accuracy of 86%, albeit biased toward overrepresented diploid classifications. By testing our model exclusively on aneuploids and collating results at the sample level, we see a best overall accuracy of 86% with better discrimination between ploidy (near haploid, low hypodiploid, diploid, and hyperdiploid). Ongoing challenges stem from low coverage, error rate and class imbalance in our dataset. Despite these challenges, our work shows Nanopore RNA-seq has diagnostic potential in the hope of developing diagnostic, point-of-care tests for pediatric patients in LMICs.

Session Title: Cancer Poster Session II

PB5108 Learning drug resistance mechanisms enables AI to generate rational anti-cancer combination therapies

Authors:

M. Sherman[1], L. McDaniel[1], O. Priebe[1], E. Farias[1], T. Ideker[2], A. Yaari[1]; [1]Serinus BioSci.s Inc, New York, NY, [2]Univ California, San Diego, San Diego, CA

Administering therapies in combination improves survival of cancer patients, but combination therapies are challenging to develop due to the complexity of identifying clinically effective and non-toxic drug pairings out of the billions of possibilities. We designed a deep learning framework to generate rational combinations by 1) learning clinically relevant genomic mechanisms of resistance for a drug of interest and then 2) identifying existing compounds that will counteract these resistance processes. The key innovation is the model's architecture that, by mimicking tumor cell proteomic organization, learns an embedding space where each dimension reflects an interpretable relationship between a cellular process and drug response, conditioned on a tumor cell's genetic, epigenetic, and/or transcriptomic state.

.

We applied the framework to learn genetic correlates of response and resistance for 1,950 drugs and 17,386 CRISPR gene knockouts screened in human cancer cell lines. The learned embeddings reflected known and novel gene-drug relationships. For example, *RAF* inhibitors (N=6), *MEK* inhibitors (N=3), and *BRAF* CRISPR knockout colocalized ($P=1.7\times10^{-11}$) due to their dependency on hyperactivation of RAF signaling; conversely, the *CDK4/6* inhibitor palbociclib shared key genetic dependencies with *CDK6* and *CDK2* loss-of-function but, surprisingly, not *CDK4* loss-of-function. To demonstrate clinical applicability of the framework, we retrospectively predicted response of 70 ER+ metastatic breast cancer patients treated with palbociclib based on the learned resistance embedding. Patients with predicted response in the bottom standard deviation (N=13) had significantly shorter treatment duration than patients in the top standard deviation (N=9) (15.2 months vs 21.7 months, log-rank test P=0.05) with no progression free survival benefit relative to patients not treated with palbociclib (P=0.35).

.

Finally, we implemented a zero-shot learning paradigm to score drug pairings for potential synergy based on their learned genetic resistance embeddings. The approach recovered clinically successful combinations such as RAF+MEK inhibitors, and in a systematic evaluation of 986 previously screened combinations, predicted synergy scores were significantly correlated with experimentally derived scores (Spearman correlation $P=6.6\times10^{-4}$). The framework has proposed dozens of new combinations that are now being experimentally tested. These results highlight the promise of biologically tailored deep learning to learn complex cellular processes and accelerate development of anti-cancer combination therapies.

Session Title: Cancer Poster Session III

PB5109 Leveraging polygenic scores to reveal the interplay of serum bilirubin, smoking, and cancer risk in a diverse Los Angeles biobank

Authors:

V. Venkateswaran[1], A. Bhattacharya[2], K. Boulier[1], E. Petter[1], Y. Ding[1], B. Pasaniuc[1]; [1]UCLA, Los Angeles, CA, [2]Univ. of California, Los Angeles, Los Angeles, CA

Recent studies identify serum bilirubin (SB) as a metabolic hormone with potent antioxidant effects, linking low SB levels with cancers, and metabolic and cardiovascular diseases. Additionally, tobacco smoking is reported to contribute to low SB levels. Thus, the associations between SB and cancers are theorized to be secondary to interactions with tobacco smoking. Using electronic health records data (EHR) on ~400,000 individuals and a polygenic score for SB on ~60,000 individuals, we examine the interplay of SB with head and neck cancer (HNC) and tobacco smoking within the UCLA ATLAS biobank, a diverse EHR-linked biobank with extensive de-identified phenotypic and demographic information.

We find that SB is inversely correlated with smoking (Linear coefficient: -0.02, CI [-0.0250, -0.0152]) and HNC (Linear coefficient: -0.16, CI [-0.19, -0.13]) after adjusting for age, sex, and self-identified race and ethnicity. Further, in a group of propensity score-matched HNC cases and controls (2040 cases and controls), matched on patient age, sex, smoking history, and self-identified race and ethnicity, we find a similar inverse association with bilirubin (Linear coefficient: -0.16, CI[-0.18,-0.12]).

Lastly, we used a polygenic score (PGS) for ‘total bilirubin’ from the PGS catalog (PGS002160) as a genetic fixed point to identify the direction of the associations between SB, smoking, and HNC. We imputed the PGS in European genetic ancestry individuals in ATLAS and validated the predictive ability against observed total bilirubin from the EHR (Linear coefficient: 0.22, CI[0.21, 0.23]). Next, we tested the association of the validated bilirubin PGS with smoking history and HNC respectively, finding no significant associations (Linear coefficients: -0.004, CI [-0.0116,0.0035] and 0.0002, CI [-0.0014, 0.0018], respectively).

This study is the first reported evaluation of the associations between SB, smoking, and HNC. Our results suggest that low SB is likely secondary to HNC or a common unidentified factor that influences control over both HNC risk and SB and is independent of smoking.

PB5110 Long-read sequencing of cervical cancer reveals the structure of DNA ends during Breakage-Fusion-Bridge events

Authors:

M. Dean[1], I. Rodriguez[2], N. M. Rossi[2], A. Keskus[3], Y. Xie[2], T. Ahmad[4], H. Lou[5], J. Godinez Paredes[2], V. Mukhina[6], D. Gaykalova[6], L. Malik[7], K. Billingsley[7], C. Blauwendraat[7], M. Kolmogorov[7]; [1]NCI, Frederick, MD, [2]NCI, Rockville, MD, [3]NIH, BETHESDA, MD, [4]NCI, Bethesda, MD, [5]NCI - Frederick, Rockville, MD, [6]Univ MD Sch. of Med., Baltimore, MD, [7]NIH, Bethesda, MD

Cervical cancer is the most common cause of cancer death in low-resource countries, and there are no targeted therapeutic approaches. We characterized 22 cervical cancer cell lines using long-read DNA and RNA sequencing to provide improved models. We identified the human papillomavirus (HPV) types, HPV integration sites, and cancer driver mutations. Cervical cancer cell lines have recurrent chromosomal alterations, and structural variation analysis revealed telomeric deletions associated with DNA inversions (breakage-fusion-bridge (BFB) cycles). BFB events are a common mechanism of chromosomal alteration in cancer, but, to our knowledge, this is one of the first analyses of BFB events using long-read sequencing. Analysis of the inversion sites revealed staggered ends consistent with exonuclease deletion of the DNA after breakage. Some BFB events are complex, involving the insertion of DNA from another chromosome or local rearrangements. BFB events are thought to resolve by adding a telomere at the chromosome break, but we did not find telomere sequences at any BFB site. BFB events have been associated with chromothripsis; however, we only observed this in 1/12 BFB breakpoints. Three cell lines have a chr11q BFB event, with *YAP1/BIRC2/BIRC3* gene amplification. *YAP1* amplification is associated with a 10-year earlier age of diagnosis and is three times more common in African Americans. The major molecular subtypes of cervical cancer are represented in this panel and will allow the development of targeted therapies. In summary, using long-read sequencing, our data provide new insight into a critical type of chromosomal alteration in cancer.

Session Title: Cancer Poster Session II

PB5111 Lung cancer in ever- and never-smokers: Findings from multi-population GWAS studies.

Authors:

Y. Li[1], X. Xiao[1], J-R. Li[1], G. Fernandes[1], M. Zhu[2], Y. Han[1], J. Xia[3], C. Cheng[1], C. Amos[1], INTEGRAL-ILCCO Lung Cancer Consortium; [1]Baylor Coll. of Med., Houston, TX, [2]Nanjing Med. Univ., Nanjing, China, [3]Creighton Univ., Omaha, NE

Clinical, molecular, and genetic epidemiology studies displayed remarkable differences between ever- and never-smoking lung cancer. Association analysis stratified by smoking behavior has the potential to identify novel variants that confer risk in only ever- or never-smoking group and were missed by prior main-effect association studies. We conducted a stratified multi-population (European, East Asian and African-American) association study in 44,823 ever-smokers and 20,074 never-smokers. Five independent novel loci, including *GABRA4* from ever-smoking and *LRRC4C* and *LCNL1* from never-smoking lung cancer, were identified with association evidence from two or three populations ($P < 5x10^{-8}$). In addition, we also validated the lung cancer risk effect for known variants at *VTI1A* and *ACVR1B* in never-smoking African American women. Further functional analysis provided multiple lines of evidence suggesting the variants affect lung cancer risk through excessive DNA damage (*GABRA4*) or cis-regulation of gene expression (*LCNL1*). For the variants with association effect in ever-smoking lung cancer (including the known variants), we examined their risk effect among never-, light- (packyear <= 20) and moderate-to-heavy- (MtoH) (packyear > 20) smokers with European ancestry. 9 out of 12 independent variants had increased lung cancer risk in MtoH-smokers compared with light-smokers. We also observed high correlation (79.19%, P=0.01) between ever- and never-smoking lung cancer suggesting the common variants shared by them. The high heritability (9.80%) of ever-smoking lung cancer suggests certain signaling pathways induced by smoking behavior in lung carcinoma; the low heritability (2.62%) of never-smoking lung cancer is aligned with the uncommon variants identified in this disease subtype.

Session Title: Cancer Poster Session III

PB5112 Meta-analysis of Rare Loss of Function Variant Data from the UK Genetic Prostate Cancer Study (UKGPCS) Identifies Genes Associated with Risk of Aggressive Prostate Cancer.

Authors:

E. Saunders[1], T. Dadaev[1], M. N. Brook[1], S. Wakerell[1], K. Govindasami[1], R. Rageevakumar[1], N. Hussain[1], A. Osborne[1], D. Keating[1], A. Lophatananon[2], K. Muir[2], UKGPCS Collaborators, A. C. Antoniou[3], R. A. Eeles[1,4], Z. Kote-jarai[1]; [1]Inst. of Cancer Res., London, United Kingdom, [2]Univ. of Manchester, Manchester, United Kingdom, [3]Univ. of Cambridge, Cambridge, United Kingdom, [4]Royal Marsden NHS Fndn. Trust, London, United Kingdom

Prostate Cancer (PrCa) is the second most frequently diagnosed cancer among men globally, and a substantial cause of mortality. Despite this, the majority of PrCa patients experience indolent, slow-developing disease, although a subset develop aggressive forms with poorer prognosis. Several candidate genes have been proposed in which rare germline mutations may increase PrCa risk, however due to sample size limitations only the *BRCA2* gene has been robustly validated to date, alongside less consistent evidence in support of a handful of additional genes. In order to maximise achievable power for the detection of genes associated with risk of aggressive PrCa, we have accumulated a cohort of 6,809 PrCa cases, through a meta-analysis of rare variant sequencing data from men in the UK Genetic Prostate Cancer Study (UKGPCS), sequenced as part of six previously reported studies. We curated a set of 10 genes (*ATM*, *BRCA1*, *BRCA2*, *CHEK2*, *MLH1*, *MSH2*, *MSH6*, *MUTYH*, *NBN* and *PALB2*) that had been sequenced in all samples available for the meta-analysis as well as having been previously proposed as candidate moderate penetrance genes contributing towards PrCa susceptibility or aggressiveness. We examined association between rare putative loss of function variants in each gene and aggressive disease (defined as cause of death recorded as PrCa, or at diagnosis any of metastatic disease, stage T4, or both stage T3 and Gleason score >7), whilst secondary analyses examined association with individual phenotypic indicators of aggressiveness (presence of metastases, nodal spread or Gleason score >7). We observed significant evidence for association between mutations in 3 genes (*ATM*, *BRCA2* and *NBN*) and risk of aggressive PrCa at the time of diagnosis after adjusting for multiple testing ($P<0.005$). A further 2 genes (*MLH1* and *MSH2*) demonstrated nominally significant evidence ($P<0.05$) for association with two or more of the phenotypes examined in the primary and secondary analyses. Additionally, through Cox proportional-hazards modelling and Kaplan-Meier survival analyses, we found evidence that carriers of germline mutations in the 5 candidate genes associated with aggressive phenotypes experience shorter all-cause (HR=2.24, 95% CI 1.91-2.63, $P=3.4\times10^{-23}$) and PrCa-specific survival (HR=2.34, 95% CI 1.93-2.84, $P=5.1\times10^{-18}$) than patients who do not carry a mutation. These observations support the role of rare pathogenic germline mutations in risk of aggressive PrCa and could help define the panel of genes for which sequencing may be informative for the identification of men at elevated risk of PrCa with poorer prognosis.

Session Title: Cancer Poster Session I

PB5113 Metabolic liver cancer: Associations of rare and common germline variants in one-carbon metabolism and DNA methylation genes

Hosp., Univ. of the Basque Country (UPV/EHU), San Sebastian, Spain, [8]BCLC Group, Liver Unit, ICMDM, IDIBAPS, Hosp. Clinic of Barcelona, Univ. of Barcelona, Barcelona, Spain, [9]Inst. of Biomedicine of Seville (IBiS), Virgen del Rocio Univ. Hosp./CSIC/Univ. of Seville, Seville, Spain, [10]Karolinska Univ. Hosp., Karolinska Inst., Stockholm, Sweden, [11]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Background: Animal studies implicate one-carbon metabolism and DNA methylation genes in hepatocellular carcinoma (HCC) development in the setting of metabolic perturbations. We investigated this in humans by assessing the associations between common and rare variants in these closely related biochemical pathways and risk for metabolic HCC in a multicenter international study. **Methods**: Targeted exome sequencing of 64 genes was performed among 556 metabolic HCC cases and 643 cancer-free controls with metabolic conditions. Multivariable logistic regression was used to calculate odds ratios (ORs) and 95% confidence intervals (CIs), adjusting for multiple comparisons. Gene-burden tests were used for rare variant associations. Analyses were performed in the overall sample and among non-Hispanic whites. **Results**: Among non-Hispanic whites, presence of rare functional variants in *ABCC2* was associated with 7-fold higher risk of metabolic HCC (OR=6.92, 95%CI: 2.38-20.15, p=0.0004), and this association remained significant when analyses were restricted to functional rare variants observed in ≥2 participants (cases 3.2% vs. controls 0.0%, $p=1.02 \times 10^{-5}$). In the overall multiethnic sample, presence of rare functional variants in *ABCC2* was nominally associated with metabolic HCC (OR=3.60, 95%CI: 1.52-8.58, p=0.004), with similar nominal association when analyses were restricted to functional rare variants observed in ≥2 participants (cases 2.9% *vs.* controls 0.2%, p=0.006). A common variant in *PNPLA3*-rs738409[G] was associated with higher HCC risk in the overall sample ($p=6.36 \times 10^{-6}$) and in non-Hispanic whites (p=0.0002). **Conclusions**: Rare functional variants in *ABCC2* are associated with susceptibility to metabolic HCC in non-Hispanic whites. *PNPLA3*-rs738409 is also associated with metabolic HCC risk.

Session Title: Cancer Poster Session II

PB5114 Methods to characterize mosaic and engineered variants in HG002 using HG002 T2T diploid assembly

Authors:

A. Abdulkadir[1], C. Daniels[1], M. Cleveland[2], N. Olson[2], N. Dwarshuis[2], M. de Mars[1], J. Zook[3]; [1]Med. Device Innovation Consortium (MDIC), Arlington, VA, [2]Natl. Inst. of Standards and Technology (NIST), Gaithersburg, MD, [3]Natl. Inst. of Standards and Technology, Gaithersburg, MD

The Somatic Reference Sample (SRS) Initiative is a program led by the Medical Device Innovation Consortium (MDIC) to improve the accuracy, reliability and transparency of NGS-based oncology tests by developing well characterized somatic variant reference samples and benchmarks. The pilot project involves using CRISPR to engineer individual cancer variants into the well characterized Genome in a Bottle Consortium HG002 cell line. Currently, the Telomere-to-Telomere Consortium (T2T) is working towards a highly accurate diploid assembly of the HG002 cell line. In advance of having the engineered SRS materials, we will evaluate whether the HG002 T2T assembly can be used to detect on and off-target edits in the SRS materials. To do this, we first will simulate the products of in-vitro SRS engineering by conducting in-silico genome editing of real HG002 data, resulting in ten edited genomes that each contain a clinically relevant somatic (cancer) variant and simulated "off-target" edits. An unedited HG002 genome will be treated as the normal sample input while each edited HG002 genome will be treated as the tumor input for somatic variant calling. We hypothesize that mapping reads to the paternal or maternal haplotypes will reduce biases in mapping and somatic variant calling, particularly around structural variants and complex variants. We will evaluate this hypothesis by comparing variants called using the current human genome reference (GRCh38) as a reference vs T2T-HG002 as a reference for different somatic and mosaic variant callers. By evaluating the in-silico edit results using the HG002 T2T assembly, we aim to help comprehensively capture a wide range of human genetic variation and fine tune SRS analyses.

Session Title: Cancer Poster Session III

PB5115 Methylation Detection in Cancer Cells with Long Read Sequencing Technology

Authors:

J. Zhang, B. Wong, L. Liu, P. Collins, N. Fitzpatrick, S. Wood, J. Pearson, N. Waddell; QIMR Berghofer Med. Res. Inst., Brisbane, Australia

DNA methylation of cytosine is an epigenetic mechanism that can transform cell gene expression. It plays important roles in biological processes in normal cells and aberrant DNA methylation is a hallmark of cancer cells. Traditional methods for profiling cytosine methylation in DNA rely on bisulfite conversion. The Oxford Nanopore long-read sequencing technologies provide distinct advantages by directly sequencing DNA molecules allowing the detection of base modifications in real-time. Long reads are also ideal for phasing haplotypes which enable the identification of allele-specific methylation events. Several tools have been developed to detect cytosine methylation status using the raw sequencing signals from the Oxford Nanopore sequencing technologies. However, the reliability of prediction of these approaches has not been benchmarked in cancers in which tumour purity and heterogeneity have large effects on the results.Here, we evaluate the performance of multiple tools using two cancer cell lines (COLO829, HCC1937) and matched non-cancer cell lines. Existing EPIC Array data of the normal-tumour paired cell lines were used as a gold standard for assessment. To understand the effect of tumour purity on cytosine methylation detection, we physically simulate tumour purity by mixing DNA from tumour and non-tumour cell lines to mimic different tumour purities (100%, 80%, 60%, 40%, 20%, 0%) for Nanopore sequencing. Subsequently, we test the best thresholds to use for each tumour purity and assess the point where the signal from the tumour becomes in-detectable. Our results include the improvement of both base calling and modification calling from using R9.4 chemistry to the latest R10.3 chemistry.Together, this study systematically evaluates the modification base calling of different tools in cancer cells with Nanopore long-read sequencing and exams the impact of purity on detection. It will serve as a guide for the best practice in tumour cytosine methylation detection in tumour tissue samples.

Session Title: Cancer Poster Session I

PB5116 MiR-206 expression in the differential diagnosis of pediatric sarcomas.

Authors:

A. Ahmed[1], L. Yermakov[2], G. Elizabeth[3], M. Zapata-Tarres[4], R. Cardenas-Cardos[5], L. Velasco-Hidalgo[5], C. Corcuera-Delgado[5], R. Rodriguez-Jurado[5], L. García-Rodríguez[6], A. Parrales[3], T. Iwakuma[3], M. Farooqi[3], T. Flatt[3]; [1]Seattle Childrens Hosp., Seattle, WA, [2]Univ. of Washington, Seattle, WA, [3]Childrens Mercy Hosp., Kansas City, MO, [4]Res. Coordination Mexican Inst. of Social Security Fndn., Mexico City, Mexico, [5]Inst. Natl. de Pediatría, Mexico City, Mexico, [6]Univ. de Monterrey, Monterrey, Mexico

Background: MicroRNAs (miRNAs) are short non-coding RNAs that function as post-transcriptional regulators of genes involved in vital physiologic processes within the cell. Their dysregulation has been shown to play a role in development and progression of cancer. Expression patterns of miRNA can be used to discriminate tumor types and to predict outcome. Materials and Methods: A total of 108 tumors in children have been analyzed for microRNA expression including 32 osteosarcoma (OS), 26 Ewing sarcoma (EWS), and 50 rhabdomyosarcoma (RMS) cases, collected from two Children's hospitals, in the USA and Mexico. RNA, retrieved from formalin-fixed paraffin-embedded tumor tissue scrolls from de-identified patients, was used for experiments on the NanoString multiplex platform (nCounter Human miRNA Expression Assay kit). The expression of 827 human miRNAs have been sequenced for clinically relevant miRNAs. Results were analyzed for read distribution percentages and data visualization through heat maps and volcano plots and compared via fold changes and p-values generated using statistical methods. Results: In comparison to EWS and OS, the RMS tumors had a total of 56 differentially expressed miRNAs [>3 fold change and $p<0.01$]. Among them, miR-206 was the most significantly overexpressed and miR-29a-3p most significantly downregulated in RMS compared to EWS. miR-206 was also among the most significantly upregulated miRNA in RMS compared to OS. miR-206 had the highest significant overexpression (>55 fold change, $p<0.0001$) in RMS and exhibited the highest sensitivity and specificity in differentiating RMS from EWS and OS. A set of eight miRNAs can differentiate embryonal from alveolar RMS, including let-7e-5p which was most significantly overexpressed in embryonal RMS [>2 fold increase, $p<0.01$]. A total of 47 miRNAs were differentially expressed in EWS versus OS. There were no significant racial or ethnic differences in miRNA expression. Conclusions: Knowledge of differentially expressed miRNA helps in further understanding of pediatric tumor biology. Specific miRNAs show potential in differentiating the common pediatric sarcomas and in differentiating between two most common subtypes of rhabdomyosarcoma.

Session Title: Cancer Poster Session II

PB5117 MiSeVis: A R-Shiny based platform for visualizing disease candidate genes with mutated protein structures caused by missense variants and predicting drug targets of candidate biomarkers.

Authors:

I. Hou; The John Cooper Sch., The Woodlands, TX

Background: Ovarian cancer is one of the leading killers in the US for women. The American Cancer Society (ACR) ranks ovarian cancer as the fifth leading cause of cancer deaths among women. This cancer is inheritable, with higher chances if the patient has a family history of ovarian cancer. The Cancer Genome Atlas (TCGA) is a joint-effort project by NCI and NHGRI that generates genomic data for the cancer patients and matches normal data samples with these patients. Missense mutations are Single Nucleotide Polymorphisms (SNPs) that modify the amino acids. A missense mutation can disrupt protein structures, possibly altering the function of the affected protein. There is an urgent need to discover potential genes with pathogenic repercussions and visualize the alterations in their 3D protein structure. This study developed a user-friendly platform for automatically prioritizing cancer genes by integrating multiple databases and visualizing changes in protein structure.
Methods and Results: Using my previous research results, I created a convenient platform called MiSeVis using R-Shiny by combining all analyses steps. MiSeVis has a protein visualization function where the user can choose a PDB file and visualize the 3D protein structure based on the file. The user can also choose between mutated and non-mutated files and examine the exact locations of the mutations with different imaging options. The platform has a function in the tool that allows the user to view the contents of both FASTA and PDB files and input their own files as well. As a case study, I visualized a gene Prosaposin (PSAP) with a mutation at amino acid position 469. The software clearly showed how the protein structure is altered and reported its drug targets.
Conclusions: In this study, I implemented a R-Shiny based tool - MiSeVis that allowed the user to visualize protein structure changes and report potential therapeutic drug targets for a given gene. By using the developed platform, I successfully identified genes that have pathogenic consequences in ovarian cancers. MisSeVis can simultaneously visualize the structures of both wild-type and mutant proteins, making it a useful tool for identifying candidate genes resulting from variant-causing structural alteration. It could guide medical researchers to determine the most effective treatment based on the precise alterations in the protein structures that make up a person's particular collection of biomarkers. Scientists can also use these specific biomarkers to develop drugs that specifically target them.

Session Title: Cancer Poster Session III

PB5118 Molecular and clinical features of high-grade serous ovarian cancers in BRCA1 and BRCA2 mutation carriers

Authors:

M. Walters[1], S. J. Winham[1], J. M. Cunningham[2], S. M. Armasu[1], H. J. Atkinson[1], B. M. McCauley[1], A. Mishra[1], C. Wang[1], A. V. Bhagwate[1], E. L. Goode[1]; [1]Mayo Clinic, Rochester, MN, [2]Mayo Clinic & Fndn, Rochester, MN

Background: Pathogenic germline mutations in BRCA1 and BRCA2 represent one of the most significant genetic risk factors for high-grade serous ovarian cancer (HGSOC). However, much remains unknown about clinical and molecular correlates for affected mutation carriers. Methods: HGSOC cases with pathogenic germline mutations in BRCA1 (N=117) or BRCA2 (N=92) were identified through comprehensive gene-based sequencing. Histopathology was confirmed using IHC-assisted review (WT1 and p53). A pathogenic mutation was defined based on annotation of 'likely pathogenic' or 'pathogenic' mutations of potential clinical significance in ClinVar. Medical record abstraction provided age at diagnosis, disease stage (early, advanced), extent of residual disease (any, no macroscopic disease), and neoadjuvant treatment (yes, no). Cases were followed for at least five years. RNA extracted from fresh frozen tissue (>70% tumor) was interrogated with gene expression for estimation of tumor molecular subtype (C1.MES mesenchymal, C2.IMM immunoreactive, C4.DIF differentiated, C5.PRO proliferative). Tumor cores of archival tissue on tissue microarrays were scored by extent of CD8+ tumor infiltrating lymphocytes (TILs; none, low, medium, high). Results: Overall, mean age at HGSOC diagnosis was 58.5 (range, 28 - 84), 92.5% were advanced stage, and 23% received neoadjuvant treatment. Surgeries left no macroscopic disease for 59.2% of cases, and five-year overall survival was 47.1%. As expected, older age, advanced stage, and macroscopic disease were associated with shorter survival time ($p< 0.05$). BRCA1 mutation carriers were more likely than BRCA2 mutation carriers to be fully surgically resected with no macroscopic residual disease (63.6% v 53.3%). However, among cases with chemo-naïve tumors, BRCA1 mutation carriers were more likely than BRCA2 mutation carriers to have C1.MES molecular subtype tumors (29.4% v 19.7%); this finding is inconsistent with the premise that C1.MES tumors may be more challenging to resect. BRCA1 mutation carriers were less likely than BRCA2 mutation carriers to have C2.IMM molecular subtype tumors (7.1% v 19.7%), although frequencies of CD8+ TILs were similar among both mutation carrying groups. There was no difference in survival between BRCA1 and BRCA2 mutation carriers after adjustment for age, stage, residual disease, molecular subtype, and CD8+ TILs ($p=0.69$). Conclusion: Laying the foundation for larger scale analyses, results suggest a potentially complex interplay between tumor molecular subtype, surgical resectability, and immune features in HGSOC that differs by germline BRCA1 and BRCA2 mutation status.

Session Title: Cancer Poster Session I

PB5119 Molecular characterization of appendiceal epithelial cancer using integrated single-cell RNA sequencing

Authors:

L. Bui-Raborn[1], X. Cao[2], J. wang[3], F. Meng[2], M. Feng[2], L. Arvanitis[2], R. Mannan[2], M. Raoof[2], N. Banovich[1]; [1]Translational Genomics Res. Inst., Phoenix, AZ, [2]City of Hope, Duarte, CA, [3]city of hope, Monrovia, CA

Appendiceal cancer develops from the cells of the appendix and is a rare cancer with 1-2 cases per 1 million individuals. Epithelial appendiceal malignancy starts from the lining cells of the appendix, in most cases it leads to the accumulation of mucins, appendix rupture, and spread inside the abdominal cavity. Epithelial appendiceal cancer is characterized by low-grade or high-grade invasive adenocarcinomas or appendiceal mucinous neoplasm. Without a reliable blood or urine test, diagnosing appendiceal cancer at its early stages is challenging and the classification of cancer grades can only be done on tissue specimens by a pathologist.To comprehensively characterize the cell types and molecular mechanisms driving cellular remodeling in appendiceal epithelial cancer, we performed an integrated scRNA-seq study on 127,000 cells from 16 appendix samples (11 peritoneal metastases samples and 5 healthy controls). We identify 38 distinct cell types/cell states with 9 being cancer-specific. Overall, we observe a remarkable shift in the transcriptional profile of many cell types in different pathology groups compared to control samples. Specifically, cancerous CD4+ T cells display lower expression levels of naive markers (TCF7, SELL, LEF1) while the expression of regulatory markers like IL2RA and IL4R is upregulated in cancerous Tregs compared to normal cells. PDL1-related immune checkpoints genes such as TNFRSF4, CD28, and CTLA4 display dysregulation in tumor T cells compared to controls. We identify three subtypes of cancer-associated fibroblasts (CAFs) - iCAFs, myCAFs and apCAFs, in the cancerous samples, but not in the healthy controls. Consistent with the histology classification of appendix biopsies, we report a highly expressed MUC5B+ cell cluster in the mucinous goblet-cell adenocarcinoma samples. Ligand/receptor analyses show an upregulation of many signaling pathways, including Midkine and PTN pathways, in the immune cells and CAFs derived from mod/high-grade and goblet-cell adenocarcinoma samples. Together, our study provides high-resolution insights into the complexity and plasticity of different appendiceal cancer pathologies and is a valuable resource for the development of biomarkers to classify appendiceal cancer grades.

Session Title: Cancer Poster Session II

PB5120 Molecular landscape of non-driver genes in myeloproliferative neoplasms through next generation sequencing; insights to reveal in Pakistan

Authors:

R. Ahmed[1,2], M. Rashid[2], M. Usmani[3], S. Mukry[2], U. Zaidi[2]; [1]Univ. of Karachi, Karachi, Pakistan, [2]Natl. Inst. of Blood Disease and Bone Marrow Transplantation, Karachi, Pakistan, [3]Univ. of Maryland, Baltimore, MD

Background: Discoveries of driver mutations in myeloproliferative neoplasms (MPNs) have filled the diagnostic gap however non-driver genes also play an important role in the phenotype of the disease. Mutations in driver genes *JAK2, CALR* and *MPL,* defining phenotypic alterations, aid in differential diagnosis of MPNs subcategories polycythemia (PV) vera, essential thrombocythemia (ET) and primary myelofibrosis (PMF). However, a triple negative MPNs group also exists with wild type driver genes that exhibits the diagnostic and prognostic utility of comprehensive mutational analysis of non-driver genes. Therefore, in order to understand the complex pathophysiology of MPNs beside driver mutations; defects in non-driver genes are the subject of extensive current research. This study is the first to evaluate the molecular landscape of non-driver genes in MPNs patients from Pakistan. **Methods:** This cross sectional study was designed within the ethical boundaries mentioned in the declaration of Helsinki. A cohort of fourteen MPNs patients (eight ET, five PMF and one PV) was investigated by the next generation sequencing, using 333 cancer gene panel, to attain comprehensive genomic analysis. Diagnosis of PV, ET and PMF was done according to the WHO diagnostic criteria. Basic demographical and haematological parameters, *JAK2*V617F (ARMS PCR), *CALR* and *MPL* status (Sanger sequencing) were reviewed from the patient's medical record. Chi square test was run in SPSS 22.0 to check association of non-driver genes with sub categories of MPNs. **Results:** Among 333 oncology related genes, possible pathogenic variations were identified in 2.1% of analyzed genes (7/333). *TP*53 and *KIT* were the only known non-driver genes in MPNs which were mutated in this cohort. The highest frequency (85.7%) was found of *UGT1A1* gene variant **28* with 71.4% heterozygous genotype (*1/*28) and 14.2% homozygous genotype (*28/*28). Second most common (64.2%) detected gene variants were of *MTHFR* with WT/A1298C, A1298C/A1298C and C677T/A1298C genotypes 28.5%, 28.5% and 7.1%, respectively. Frequency of *TP*53 substitution c.215C>G was 57.1% and *XRCC1* Q399R was 42.8%. *KIT* CNV was 42.8% whereas *KIT* substitution c.1924A>G was 7.1%. The frequency of *DPYD* genotype *9A/c.496A>G/ IVS1 0-15T>C and *2A/*9A/c.496A>G was 21.4%. The lowest frequency (7.1%) was observed of *CYP*2D6 *4/*41. *KIT* was significantly (*P*=0.026) frequently mutated in PMF patients (4/5). **Conclusion:** A distinct molecular landscape of non-driver genes was observed in MPNs from Pakistan and most of the genes variants detected belonged to drug metabolizing pathways.

Session Title: Cancer Poster Session III

PB5121 Multidimensional mutational scanning of the human insulin receptor gene to accelerate diagnosis and enable translational studies

Authors:

V. Aslanzadeh[1], G. Brierley[2], K. Matreyek[3], G. Kudla[1], R. Semple[1]; [1]The Univ. of Edinburgh, Edinburgh, United Kingdom, [2]Anglia Ruskin Univ., Cambridge, United Kingdom, [3]Case Western Reserve Univ., Cleveland, OH

Loss-of-function variants in the human insulin receptor gene, *INSR*, lead to severe insulin resistance, which is often fatal in infancy or childhood when variants are biallelic. More than 150 pathogenic mutations have been described, but few have been functionally studied, posing challenges for accurate genetic diagnosis. It also impedes patient stratification for novel candidate treatments such as peptide, antibody, and small molecule ligands that activate the receptor through non-canonical mechanisms. Discriminating pathogenic alleles from insignificant variants, and establishing which are expressed and responsive to atypical ligands, and achieving this at scale, will be critical for implementing translational studies. To address this challenge, we used plasmid-based saturating mutagenesis coupled to massively multiplexed Flow-Seq-based assays in mouse embryo fibroblasts in which endogenous insulin and IGF-1 receptors had been knocked down or out respectively. This permitted interrogation of the effect of 14,000 missense variants (around 75% of all possible variants) in the human INSR extracellular domain. Our analysis identified variants that reduce or eliminate receptor cell surface expression, and variants that maintain cell surface expression but exhibit selectively impaired insulin binding and/or signalling. A small number of variants also conferred gain of function in the assays used. We also assayed binding of two bivalent anti-receptor monoclonal antibodies that we have previous shown to act as partial agonists at some expressed mutant receptors. This identified a group of mutations with greater signalling in response to antibody than to insulin, clustering in known insulin-binding domains. These mutations are promising candidates for therapeutic targeting with such anti-receptor monoclonal antibodies. Our assays confirmed previous studies of characteristics of limited numbers of disease-causing variants, agree well with available molecular structures of the insulin receptor, and provide a multidimensional sequence-function map for INSR variant interpretation. The empirical data are currently being compared to outputs of a panel of computational predictors of functional effects of coding variants, and a prediction tool to aid in clinical diagnosis of rare pathogenic INSR variants is being developed. This will also enable rapid identification of variants with attributes amenable to activation by non-canonical INSR ligands, and will inform stratification of variants in population-based reverse genetic studies.

Session Title: Cancer Poster Session I

PB5122 Mutational processes of tobacco smoking and APOBEC activity generate protein-truncating mutations in cancer genomes

Authors:

J. Reimand[1,2], A. T. Bahcheli[1,2], K. Cheng[1,2], K. N. Al-Zahrani[3], M. Slobodyanyuk[1,2], D. Pellegrina[2], D. Schramek[1,3], N. Adler[2]; [1]Univ. of Toronto, Toronto, ON, Canada, [2]Ontario Inst. for Cancer Res., Toronto, ON, Canada, [3]Lunenfeld-Tanenbaum Res. Inst., Toronto, ON, Canada

Mutational signatures represent a footprint of tumor evolution and its endogenous and exogenous mutational processes. However, their functional impact on the proteome remains incompletely understood. We analysed the protein-coding impact of single base substitution signatures in 12,341 cancer genomes from 18 cancer types. Stop-gain mutations (SGMs) were strongly enriched in the signatures of tobacco smoking, APOBEC cytidine deaminases, reactive oxygen species (ROS), and less-frequent carcinogenic signuatures. These mutational processes affect specific trinucleotide contexts to substitute serine and glutamic acid residues with stop codons and thus provide a mechanistic model of the SGM-generating mutational processes. The signature-associated SGMs are enriched in cancer hallmark pathways and dozens of known and putative tumor suppressor genes including TP53, FAT1, and APC, tying together the mutational processes and positive selection in cancer genomes. Tobacco-driven SGMs in lung cancer correlate with lifetime smoking history and highlight a preventable lifestyle determinant of these harmful mutations. In breast cancer, the burden of APOBEC-driven SGMs is correlated with gene expression of APOBEC3 enzymes, associating these mutations with the expected molecular pathway. In summary, our study exposes SGM expansion as a genetic mechanism by which endogenous and carcinogenic mutational processes contribute to protein loss-of-function, oncogenesis, and tumor heterogeneity, providing potential translational and mechanistic insights.

Session Title: Cancer Poster Session II

PB5123 Mutational spectrum of Korean patients with T-cell acute lymphoblastic leukemia

Authors:

H. Kim[1], S. Jo[2], H. Kim[1], S. Oh[3], I. Kim[3]; [1]Pusan Natl. Univ. Hosp., Busan, Korea, Republic of, [2]Seegene Med. Fndn., Busan, Korea, Republic of, [3]Pusan Natl. Univ. Yangsan Hosp., Yangsan, Korea, Republic of

Introduction: The landscape of genetic alterations implicated in the pathogenesis of T-cell acute lymphoblastic leukemia (T-ALL) has been revealed in recent years, but there are limited data that have thoroughly analyzed these variant patterns in Korean patients. We investigated the results of gene panel tests performed on Korean patients with T-ALL. **Methods:** The study included 19 Korean patients newly diagnosed with T-ALL between January 2016 and December 2021, eight of which were classified as early T-cell precursor ALL (ETP-ALL) patients. We performed customized multigene panel tests targeting at least 101 genes with next-generation sequencing. Clinical data and other laboratory findings including immunophenotypes, cytogenetics, and bone marrow studies were also reviewed. **Results:** A total of 78 clinically significant or reportable mutations were identified in 40 genes, and all patients harbored at least two mutations (range 2-8 per patient). The median of variant allele frequencies (VAFs, %) and bone marrow blasts at diagnosis (%) were 43% (range 3% to 96%) and 79% (range 21%-92%), respectively. Variants in NOTCH signaling genes were found in 11 patients (58%), including all non-ETP ALL patients. Mutations related to the JAK-STAT pathway, epigenetic factors, and PI3K-AKT pathway were detected in 32% (6/19), 26% (5/19), and 11% (2/19) of patients, respectively, and most patients (79%, 15/19) had genetic alterations implicated in two or more pathways. **Conclusion:** Using multigene panel testing, we detected clinically significant genetic mutations in all T-ALL patients in this study, including those with normal cytogenetics. Despite the small number of patients, this study provides insight into the mutational spectrum implicated in the leukemogenesis of T-ALL in Koreans.

Session Title: Cancer Poster Session III

PB5124 Myelodysplastic syndromes progression: A comprehensive expression-based *in silico* analysis.

Authors:

B. McKinney, J. Ferreira de Vasconcellos; James Madison Univ., Harrisonburg, VA

Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal disorders characterized by ineffective hematopoiesis in the bone marrow leading to cytopenias in the peripheral blood and predisposition to secondary Acute Myeloid Leukemia (sAML). The current overall survival of sAML is 5 months in patients younger than 60 years of age and 4.7 months in patients ≥ 60 years of age. As a result, the discovery of novel biomarkers and treatment strategies to prevent the progression from MDS to sAML are urgently needed. Here we investigated novel critical molecular pathways that support MDS-to-sAML transformation. Using a publicly available dataset from the Gene Expression Omnibus database (https://www.ncbi.nlm.nih.gov/geo/) we generated a list of differentially expressed genes comparing the datasets from 164 MDS to 202 sAML patients to systematically identify molecular pathways that are predicted to support MDS-to-sAML transformation in the bone marrow niche. In addition, we performed pathway analyses using Metascape v3.5.20230101 (https://metascape.org) and ShinyGO 0.77 (http://bioinformatics.sdstate.edu/go/). Our results identified 232 differentially expressed genes (log2 fold change: ≥1.5 or ≤ -1.5) where 206 genes were up-regulated and 26 genes were down-regulated. In addition, the gene expression signature from MDS compared to sAML datasets identified enriched molecular pathways, such as regulation of hemopoiesis, hematopoietic stem cell differentiation, immune system development and skeletal system development. Overall, these results have an important positive impact because they address aspects of unique importance to MDS transformation, including fundamental insights in the disease biology that will be investigated as potential biomarkers and/or new targets for therapeutic intervention.

Session Title: Cancer Poster Session I

PB5125 Noncoding and germ line mutations in African American esophageal squamous cell carcinoma

Authors:

R. Wadleigh[1], H. Erkizan[2]; [1]DC VA Med. Ctr., Washington, DC, [2]Inst. for Clinical Res., DC VAMC, Washington, DC

Esophageal Squamous Cell Carcinoma (ESCC) ranks among the most lethal cancers and is particularly aggressive among African Americans (AA). To conduct an extensive mutation screening, we performed whole exome sequencing in 10 paired AA ESCC and control tissues. Mutations included nonsynonymous mutations in multiple genes and copy number variations. Here, we report on further analysis of the WES data to identify noncoding region and germ line genetic alterations. Late-stage disease showed 340 genomic mutations, two thirds of which occurred mostly in the 3`UTR of differentially expressed genes (DEGs) suggesting association of dysregulation at the 3`UTR with metastasis. AA ESCC related changes in promoter regions were detected, and 70% of these mutated sites were revealed in the RNA polymerase (*POLR2A*) binding site. In addition, germ line variants were displayed 21 DNA damage repair (DDR) genes. *RAD52*, a gene involved in repair of DNA double-stranded break, that has been reported previously to exert a role in genetic susceptibility for squamous cell cancer of the upper aerodigestive tract, carried >20 different mutations in 10 control tissues. *BLM*, which encodes a DNA helicase that has been reported as a genome stabilizer displayed a missense mutation with a high deleteriousness (CADD) score. Five other germ line variants were presented in *TP53*. We propose that the combined effect of these genetic and coding region mutations that exert a large impact on poor prognosis in AA ESCC may yield targets for developing candidate therapeutics.

Session Title: Cancer Poster Session II

PB5126 Novel genetic loci associated with cirrhosis and primary liver cancer in the Million Veteran Program suggest potential therapeutic relevance for EPHA2 and JAK2 signaling

Authors:

M. Vujkovic[1], T-H. L. Schwantes-An[2], D. Dochtermann[3], B-L. Chang[4], M. G. Levin[4], C. V. Schneider[5], D. Gill[6], S. Mukherjee[4], A. Verma[4], A. Mezina[4], S. Pyarajan[7], P. Devineni[3], L. Bastarache[8], A. Lewis[8], K-M. Lee[9], C. C. Teerlink[9], P. S. Tsao[10], D. J. Rader[4], B. F. Voight[4], J. A. Lynch[9], A. Shaked[4], M. A. Hoteit[4], T. R. Morgan[11], Million Veteran Program, D. E. Kaplan[1], K-M. Chang[1]; [1]Corporal Michael J. Crescenz VA Med. Ctr., Philadelphia, PA, [2]Indiana Univ. Sch. of Med., Indianapolis, IN, [3]VA Boston Hlth.Care System, Boston, MA, [4]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA, [5]Univ. Hosp. RWTH Aachen, Aachen, Germany, [6]Imperial Coll. London, London, United Kingdom, [7]VA Boston Hlth.care System, Boston, MA, [8]Vanderbilt Univ. Med. Ctr., Nashville, TN, [9]VA Salt Lake City Hlth.Care System, Salt Lake City, UT, [10]VA Palo Alto Hlth.Care System, Palo Alto, CA, [11]VA Long Beach Hlth.care System, Long Beach, CA

Chronic liver disease (CLD) is a leading cause of death worldwide due to associated cirrhosis and hepatocellular carcinoma (HCC). Regardless of underlying causes, a subset of patients with CLD will progress to cirrhosis, and subsequently a subset of cirrhotic patients will develop HCC. We aimed to better define the genetic architecture of liver disease progression by disentangling the genetic contributions to cirrhosis and HCC, and to identify causative genes and downstream signaling pathways for potential pharmacologic manipulation. We conducted two multi-ancestry genome-wide association studies (GWAS) of all-cause cirrhosis and HCC in the Million Veteran Program (MVP) biobank. The cirrhosis GWAS with 10,931 cirrhosis cases and 162,603 non-cirrhotic CLD controls (66% European, 22% African American, 12% Hispanic) identified 14 independent genome-wide significant loci, including 4 known loci (*PNPLA3, HSD17B13, SERPINA1, TMS6F2*). Eleven loci are known to promote metabolic and liver disease and implicate genes with differential liver cell type expression. A target-based screening for drug repurposing using DrugBank data identified JAK2 inhibitors as a potential therapeutic target for cirrhosis. For the HCC GWAS, we performed a genome-wide meta-analysis of 5,047 HCC cases and 11,092 cirrhotic controls from several studies and identified 3 novel (*EPHA2, MYC, RAB28,* and *SAMD5*) and 3 known loci (*PNPLA3, TM6SF2,* and *TERT).* A drug screen identified EphA2 signaling as having a potential therapeutic role in HCC. We therefore performed drug target MR analysis of genetically-proxied EphA2 signaling using instrumental variables based on liver tissue gene expression data from the GTEx project and circulating plasma protein levels from the deCODE consortium, respectively. In contrast to previous reports of HCC suppression by EphA2 inhibition, we showed that genetically-proxied increased EphA2 levels were associated with reduced HCC risk in analyses both considering gene expression (OR 0.62, 95%CI 0.53-0.71, $P=2x10^{-11}$) and plasma protein levels (OR 0.59, 95%CI 0.40-0.87, P = 0.008). These findings were corroborated by high colocalization at the EPHA2 locus for gene expression, protein concentration, and risk of HCC. In summary, we provide novel insights into the pathophysiology of cirrhosis and HCC and demonstrate both distinct and shared genetic risk loci for the progression of chronic liver disease to cirrhosis and HCC. Our drug target MR supports that EphA2 signaling plays a role in HCC, however the directionality of effect warrants further study, particularly in the context of ongoing clinical investigation of EPHA2 inhibitors for treating HCC.

Session Title: Cancer Poster Session III

PB5127 *NSD2* expression driven by the t(4;14) translocation disrupts the DNA methylation landscape in multiple myeloma

Authors:

R. Chavez[1], D. R. Powell[1], K. Lakhani[1], A. Cook[2], M. Hamilton[2], G. Mulligan[2], D. Auclair[3], J. J. Keats[4], P. M. Vertino[5], L. H. Boise[1], S. Lonial[1], K. N. Conneely[1], B. G. Barwick[1]; [1]Emory Univ., Atlanta, GA, [2]Multiple Myeloma Res. Fndn., Norwalk, CT, [3]AstraZeneca, Waltham, MA, [4]Translational Genomics Res. Inst., Phoenix, AZ, [5]Univ. of Rochester, Rochester, NY

The t(4;14) chromosomal translocation, which places the histone methyltransferase gene NSD2 under the regulatory control of an enhancer of IGH, is observed in 15-19% of multiple myeloma patients and is associated with poor prognosis. The alteration gives rise to a transcriptionally distinct subtype of myeloma, but the mechanisms by which the translocation alters gene expression and leads to high-risk disease are poorly understood. It is known that H3K36me2, which is deposited by NSD2, is widely distributed at high levels in t(4;14) myeloma. Additionally, it has been shown that the PWWP domains of de-novo DNA methyltransferases recognize H3K36me2. To better understand how increased NSD2 activity and widespread H3K36me2 lead to epigenetic and transcriptional dysregulation, we generated DNA methylation (DNAm) data by whole genome bisulfite sequencing on 415 samples from the MMRF CoMMpass study and integrated these data with existing genetic, transcriptional, and clinical data. A differential methylation analysis between samples of the t(4;14) subtype and samples of other subtypes indicated t(4;14) was the most epigenetically distinct form of myeloma and identified 2,075,489 differentially methylated loci ($p < 1e\text{-}9$). The vast majority of these loci (92%) were hypermethylated in t(4;14) samples and were largely located in heterochromatic, late replicating regions of the genome. These hypermethylated loci were significantly enriched within several classes of transposable elements (TEs) from the RepeatMasker database ($1.02 < OR < 1.59$, $p < 0.001$) but roughly evenly distributed between gene body and intergenic DNA (51% to 49%, respectively). This pattern was specific to NSD2 expression as analysis of myeloma cell lines with NSD2 ablation showed a marked decrease in DNAm. Gene set enrichment analysis on differentially expressed genes in t(4;14) patient samples showed downregulation of biological processes including translation, immune signaling, and oxidative phosphorylation, demonstrating biological implications of this aberrant epigenetic programming. These results indicate that t(4;14) driven NSD2 expression and resulting widespread H3K36me2 disrupts the DNAm landscape leading to a transcriptionally distinct and high-risk form of multiple myeloma.

PB5128 Olink Insight and Human Disease Blood Atlas to uncover human disease proteome and accelerate adoption of proteomics.

Authors:

M. Förster[1], M. Rucevic[1], M. Bueno Álvez[2], M. Uhlen[2], O. Caster[3], H. Andersson[3], F. Edfors[2], L. Fagerberg[2]; [1]Olink Proteomics, Waltham, MA, [2]Sci. for Life Lab., Dept. of Protein Sci., KTH Royal Inst. of Technology, Stockholm, Sweden, [3]Olink Proteomics, Uppsala, Sweden

Despite decades of outstanding research and the impact of genomics, cancer remains an overwhelming burden on global healthcare resources and challenge for the scientific community. Next generation proteomics technologies are increasingly emerging to better understand cancer biology and identify early diagnostic, prognostic, and therapeutic response biomarkers essential to drive development of new, more effective therapies. To progress cancer research more rapidly, data sharing and free access to generated data remains an essential step forward. Here, comprehensive proteome profiling, using Olink Explore platform, was used to measure 1,463 high and low-abundant proteins in plasma, collected at the time of diagnosis and before treatment, from more than 1,500 patients representing 15 common cancer types. The obtained results were used as a foundation for establishment of the Olink Insight platform, an open-access digital knowledge data resource to accelerate adoption of proteomics in the research community. Olink Insight comprises key features such as pathway browser, panel and biomarker selection, and proteomics publication explorer. In Olink Insight, we are creating a collection of proteomic profiles for some of our most important diseases, starting here with cancer. Results can be interactively explored through a variety of analyses and visualizations, including differential expression analysis, pathway enrichment, pathway annotation with hexmaps, and predictive protein groups identified by machine learning. Using a complementary multi-step statistical approach for the Human Protein Atlas (HPA) platform, a panel of 83 proteins was identified that can discriminate 12 different types of human cancer with extremely high accuracy. The plasma profiles for all measured proteins across 12 types of cancers are available in HPA. Olink Insight and the Human Disease Blood Atlas represent a significant step towards uncovering the human disease proteome and will be a valuable resource for researchers in many areas of medicine and biology.

PB5129 Optical genome mapping for genome-wide structural variation analysis in hematologic malignancies: results of a prospective study and impact on diagnosis and management

Authors:

T. Sahoo[1], S. J. Wicks[1], J. Hauenstein[1], A. Mylavarapu[1], B. Matthews[1], M. Younan[1], K. Hovanes[1], M. Naik[2], N. Ojha[2], R. Arora[2], V. Khushoo[2], V. Babu[2], N. Dhakate[2], P. Jain[2], P. Jain[2], G. Babu[2], S. Rao[2], S. Jadhav[2]; [1]Bionano Lab., San Diego, CA, [2]Hlth.Care Global, Bengaluru, India

Structural variations (SV) play a key role in the pathogenesis of hematologic malignancies. Standard-of-care (SOC) cytogenomic methods, including chromosome karyotyping (KT) and fluorescence *in situ* hybridization (FISH), have inherent limitations, while next-generation sequencing (NGS) technologies have limited ability to detect most SVs. Optical genome mapping (OGM) is a high-resolution technique that overcomes these challenges and allows detection of all classes of SV. Recent studies, mostly retrospective, demonstrate the diagnostic value of OGM for both hematologic malignancies and constitutional genetic disorders. This prospective study, utilizing OGM as a validated laboratory developed test (LDT), included 115 samples from a broad variety of hematologic malignancies undergoing active clinical workups and management. OGM was successful for 107 of 115 samples (93%; eight failed); 76 had abnormal and 31 normal results by OGM (71% and 29% respectively); 48% of abnormal OGM results were classified as complex. Karyotyping and FISH results were available for 45 and 52 samples, respectively. Of the 22 cases with an abnormal KT, 20 were also abnormal and concordant by OGM and identified additional SV in the majority; of the 28 cases with abnormal FISH, 23 were abnormal and concordant by OGM and majority of samples had additional findings. Guideline and SOC result-based disease risk stratification was possible for 50 cases at initial diagnosis with 19 graded as high, 15 as intermediate and 16 as low-risk; the disease risk stratification was reevaluated for 61 cases after completion of OGM analysis and resulted in a change to 28 as high, 13 as intermediate and 28 as low-risk. A final risk assessment (no change, down- or upgrading of risk status) to direct clinical management in 67 cases resulted in 13 as upgraded, 2 as downgraded and 52 with no change in risk status. Additionally, the change in therapeutic management based on addition of OGM results (and likely change in risk status) was also evaluated for 92 and revealed initiation of more intensive therapy in 6 and no change in 86 cases. In summary, OGM identified a case abnormality rate of 71%, a change in disease risk stratification in 22% of cases, and a change in clinical management in 6.5% of cases. The impact of OGM on disease risk stratification and patient management is in alignment with previously published studies and not only provides improved diagnostic assessment but also adds significant prognostic information for better patient management and care. Also, this study suggests a significant role for OGM in providing results with early diagnostic and prognostic potential compared to conventional cytogenetics.

Transposons make up about half of the human genome, and some full-length elements create novel insertions in germ cells and somatic tissue of both healthy and diseased individuals. These genetic elements have the potential to generate chimeric transcripts consisting of transposons and non-transposons, which may result in the production of abnormal proteins or immunogenic molecules. However, accurate identification of these transposon fusion events from short RNA-seq reads is challenging due to the repetitive nature of transposon sequences and read alignment errors near exon-intron junctions. To address this, we have developed a computational pipeline, rTea (RNA Transposable Element Analyzer) to detect various types of transposons-fusion transcripts from reference and non-reference, i.e., polymorphic or somatic transposon insertions from RNA-seq data. We applied rTea to analyze 10,257 cancer samples across 34 cancer types, as well as 3,088 normal tissue samples from the TCGA/ICGC, our unpublished colorectal cancer cohort, and the GTEx consortia. We realigned all RNA-seq reads for unified processing on Google Cloud Platform (GCP) using GenomeFlow, a tool to design scalable distributed processing architectures to optimize computational resources and reduce compute costs. We identified 30,016 fusions with an average of 203 events per normal sample, particularly abundant in the testis. We also identified 52,277 cancer-specific fusions that were not detected in the corresponding normal tissues, with an average of 30 events per cancer sample. We found that the somatic cancer fusions were enriched in known cancer genes, suggesting their involvement in tumorigenesis. Furthermore, we discovered distinct splicing hotspots and DNA methylation changes associated with fusions from different families of source transposons. Our in silico immunogenicity modeling and experimental validation confirmed that several peptides derived from transposon fusions in cancers bind to MHC-I and activate CD8+ T cells to a comparable extent to EBV viruses. Our findings highlight the potential of endogenous retroelements as novel therapeutic targets and a significant source of neoantigens. rTea is available at https://github.com/ealeelab/rtea.

Session Title: Cancer Poster Session I

PB5131 † Parent-of-origin assignment of allelic variants without parental data across multiple hereditary cancer syndromes

Authors:

K. Schrader[1], V. Akbari[2], V. Hanlon[3], K. Dixon[4], K. O'Neill[5], A. Roston[4], L. Cordova[6], Y. Shen[5], A. Sharma[7], K. Wong[7], J. Senz[8], Y. Wang[8], D. Chan[8], A. Fok[8], J. Nuk[8], Q. Ctr., Vancouver, BC, Canada, [6]Univ British Columbia, Vancouver, BC, Canada, [7]Hereditary Cancer Program, BC Cancer, Vancouver, BC, Canada, [8]BC Cancer, Vancouver, BC, Canada, [9]Dept. of Med. Genetics, Univ. of British Columbia, Vancouver, BC, Canada, [10]BC Cancer, as part of the Provincial Hlth.Services Authority, Vancouver, BC, Canada

Background: Although genetic testing can inform a patient's inherited risk for disease, predicting which side of the family an autosomal variant comes from is a key limitation of current clinical technologies. Parent-of-origin-aware genomic analysis (POAga) using Oxford Nanopore Technologies long-read sequencing combined with Strand-seq enables assignment of any autosomal variant to either parent with 99% accuracy using only the blood sample of the proband. Knowledge of predicted parental segregation is essential in risk management, variant curation, and facilitating cascade genetic testing. We sought to assess POAga in common Tier 1 hereditary cancer conditions such as hereditary breast and ovarian cancer (HBOC) and Lynch syndrome due to germline pathogenic variants in *BRCA1*, *BRCA2*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, and *EPCAM* on chromosomes 17, 13, 3, 2, 7, and 2, respectively, rarer syndromes with parent of origin effects such as hereditary paraganglioma and pheochromocytoma due to paternally inherited pathogenic variants in *SDHD* and *SDHAF2* on chromosome 11 and other genes predisposing to breast cancer and gastrointestinal malignancies, such as *ATM*, *PALB2*, and *CDH1* on chromosomes 11 and 16.**Method:** To determine the analytic validity of POAga, blood samples from carriers of pathogenic variants in *ATM*, *BRCA1*, *BRCA2*, *CDH1*, *MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*, *PALB2*, *SDHD* and *SDHAF2* of differing age, sex, ethnicity, and cancer status with known parental segregation are currently being ascertained and subjected to Strand-seq and long read sequencing to determine parent-of-origin according to previously described methods (Akbari V, Hanlon VCT, et al. Cell Genom. 2022 Dec 21;3(1):100233.) under an REB approved protocol.**Results:** Thus far 43 informative samples have been been ascertained for POAga across multiple cancer susceptibility
genes, *SDHD* (n=19), *SDHAF2* (n=2), *BRCA1* (n=4), *BRCA2* (n=6), *MSH2* (n=2), *MSH6* (n=5), *PMS2* (n=4), and *EPCAM* (n=1). Sequencing is ongoing for 24 samples. Analysis is complete for 19 samples in *SDHD* (n=18) and *SDHAF2* (n=1), which has demonstrated 100% concordance with known clinical segregation.**Conclusion:** Results to date support the ability of POAga to correctly infer germline variant parent-of-origin using blood samples from hereditary cancer patients with known parental segregation. Ongoing ascertainment and analysis will shed light on the real-world accuracy of POAga and potential to clinically translate this transformational advance in genetic assessment.

Session Title: Cancer Poster Session II

PB5132 PDPR gene variant predisposing to familial papillary thyroid cancer

Authors:

T. Nieminen[1], P. Brock[2], M. Sevigny[1], S. Liyanarachchi[2], W. Li[3], D. F. Comiskey[2], H. He[2], S. Saarinen[1], A. Yilmaz[2], M. Ringel[4], S. Ollila[5], P. Peltomaki[1]; [1]Univ. of Helsinki, Helsinki, Finland, [2]The Ohio State Univ., Columbus, OH, [3]The Ohio State Unversity, Columbus, OH, OH, [4]The Ohio State Univ., columbus, OH, [5]Univ Helsinki, Helsinki, Finland

BACKGROUND: Thyroid cancer is the 12th most common cancer in the USA, with papillary thyroid cancer (PTC) as the predominant subtype. PTC clusters in families in 5 to 15 % of all thyroid cancer cases. No established highly penetrant predisposing variants for familial PTC exist, despite intensive research efforts. **AIM**: Our aim was to identify novel genes and mechanisms underlying PTC susceptibility. **MATERIAL AND METHODS**: Our previous investigation on 17 PTC families led us to conduct a closer analysis on one PTC family (64557) with whole-genome sequencing (WGS) data available on three PTC-affected individuals. Our analysis identified *PDPR* (Pyruvate Dehydrogenase Phosphatase Regulatory Subunit) as a promising candidate gene predisposing to PTC. We subsequently screened 323 sporadic thyroid cancer cases and 12 Familial adenomatous polyposis (FAP) individuals with secondary thyroid cancer for *PDPR* variants from whole-exome sequencing (WES) and WGS data, respectively. We studied the functional and metabolic consequences of the *PDPR* variants by creating PDPR mutant cell lines using CRISPR-Cas9. Finally, we evaluated the Cancer Genome Atlas (TCGA) data for *PDPR* expression in thyroid cancer**. RESULTS**: We found truncating splice donor variants in PTC-affected family members from 64557 (NM_017990.4:c.361+1G>C) and in a sporadic case, SL250416 (NM_017990.4:c.443+1G>C). Nine other sporadic cases as well as a FAP-PTC patient revealed constitutional *PDPR* variants of the missense type. The *PDPR* c.361+1G>C variant segregated perfectly with patients with PTC (n=4) and with a parotid cancer patient (n=1) from family 64557, and was absent in unaffected members (n=2). RNA sequencing data (TCGA) of thyroid cancer tumor with matching normal pairs (n=59) showed significantly lower *PDPR* gene expression ($p<0.0001$) compared to matching normal thyroid tissue. PDPR mutant cells presented with elevated phosphorylation of pyruvate dehydrogenase and displayed metabolic changes. **CONCLUSIONS**: Our finding of a novel truncating *PDPR* germline variant in a three-generation PTC family, together with constitutional (and somatic) *PDPR* variants in additional cohorts, suggests a role for *PDPR* in PTC predisposition. PDPR is a regulatory protein of the Pyruvate dehydrogenase complex (PDC), and our functional data suggests dysregulation of energy metabolism as a potential mechanism mediating the pathogenicity of *PDPR* loss-of-function variants. Full characterization of the role of *PDPR* in thyroid cancer tumorigenesis warrants further investigations.

Session Title: Cancer Poster Session III

PB5133 Performance of Somatic Structural Variant Calling in Lung Cancer using Oxford Nanopore Sequencing Technology

Authors:

Sydney, Sydney, Australia, [6]Dept. of Thoracic Med., Sunshine Coast Univ. Hosp., Birtinya, Australia, [7]Dept. of Thoracic Med., Gold Coast Univ. Hosp., Southport, Australia, [8]Dept. of Thoracic Med., Royal Adelaide Hosp., Adelaide, Australia, [9]Dept. of Respiratory and Sleep Med., John Hunter Hosp., Newcastle, Australia

Background: Lung cancer is a heterogeneous disease and the primary cause of cancer-related mortality worldwide. At diagnosis, over 70% of patients have metastatic disease, with only one-third of patients having an earlier-stage disease that is potentially curable with multimodality therapy. Somatic mutations are important biomarkers for selecting targeted therapy and predicting outcomes for lung cancers. The identification of somatic mutations through genome sequencing of tumors has revolutionized cancer research, playing a crucial role in uncovering driver events, tumorigenesis mechanisms, potentially actionable targets, and intra- and inter-tumor heterogeneity. A key driver of many cancers is somatic structural variants (SVs). Genomic studies in lung cancer have been conducted using short-read sequencing. Emerging long-read sequencing (LRS) technologies, such as the Oxford Nanopore Technologies (ONT), which sequences DNA directly to provide simultaneous whole genome sequencing and methylation profiling is a promising approach to studying somatic SVs and tumor heterogeneity. However, the analysis of LRS genome data is challenging with no consensus on how to process data and call somatic mutations. **Methods:** In this study, we examine the reliability of ONT LRS to detect somatic SVs using a panel of lung cancer samples. We comprehensively benchmark the performance of 3 sequence aligners and 6 SV computational tools. The SV tools include three generic SV callers (sniffles2, cutesv, svim) and three somatic SV callers (delly, nanomonsv, savana). We investigated factors affecting the variant callers and evaluated their performance against high-confidence somatic SV events identified from short-read whole genome sequencing. **Results:** Our results show that different combinations of aligners and variant callers influence somatic SV detection. In particular, the choice of SV callers has a significant influence on somatic SV detection in terms of variant type, size, sensitivity, and accuracy. The recall rate for somatic SV callers (~89%) is higher than generic SV callers (~65%). We will provide a recommendation on the most appropriate computational tools for the detection of somatic SV events from LRS. **Conclusion:** This research enables the development of standardized, efficient, and accurate computational pipelines for long-read somatic SV detection. Better characterization of somatic SV events will contribute to our understanding of cancer development and inform personalized cancer treatment and will have a valuable impact on the field of cancer research.

Session Title: Cancer Poster Session I

PB5134 Plasma Proteomic Signature, Clonal Hematopoiesis and Risk of Myeloid Neoplasm in 46,237 Healthy Individuals

Authors:

D. Tran[1], J. Beeler[1], J. Liu[1], B. Wiley[1], I. Chan[1], M. Kramer[1], A. Batchi-Bouyou[1], X. Zong[1], M. Walter[1], S. Chlamydas[2], F. Ferraro[1], B. Busby[3], D. Link[1], Y. Cao[1], K. Bolton[1]; [1]Washington Univ. in St. Louis, Saint Louis, MO, [2]Olink Proteomics, Frankfurt, Germany, [3]DNAnexus, Mountain View, CA

The presence of clonally expanded mutant hematopoietic stem cells, clonal hematopoiesis (CH), is known to predispose to hematologic malignancy, particularly myeloid neoplasms (MN). However, the overall risk of developing MNs among individuals with CH is low (<0.5% per year) and our poor ability to predict who with CH will progress to MN is a barrier to prevention strategies. The human proteome reflects the downstream impact of complex interactions between genetic and epigenetic regulation of biologic systems. We hypothesized that plasma proteomic markers might be associated with MN risk, and if so, could inform our understanding of the mechanisms promoting CH and MN development. We jointly characterized CH and plasma proteomic profile among 46,237 individuals in the UK Biobank with whole exome sequencing data of the blood and plasma proteomic profiling using the Olink Explore 1536 platform (1,463 unique proteins). Cox proportional hazard models were used to assess the prospective association between the level of each plasma protein and risk of MN; while controlling for age, sex, genetic ancestry, smoking status, blood counts, and sample collection year. The relative contribution of clinical, CH, and proteomics features in prediction of incident MN was assessed using lasso regression analysis with 100-fold cross validation. A total of 115 participants developed MN at least 3 months after study entry (median 83 months). We identified 115 proteins significantly associated with incident MN (FDR-corrected p-value <0.05), many of which (N=34) were also significantly associated with CH. Most of the top 25 associated MN proteins have known roles in immune cell function. These include known regulators of the adaptive immune system (AMIGO2, LAG3, SEMA7A), innate immune system (GCNT1, ICAM, CD244, CLEC6A, FCGR2A, VCAM1, SIGLEC6, LY9, AXL), leukocyte trafficking (CXCL11 or I-TAC, SDC4 or Syndecan-2, ADGRE5 or CD97), hematopoietic stem cell self-renewal (SIRBP1, THPO), and platelet activation (GP1BA, PEAR1). Inclusion of proteomics features significantly (AUC=0.85, p=5e-9) improved prediction of incident MN beyond clinical factors and CH (AUC=0.80). In summary, we show that plasma proteomic markers predict both CH and risk of progression to MN, improving MN risk prediction beyond basic clinical and CH features. These data highlight the promise of protein and genetic biomarker integration for early diagnosis of MN and further support the role of immune cell regulation in early leukemogenesis.

Session Title: Cancer Poster Session II

PB5135 Polygenic risk score and age at onset in breast cancer: Insights from the Korean population.

Authors:

J. Hwang[1], Y-J. Lee[2], S. Lee[2], T-K. Yoo[2], K. Nguyen[3], J. Lee[2], J. Hopper[3], J. Sung[1]; [1]Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Asan Med. Ctr., Seoul, Korea, Republic of, [3]Univ. of Melbourne, Carlton, Australia

Background: Compared to Europeans, East Asian populations, particularly in South Korea, exhibit a higher incidence of early-onset breast cancer (BC), occurring before 40 years of age. Alarmingly, this trend continues to escalate. Early-onset BC imposes significant challenges to both preventative measures and clinical management due to its poorer prognosis. It is broadly accepted that early-onset BC carries a higher genetic load, especially with regards to high-penetrance genes such as *BRCA1/2* mutations. However, our understanding of potential polygenic burdens in early-onset BC remains incomplete. This study thus sought to explore the association between polygenic risk scores (PRS) and age-dependent risks of BC within the Korean population, using data from Korean Genome and Epidemiology Study (KoGES), a nationwide population-based biobank in Korea.**Methods**: The study population consisted of 46,323 Korean women, including 67 early-onset and 575 late-onset BC cases. We calculated PRS using a validated 313-SNP PRS (PRS313) model derived from European ancestry. Logistic regression analysis was performed to calculate the odds ratios (ORs) per standard deviation (SD) increase in PRS and their corresponding 95% confidence intervals (CIs) across different age groups.**Results and Interpretations**: Our analysis revealed an age-dependent relationship between PRS and BC risk in the Korean population. For the younger age group (age 40 or earlier), each SD increase in PRS was associated with a higher risk of breast cancer (OR=1.49, 95% CI: 1.17-1.91) compared to the older age group (OR=1.39, 95% CI: 1.28-1.51). Furthermore, comparing the highest PRS quintile with the lowest, BC risk in the younger age group increased 3.63-fold (95% CI: 1.64-9.16), while it increased 2.69-fold (95% CI: 2.04-3.60) in the older group.This study demonstrates the significance of considering PRS in understanding the age-related risk of breast cancer within the Korean population. Our findings suggest that preventative strategies for early-onset BC would be more effective if they incorporate the patients' polygenic profiles.

Session Title: Cancer Poster Session III

PB5136 Population specific breast cancer risk variants associated with estrogen-receptor negative breast cancer in women of African ancestry on chromosome 3q.

Authors:

Ctr., Seattle, WA, [3]Dept. of Preventive Med., Keck Sch. of Med. and Norris Comprehensive Cancer Ctr., Univ. of Southern California, Los Angeles, CA, [4]Dept. of Population and Quantitative Hlth.Sci., Case Western Reserve Univ., Cleveland, OH, [5]Div. of Epidemiology, Dept. of Med., Vanderbilt Epidemiology Ctr., and Vanderbilt-Ingram Cancer Ctr., Vanderbilt Univ. Sch. of Med., Nashville, TN, [6]Ctr. for Cancer Genetic Epidemiology, Dept. of Publ. Hlth.and Primary Care, Univ. of Cambridge, Cambridge, United Kingdom, [7]Ctr. for Cancer Genetic Epidemiology, Dept. of Oncology, Univ. of Cambridge, Cambridge, United Kingdom, [8]Slone Epidemiology Ctr., Boston Univ., Boston, MA, [9]Div. of Cancer Epidemiology and Genetics, Dept. of Hlth.and Human Services, Natl. Cancer Inst., NIH, Bethesda, MD, [10]Dept. of Publ. Hlth.Sci., Univ. of Chicago, Chicago, IL

Background. Expansion of genome-wide association studies across population groups is needed to improve our understanding of shared and unique genetic contributions to breast cancer. We performed an association study guided by *a priori* linkage findings from African ancestry (AA) relative pairs. Methods. We performed a fixed-effect inverse-variance weighted meta-analysis under a significant AA breast cancer linkage peak on chr3q26-27 in 9,241 AA cases and 10,193 AA controls. We examined associations with risk of overall breast cancer as well as estrogen receptor (ER)-positive and negative subtypes (47,737 SNPs in total). We performed validation of chr3 rare variant associations using whole genome sequencing (WGS) data obtained from 1340 cases and 675 controls included in the African-ancestry Breast Cancer Genetic Consortium (AABCG). Results. In our chr3 region, we identified two associations with ER-negative disease (rs184090918, OR=3.70, $p=1.23x10^{-5}$; rs76959804, OR=3.57, $p=1.77x10^{-5}$) that exceeded the multiple testing significance threshold. In the AABCG validation study, the SNP associations were significant and effect sizes were larger (rs184090918, OR: 6.66, 95% CI: 1.43, 31.01; rs76959804, OR: 5.24, 95% CI: 1.70, 16.16). These two SNPs are upstream to open chromatin ENSR00000710716, a regulatory feature that is actively regulated in mammary tissues. Conclusions. Chromatin state data show it is strongly transcribed and enhanced in mammary tissue, providing evidence that variants in this chr3 region may have a regulatory role in our target organ. These two identified chr3 SNPs, which are monoallelic in non-African ancestry population groups, may represent population specific breast cancer risk variants. Further functional characterization at this locus is needed. We are conducting additional analyses to replicate the findings. Our study provides support for the discovery of breast cancer risk variants using prioritization of variants based on linkage evidence.

Session Title: Cancer Poster Session I

PB5137 Preclinical evaluation of JAK2 specific investigational oligonucleotide for the treatment of MDS/PV

Authors:

B. Przychodzen; Vanda Pharmaceuticals, Washington DC, WA

Myeloproliferative disorders (MPD) are clonal hematopoietic stem cell malignancies with cytokine independency or hypersensitivity. Polycythemia vera (PV), an acquired MPD characterized by increased blood cell mass and hematocrit and leukocyte count, is associated with incidental myelofibrosis (MF). MDS is characterized by cytopenia and the presence of morphological dysplasia of precursor and mature bone marrow blood cells. PV and MDS leave patients at risk for progression to acute myeloid leukemia.

Abnormal cytokine signaling due to an aberrant JAK2-STAT pathway has a vital role in PV and MDS pathogenesis. JAK2 mutations can result in hematologic malignancies, where hyperactive signaling of the JAK2-STAT pathway promotes tumor cell proliferation, invasion, and angiogenesis. Increased JAK2 kinase activity is observed in hematologic malignancies; somatic $JAK2^{V617F}$ gain-of-function mutations are found in at least 95% of PV patients and is implicated in MDS cases. We hypothesize that preventing JAK2 transcription by ASOs mediated exon masking of the *JAK2* intron-exon junction will result in reduced *JAK2* mRNA, and thus JAK2 protein, by providing nonsense mediated decay (NMD) in the reading frame.

This study utilized a HEL cell line harboring the V617F *JAK2* gain-of-function mutation. We designed a series 19mer ASO targeting *JAK2* exon-intron junctions (*JAK2* intron-exon junction providing NMD in the reading frame, steric, non-RNAse H1) and tested these at a range of concentrations. The ASOs were designed with a PS 2'-O-methoxyethyl backbone and prioritized based on *in silico* binding affinity and limited off-target binding. HEL cells underwent ASO treatment (1µM) and 72-hour incubation.

We observed significant JAK2 protein decrease (~50%) in ASO-treated samples compared to untreated samples. JAK2 qPCR results confirmed 40-60% of target transcript. STAT5 phosphorylation status further confirmed this effect, and we report a 35% pSTAT5 reduction. Furthermore, this ASO showed limited off-target effects *in silico*. siRNA and CRISPR knockout lysate were used as controls. Our preclinical data support this ASO as a highly specific JAK2 agent, affecting direct levels of JAK2 as well as downstream STAT signaling.

Around 50-60% of primary MF patients harbor the $JAK2^{V617F}$ gain-of-function mutation. ASOs offer the capability to directly target *JAK2* mutations with high precision and effectively reduce JAK2 protein production, without off-target kinase effects. The ability to reduce JAK2 protein may alleviate the disease burden that patients with hematologic malignancies face, resulting in a higher quality of life through prevention and treatment.

Sch., The Univ. of Melbourne, Parkville, Australia

Introduction Renal cell carcinoma (RCC) is the most common form of kidney cancer with a mortality rate of 25% within 5 years. RCC is a feature of several heritable (autosomal dominant) cancer syndromes and has been associated with germline pathogenic and likely pathogenic (PLP) variants in at least 21 susceptibility genes. PLP variants in these genes are clinically actionable in Australia and germline panel sequencing is available to individuals with a family history of kidney cancer or a personal history suggestive of a cancer syndrome. Studies that have screened population-based RCC cases with a panel of cancer predisposition genes have identified a high prevalence of PLP germline variants (6-26%), a proportion of which (1-4%) were identified in established RCC susceptibility genes. This study assessed the prevalence of PLP variants in renal cancer predisposition genes actionable in the Australian setting in a population-based study of RCC.
Method Germline DNA was obtained from 1,034 individuals diagnosed with RCC, recruited through the Victoria and Queensland cancer registries into the population-based Consortium for the Investigation of Renal Malignancies (CONFIRM) study. A custom amplicon-based panel of 21 genes was used to sequence participants. Variants were classified as PLP according to ClinVar (2 stars) or manually classified according to current ACMG recommendations.
Results Eighteen participants (2%) were found to carry a PLP variant. The mean age and standard deviation at diagnosis of RCC was 58 ± 10 years and eleven (61%) were men. The gene with the most PLP variants identified was *MITF* with five individuals carrying c.952G>A;(p.Glu318Lys). Other genes with PLP variants included *FLCN*, *FH*, *MSH6*, *VHL*, *BAP1*, *SDHB* and *TSC1*. No PLP variants were identified in *CDC73*, *EPCAM*, *MET*, *MLH1*, *MSH2*, *PMS2*, *POLD1*, *POLE*, *PTEN*, *SDHC*, *SDHD*, *TP53* or *TSC2*.
Discussion PLP variants were identified in eight established RCC predisposition genes. Our findings are consistent with previous studies that, when looking only at genes with a proven association with RCC, identified PLP variants in 1-4% of a population-based sample of RCC. This is likely an underestimation of the true prevalence of PLP variants due to the difficulty in interpreting the many variants of uncertain significance identified in this study, the experimental design not enabling the detection of deep intronic, UTR, structural and copy-number variants, and it being likely that further RCC susceptibility genes remain to be identified. Further exploration of the clinical utility of gene panel susceptibility testing for all RCCs is warranted.

PB5139 Prevalence of Germline Pathogenic Variants in Patients with Pancreatic Cancer: Results from a Single-Center Prospective Cohort Study in Mexico

Authors:

M. Mendizábal Rodríguez[1], B. Aceves-Poveda[2], P. Nuñez-Martínez[2], Y. Sánchez-Contreras[2], V. Fragoso-Ontiveros[2], M. Herrera-Martínez[3], M. De la Fuente-Hernández[2], R. Álvarez-Gómez[2,4]; [1]Natl. Inst. of Pediatrics, Mexico city, Mexico, [2]Hereditary Cancer Clinic, Natl. Cancer Inst., Mexico city, Mexico, [3]Med. Oncology Dept., Natl. Cancer Inst., Mexico city, Mexico, [4]Fellow of general directorate of quality and education in Hlth., Ministry of Hlth., Mexico City, Mexico

Background/Purpose. Pancreatic cancer (PC) represents the thirteenth cause of cancer in the Mexican population, with a reported incidence of 2.5%. According to other series, between 4-20% of the patients with PC harbor a germline pathogenic variant (PV) in genes associated with hereditary cancer susceptibility syndromes. Prevalence of PV in PC is unexplored in the Mexican population, for which we aimed to describe the clinical features and prevalence of PV in a group of Mexican patients with PC.

Methods. At the Hereditary Cancer Clinic, of the National Institute of Cancerology in Mexico City, we conducted an observational prospective study. We included patients with PC from February 2016 to October 2022 who meet criteria for genetic testing. A complete cancer risk assessment was conducted, highlighting the oncology background. A peripheral blood sample was obtained, and next generation sequencing (NGS) was performed on the Illumina commercial platform (Illumina, SD, USA), using two panels of 263 and 322 genes, associated with increased risk of cancer. In this study, deleterious or suspected deleterious variants were classified as PV. Variants for which the clinical significance could not be determined were classified as a Variant of Uncertain Significance (VUS). Data was collected in SPSS v25, and descriptive statistics was applied to describe the characteristics of the population. The mean was calculated with the statistical program R (version 3.6.3).

Results. A total of 38 patients were included in our cohort, 26(68.4%) were females and 12(31.6%) were males. Diagnosis of pancreatic cancer was present in 30(78.9%) patients, 5(13.2%) bile duct and 3(7.9%) ampullary. The most common histology was adenocarcinoma in 33 patients (81.3%). The mean age at diagnosis was 56 years. Positive cancer family history was present in 24 patients (59.4%). Molecular testing identified 7 patients (18.4%) harboring a PV, of which 4(57%) were doble heterozygous with an additional VUS. In addition, in 18(47.4%) of patients a VUS was identified and 13(34.2%) had negative results for both; PV and VUS. Among the patients with a PV, 4(57.1%) were females, with family history of cancer. The distribution by gene in the patients with a PV was: *BRCA2* in 3(42.9%) cases, *BRCA1* in 2(28.6%), *MRE11* and *ATM* 1(14.2%).

Conclusions. In 18.4% of the cases, we identified a PV in genes associated to an increased risk of PC. This finding is similar to the rates reported in other countries. To our knowledge, this is the first descriptive study that explores this area in the Hispanic Population and thus provide significative evidence of the prevalence of PV in underrepresented populations.

Session Title: Cancer Poster Session I

PB5140 Prioritizing candidate cancer driver mutations in ovarian cancer susceptibility regions.

Authors:

P-H. Lai[1], J. Tyrer[2], P. Pharaoh[1], S. A. Gayther[3], M. R. Jones[3], P-C. Peng[1]; [1]Dept. of Computational and Biomedicine, Cedars Sinai Med. Ctr., West Hollywood, CA, [2]CR-UK Dept. of Oncology, Univ. of Cambridge, Strangeways Res. Lab., Cambridge, United Kingdom, [3]Ctr. for Bioinformatics and Functional Genomics, Dept. of BioMed. Sci., Cedars Sinai Med. Ctr., Los Angeles, CA

Ovarian cancer genetics research has traditionally focused on germline or somatic mutations independently. Emerging evidence suggests that the somatic mutational landscape can be shaped by the germline genetic background. However, the extent of the interplay between somatic mutations and germline variants is not well understood. In this study, we aim to unravel the role of somatic mutations within the ovarian cancer susceptibility regions, by incorporating functional annotations.

We curated 33 ovarian cancer germline susceptibility regions identified from genome-wide association studies (GWAS) and integrated them with somatic mutation data from the Pan-Cancer Analysis of Whole Genomes (PCAWG) project (n=110). We first asked whether ovarian cancer susceptibility genes are associated with somatic mutational signatures. We found significant associations of genes such as RCCD1 and PANK1 with age-related mutational signatures (p-value=0.004). Since most germline risk regions are located in the non-coding genome, we annotated the genome with 28 cell-type agnostic annotations from the ENCODE and Roadmap Epigenomics projects. To identify frequently mutated elements in these germline risk regions, we applied a statistical model called ActiveDriverWGS. Our results revealed that among the 33 risk regions, the 8q24.21 locus has frequently mutated elements in the coding region (p-value=0.011), while the 8q21.13 locus shows significant somatic mutation enrichment in the promoter region (p-value=0.028). Given that tissue-specific annotations better elucidate disease pathogenesis in the non-coding genome, we incorporate seven chromatin states (active/weak promoter/enhancer, active region, insulator, transcribed region) from seven ovarian precursor or cancer cell lines. We identified that weak enhancer chromatin state is frequently mutated in 14 out of 33 ovarian cancer risk regions (average p-value=0.007). In conclusion, by combining germline and somatic mutations with regulatory and epigenomics data, we provide insights into the genetic basis of somatic mutations in the ovarian cancer susceptible regions, and prioritize candidate driver mutations.

Session Title: Cancer Poster Session II

PB5141 Prostate cancer polygenic risk score associated with risk of upgrading and prostate tumor features in men on active surveillance.

Authors:

L. B. Goss[1,2], M. Liu[2], Y. Zheng[2], B. Guo[1], D. V. Conti[3], C. A. Haiman[3], W. J. Catalona[4], J. S. Witte[5], D. W. Lin[1,2], L. F. Newcomb[1,2], B. F. Darst[2]; [1]Univ. of Washington, Seattle, WA, [2]Fred Hutchinson Cancer Ctr., Seattle, WA, [3]Univ. of Southern California, Los Angeles, CA, [4]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL, [5]Stanford Univ., Stanford, CA

BACKGROUND: Recent attention has been drawn to the potential clinical utility of polygenic risk scores (PRS) in prostate cancer screening and disease management. However, the impact of PRS on prostate tumor features is not well characterized. In a case-only study of men on active surveillance, we investigated the implications of PRS on prostate tumor features, particularly risk of upgrading.
METHODS: This study included 1,041 non-Hispanic White men with prostate cancer on active surveillance in the Canary Prostate Active Surveillance Study (PASS). A previously developed multi-ancestry PRS of 451 prostate cancer risk variants was constructed in PASS as a weighted sum of the number of risk alleles carried. We also evaluated this PRS after excluding 51 variants previously associated with prostate specific antigen (PSA). Associations between PRS and prostate tumor features, including grade reclassification at follow up and prostate size, PSA, PSA density, AUA symptom score, quality of life urinary score, percent of biopsy cores with cancer (as a proxy measure of tumor multifocality), and Gleason grade at diagnosis, were conducted using regression models adjusted for age and principal components of ancestry.
RESULTS: Each SD unit increase in the 451 PRS was associated with a 20% increased risk of grade reclassification (95% CI = 1.05 - 1.36, P = 6.1x10-3), while the 400 PRS was associated with a 25% increased risk (95% CI = 1.10 - 1.42, P= 6.2x10-4). The 451 PRS was also associated with 1.37 higher percentage points of biopsy cores with cancer (95% CI = 0.74 - 1.99, P = 1.8x10-5), 0.26 ng/mL higher PSA (95% CI=0.08-0.44, P=6.0x10-3), and increased PSA density (beta= 0.01; 95% CI=0.01- 0.02, P = 1.9x10-5). The 400 PRS was associated with a larger percentage of positive biopsy cores (beta = 1.43; 95% CI = 0.82 - 2.05, P = 6.0x10-6) and had a weaker association with PSA (beta = 0.18; 95% CI = -0.01 - 0.36, P = 0.06) and PSA density (beta = 0.01; 95% CI = 0.01 - 0.02, P = 7.3x10-5). Although the 451 PRS was not associated with prostate size (P = 0.27), the 400 PRS was associated with a 1.63 cc smaller prostate size (95% CI = -3.03 - -0.23, P = 0.02). Neither PRS was associated with AUA symptom scores, quality of life urinary scores, or Gleason grade at diagnosis (P>0.12).
CONCLUSION: In men on active surveillance, high PRS was associated with risk of upgrading and possibly tumor multifocality. Excluding PSA variants from the PRS enhanced these associations and revealed an association with smaller prostate size, which has been previously associated with more aggressive tumors in men with comparable serum PSA levels. Our findings suggest that men with high PRS may benefit from more intensive surveillance.

PB5142 Rare genetic determinants of clonal hematopoiesis and progression to hematologic malignancies in 479,117 individuals

Authors:

J. Liu[1], B. Wiley[1], I. Chan[1], D. Tran[1], A. Batchi-Bouyou[1], X. Zong[1], L. Ding[1], Y. Cao[1], M. Walter[1], N. Chatterjee[2], K. Offit[3], L. Godley[4], D. Link[1], Z. Stadler[3], K. Bolton[1]; [1]Washington Univ. Sch. of Med. in St. Louis, St. Louis, MO, [2]Johns Hopkins Univ., Gaithersburg, MD, [3]Mem. Sloan Kettering Cancer Ctr., New York, NY, [4]The Univ. of Chicago, Chicago, IL

Clonal hematopoiesis (CH), while common with aging, confers a high relative risk of hematologic malignancies (HM). Genome-wide association studies have identified common germline predisposition loci for CH. Here we sought to characterize the contribution of rare germline mutations to CH and HM. We used the UK Biobank (UKBB) as a discovery cohort (N=454,859) with validation in the Memorial Sloan Kettering (MSK) IMPACT and Cancer Genome Atlas (TCGA) cohorts (N=24,258). We profiled whole exome sequencing (WES) for pathogenic/likely pathogenic germline variants (PGVs) in 241 known/hypothesized cancer predisposition genes. We simultaneously analyzed WES for CH driven by single nucleotide variants/indels and SNP array data for copy number events (mCAs). Overall, 8.9% of individuals in the UKBB harbored PGVs (5.2% if restricted to HM-related genes). Heterozygous PGVs in 15 genes (8 of which are novel) conferred a significantly increased risk of CH. Prominently featured pathways include DNA damage repair/sensing (*TP53, ATM, CHEK2, NBN*), telomere maintenance (*TINF2, CTC1, POT1*) and RAS, JAK/STAT signaling (*KRAS, PTPN11, SAMD9L, SOS1, MPL*). Through pairwise analysis, we identified an additional 102 germline genes that predispose to CH in specific genes or genetic regions; 30 of these CH-specific associations were also significant in our replication cohort ($p<0.05$). Of the remaining 31 with at least one CH positive germline carrier, all but six were directionally consistent. Overrepresented pathways include immune regulation (heterozygous PGVs in *UNC13D* and *DOCK8* associated with several mCAs and *ADA* associated with CH in *DNMT3A*), homologous recombination deficiency (heterozygous PGVs in *FANCA*, *RAD51D*, *BRIP1* and *BRCA1* associated with multiple mCAs) among others. During 14-years of follow-up, 4,596 UKBB participants developed HM. Several germline genes that predispose to CH also were significantly associated with HM (N=18), including several genes not been previously linked to HM in the heterozygous state (*CTC1*, *BLM*, and *WNR*, among others). We observed synergistic effects between germline PGVs and CH on the risk of HM whereby CH carriers with PGVs have a significantly higher risk of developing HM (HR: 1.31; $p<0.001$) compared to those without PGVs. CH in genes/genetic regions that are moderately/strongly associated with specific PGVs confer higher risk of progression to HM than CH showing weak or no association with PGVs. In summary, we identify several novel genes where PGVs contribute to CH predisposition and to its progression to HM. Our findings highlight the importance of germline-CH interactions in determining the risk of CH progression to HM.

Session Title: Cancer Poster Session I

PB5143 Re-classification of *PMS2* Kozak sequence variants using a fast and easy in vitro assay.

Authors:

E. Matoy, J. Plowman, B. Michael, H. Feser Stessman; Creighton Univ., Omaha, NE

Lynch Syndrome (LS) is the most common hereditary cancer syndrome affecting 1 in 279 people. Heterozygous loss-of-function variants in *PMS2* are linked to LS. While these variants are not directly cancer initiating, PMS2 functions in the DNA mismatch repair pathway such that reduced function results in the accumulation of somatic variants and increased cancer risk over time. We recently identified a suspected hereditary cancer family carrying a 5' UTR variant in *PMS2* (ENST00000265849.7:c.-7T>C; MAF: 0.00032 across all races) that had conflicting interpretations of pathogenicity in ClinVar. This variant lies within the Kozak sequence of *PMS2*, the well-described protein translation initiation motif in eukaryotes. This sequence is highly conserved among higher eukaryotes and is defined as the 9 basepairs upstream of the translation start codon through the first 4 bases of the translated sequence (5'-GTTGCATCCATGG-3'; human *PMS2* NM_000535.7). Variants in the Kozak sequence have been shown to reduce the translation of genes such as those necessary for heart development resulting in congenital heart disease. However, all Kozak sequence variants in *PMS2* in ClinVar are currently classified as variants of undetermined significance (VOUSs) due to a paucity of research on this non-coding region. We hypothesized that variants that significantly disrupt the Kozak sequence motif of *PMS2* would decrease PMS2 protein expression contributing to increased cancer risk over time. Using the psiCHECK™-2 Vector (Promega) and site-directed mutagenesis, we modified the endogenous Renilla luciferase Kozak sequence (but not the Firefly luciferase sequence) to the human *PMS2* sequence. A second round of mutagenesis was similarly used to generate ClinVar *PMS2* Kozak sequence variants. Plasmids (wild-type human *PMS2* or *PMS2* Kozak variants) were individually transfected into HEK 293 TK cells, grown for 48 hours, and translation efficiency was determined as the ratio of Renilla/Firefly expression using the Dual-Glo® Luciferase Assay (Promega). In the case of the c.-7T>C Kozak sequence variant, we identified no significant difference in activity between this variant and the wild-type human *PMS2* sequence supporting a benign clinical classification. In summary, we present a novel method for the high-throughput classification of human *PMS2* Kozak sequence variants that can contribute to the re-classification of VOUSs identified in human patients.

Session Title: Cancer Poster Session II

PB5144 Risk of second primary cancers after a diagnosis of first primary cancer: a pan-cancer analysis and mendelian randomization study

Authors:

Y. Na[1], R. Xiaohao[2], H. Da[2]; [1]The Univ. of Hong Kong, Hong Kong, China, [2]Shanghai Jiao Tong Univ. Sch. of Med. affiliated Ruijin Hosp., Shanghai, China

Background: The risk of second primary cancers (SPC) is increasing after the first primary cancers (FPC) are diagnosed and treated. The underlying causal relationship remains unclear. **Methods**: We conducted a pan-cancer association (26 cancers) study in the Surveillance, Epidemiology, and End Results (SEER) database. The standardized incidence ratio (SIR) was estimated as the risk of SPCs in cancer survivors based on the incidence in the general population. Furthermore, the causal effect was evaluated by two-sample Mendelian Randomization (MR, 13 FPCs) in the UK Biobank (UKB, n=459,136) and robust analysis (radial MR and Causal Analysis Using Summary Effect estimates, CAUSE). **Results**: We found 11 significant cross-correlations among different cancers after harmonizing SIR and MR results. Whereas only 4 of them were confirmed by MR to have a robust causal relationship. In particular, patients initially diagnosed with oral pharyngeal cancer would have an increased risk of non-Hodgkin lymphoma (SIR_{SEER}=1.18, 95%Confidence Interval [CI]:1.05-1.31, $OR_{radial\text{-}MR}$=1.21, 95%CI:1.13-1.30, *P*=6.00×10-3; OR_{cause}=1.17, 95%CI:1.05-1.31, *P*=8.90×10-3). Meanwhile, ovary cancer was identified to be a risk factor for soft tissue cancer (SIR_{SEER}=1.72, 95%CI:1.08-2.60, $OR_{radial\text{-}MR}$=1.39, 95%CI:1.22-1.58, $P=1.07\times10^{-3}$; OR_{cause}=1.36, 95%CI:1.16-1.58, *P*=0.01). And kidney cancer was likely to cause the development of lung cancer (SIR_{SEER}=1.28, 95%CI:1.22-1.35, $OR_{radial\text{-}MR}$=1.17, 95%CI:1.08-1.27, *P*=6.60×10-3; OR_{cause}=1.16, 95%CI:1.02-1.31, *P*=0.05) and myeloma (SIR_{SEER}=1.54, 95%CI:1.33-1.78, $OR_{radial\text{-}MR}$=1.24, 95%CI:1.21-2.45, *P*=0.02; OR_{cause}=1.49, 95%CI:1.04-2.34, *P*=0.02). **Conclusions**: A certain type of primary cancer may cause another second primary cancer, and the profound mechanisms need to be studied in the future.

Session Title: Cancer Poster Session III

PB5145 scLongTree: a novel highly-accurate and scalable computational tool to infer the longitudinal tree from longitudinal scDNAseq data

Authors:

R. Khan, X. Mallory; Florida State Univ., Tallahassee, FL

Cancer grows by acquiring new mutations at different stages. At each stage, there could be multiple subclones of tumor cells coexisting in one tumor, a notoriously difficult-to-treat problem called intra-tumor heterogeneity (ITH). It is important to gain the knowledge of which set of mutations is acquired at each specific time point so that personalized treatment plans, prognosis, and diagnosis can be made. Single-cell DNA sequencing (scDNAseq) makes it possible to decipher ITH. Moreover, the decreasing cost of scDNAseq in recent years makes it possible to sequence cancer patients once every few years, which eventually renders longitudinal data, the data corresponding to one sample but is available for multiple time points.

Given the scDNAseq longitudinal data, we aim to recover the longitudinal tree, on which the nodes represent subclones of cells, and edges represent the new mutations gained on the child nodes. As far as we know, LACE is the only existing method that can infer such a longitudinal tree given the scDNAseq longitudinal data. However, LACE is limited in terms of scalability. It does not scale up to the case when the number of timepoints > 4.

We developed a novel highly-accurate and scalable computational tool, scLongTree, that infers a longitudinal tree from scDNAseq. Different from LACE, scLongTree clusters single cells across all time points before inferring the tree, greatly reducing the computational complexity of inferring the tree. The cell-clustering results are further refined based on the knowledge of time points using a maximum likelihood approach. We then infer the parent-child relationship among the clusters of cells, now viewed as subclones, between two consecutive time points. For the case when two sequencing timepoints are far away from each other and an important subclone has not been sequenced before it evolved into different subclones, scLongTree will also infer such unobserved subclones.

We compared scLongTree with four other methods, LACE, SiCloneFit, SCITE and CALDER on nine simulated datasets, each with a varying parameter. On the default dataset when the number of timepoints is 4, scLongTree achieved the highest accuracy (0.979), to be compared with LACE (0.648), SiCloneFit (0.737), SCITE (0.778), and CALDER (0.558). Such a highest accuracy is gained by using the least running time. In addition, unlike LACE, scLongTree is scalable to the datasets with > 4 timepoints. We also applied scLongTree to real data samples, one of which is SA501, a triple-negative breast tumor that has longitudinal targeted scDNAseq data. ScLongTree was able to correctly place 17 mutations out of 20 mutations on the inferred longitudinal tree.

Cancer Inst., Bethesda, MD, [32]Dept. of Med., Univ. of Chicago, Chicago, IL, [33]Dept. of Computer Sci., Univ. of Chicago, Chicago, IL

CDKN2A is the major high-risk cutaneous melanoma (CM) susceptibility gene with pathogenic variants (PVs) detected in 20-40% of CM-prone families. Multiple much rarer high-risk CM genes have also been discovered (*CDK4*, *BAP1*, *POT1*, *ACD*, *TERF2IP*, *TERT*). Identifying new CM genes has been challenging, thus, we initiated a cloud-based project within the Melanoma Genetics Consortium GenoMEL to combine raw next-generation sequencing (NGS) data and use uniform workflows to identify novel CM risk genes. Groups (n=17) from nine countries (Australia, France, Italy, Latvia, Netherlands, Poland, Spain, Sweden, USA) contributed data. After quality control, there were 1255 subjects (731 families) including 315 multiple-case families (839 CM patients) of which 119 families had >=3 sequenced CM cases. To search for high-risk CM genes, we combined evidence for co-segregation in the families with the web-based tool VarElect (ve.genecards.org), a comprehensive phenotype-dependent variant/gene prioritizer, which leverages the wealth of information in GeneCards and its affiliated databases. In the 315 multiple-case families, there were 233,550 non-synonymous variants with minor allele frequency (MAF)<0.0005. We used families with >=3 CM cases sequenced to identify potential candidate genes and detected 1023 genes based on evidence for co-segregation that required variant(s) to be coded as high/moderate impact and MAF<0.001. There was no new *CDKN2A*-like gene observed; that is, no new high-risk gene at a frequency as is seen with *CDKN2A*. Based on a VarElect score >6.5 and multiple families (any size) with supportive evidence for co-segregation, 16 candidate genes were selected for further evaluation of association with CM in the United Kingdom Biobank (UKBB) database. For UKBB, variants (MAF<0.01, 0.005, or 0.001) were classified as pathogenic based on ClinVar and/or InterVar, or if predicted to be damaging by most in silico algorithms inspected. Among the 16 genes examined using logit regression, gene-based rare PVs in *TYR* (p<0.0003), *POLH* (p<0.001) and *FLCN* (p<0.02) were associated with CM in UKBB. Further, individual variants in *FLCN* (c.611C>T, p.Ala204Val), *TYR* (c.1118C>A, p.Thr373Lys), and *BMPR1A* (c.943G>A, p.Gly315Arg) also showed associations with CM in UKBB (p<0.001). In summary, we investigated NGS data from 731 CM families using uniform workflows. Several candidate high-risk CM genes were uncovered and replicated in UKBB but no new

frequent *CDKN2A*-like gene was identified. Further study is required to confirm the findings and to assess whether the genetic risks in many of these CM families result from moderate- or low-risk genes rather than high-risk genes.

Session Title: Cancer Poster Session II

PB5147 Severus: a computational tool to characterize complex structural variations from long-read sequencing.

Authors:

A. Keskus[1], A. Tanveer[1], A. Donmez[1], A. Bryant[1], I. Rodriguez[1], N. Rossi[1], Y. Xie[1], B. Yoo[2], R. Milano[1], H. Lou[1], J. Park[3], J. Gardner[3], B. McNulty[3], K. Miga[3], M. Farooqi[2], B. Paten[3], M. Dean[1], M. Kolmogorov[1]; [1]NIH, BETHESDA, MD, [2]Children's Mercy Hosp, Kansas City, MO, [3]UC Santa Cruz Genomics Inst., Santa Cruz, CA

Most current cancer genomic studies capitalize on small genomic variations (point mutations or small indels) in protein-coding regions to identify diverse, evolutionary trajectories, classify cancers into subtypes, or inform treatment.

Pan-cancer whole-genome sequencing studies revealed diverse classes of structural variants (SVs) in cancer genomes, which may contribute to carcinogenesis and tumor progression through direct modification of coding region as well as alterations in transcriptional regulation, i.e., copy number alterations, enhancer hijacking, or topological domain modification.

Short-read sequencing data excel in small variant discovery but faces limitations in repetitive regions of the genome and the discovery of SV that are longer than the read length. In contrast, long-read sequencing has superior SV sensitivity and precision. However, most current long-read tools were designed for “healthy” genomes, and fail to capture somatic variants, complex rearrangements, and heterogeneity in cancer genomes. Here we present Severus to detect and annotate a wide range of SVs, from simpler indels to complex rearrangements with multiple breakpoints using long-read sequencing. Severus is designed to work in single-sample, somatic (disease vs. normal), and multi-site modes. The algorithm takes bam file(s) as input and, using split alignments, detects a confident set of SVs. Next, SV calls are used to build a breakpoint graph in which complex events with multiple breakpoints form connectivity clusters to characterize the structure of the derived cancer genome. Severus can also use phased bam files to generate haplotype-aware SV calls.

Severus outperforms existing tools in SV recall measured against the multiplatform validated somatic SV set for the COLO829 cell line. Further, we sequenced five cancer cell lines and their matching normals with ONT and compared them to Illumina SV calls. As expected, long-read sequencing substantially improved SV detection. We also show that in addition to indels, Severus can accurately detect known complex rearrangements, chromothripsis, chromoplexy, breakage-fusion-bridge (BFB), inversions with amplifications/deletions, and intrachromosomal long insertions.

We also sequenced HPV-infected cervical cancer cell lines (CaSki, SNU1000, SCC152, HT3), revealing mosaic amplifications near the HPV integration sites. We also detected at least one BFB event per sample, which interestingly were exclusive to chromothripsis events in almost all cases.

Finally, matching tumor/normal sequencing of three clinical cases of two pediatric AML and one LCL with Pacbio HiFi revealed novel SVs in coding sequences.

Session Title: Cancer Poster Session I

PB5149 † Sex differences in transcriptomes: Pan-cancer analysis of The Cancer Genome Atlas (TCGA)

Authors:

C. Printzis[1], L. Pesce[1], C. Stanhope[1], R. Huang[2], B. Stranger[1]; [1]Northwestern Univ., Chicago, IL, [2]Univ Minnesota, Minneapolis, MN

Cancer is a leading cause of death worldwide and biological sex differences exist in incidence, treatment response, and mortality across cancer types. We characterized sex differences between male- and female-derived tumor transcriptomes for 21 non-sex-specific cancers from The Cancer Genome Atlas (TCGA). This enabled the discovery of functions impacted by sex in tumors. We assessed sharing of transcriptomic sex-differences across cancers and compared results to matching tissues from the Genotype-Tissue Expression (GTEx) project. We analyzed 6,430 transcriptomes (N = 3,754 males; N =2,676 females) across 21 TCGA cancers, testing for gene expression sex differences (sex-DE). We identified sex-DE genes ranging from 100 genes in uveal melanoma to 5,103 in liver hepatocellular carcinoma and grouped cancers by the number of identified sex-DE genes into “less-differentiated” and “more-differentiated”. Across the 7 “more-differentiated” cancers, more sex-DE genes are shared, but few are common across all 21. Of 19 sex-DE genes shared across all cancers, 16 are X chromosome genes, e.g., XIST. Sharing of sex-DE genes was quantified with the metric $\pi 1$ to estimate the true positive rate in a replication set. A median $\pi 1$ of 0.45 was found between 7 independent cancer datasets and their matching TCGA cancer. Additionally, $\pi 1$ was estimated for 39 TCGA cancer and normal GTEx tissue pairs. Unsurprisingly, we observed that some of the sex effects on gene expression in normal tissues are not maintained in the matched tumor (median $\pi 1$ GTEx to TCGA; 0.18). Interestingly, we observed many sex-DE genes that were specific to the tumor, i.e., not DE in the matching normal tissue (median $\pi 1$ TCGA to GTEx; 0.26). Gene set enrichment analysis (GSEA) of the sex-DE genes revealed distinct functions and processes enriched in male- and female- biased genes. Furthermore, when comparing GSEA results between TCGA and GTEx, we observed tumor-specific functional enrichment, indicating tumor sex differences in gene expression do not simply reflect the tissue of origin. To explore the relationship between sex, gene expression, disease progression (PFI), and overall survival (OS), we used Cox proportional hazards models to test for gene expression and sex-by-gene expression effects on PFI and OS. We identified 60 unique genes across 4 cancer types with significant sex by gene effects on OS and 13 unique genes across 3 cancer types with significant sex by gene effects on PFI. In summary, our results provide a diverse characterization of sex differences in TCGA tumors which provide novel insights into disease, including progression and survival, and may enable development of new therapies.

PB5150 Single-cell Transcriptomic Profiling of Colorectal Cancer Tumors Reveals Potential Biomarkers

Authors:

O. Awe[1], B. Kamau[2], R. A. Serage[3], H. Ndugwa[2], B. Onyango[4], J. Wachira[5]; [1]Univ. of Ibadan, Ibadan, Nigeria, [2]Dept. of Biochemistry and Biotechnology, Sch. of Pure and Applied Sci., Pwani Univ., Nairobi, Kenya, [3]South African Natl. Bioinformatics Inst., Faculty of Natural Sci., Univ. of the Western Cape, Cape Town, South Africa, [4]Pwani Univ., Nairobi, Kenya, [5]Dept. of Biochemistry, Faculty of Sci. and Technology, Univ. of Nairobi, Nairobi, Kenya

Colorectal cancer (CRC) is a major cause of death worldwide and its extreme heterogeneity makes it difficult to diagnose in its early stages. Cancer-related biomarkers are crucial for their early detection and management but traditional cancer diagnostic techniques can be biased. Recent advancements in next-generation technologies have led to high-dimensional datasets being generated whose analysis depends on machine learning. In this study, we utilized single-cell transcriptomic datasets coupled with machine learning in identifying CRC biomarkers.
Three scRNA-seq datasets related to CRC were downloaded from the Gene Expression Omnibus (GEO) database and merged for further analysis. Data preprocessing and count matrix generation were performed using the Scanpy toolkit. Two machine learning algorithms (LightGBM and XGBoost) were explored as classifiers to identify genes that can be used as CRC biomarkers. The accuracy, F1 score, and Matthew's Correlation coefficient metrics were used in evaluating the performance of the different models. The Shap Explainer was finally used to extract information about the key genes acting as major contributors to the trained machine learning models and their weights. All methods were automated and made reproducible using Nextflow programming.
LightGBM slightly outperformed XGBoost. We identified two novel biomarkers from eleven potential biomarkers for colorectal cancer. These genes can be further analyzed to identify CRC hub genes.
This study further highlights the combined use of machine learning and scRNA-seq data as an alternative method for finding CRC-related genes. These biomarkers can be used for developing drug targets or therapies for colorectal cancer.

Session Title: Cancer Poster Session III

PB5151 † SoMAS: Finding somatic mutations associated with alternative splicing in human cancers

Authors:

H. Tan[1], D. O. Holland[1], V. Gotea[1], L. Elnitski[2]; [1]NIH, Bethesda, MD, [2]NHGRI, Rockville, MD

Aberrant alternative splicing (AS) is prevalent in cancer and affects most cancer hallmarks involving proliferation, angiogenesis, and invasion. Somatic point mutations, recognized as the major driving force of human oncogenesis, can exert their functions via splicing disruption. We propose SoMAS (Somatic Mutation associated with Alternative Splicing), a computational pipeline that explores the role of somatic mutations in shaping the landscape of alternative splicing at the transcriptome level.

Different from existing methods that examine the direct, one-to-one association between each single nucleotide variant (SNV) and a specific AS event, SoMAS measures the association between each eligible SNV and the overall expression pattern of the whole transcriptome consisting of ~73K annotated transcripts, using the principal component analysis (PCA) technique. We show that SoMAS is more efficient and versatile than existing methods in identification of AS-associated SNVs on several aspects: (1) Reduces the computational complexity significantly; (2) Detects both cis- and trans-regulatory SNVs simultaneously; (3) Lowers the false positive rate incurred by the traditional gene-by-gene association study.

Applying SoMAS to 33 cancer types consisting of 9,738 tumor samples in The Cancer Genome Atlas (TCGA), we identified 7,140 SoMAS genes (i.e., genes whose mutation is significantly associated with differential isoform expression of genes located in either cis- or trans-loci) in human cancers (with trans-associations dominating), among which 908 are present in three or more cancer types. These SoMAS genes include many well-known oncogenes (e.g., the Ras family), tumor suppressors (e.g., TP53, PTEN), RNA binding proteins (e.g., RBM10, RANBP2), splicing factors (e.g., SF3B1, SPEN) and transcription regulators (e.g., CTNNB1, SMARC4A).

Functional analysis further confirmed the biological and clinical significance of these identified SoMAS genes and associated genes. Specifically, the 908 “pan-cancer” SoMAS genes are significantly enriched in cancer cell growth and metastasis related pathways/gene sets, and better stratify patients in survival rate when integrating their mutation status and the isoform expression level of their associated genes. SoMAS genes were widely corroborated to affect gene splicing by previous studies with independent cohorts and/or methodologies.

With SoMAS, we for the first time demonstrate the impact of somatic mutations on the overall splicing and transcription profiles in human cancers and bridge the genetic and epigenetic regulation of human oncogenesis in an innovative and biologically meaningful way.

Session Title: Cancer Poster Session I

PB5152 Stable Overexpression of HDM2 Differentially Modulates the Molecular Phenotype of Non-Small Lung Cancer Cells of Varying p53 Genotypes.

Authors:

Y. Wang, K. Ramos; Texas A&M Inst. of BioSci.s and Technology, Houston, TX

Retrotransposons, particularly Long Interspersed Element-1 (LINE-1), have emerged as significant drivers of genome plasticity in humans. LINE-1, the only autonomous retrotransposon that remains active in the human genome, has been closely linked with poor prognosis of non-small cell lung cancers (NSCLC). Previous studies by our group have reported a marked increase in HDM2 (human homolog of mouse double minute 2) mRNA levels in transformed human bronchial epithelial carrying an intronic LINE-1 insertion in the NACC2 locus. HDM2 possesses E3 ubiquitin ligase activity towards p53 and functions as a negative regulator of p53 via polyubiquitination in transformed cells. However, a recent study reported that following DNA damage, HDM2 can switch from a negative to a positive regulator by binding to p53 mRNA to promote translation of the p53 mRNA. This change in HDM2 activity appears to be governed by ataxia telangiectasia mutated kinase-mediated phosphorylation leading to structural changes that impact the HDM2 interactome. To further define the critical genetic interactions regulated by HDM2 in NSCLC, we stably overexpressed HDM2 in NCI-460 (p53 wt) and NCI-1299 (p53 mut) lung cancer cell lines and subsequently examined the expression of critical molecular targets. HDM2 overexpressionincreased LINE-1 ORF-1p levels in NCI-460 cells, but reduced expression in NCI-1299 cells. p53 levels increased in NCI-460 cells and were undetectable in NCI-1299 cells. RB selectively decreased in NCI-460 cells but remained unchanged in NCI-1299 cells. Together, these findings highlight key molecular interactions of the HDM2 oncogene involved in the regulation of lung cancer phenotypes. Understanding of the intricate relationships between and within the HDM2/p53/RB axis and LINE-1 retrotransposons may pave the way for thedevelopment of therapeutic strategies tailored to specific NSCLC molecular phenotypes.

PB5153 Structural and functional insights from single cell transcriptional profiles of pituitary tumors

Authors:

M. Brunner, F. Santoni, M. Messerer, R. Daniel, A. Messina, J. Meylan-Merlini, M. Muriset; CHUV, Lausanne, Switzerland

The pituitary gland is a main component of the endocrine system and a master controller of hormones production and secretion. Unlike neoplastic formation in other organs, Pituitary Neuroendocrine Tumors (PitNETs) are frequent in the population (15%) and are almost exclusively benign. Here, we present the single cell transcriptome analysis on 12 independent tumors for a total of ~70'000 single cells: 4 bi-hormonal (GH-PRL) tumor, 3 corticotropic macro-adenoma, 4 non-secreting adenomas and one prolactinoma. Characterization of all tumors showed heterogeneous cell populations. We discover that G*ATA2*, a transcription factor for early gonadotrophs differentiation is exclusively expressed in non-secreting adenoma. GATA2 inhibits GNRH receptor, leading to a decrease in *LHB* and *FSHB* production possibly explaining the non-secreting phenotype.
Furthermore, *GATA2* expression profile in single nuclei RNAseq from healthy pituitary glands shows restricted transcription in prepubescent individuals suggesting a come-back to a pre-differentiated state for gonadotroph cells in non-secreting adenomas. In three tumors we identified an unexpected small population of proliferative cells (*MKI67+*, *TOPA2+*, *BIRC5+*, *PBK+*). Intriguingly, *IQGAP3*, a gene already known to be a bad prognostic marker in different type of carcinomas, was expressed in this cluster, suggesting a correspondence between proliferative markers in PitNETs and malignant adenomas. Moreover, taking advantage of WGS data from both patient and tumor, we were able to detect somatic variants and, using VarTrix, to isolate clear subsets of tumor and normal cells with a limited efficiency due to a lack of coverage in scRNA-seq data. To overcome this issue, a machine learning approach (scANVI) was used to predict the nature of the remaining cells. Pseudobulk differential gene expression analysis revealed a decreased ribosomal activity as well as an increase activity of mitochondria in tumorigenic cells. Additionally, in non-secreting adenomas, tumor cells were the ones expressing *GATA2* and, to a minor extent, *CD274* (PD-L1). Taken together, our results give a new perspective on the comprehension of the structural composition and the dynamic progression of pituitary tumors and of adenomas in general.

Session Title: Cancer Poster Session III

PB5154 Structural variation in *CYP2A6* is associated with risk of lung, but not ovarian, cancer in the UK Biobank

Authors:

A. Langlois[1,2], A. El-Boraie[1,2], J. Pouget[2,3], J. Knight[4], M. Chenoweth[1,2,3], R. Tyndale[1,2,3]; [1]Dept. of Pharmacology and Toxicology, Univ. of Toronto, Toronto, ON, Canada, [2]Campbell Family Mental Hlth.Res. Inst., Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada, [3]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada, [4]Data Sci. Inst. and Med. Sch., Lancaster Univ., Bailrigg, United Kingdom

CYP2A6 is the primary nicotine-metabolizing enzyme. *CYP2A6* is polymorphic, with structural variants (SV) including gene deletions (e.g. *CYP2A6*4*), duplications (e.g. *CYP2A6*1x2*), and hybrids with the pseudogene *CYP2A7* (e.g. *CYP2A6*12, *34, *53*). Two recent genome-wide studies (one in *BRCA1* pathogenic variant carriers) explored the associations of copy number variants (CNV) with ovarian cancer (OC) risk; both found significant associations between putative *CYP2A7* deletions and OC risk (albeit in opposite directions). We hypothesized that these putative *CYP2A7* deletions may be known *CYP2A6* SVs, misidentified by CNV prediction software (PennCNV), and demonstrated this using PennCNV in an internal dataset with known *CYP2A6* SV diplotypes. Using a validated SV imputation reference panel, we sought to investigate associations of *CYP2A6* SVs with OC and lung cancer (LC) in the UK Biobank. Furthermore, we investigated the association of *CYP2A6* SVs with squamous cell carcinoma (SCC), an LC subtype strongly associated with cigarette smoking.
To impute *CYP2A6* SV diplotypes for UK Biobank participants, we used an internal reference panel composed of array-genotyped and imputed SNP haplotypes from European-ancestry (EUR) individuals with known *CYP2A6* SV diplotypes (n=935). Our case-control design used the presence of at least one deleterious *CYP2A6* SV (*CYP2A6*4*, **12*, **34*, or **53*) as the exposure, testing for an association with case status using multiple logistic regression. Analyses were limited to genetically identified EUR UK Biobank participants, controlling for age and the first ten principal components. OC analyses were limited to females and additionally adjusted for smoking status, while LC analyses were stratified by smoking status and additionally adjusted for sex.
Deleterious *CYP2A6* SVs were not associated with OC risk (adjusted OR=1.1; 95% CI: 0.80-1.37; p=0.7). In current smokers, deleterious *CYP2A6* SVs were associated with lower overall LC risk (adjusted OR=0.4; 95% CI: 0.29-0.64; p<0.0001) and lower SCC risk (adjusted OR=0.2; 95% CI: 0.08-0.58; p<0.01). No significant associations were observed for LC or SCC in former or never smokers.
In conclusion, we found that deleterious *CYP2A6* SVs were not associated with OC risk. However, deleterious *CYP2A6* SVs conferred protection against overall LC and SCC risk within current smokers. Further analyses could examine OC risk in BRCA1 pathogenic variant carriers, and investigate whether decreased smoking exposure explains the protective effect of deleterious *CYP2A6* SV on LC and SCC risk.

Session Title: Cancer Poster Session I

PB5155 *TGFBR1**6A and risk for colorectal cancer

Authors:

A. M. Johansen[1], K. Agyemang[1], M. Pennison[1], H. Jimenez[1], Colon CFR, A. Cristofano[2], J. Ziegler[1], J. A. Baron[3], C. Langefeld[1], B. C. Pasche[1]; [1]Wake Forest Univ. Sch. of Med., Winston Salem, NC, [2]Albert Einstein Coll. of Med., New York, NY, [3]UNC Chapel Hill, Chapel Hill, NC

Background:
*TGFBR1**6A (rs11466445), a hypomorphic variant of the type 1 TGF-beta receptor, has been associated with breast and ovarian cancer risk. However, the evidence of its role in the risk for colorectal cancer is inconclusive. We have observed that *TGFBR1**6A allele frequency varies by genetic ancestry. Here we are the first to elucidate the *TGFBR1**6A risk association with colorectal cancer after adjusting for population substructure.
Methods:
We developed novel knockin mouse models *of TGFBR1* (9A) and *TGFBR1**6A (6A) crossed with Apc^{min} mice. We assessed intestinal polyp development at 12 weeks in 9A/9A, 9A/6A and 6A/6A mice. We genotyped *TGFBR1* exon 1 in 2,147 patients with a biopsy-proven diagnosis of colorectal cancer and 1,184 healthy controls recruited by the NCI-sponsored Colon Cancer Family Registry (CCFR). Additionally, we imputed the TGF-β region of chromosome 9, including the *TGFBR1**6A genotype, in 3,419 individuals using Impute2 and the 1,000 Genomes phase 3 reference panel. Admixture estimates (Admixture) were computed using the GWAS data with HapMap CEU, YRI, CHB, MEX samples as anchoring populations.
Results:
There were significantly fewer polyps among 9A/6A (21.8±2.21) and 6A/6A (28.2±5.4) mice than among 9A/9A (43.4±4.1) mice (p=0.01). In the CCFR cohort, individuals with the 6A allele were associated with a decreased colorectal cancer risk, OR=0.84 (additive genetic model; 95%CI: 0.78-0.90, p=0.02); 6A allele frequency of 0.109 for cases and 0.130 for controls. When adjusting for siblings only and under an additive genetic model, 6A was associated with an even lower risk for colorectal cancer, OR=0.56 (95%CI: 0.43-0.72 p=0.02).
Conclusions:
*TGFBR1**6A is associated with a decreased risk for colorectal cancer with consistent findings in mice and humans. Together, these results provide important supportive evidence that *TGFBR1**6A is a high frequency, low penetrance colorectal cancer susceptibility allele.

Session Title: Cancer Poster Session II

PB5156 The added value of multi-tissue analysis in the identification of mosaicism in tumor suppressor gene syndromes.

Authors:

M. Broekema[1], L. Damen[1], E. Dubbink[2], W. Dinjens[2], L. Van Hest[1]; [1]Amsterdam UMC, Amsterdam, Netherlands, [2]Erasmus MC, Rotterdam, Netherlands

Introduction: Mosaicism refers to the presence of multiple cell clones with distinct genotypes. Mosaicism arises when certain cell lineages acquire pathogenic variants during postzygotic development. The phenotype of mosaic individuals depends on the extent of mosaicism, ranging from localized to generalized. Here, we report three diagnostically challenging cases with previously unrecognized mosaicism in the tumor suppressor gene syndromes Von Hippel Lindau (VHL) syndrome, neurofibromatosis 1 (NF1) and neurofibromatosis 2 (NF2). **Methods and results:** In a 49-year-old male with multiple paraganglioma and pheochromocytoma, no pathogenic variant was detected in genes associated with an increased risk for paraganglioma and pheochromocytoma in DNA from blood. A targeted hereditary cancer gene panel on DNA retrieved from pheochromocytoma and normal tissue revealed a pathogenic variant in the *VHL* gene c.499C>T; p.R167W at varying allele fractions (VAF; ranging from 6.2-40%). Re-examination of the blood NGS data identified this variant in 7.0% of the allele fraction, confirming VHL mosaicism. The second patient is a 35-year-old female with multiple neurofibromas, multiple café au lait macules, Lisch noduli and freckling, in whom no pathogenic variant in the *NF1* gene was identified in DNA extracted from blood. *NF1* analysis by NGS on multiple neurofibroma identified the c.3826C>T; p.R1276* pathogenic variant at varying VAFs (range: 22-34%). NF1 mosaicism was confirmed by detection of this variant in 5.8% and 5.4% of the reads in DNA extracted from buccal mucosa and blood, respectively. The third patient is a 37-year old female with a clinical diagnosis of NF2. She was diagnosed with bilateral vestibular schwannoma, multiple meningioma, and a schwannoma. No pathogenic variant was identified in the *NF2* gene in DNA from blood. *NF2* analysis by NGS on two meningioma and the schwannoma revealed the c.592C>T; p.R198* pathogenic variant in VAFs ranging from 45%-70%. In retrospect, low-grade NF2 mosaicism was confirmed in blood (1% of the reads). **Conclusion:** Recent advances in NGS along with the opportunity for multi-tissue sampling is an effective strategy in the detection of low-level mosaicism. Identification of previously undiagnosed cases allows for more precise and accurate genetic counseling. More cases of mosaic tumor suppressor gene syndromes will likely be identified.

Session Title: Cancer Poster Session III

PB5157 The age-dependent dynamics of healthy clonal haematopoiesis in UK Biobank

Authors:

H. MacGregor, D. Easton, J. R. Blundell; Univ. of Cambridge, Cambridge, United Kingdom

Clonal haematopoiesis (CH), the expansion of somatic mutant clones under positive selection among haematopoietic stem cells (HSCs), is almost ubiquitous in older adults. CH is a known precursor to several haematological cancers and the presence of CH in blood can confound efforts to find rare germline risk-associated variants. The dynamics of CH are not yet fully understood, and an accurate quantitative model of clonal expansion in healthy people could inform early detection strategies.

We analysed the variant allele frequency (VAF) distributions of common CH driver variants in *DMNT3A, JAK2* and *SF3B1* from the exomes of 400,000 cancer-free UK Biobank participants and estimated mutation rates and clonal fitness parameters that were similar to previously published work. However, when stratified by age, the VAF distributions predicted by a simple model assuming constant exponential growth are inconsistent with the data, underpredicting the frequencies at younger ages and implying a significant deceleration of clonal expansion with age.

We considered several alternative models of clonal dynamics to that might be able to explain this conundrum. First we show that variation in fitness of variants among individuals (e.g., due to genetic susceptibility) is unable to resolve the inconsistency. Second, we considered an ageing model where HSC division slows down with increasing age in all people. Third, we considered a clonal competition model in which clonal expansion in later life is inhibited by competition with an unobserved background of other expanding clones. The observed age-specific VAF distributions are consistent with both the ageing and clonal competition models with plausible parameters. To further interrogate these two models, we considered a large data set of longitudinal growth rates obtained from serial samples of blood. These data suggest a likely role for both clonal competition and general slowdown of HSC division rates in shaping the genetic diversity of ageing blood.

Genetics, Cardiff, United Kingdom, [1112]Ambry Genetics, Los Angeles, CA, [13]Mayo Clinic, Rochester, MN, [14]Univ. of California Davis, Davis, CA, [15]Univ. of Edinburgh, Edinburgh, United Kingdom, [16]RigsHosp.et, Copenhagen, Denmark, [17]GGC, Greenwood, SC, [18]Baylor Coll. of Med., Houston, TX, [19]IDIBELL, Barcelona, Spain, [20]Polyposis Registry, St Mark's Hosp., London, United Kingdom, [21]Human Variome Project, Melbourne, Australia, [22]Huntsman Cancer Inst, Salt Lake City, UT, [23]Univ Vermont, Burlington, VT

The ClinGen-InSiGHT Hereditary Colon Cancer/Polyposis Variant Curation Expert Panel (VCEP) was formed in 2021 to create variant curation specifications for the known genes causing these conditions.
The *MUTYH* subcommittee of this VCEP is nearing the release of gene-specific recommendations for ACMG variant classification. *MUTYH*-associated polyposis (MAP) is an autosomal recessive disorder caused by germline biallelic variants in the base excision repair gene *MUTYH*. *MUTYH* encodes a glycosylase that identifies and excises adenines mispaired with the oxidation product 8-oxo-deoxyguanosine (OG), which, if left incorporated, lead to somatic G>T transversions. Through developing ACMG criteria for *MUTYH*, experts from functional, clinical, and computational fields have identified key gaps in understanding transcript expression, functional studies, and clinical features, plus inadequate communication among researchers in these fields. We first identified nomenclature discrepancies because of confusion in application of the Matched Annotation from NCBI and EMBL-EBI (MANE) *MUTYH* transcript. The *MUTYH* MANE Select transcript (NM_001048174) encodes a 521 AA protein. However, transcript NM_001128425, which encodes a 549 AA protein, is the most used by clinical labs. Our VCEP successfully had this second transcript officially recognized as MANE Plus Clinical, harmonizing historical data with current clinical reports. Another issue the VCEP addressed was establishing specific phenotypic descriptions of affected individuals. These are needed since MAP patients present with a variable number of polyps, age of onset, extracolonic features, and association with colorectal carcinoma. Somatic genomic analysis for G>T transversions, mostly done in colorectal cancer, provides strong support for MAP diagnosis, but these tests are rarely done, so data for MAP-specific cohorts are lacking. For ClinGen, *MUTYH* is the first autosomal recessive cancer gene assessed which requires additional ACMG criteria. Per ACMG guidelines, only evidence from “well-established” functional assays can be used for applying criteria PS3 and BS3. Satisfactory functional assays are lacking due to inadequate use of controls and inattention to statistical principles that establish the strength of evidence, despite years of research on *MUTYH*. Improved communication among academics, clinicians, and industry labs is needed. Here, we identify the knowledge gaps in developing *MUTYH*-specific ACMG recommendations in the hopes of galvanizing these communities to generate the needed data for this routinely assessed cancer susceptibility gene.

Session Title: Cancer Poster Session II

PB5159 The development of Korea Cancer Omics Research (K CORE) web portal

Authors:

J. Hwang, H. Koo, S. Kong, K. Choi, H-J. Kim; Natl. cancer center, goyang-si, Korea, Republic of

Background Multi omics analysis in cancer research is an important approach to integrate high dimensional datasets to better understand the molecular biology of cancer. In addition, integrating individual clinical information with omics profile may provide significant opportunities for precision oncology. Therefore, this study aims to design and develop a user-friendly web portal that enables comprehensive analysis of clinical features and omics data of cancer patients. **Methods** The web portal development was carried out as follows: 1) Derivation of requirements for integrated analysis of multi-dimensional data via available related portals; 2) Acquisition of sample data for clinical and omics information from the Korea National Cancer Center; 3) Design of system through data structure and interface discussion; 4) Development and validation of an integrated analytics portal using R or Python; and 5) Open beta testing with multiple stakeholders **Results** An open access web portal called Korea Cancer Omics REsearch (K CORE) was developed to provide visualization and download of analysis results through multidimensional linkage of omics data and clinical information. This web portal allows users to upload their data to the portal for integrated analysis of various clinical and omics profiles. Users can implement a variety of integrated visualization analysis within this portal (e. g. Circos Plot, Oncoprint, Lollipop Plot, Heatmap, Kaplan-Meier, Cox-regression, Correlation Plot, CNV Plot, and Boxplot). Patient-specific drug information can be also checked through the report function. In addition to integrated analysis, we provide a single analysis for each dimension of data and plan to continue to expand. **Conclusion** K CORE (https://cancerdata.re.kr/k-core) may be used as a meaningful web analysis tool in precision oncology by enabling integrated analysis of high dimensional information including clinical and omics data in cancer patients.

Session Title: Cancer Poster Session III

PB5160 The genetic breast cancer risk factors in Ghanaian women.

Authors:

C. Anyigba[1,2], L. N. Amenga-Etego[1,2], l. Paemka[1,2]; [1]Univ. of Ghana, Accra, Ghana, [2]West African Ctr. for Cell Biology of Infectious Pathogens, Accra, Ghana

Breast cancer genetics is largely unexplored in the Ghanaian population despite the increasing associated mortality and prevalence of early-onset breast cancer (EOBC) and aggressive presentations. The only available genetic study investigated the germline drivers using a Eurocentric 34-gene known and putative breast cancer panel. This study essentially highlighted the contribution of some of the known gene variants genes to EOBC and identified some novel variants in Ghanaian women, however, it was limited in discovering potentially novel genes and variants. Therefore, this study sought to profile the genetics of breast cancer in Ghanaian women using whole exome sequencing. With informed consent, exomes from 86 neoadjuvant-naïve breast cancer patients were sequenced and analyzed for germline and somatic variants. Novel pathogenic germline variants were detected in *BRCA2* and three potentially novel genes. Interestingly, the *IRF5* variant (rs2004640), which was previously associated with systemic lupus erythematosus (SLE), was detected in 27% of patients and no controls. While this association remains debated, it is worth noting that the loss of *IRF5* expression reportedly contributes to breast cancer metastasis, suggesting that this variant may drive breast tumorigenesis. A well-powered study will help determine the relative risks and penetrance of the identified pathogenic variants. Notably, the known somatic drivers were not detected in this study but the somatic events observed were mediated by defective homologous recombination, DNA mismatch repair, and *APOBEC* cytidine deaminase activity. Somatic interaction analysis detected 3 mutually exclusive and 19 co-occurrence interactions. Of note is a co-occurrence interaction between *SCUBE2* and *UGT2A1* in 10 patients. Previous studies suggest that *SCUBE2* may be a novel breast tumor suppressor and an independent disease-free breast cancer survival prognosticator. However, *SCUBE2* overexpression has been associated with triple-negative breast cancer (TNBC; the most aggressive form) aggression and metastasis; a high TNBC prevalence is observed in Ghanaian women. *UGT2A1* variants have been implicated in drug resistance. Thus, *SCUBE2* and *UG2TA1* cancer driver mutations may confer poor breast cancer prognosis.

Session Title: Cancer Poster Session I

PB5161 The GOBACK study: High molecular diagnostic rate in individuals with pediatric cancer and birth defects.

Authors:

H. Gu[1], Y. Yu[2], S. Dushyant Sisoudiya[1], P. Mishra[1], H. Li[1], J. M. Schraw[1], M. E. Scheurer[1,3], D. Muzny[1], D. Mitchell[1], O. Taylor[1], R. A. Gibbs[1], C. Huff[4], S. E. Plon[1,3], P. J. Lupo[1,3], A. Sabo[1]; [1]Baylor Coll. of Med., Houston, TX, [2]UT MD Anderson Cancer Ctr., Houston, TX, [3]Texas Children's Hosp., Houston, TX, [4]U.T. MD Anderson Cancer Ctr, Pearland, TX

Background: While having a birth defect is one of the strongest risk factors for developing pediatric cancer, the genetic underpinnings of these associations remain unclear. We sought to characterize germline genetic susceptibility in children with both birth defect(s) and cancer diagnosis.
Methods: Children with birth defects and cancer were recruited through the Genetic Overlap Between Anomalies and Cancer in Kids (GOBACK) Study. For this analysis, the cohort included 39 probands, as well as biological parents and siblings. We conducted whole-genome sequencing (WGS) and evaluated single nucleotide variants, indels, and structural variants. Variants were excluded if the minor allele frequency was >1% or if classified as intergenic, intronic, or synonymous without dbscSNV scores and/or any reports in clinical variant databases. Finally, pathogenic, and likely pathogenic (P/LP) variants were identified using American College of Medical Genetics (ACMG)/Association of Molecular Pathology (AMP) criteria and evaluated in the context of the proband's phenotype.
Results: We identified P/LP variants in 25% (10/39) of the probands undergoing sequencing. Among the 10 probands: 1) four had P/LP variants in genes known to underlie both the birth defect and cancer diagnosed in the individual (*WT1, USP9X, PTPN1, LZTR1*); 2) four had P/LP variants in genes associated with the birth defect (*MMUT, FBN1, COL3A1, and KAT6B*); and 3) two had P/LP variants in *TP53*, an established cancer predisposition gene. The loss of function (LOF) variant in the *KAT6B* gene was found in one proband with genitopatellar syndrome (GPS) and neuroblastoma. Notably, a previous study reported a different LOF variant in *KAT6B* in an individual with GPS and neuroblastoma (Knight et al., 2018). To further characterize the role of germline *KAT6B* variants in neuroblastoma risk, we conducted gene-based test using WGS data from 409 neuroblastoma cases and 952 control samples from the Gabriella Miller Kids First Pediatric Research Program and found a significant enrichment of rare, predicted deleterious variants in *KAT6B* in neuroblastoma cases (p-value = 0.017).
Conclusion: Our study demonstrates a higher molecular diagnostic yield (25%) in individuals with birth defects and pediatric cancer than cancer cohorts alone. The results elucidate the contribution of genetic variants in explaining either cancer, birth defects, or both, which can provide valuable insights for both research and clinical applications. Additionally, our study adds to a body of evidence suggesting *KAT6B* is a novel neuroblastoma predisposition gene.

PB5162 The Interaction Between TCE Permissiveness and HLA Class I Non-coding Mismatches May Impact Outcomes of Hematopoietic Cell Transplantation

Authors:

M. Askar[1,2], T. Mosbruger[3], G. Shaw[3], Y. Duan[4], A. Allen[4], J. Duke[3], T. Olson[3,5], D. Monos[3,5], T. Hayeck[6,5]; [1]1QU Hlth.and Dept. of Immunology, Coll. of Med., Qatar Univ., Doha, Qatar, [2]Be The Match / 2Natl. Marrow Donor Program (NMDP), Minneapolis, MN, [3]Div. of Genomic Diagnostics, Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia, Philadelphia, PA, [4]Dept. of Biostatistics and Bioinformatics, Duke Univ., Durham, NC, [5]Dept. of Pathology and Lab. Med., Perelman Sch. of Med., Univ. of Pennsylvania, Philadelphia, PA, [6]Div. of Genomic Diagnostics, Dept. of Pathology and Lab. Med., Children's Hosp. of Philadelphia, Philadephia, PA

Hematopoietic cell transplantation (HCT) is the only curative treatment for many hematological malignancies, such as leukemia, immunodeficiencies and other disorders. However, HCT from carries a significant risk of acute graft-versus-host disease (aGVHD) and treatment-related mortality (TRM). Matching at HLA loci in transplantation settings is crucial to improve outcomes. The primary focus is matching coding variants, specifically the antigen recognition domain (ARD), of both Class I and Class II HLA molecules. Furthermore, strategies have been developed to detect compatible T-cell epitopes (TCEs) and distinguish between permissive and non-permissive mismatches in HLADPB1. The role of non-coding variation in HCT outcomes remains unclear.We performed a retrospective study with ultra-high resolution (UHR)HLA typing in 5,109 HCT patient-donor pairs transplanted between 2008 and 2017 and reported to CIBMR. In this study we examine the impact of mismatches at non-coding sequences of HLA class I alleles compared to UHR matches. UHR matches referred to patient-donor pairs that exhibited a match on all 12 class I and class II HLA genes at the highest available resolution. To account for potential confounding factors, Cox proportional hazard models were weighted by inverse probability of matching. We investigated whether such impact is influenced by the TCE permissiveness of HLA-DPB1 mismatches. We found that TCE non-permissive mismatches combined with ≥1 non-coding mismatches (excluding individuals with coding mismatches) was associated with increased risk of acute graft vs. host disease (aGVHD) in T cell replete (HR: 1.6, p = 0.0003) but not T cell deplete and increased risk of transplant related mortality (TRM) in the T-cell-deplete (HR: 1.8, p = 0.006) but not in T cell replete transplants. There were no significant association between TCE non-permissive mismatches combined with ≥1 non-coding mismatches and risk of chronic GVHD (cGVHD) or between any of the studied outcomes and non-coding sequencing mismatches in TCE permissive transplants.These results suggest there may be an interaction between the impact of non-coding mismatches, TCE permissiveness, and the graft manipulation and/or composition on transplant outcome. This is consistent with the literature reporting association with non-coding mismatches and level of expression of different HLA loci that correlates with HTC outcomes. These results need to be validated in larger studies, ideally with a mechanistic component.

Session Title: Cancer Poster Session III

PB5163 The mammalian female reproductive tract at single-cell spatial resolution

Authors:

A. Goncalves, I. Winkler, A. Tolkachov, P. Lacour, F. Lammers, K. Daugelaite, N. Schneider, M-L. Koch, A. Schneider, D. Odom; DKFZ, Heidelberg, Germany

The study of female-specific biology has historically been overlooked and undervalued. In this presentation, I will showcase a large-scale project that involves generating and analyzing single-cell and spatial transcriptomics data from 50 different cell types found in 5 reproductive organs. This data was collected throughout 5 phases of the estrous cycle and during pregnancy in young mice, as well as during 6 different time points as the female reproductive tract (FRT) ages. Our findings provide a comprehensive atlas of the FRT throughout the lifespan and shed light on the consequences of unresolved recurrent inflammation and tissue repair.
During each reproductive cycle, the FRT undergoes significant remodeling, which is regulated by systemic changes in sex hormones. However, it remains unknown whether this recurrent remodeling influences the aging process of specific organs within the FRT. To address this question, we conducted a systematic analysis at the single-cell level to examine the morphological and transcriptional changes that occur in the ovary, oviduct, uterus, cervix, and vagina at each phase of the mouse estrous cycle, during decidualization, and throughout the aging process. We investigated whether the cyclic inflammation and remodeling that naturally occur during the reproductive lifespan of young mice lead to age-related chronic inflammation and fibrosis. In-depth characterization of fibroblasts and their communication networks revealed that transcription factors and communication pathways involved in fibroblast activity during the estrous cycle and aging are enriched in extracellular matrix (ECM) remodeling and inflammation. Remarkably, these findings were consistent between human and mouse uteruses. Our research establishes a direct link between the intensity of inflammation and ECM activity during the estrous cycle and the severity of chronic inflammation and fibrosis in old age. Our data supports a model where incomplete resolution of inflammation and ECM remodeling over multiple cycles gradually leads to the development of fibrosis and chronic inflammation, making organs more susceptible to disease. Furthermore, using a mouse model of premature menopause, we isolated the effects of aging and cycling on fibrosis development, confirming the contribution of cycling. Our single-cell atlasing efforts implicate fibroblasts in maintaining a "memory" of past inflammation and propose a unifying mechanism to explain the epidemiological association between various factors that modify the number of cycles and the risk of endometrial cancer in humans.

Session Title: Cancer Poster Session I

PB5164 The molecular landscape of myeloid malignancies with ring chromosomes

Authors:

Y. Zou, J. B. Murry; Johns Hopkins Univ., Baltimore, MD

Background: Ring chromosome (RC) is a cytogenetic abnormality reported infrequently in myeloid malignancies, and we sought to evaluate the incidence internally. As the molecular profiles of cases with concomitant myeloid-associated RC are not well-known, we sought to evaluate the gene mutations in these RC. **Methods:** We reviewed 13,124 hematological malignant specimens that underwent routine chromosome analysis performed internally from 2014 to 2022. 83 (~0.6%) hematological malignant specimens had RC. Identified myeloid malignancies (n=58) in decreasing frequency included acute myeloid leukemia (n=36)(62.1%), myelodysplastic syndromes (n=19)(32.8%), chronic myeloid leukemia (n=2)(3.4%), and chronic myelomonocytic leukemia (n=1)(1.7%). 52 identified myeloid RC also had Next-Generation-Sequencing-based results. **Results: Of the** 58 myeloid RC, 55 (94.8%) had complex karyotypes (ck) with >three independent cytogenetic abnormalities, and copy number variants (CNVs) in these cases included monosomy 5/5q deletion (5q-)(67.9%), monosomy 7/7q deletion (7q-)(60.4%), a gain of marker chromosome(s) with unknown origin (+mar)(56.6%), monosomy 17/17p deletion/abnormality (17p-)(37.7%), monosomy 13/13q deletion (13q-)(20.7%), monosomy 20/20q deletion (20q-)(15.1%), and trisomy 8 (+8)(9.4%). Ten (18.9%) had multiple RCs (rr), and 9 out of 10 had both rr and +mar of unknown origin. Myeloid RC with ck had pathogenic mutations
in *TP53* (77.6%), *NRAS* (10.2%), *TET2* (10.2%), *SETBP1* (8.2%), *ASXL1* (6.1%), *CEBPA* (6.1%), *FLT3* (6.1%), *DNMT3A* (6.1%), *ABL1* (4.1%), *NF1* (4.1%), *JAK2* (4.1%), *NPM1* (4.1%), *KRAS* (4.1%), etc. Three (5.2%) lacking ck showing the following karyotypes: 1) 46,XY,-7,+r, 2) 46,XY,-18,+r, and 3) 48,XX,+4,+r. All three myeloid RC without ck had a pathogenic mutation in *TET2* (100%), two had two pathogenic mutations in *TET2* with a *DNMT3A* mutation (67%), and none had a *TP53* mutation. **Conclusions:** A subset (~0.6%) of myeloid RC was identified in our institution. Most myeloid RC were associated with ck and had recurrent myeloid-associated CNVs, with 5q- and 7q- being the most common, followed by 17p- abnormalities. Over two-third of RC with ck had pathogenic mutations in *TP53*. All RC without ck had pathogenic mutations in *TET2* and no *TP53* mutation. Most RC with rr also had +mar, suggesting genomic instability secondary to RC formation. Overall, this study identified specific molecular profiles that may be associated with distinct RC subtypes in myeloid malignancies. These data indicate that future study of the molecular profiles and their impact on the outcomes of the different myeloid RC subtypes are needed to inform clinical decision-making.

Session Title: Cancer Poster Session II

PB5165 The mutational landscape defines the proteome and spatial organization of tumor, stroma and immune cells in ovarian cancer

Authors:

M. Jones[1], K. Dabke[2], N. Gull[1], S. kreimer[1], P-C. Peng[3], N. Ng[1], K. Lawrenson[3], B. Rimel[1], B. Karlan[4], S. Knott[3], S. Gayther[2], S. Parker[3]; [1]Cedars Sinai Med Ctr, Los Angeles, CA, [2]Cedars Sinai Med. Ctr., Los Angeles, CA, [3]Cedars-Sinai Med. Ctr., Los Angeles, CA, [4]David Geffen Sch. of Med. at UCLA, Los Angeles, CA

High-grade serous ovarian cancer (HGSOC) is highly aggressive and lethal, with clinical challenges to both diagnosis and treatment . The genomic instability of HGSOC, further complicated by homologous recombination deficiency (HRD), leads to heterogeneity in the HGSOC tumors and patient response to treatment. Proteogenomic studies have provided some insight into HGSOC biology, but a deeper understanding of the effects of chemotherapy and HRD on the HGSOC proteome is needed. We have profiled the complete proteome of tumors from 32 HGSOC patients before and after multiple rounds of chemotherapy. We identified a stable methylome, transcriptome and proteome throughout progression and the development of resistance, despite an increasing somatic mutational burden. Tumors with germline or somatic loss of BRCA1 or BRCA2 had increased expression of proteins related to immune pathways, more shared TCR CDR3 repertoires of tumor-infiltrating T cells, increased neoantigen counts, and enriched immune clusters within HGSOC tissue after chemotherapy. Single cell spatial profiling of 24 paired primary and recurrent tumors was performed with Akoya FUSION to capture tumor, stroma and immune cell populations (27 protein panel). We identified increased immune cell infiltration in recurrent tumors and defined specific cell population differences based on homologous recombination deficiency that correlated with survival. Through proteo-genomic and spatial analysis, this work has shown that the immune landscape of HGSOC tumors is influenced by homologous recombination status and identified candidate drivers of HGSOC biology.

Session Title: Cancer Poster Session III

PB5166 The performance characteristic of the low inputtagmentation-based Whole Genome Sequencing in high quality somatic variant calling

Authors:

C. Dalgard, X. Zhang, G. Sukumar, M. Wilkerson, L. Jiang; USUHS - TAGC, Bethesda, MD

Whole genome sequencing (WGS) is widely used for cancer diagnostic and therapeutic applications in clinical practice and clinical trials. Currently, the Truseq PCR-free library preparation methods are routinely used in genomics laboratories. However, microgram amounts of DNA input is a limitation due to limited materials often from clinically-derived specimens. Here, we evaluated a novel low input (100-300 ng) PCR-free tagmentation (TAG) based library preparation for WGS. Replicates of TAG- and ligation-based (Illumina TruSeq)sequencing libraries were prepared from 3 pairs of breast cancer-derived tumors (HCC1195, HCC1143 and HCC1187) and matched B-lymphocyte-derived normal (HCC1195BL, HCC1143BL and HCC1187BL) cell lines. Libraries were sequenced on Illumina Novaseq 6000 platforms to target 30x and 90x mean coverage for normal and tumor samples respectively. Raw sequencing data were aligned to the hg38 by Isaac Aligner before variant analysis by Strelka2. Technical sequencing metrics demonstrated high similarity between TAG- and ligation-based workflows, including passing filter reads, Q30%, aligned reads, mean coverage. Germline variants of HCC1395BL showed greater than 98% precision and sensitivity using ligation-based variants as a reference. For somatic mutation calling from TAG-based libraries, HCC1395, HCC1143 and HCC1187, 88%, 85% and 86% precision and 81%, 70%, 68% sensitivity was observed, respectively, compared to the ligation-based method. Furthermore, using the SEQC2 Consortium high-confidence mutation set, TAG- and ligation- based variant calls of HCC1395 had 90% and 93% precision and 74% and 73% sensitivity, respectively with this high confidence reference. Further investigation showed that a high fraction of false negative calls was associated with low variant allele frequency (<10%). Compared to an available reference dataset for benchmarking somatic calling pipelines from New York Genome Center, TAG- and ligation-based variant calls of HCC1143 yielded 85% and 83% precision and 63% and 63% sensitivity, respectively; TAG- and ligation-based variant calls of HCC1187 resulted in 91% and 92% precision and 81% and 79% sensitivity, respectively. In summary, the low input TAG-based WGS protocol produced highly reproducible variant calls with highly concordant somatic variant calls compared to the commonly-used PCR-free ligation-based methods and to reference callset. Further evaluation is warranted to broaden clinical application from minimal starting material.

Session Title: Cancer Poster Session I

PB5167 The relation between vitamin D receptor (rs2228570) polymorphism and prostate cancer.

Authors:

P. Khademi; Yeditepe Univ., Istanbul, Turkey

Most chronic diseases are associated with vitamin D deficiency in the body. The sun helps our body produce vitamin D, which is the main source of this vitamin. Vitamin D shortage is accompanied by diseases such as bone pain, increased blood pressure, and depression. You may know that the main supply of vitamin D is out of your home and through sunlight. Muscle growth and strengthening bones, lowering blood pressure, reducing pain caused by fibromyalgia, and slowing the progression of MS symptoms are all associated with adequate levels of vitamin D inside the body, however, a lack of this vitamin causes symptoms such as muscle weakness, rising blood strain, bone pain, and depression. It has even been said that the prevalence of MS is higher in regions where there is not enough sunlight. However, you may not know that many chronic diseases are the result of low surfaces of vitamin D, and prostate cancer has been proven throughout the world. Prostate cancer is directly related to vitamin D shortage in the body. This occurs mainly in older men and, according to the American Cancer Society, The most common disease and a leading cause of death in men is carcinoma. Moreover, the antiproliferative effect on prostate cells is mediated by the vitamin D receptor active form of vitamin D. In a case-control study, we reviewed whether the vitamin D receptor (VDR) gene (RS2228570)polymorphism could influence PC sensitivity. Keywords: Vitamin D, deficiency, Prostate cancer, connection between, (VDR) gene(RS2228570) polymorphism

Session Title: Cancer Poster Session II

PB5168 The Sherlock Lung cancer study: A Pilot Study of Lung Cancer in Never Smokers in Nigeria

Authors:

O. Omonijo[1], S. Isreal-Isah[1], M. Kojusola[1], E. Jonathan[1], A. Ndubuisi[2], P. Jibrin[3], J. Ahmed[3], I. M. Ibrahim[3], A. Omotosho[4], E. Jedy-Agba[1]; [1]Inst. of human Virology Nigeria, Abuja, Nigeria, [2]Natl. Hosp. Abuja, Abuja, Nigeria, [3]Aminu Kano Teaching Hosp., Kano, Nigeria, Kano, Nigeria, [4]Univ. of Calabar Teaching Hosp., Nigeria, Calabar, Nigeria

Background: Lung cancer is a leading cause of mortality from cancer globally. It occurs in approximately 10 - 20% of never smokers worldwide (National Institutes of Health, 2021). The various risk factors for lung cancer in never smokers were explored in the Sherlock Lung Cancer Study. **Methodology:** This was a pilot cross-sectional study conducted at 3 participating hospitals in Nigeria: The National Hospital Abuja (NHA), Aminu Kano Teaching Hospital Kano (AKTH) and the University of Calabar Teaching Hospital (UCTH). All patients who presented with symptoms highly suggestive of lung cancer at each of these hospitals were invited to participate in the study. All patients included in the study were never smokers who had no previous cancer diagnosis. The sample size was 15 based on a feasibility assessment of annual cases of lung cancer reported in these hospitals over a period of 3 years. Questionnaires were administered, blood samples and lung tissue biopsy samples were collected from consented participants. Data was entered into REDCap. **Results:** A total of 21 suspected cases of lung cancer were enrolled into the study,13 participants were confirmed lung cancer cases in never smokers. 7 (53.85%) of the cases were male, 6 (46.15%) were female respectively. Most cases have the same risk factor of being exposed to air pollution from cooking with smoky coal and wood, passive smokers make up for 11 (84.62%), 11 (84.62%) wood burning and 6 (46.15%) coal burning being major contributors. Moreover, there are varying degrees of comorbidities in participants such as: 8 cases of peptic ulcer disease (61.54%), 5 cases of HBP (38.46%), 2 cases of asthma (15.39%), 2 cases of COPD (15.39%), 1 case of tuberculosis (7.69 %), and 1 case of pneumonia (7.69%), respectively. 7 (53.84%) were shown to have at least two types of comorbidities, while 3 (23.07%) showed no presence of any form of comorbidity. Mortality rate is 53.84% (1 in every 2 cases). **Conclusion:** The relationship between environmental factors, comorbidities & lung cancer cannot be fully established suggesting a need for more elaborate study. However, there is need for more awareness on lung cancer in LMICs to avoid late presentations to hospitals and lower mortality rate.

Session Title: Cancer Poster Session III

PB5169 The somatic landscape of low-grade epilepsy-associated tumors across 275 surgically accessible human epileptogenic brain lesions

Authors:

C. Leu[1], C. Boßelmann, M[2], L. Hoffmann[3], S. Baldassari[4], R. Coras[5], K. Kobow[5], H. Hamer[5], S. Brandner[5], K. Rössler[6], C. Bien, G[7], T. Kalbhenn[7], T. Pieper[8], T. Hartlieb[8], K. Becker[9], J. Altmüller[10], L. Ferguson[2], R. Busch[2], S. Baulac[4], P. Nürnberg[9], I. Najm[2], I. Blümcke[5], D. Lal[1]; [1]McGoven Med. Sch., UTHlth.Houston, Houston, TX, [2]Cleveland Clinic, Cleveland, OH, [3]Univ. clinic Erlangen, Erlangen, Germany, [4]Pitié-Salpêtrière Univ. Hosp., Paris, France, [5]Univ. Hosp. Erlangen, Erlangen, Germany, [6]Med. Univ. of Vienna, Vienna, Austria, [7]Bielefeld Univ., Bielefeld, Germany, [8]Schoen Clinic Vogtareuth, Vogtareuth, Germany, [9]Univ. of Cologne, Cologne, Germany, [10]Charité Med. Univ. Berlin, Berlin, Germany

Our understanding of the molecular mechanisms involved in the etiology of epileptogenic brain tumors is essential for improving the treatment of drug-resistant focal epilepsy. Recent large-scale studies made significant contributions, yet our knowledge is incomplete. We aggregated 275 brain tissues with pathology-defined low-grade epilepsy-associated tumors (LEAT) and 89 brain control tissues across multiple centers in Europe and the Cleveland Clinic in the US. LEAT samples were screened with >350x whole-exome sequencing (N=154) and >1500x targeted sequencing of 122 genes selected from a previous study (N=121). Brain control tissues were screened with the 122 gene panel. Somatic variant enrichment was tested using the dNdScv model that tests for the ratio of non-synonymous (missense, nonsense, and splice site) to synonymous somatic mutations while accounting for variations in the background local mutation rate along the human genome. We used stringent Bonferroni correction after the number of genes captured by the whole-exome screens to identify genome-wide significant somatic variant-enriched genes. We also tested for association with LEAT against the brain control tissues using only panel-sequenced tissues and the burden/variant collapsing method (121 LEAT vs. 89 controls). Somatic variant enrichment analysis confirmed three genes known to cause LEAT (*NF1*, *BRAF*, and *FGFR1*) and identified one novel gene. *NF1* was enriched in 28% of dysembryoplastic neuroepithelial tumors (DNET, P=2.39x10^{-6}) and 22% of gangliogliomas (GG, P=7.30x10^{-7}). The enrichment of *BRAF* was driven by the GG pathology (31% carriers, P=3.34x10^{-10}), while *FGFR1* was mainly enriched in DNET (26% carriers, P=7.72x10^{-6}). All known genes identified in the enrichment analysis were also significantly associated with LEAT in the somatic burden analysis against controls (P_{BURDEN}<1.4x10^{-4}). Also, the burden analysis identified two additional novel genes. All three identified novel candidate genes were previously reported as potential tumor suppressor genes in various cancers. A subset of individuals carried somatic variants in >1 of identified genes. Interestingly, all individuals with multiple hits and a *BRAF* variant had the second hit in *NF1*. Our study suggests that LEAT pathologies not explained by the main known driver genes are highly heterogenic. A burden test against a small control cohort was powered enough to identify several associated genes, improving the perspective for case/control somatic association studies in brain tissues.

PB5170 The ungracious guest: how the human papillomavirus (HPV) changes the local host epigenome and transcriptome to promote tumorigenesis.

Authors:

M. M. Hoffman[1,2,3], M. Karimzadeh[2], E. Collier[2], C. Arlidge[1], A. Rostami[2], J. Zou[1], Z. Zhao[1], Y. Zheng[1], E. Leung[4,2], K. Han[1,2], S. Lheureux[1,2], M. Lupien[1,2], S. V. Bratman[1,2]; [1]Univ. Hlth.Network, Toronto, ON, Canada, [2]Univ. of Toronto, Toronto, ON, Canada, [3]Vector Inst. for Artificial Intelligence, Toronto, ON, Canada, [4]Sunnybrook Hlth.Sci. Ctr., Toronto, ON, Canada

Background: Human papillomavirus (HPV) drives almost all cervical cancers and up to 70% of head and neck cancers. Frequent integration into the host genome occurs predominantly in tumorigenic types of HPV. We hypothesize that changes in chromatin state at the location of integration can result in changes in gene expression that contribute to the tumorigenicity of HPV.
Results: We find that viral integration events often occur along with changes in chromatin state and expression of genes near the integration site. We investigate whether introduction of new transcription factor binding sites due to HPV integration could invoke these changes. Some regions within the HPV genome, particularly the position of a conserved CTCF binding site, show enriched chromatin accessibility signal. ChIP-seq reveals that the conserved CTCF binding site within the HPV genome binds CTCF in 4 HPV^+ cancer cell lines. Significant changes in CTCF binding pattern and increases in chromatin accessibility occur exclusively within 100 kbp of HPV integration sites. The chromatin changes co-occur with out-sized changes in transcription and alternative splicing of local genes. Analysis of The Cancer Genome Atlas (TCGA) HPV^+ tumors indicates that HPV integration upregulates genes which have significantly higher essentiality scores compared to randomly selected upregulated genes from the same tumors.
Conclusions: Our results suggest that introduction of a new CTCF binding site due to HPV integration reorganizes chromatin state and upregulates genes essential for tumor viability in some HPV^+ tumors. These findings emphasize a newly recognized role of HPV integration in oncogenesis.

Session Title: Cancer Poster Session II

PB5171 Three-Dimensional Nuclear Organization of Telomeres in Breast Cancer

Authors:

O. Samassekou[1], S. Mai[2]; [1]Univ. of Sci., Technics and Technologies, Bamako, Mali, [2]Univ. of Manitoba, Winnipeg, MB, Canada

Introduction:Breast cancer is the most common cancer among women, exhibiting clinical heterogeneity and diverse molecular subtypes. Within each molecular subtype, further heterogeneity exists. Breast cancer cells often demonstrate shorter telomeres compared to normal cells, and telomere alterations may serve as indicators of genomic instability. This study investigates whether the three-dimensional nuclear organization of telomeres is altered in different molecular subtypes of breast cancer. Methods:We examined the telomeric nuclear organization in 50 breast cancer patients representing various molecular subtypes. Telomere fluorescent in situ hybridization (FISH) was performed on tissue biopsies using Peptide Nucleic Acid (PNA). Three-dimensional microscopy and a quantitative method called TeloView^{TM} were utilized to assess different parameters defining telomeric nuclear organization. Results:Our findings revealed notable differences among the molecular subtypes. HER2-positive patients exhibited a higher presence of telomeric aggregates and signals compared to luminal A and basal subtypes. Conversely, luminal A and basal subgroups displayed longer telomeres than the HER2 subgroup. Additionally, we observed heterogeneity within each molecular subtype concerning telomeric aggregates, signal number, and signal intensities. This heterogeneity was particularly pronounced in the luminal A subtype. Conclusion:This study proposes a categorization of breast cancer molecular subtypes based on the nuclear organization of telomeres. The identified differences in telomeric nuclear organization provide a new approach to refine the current molecular classification of breast cancer. This knowledge may contribute to improved understanding and management of breast cancer based on its distinct molecular subtypes.

Session Title: Cancer Poster Session III

PB5172 To investigate the mutational features of the immunoglobulin heavy chain variable region gene in patients with chronic lymphocytic leukemia using immunophenotypic and molecular genetic methods

Authors:

E. Coskunpinar[1], K. Gunduz[1], S. Erdem[2], M. Yenerel[2]; [1]Univ. of Hlth.Sci., Turkey, Istanbul, Turkey, [2]Istanbul Univ., Istanbul, Turkey

CD38 expression and Zeta chain (TCR) associated Protein kinase 70 kDa (Zap-70) has an importance in prognosis of chronic lymphocytic leukemia (CLL). Furthermore, studies have shown that the mutation status of non-mutated immunoglobulin heavy chain variable (IgVH) region can be used in order to predict the prognosis of CLL cases. Generally, the cases which are positive for Zap-70 and/or CD38, indicate a worse prognosis for CLL. However, IgVH mutation is not accompanied with positive results of Zap-70 and/or CD38. The aim of this study was to examine the IgVH mutation status and CD38, an immunophenotypic marker, of 10 patients diagnosed with CLL through whole exome sequencing (WES). In this research, presence of mutation of CD38 and IgVH, and specific IgVH fragments were examined in 10 CLL cases. CD38 was analysed with flow cytometric method, whereas IgVH mutations were analysed through WES (whole exome sequencing). For detection of the pathogenic variant and association of other variants to the disease, ClinVar database was used. The results were analysed with Iliom Bioscience program. As a result, 2 out of 10 cases were CD38 positive and 8 were negative. The cut-off value in CD38 evaluation was taken as 10. In 7 patients who were included in the research, 10 distinct pathogenic variants (RARS1, OBSCN, FAH, GAA, C11orf80, SLC7A7, PEPD, TEX14, TAF4B and STRA6) were detected. Moreover, in four patients, 4 possible pathogenic variants (AK2, SERPINF2, GNB5 and CD36) were detected. In 8 out of 10 cases, mutation was detected in different IgVH segments whereas in 2 cases, no IgVH mutation was found.

Session Title: Cancer Poster Session I

PB5173 *TP53* exon 6 and intron 6 microdeletions spanning splicing regulatory elements lead to exon skipping.

Authors:

D. Canson[1], I. Llinares[2], C. Fortuno[1], L. Sanoguera[2], M. De La Hoya[3], E. Bueno[2], A. B. Spurdle[1], E. A. Velasco[2]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Inst. de Biología y Genética Molecular (CSIC-UVa), Valladolid, Spain, [3]IdISSC (Inst. de Investigación Sanitaria del Hosp. Clínico San Carlos), Hosp. Clinico San Carlos, Madrid, Spain

Most studies on splicing for *TP53* genetic variation have focused on variants that affect the donor and acceptor conserved dinucleotide positions. None have experimentally explored variants that disrupt splicing regulatory elements (SREs). We undertook a minigene construct-based study as a model for confirming the role of SREs in native *TP53* splicing. *TP53* exon 6, with a weak native donor (reference MES 2.6) flanked by putative exonic and intronic splicing enhancer elements, was prioritized for study.
Native and cryptic donor and acceptor splice motifs, and putative SRE-rich regions, in *TP53* exon 6 and intron 6 were mapped using HEXplorer. Bioinformatic prediction was performed for microdeletions spanning 3 exonic and 2 intronic SRE clusters, located outside of the native acceptor and donor splice motifs and upstream of a predicted strong cryptic donor (reference MES 9.6) positioned 64 bp downstream of the native donor. Microdeletions affecting SREs were designed such that none were predicted to create a new donor or acceptor motif. All deletions were predicted to disrupt splicing (SpliceAI ≥0.2 threshold), namely, exon 6 skipping resulting from exonic deletions and +64 cryptic donor activation resulting from intronic deletions. There is evidence for rare usage of the +64 cryptic donor as observed from 8/199,336 RNAseq samples in SpliceVault.
A 3.5 kb-insert with *TP53* exons 2 to 9 was cloned into the pMAD splicing vector (minigene mgTP53_ex2-9); 6 exonic and 4 intronic microdeletions were introduced into the minigene for assay in SKBR3 breast cancer cells. Minigene construct assays showed that all microdeletions abrogating enhancers without creating silencers led to exon 6 skipping (8-78%), with minor impact for intronic deletions (8-12%), demonstrating the utility of HEXplorer and SpliceAI in designing SRE-rich microdeletions for construct assays. In contrast to all predictions, none of the intronic deletions activated the +64 cryptic donor site, suggesting strong silencer activity affecting the cryptic site.
In summary, we effectively mapped and confirmed 5 SRE-rich regions between *TP53* exon 6 acceptor and the +64 cryptic donor in intron 6. The SREs surrounding the weak native donor explain its preferential usage over the predicted strong intronic cryptic donor. These findings demonstrate the importance of in vitro assays to confirm predictions of variant impact on splicing in SRE-rich regions. We are now using this SRE map to prioritize single nucleotide variants located within the microdeletions for splicing assays.

Session Title: Cancer Poster Session II

PB5174 Transcriptome-wide association study and causal inference analysis identifies colorectal cancer susceptibility genes with therapeutic potential.

Authors:

T. O'Mara[1], E. Hazelwood[2], P. Kho[3,1], X. Wang[1], T. Bishop[4], A. Chan[5,6,7,8], S. Gruber[9], J. Hampe[10], L. Le Marchand[11], M. Woods[12], Colon CFR, E. Vincent[13], D. Glubb[1]; [1]QIMR Berghofer Med. Res. Inst., Brisbane, Australia, [2]Univ. of Bristol, BRISTOL, United Kingdom, [3]Stanford Univ., Sunnyvale, CA, [4]Univ. of Leeds, Barnet, United Kingdom, [5]Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA, [6]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA, [7]Broad Inst. of Harvard and MIT, Cambridge, MA, [8]Harvard T.H. Chan Sch. of Publ. Hlth., Harvard Univ., Boston, MA, [9]City of Hope Natl. Med. Ctr., Duarte, CA, [10]TU Dresden, UKD, Dresden, Saxony, Germany, [11]Univ Hawaii, Honolulu, HI, [12]Mem. Univ Newfoundland, St John's, NL, Canada, [13]Univ. of Bristol, Bristol, United Kingdom

Colorectal cancer is the third most common cancer worldwide. However, the biological mechanisms underlying disease development are unclear, posing challenges in the development of effective therapeutic and preventive interventions. Previous transcriptome-wide association studies (TWAS) have revealed several genes potentially implicated in colorectal cancer development. Nevertheless, existing TWAS studies have not yet stratified by anatomical subsite or sex, and the lack of robust causal inference analysis raises concerns about spurious associations among the identified genes.

We conducted a comprehensive investigation using two multi-tissue TWAS methods (S-MultiXcan and Joint Tissue Imputation) to maximise power to detect associations. Specifically, we integrated data from a large colorectal cancer genome-wide association study (GWAS; 52,775 cases and 45,940 controls) with expression quantitative trait loci data from six relevant tissues from GTEx v8 (transverse colon, sigmoid colon, subcutaneous adipose, visceral adipose, whole blood and EBV-transformed lymphocytes). Analyses were repeated stratifying the colorectal cancer GWAS by sex and anatomical subsite. In total, we identified 78 genes at 28 loci that significantly associated with colorectal cancer risk at a stringent Bonferroni threshold. Genes were further assessed for a causal relationship using Mendelian randomization and colocalization analyses. We also assessed the causal relationship between colorectal cancer risk and genes encoding 1,263 actionable proteins that are targeted by approved drugs or are in clinical development (i.e. the “druggable genome”).

Our workflow prioritized 35 genes with evidence for a causal relationship with colorectal cancer risk, including six genes encoding proteins that are targeted by available drugs. Prioritized genes were further evaluated for therapeutic potential by performing phenome-wide MR to identify possible side effects and exploring drug repurposing opportunities using the Connectivity Map and Open Target platforms.

In summary, our study provides valuable insights into the molecular underpinnings of colorectal cancer and identifies promising candidate genes with a causal role in disease etiology. Furthermore, our findings offer potential avenues for therapeutic intervention, including the repurposing of existing drugs and the development of novel treatments.

Session Title: Cancer Poster Session III

PB5175 Transcriptome-Wide Association Study of Mammographic Density Phenotypes

Authors:

J. Rothstein[1,2], A. Sistig[2], X. Song[2], S. E. Alexeeff[3], L. C. Sakoda[3], N. Achacoso[3], E. Jorgenson[4], V. McGuire[5,6], J. A. Lipson[5], D. L. Rubin[5], M. J. Klein[2], L. A. Habel[3], P. Wang[2], W. Sieh[1,2]; [1]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX, [2]Icahn Sch. of Med. at Mount Sinai, New York, NY, [3]Div. of Res., Kaiser Permanente Northern California, Oakland, CA, [4]Regeneron Genetics Ctr., Tarrytown, NY, [5]Stanford Univ. Sch. of Med., Stanford, CA, [6]Univ. of California, San Francisco, San Francisco, CA, [7]Univ. of Toronto, Toronto, ON, Canada, [8]Univ. of Cambridge, Cambridge, United Kingdom, [9]Weill Cornell Med., New York, NY, [10]Mayo Clinic, Rochester, MN, [11]Univ. of Washington, Seattle, WA, [12]Fred Hutchinson Cancer Res. Ctr., Seattle, WA

Background: Mammographic density (MD) phenotypes are highly heritable and strongly associated with breast cancer risk. Genetic variants identified by genome-wide association studies (GWAS) explain only a small fraction of the heritability, and the responsible genes remain largely unknown. Transcriptome-wide association studies (TWAS) can improve the power of GWAS and identify genes associated with MD through their genetically regulated expression levels.
Methods: The study population included 24,158 women of European ancestry who underwent screening with Hologic (n=20,282) or GE (n=3,876) digital mammography and participated in the Research Program on Genes Environment and Health (RPGEH) at Kaiser Permanente. Dense area (DA), non-dense area (NDA), and percent density (PD) were measured centrally using Cumulus6. Gene expression was estimated using PrediXcan models for mammary tissue, fibroblast cells, subcutaneous and visceral adipose tissues, and assessed for their associations with MD in linear regression models adjusted for age, BMI and other covariates. Tissue-specific results were combined, and genes that were significant at a false-discovery rate of 0.05 were carried forward for replication ($p<0.05$) in an independent GWAS of MD in up to 27,900 European ancestry women.
Results: In the discovery sample, 58 genes in 36 distinct regions were associated with MD. In the replication sample, a subset of 32 genes in 21 regions was associated with MD, including 8 novel genes in 7 regions. *LRRC17*, *PPP2R3A*, and *TNFSF12* were novel genes for DA. *KCNN4*, *NKX6-1*, *MYEOV* and *RP11-211G23.2* (both at 11q13.3) were novel genes for NDA. *SNX16* was a novel gene for PD. Among the replicated MD genes, 17 genes in 12 regions also were associated with breast cancer risk.
Conclusion: This TWAS identified novel genes for MD and breast cancer risk, and prioritized genes at known GWAS loci that may be causally associated with MD phenotypes through their expression levels.

Session Title: Cancer Poster Session II

PB5177 Tumor cellularity bias on interpretationof genomic data in pancreatic ductaladenocarcinoma

Authors:

D. Kim[1], W-G. Yun[2], J-Y. Jang[2], D. Park[1]; [1]Ajou Univ., Suwon, Korea, Republic of, [2]Seoul Natl. Univ. Coll. of Med., Seoul, Korea, Republic of

Backgroud: Tumor cellularity, the proportion of cancer cells within a sample, is a primary consideration before performing next-generation sequencing (NGS) in cancer research. Low cellularity, a majority of non-cancer cells within a tissue, can lead to misinterpretation of cancer genomics and transcriptomics. However, little perspective exists on how low cellularity decreases the accuracy of omics data. Here, we aimed to investigate the bias of tumor cellularity on genomic interpretation from NGS data in pancreatic ductal adenocarcinoma (PDAC), a representative cancer type with low cellularity (mean < 40%). **Methods:** We performed single nucleotide polymorphism (SNP) array, whole exome sequencing (WES), and RNA-seq on 196 surgically treated patients with PDAC between 2009 and 2016. In addition, *KRAS*-targeted sequencing data were generated from the 193 matched samples. A tumor cellularity was calculated from the SNP profile per tissue. Then, we divided the patients into high (≥ 0.26) and low cellularity groups (< 0.26) and compared these groups. **Results:** First, cellularity significantly affected the sensitivity to identify *KRAS* mutation in WES; a detection rate of 86.3% (88/102) and 54.3% (51/94) in high and low cellularity groups, respectively ($p < 0.001$). This low sensitivity issue was mostly resolved by *KRAS*-targeted sequencing as *KRAS* variants were present in 40 low cellularity patients out of 43 who had no *KRAS* mutation in WES. Second, discordant tumor cellularity between DNA and RNA based methods showed that various composition of non-cancer cells within the tissues resulted in heterogeneous gene expression by low cellularity. There was a high correlation between tumor purity estimated from SNP profiles and RNA-seq in the high cellularity group (*Pearson's correlation coefficient* $r = 0.45$, $p < 0.001$). In contrast, the low cellularity group had no positive correlation ($r = -0.03$, $p = 0.77$). Third, profiling cell type abundance through RNA-seq revealed the association of molecular subtypes with cellularity. More normal acinar and immune cells were detected in low cellularity samples, whereas malignant ductal cells were more abundant in high cellularity samples. As a result, aberrantly differentiated endocrine exocrine (ADEX) subtype, originating from normal acinar cells, accounted for 23% (23/102) and 50% (47/94) of high and low cellularity samples, respectively. **Conclusion:** Low tumor purity leads to misunderstanding the nature of cancer by disturbing mutation identification, accurate cellularity assessment, and molecular subtyping. Consequently, it is necessary to interpret cancer omics data considering cellularity.

Session Title: Cancer Poster Session III

PB5178 Tumor Heterogeneity in breast cancer by cellular Telogenomics

Authors:

C. Ongoiba[1], O. Samassekou[1], G. Landoure[2], M. Traore[1], M. Keita[1], M. Ly[1]; [1]USTTB, Bamako, Mali, [2]CHU du Point G, Bamako, Mali

Introduction: Tumor heterogeneity is a prominent characteristic of breast cancer, observed at the genomic, transcriptomic, and proteomic levels. The identification and understanding of tumor heterogeneity in breast cancer can serve as valuable diagnostic, prognostic, and therapeutic biomarkers, particularly for breast cancer subgroups such as the HER2-equivocal subgroup. However, accurately assessing tumor heterogeneity at the cellular level, while considering tumor architecture and cell morphology, remains challenging due to a lack of established methodologies. Therefore, our current study aims to develop a methodology using telomere nuclear organization, referred to as cellular telogenomics, to determine tumor heterogeneity at the cellular level in breast cancer.
Objective: The objective of this study is to determine cellular heterogeneity by employing cellular telogenomics.
Methods: Breast cancer samples were collected from patients presenting with the HER2-equivocal form. Three-dimensional (3D) fluorescence in situ hybridization using telomeric probes was performed on tissue sections. Subsequently, 3D microscopy was conducted, and six parameters (telomere numbers, telomere intensities, telomere aggregates, telomere distribution, telomere volume, and nuclear volume) defining cellular telogenomics were assessed in 400 cells from various regions of the sample. Finally, a heterogeneity score was developed through statistical analysis, phenotyping each cell based on the six parameters of cellular telogenomics.
Results: Cells were successfully grouped based on their telogenomics phenotype. It was observed that certain low-grade tumoral regions exhibited a higher index of tumor heterogeneity, whereas some high-grade tumoral regions demonstrated greater genomic homogeneity. Furthermore, cell-by-cell analysis revealed that telogenomics phenotyping can determine tumor cell evolution based on their telogenomic changes. Additionally, specific telogenomic phenotypes were associated with varying levels of tumor aggressiveness, with the aggressiveness being dependent on the cellular regions exhibiting a higher heterogeneity index.
Conclusion: This study introduces a novel approach for determining tumor heterogeneity at the cellular level. Our findings suggest that a higher index of cellular heterogeneity, as defined by cellular telogenomics, can serve as an indicator of tumor aggressiveness.

Session Title: Cancer Poster Session I

PB5179 Tumor Mutation Burden calculation from a targeted gene panel

Authors:

C. O'Connor[1], R. J. Martinez[1], M. Schomaker[2], R. LaRue[1], S. A. Munro[1], S. Yohe[1], A. C. Nelson[1]; [1]Univ. of Minnesota, Minneapolis, MN, [2]Fairview Molecular Diagnostics Lab., Minneapolis, MN

Tumor mutation burden (TMB) is an emerging biomarker for identifying patients likely to respond to immune checkpoint therapies. While the least biased approach to TMB calculation is to use whole exome sequencing (WES) of paired tumor-normal samples, time and cost constraints have led to a preference for using tumor-only targeted sequencing panels to calculate TMB. To calculate TMB from a targeted gene panel we need to quantify how reductions in panel size affect TMB accuracy. Friends of Cancer Research has published recommendations for evaluating the effect of panel size on TMB; most published examples of this use a large panel (at least 1 Mb in total gene sequence length). Decisions about which variants are counted as part of the TMB calculation has several considerations including removal of artifacts, driver mutations and putative germline mutations. Due to the emerging nature of TMB as a biomarker there are still a variety of methods used to remove putative germline variants and other sequence artifacts.

We used publicly available data from The Cancer Genome Atlas (TCGA) for four types of cancer to quantify the effect of a targeted gene panel on TMB estimates compared to WES, and utilized a TMB calibration panel to refine our variant filtering process. To develop our own TMB calling pipeline, we calculated TMB from two targeted gene panels: 127 genes (0.38 Mb) and 511 genes (1.37 Mb), and studied the effects of filtering variants based on their presence in population databases, presence in databases of common cancer driver mutations, presence in an in-house variant database, synonymous/non-synonymous status, variant allele frequency and ClinVar annotation status on TMB values. We found that our targeted gene panels tended to overestimate TMB, although there was high agreement (82% for the 127 gene panel) between WES and targeted gene panel TMB rates at a threshold of greater than or less than 10 mutations/Mb. Using the TMB calibration samples and TCGA samples for validation we developed a TMB calculation algorithm that accurately calculates TMB from only a targeted gene panel.

Session Title: Cancer Poster Session II

PB5180 Two-sample Mendelian randomization study of circulating metabolites and prostate cancer risk in Hispanic populations

Authors:

H. Fuller[1], R. Rhode[2], H. Highland[2], J. Shen[3], B. Yu[4], E. Boerwinkle[4], M. Grove[4], K. E. North[2], D. V. Conti[3], C. A. Haiman[3], K. Young[2], B. F. Darst[1]; [1]Fred Hutchinson Cancer Ctr., Seattle, WA, [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC, [3]Univ. of Southern California, Los Angeles, CA, [4]Univ. of Texas Hlth.Sci. Ctr. at Houston, Houston, TX

While prostate cancer (PCa) is highly heritable, the mechanisms underlying PCa risk are not well understood, particularly in underserved populations. Here, we conducted a two-sample Mendelian randomization (MR) to assess whether serum metabolites are causally associated with PCa risk in Hispanic/Latino men. MR analyses were performed using the inverse variance weighted (IVW) method on GWAS summary statistics for 711 metabolites quantified by untargeted mass spectroscopy via the Metabolon platform for 3,166 Hispanic Community Health Study/ Study of Latinos participants and PCa GWAS summary statistics for 3,931 cases and 26,405 controls from Hispanic populations in PRACTICAL. SNPs associated with metabolites at the genome-wide significance level ($P<5x10^{-8}$) were included in the instruments after removing rare SNPs (minor allele frequency≤0.01) and pruning by linkage disequilibrium ($R^2=0.2$), which was calculated in European and African ancestry TOPMed populations in TOP-LD. A false discovery rate ($\alpha=0.05$) was implemented to account for multiple testing. A range of sensitivity analyses were utilized to assess violations of MR assumptions (IVW multiplicative, weighted mode, weighted median, MR egger, and MR PRESSO). In total, 22 metabolites were significantly associated with PCa risk, including 3 amino acids, 1 carbohydrate, and 18 lipids, which included 4 polyunsaturated fatty acids. All 4 polyunsaturated fatty acids were associated with 14-19% reduced odds of PCa: n3 DPA (22:5n-3) (OR=0.81, 95% CI=0.73-0.90, $P_{IVW\ random}=1.7x10^{-4}$), n6 DPA (22:5n-6) (OR=0.86, 95% CI=0.78-0.95, $P_{IVW\ random}=2.2x10^{-3}$), EPA (20:5n-3) (OR=0.81, 95% CI=0.77-0.85, $P_{IVW\ random}=2.8x10^{-15}$), and arachidonate (20:4n-6) (OR=0.85, 95% CI=0.82-0.88, $P_{IVW\ random}=3.3x10^{-20}$). Furthermore, increased levels of acyl choline arachidonoylcholine, also involved in fatty acid metabolism, were associated with 16% reduced PCa odds (OR=0.84, 95% CI=0.79-0.89, $P_{IVW\ random}=3.5x10^{-9}$). The most significant associations ($P_{IVW\ random}\leq3.9x10^{-40}$) observed were phosphatidylcholines 1-stearoyl-2-arachidonoyl-GPC (18:0/20:4) and 1-palmitoyl-2-arachidonoyl-GPC (16:0/20:4n-6), both of which were associated with ~15% reduced odds of PCa. Results were largely robust to sensitivity analyses. This large-scale MR study provides evidence of causal associations between a range of metabolites and PCa risk in individuals of Hispanic ethnicity. Work is ongoing to replicate these findings in individuals of European and African ancestry, conduct multi-ancestry MR for discovery, and utilize multivariate MR to further assess the potential for metabolites to serve as PCa biomarkers.

Session Title: Cancer Poster Session III

PB5181 Unified somatic calling and machine learning-based classification enhance the discovery of clonal hematopoiesis of indeterminate potential

Authors:

S. Tian[1], G. Jenkinson[2], A. Ferrer[3], H. Yan[1], J. Morales-Rosado[3], K. Wang[1], T. Lasho[4], S. Baheti[1], J. Olson[5], L. Baughn[6], M. Patnaik[4], W. Ding[3], K. Lazaridis[7], E. Klee[1]; [1]Div. of Computational Biology, Mayo Clinic, Rochester, MN, [2]Div. of Computational Biology, Mayo Clinic, ROCHESTER, MN, [3]Div. of Hematology, Mayo Clinic, Rochester, MN, [4]Div. of Hematology, Mayo Clinic, ROCHESTER, MN, [5]Div. of Epidemiology, Mayo Clinic, ROCHESTER, MN, [6]Dept. of Lab. Med. and Pathology, Mayo Clinic, Rochester, MN, [7]Div. of Gastroenterology & Hepatology, Mayo Clinic, Rochester, MN

Clonal hematopoiesis (CH) of indeterminate potential (CHIP), driven by somatic mutations in leukemia-associated genes, confers increased risk of hematologic malignancies, cardiovascular disease, and all-cause mortality. In blood of healthy individuals, small CH clones with competitive advantage can expand over time to reach 2% variant allele frequency (VAF), the current threshold for CHIP. Nevertheless, reliable detection of low-frequency CHIP mutations requires deep targeted sequencing which is costly and not scalable. In particular, no bioinformatics pipeline has been specifically developed for the discovery of CHIP mutations. Herein, we present a streamlined variant detection and refinement workflow, **UNI**fied **SO**matic calling and **M**achine learning-based classification, or UNISOM for short, to enhance CHIP discovery from whole-genome and whole-exome sequencing data that are underpowered, especially for low VAFs, due to insufficient coverage and inherent sequencing error. UNISOM utilizes a meta-calling strategy to achieve high sensitivity in variant detection, which is an ensemble of three sensitive tools benchmarked over simulated genomes with CHIP spike-in, in couple with XGBoost-based machine learning models built with variant-associated features. The model classifies annotated variants into CHIP, germline and artifact, thus minimizing the time-consuming manual inspection needed for CHIP refinement. UNISOM achieved good recall in a cohort of 25 patients with whole-exome data in Mayo Clinic CHIP clinic, recovering nearly 80% of the CHIP mutations identified in the same cohort via deep targeted sequencing. To demonstrate the utility of UNISOM in large-scale CHIP discovery, we applied UNISOM to whole-genome data from 979 individuals in the Mayo Clinic Biobank, UNISOM recapitulated the patterns previously established in much larger cohorts, including the most mutated genes, predominant mutation types and signatures, as well as strong associations of CHIP with age, TERT polymorphisms and smoking status. Most notably, 30% of the identified CHIP mutations had VAFs below 5%, demonstrating its high sensitivity toward small mutant clones. This workflow is applicable to the CHIP screening in population genomics studies. In clinic practice, implementing sensitive tools like UNISOM will improve the early detection of low-VAF CHIP mutations prior to diagnosis, enabling monitoring of the carriers and possible intervention. In particular, UNISOM is highly sensitive to CHIP with low VAFs, such as those occurring in *TP53*.

Since 2015, the University of California, San Francisco (UCSF) Clinical Cancer Genomics Laboratory (CCGL) has provided the UCSF500 cancer genetic test, a capture-based next-generation sequencing (NGS) assay in its third version currently targeting 529 cancer genes and select introns of 73 genes. These results can aid clinicians in personalizing cancer treatments, identifying suitable clinical trials, or clarifying a patient's exact cancer type. In pursuit of equitable patient care, we examine its utilization across racial and ethnic groups among cancer patients treated at UCSF to uncover and eradicate any potential disparities in accessing UCSF500. Over the past 5 years (07/01/2016-06/30/2021), we collected 3,002 UCSF500 cases, and analyzed them based on patients' race/ethnicity and juxtaposed them to the UCSF Cancer Registry 29,052 active cases. Patients' characteristics were summarized by descriptive statistics. In general, frequency and percentage were used to summarize categorical variables. Chi-squared test was applied to test if there was a statistical association between two categorical variables. The statistical significance was declared at alpha <0.05. All the analysis was done by R. Approximately 10% of the patients from the cancer registry had UCSF500 performed. Significant disparities were identified. Overall, in male population, White Non-Hispanic (WNH) were undertested than expected whereas Asian/Pacific Islander and Hispanic were over tested but no difference in female population. When examining each cancer type independently, it was in respiratory system (African American (AA) underrepresented), urinary system (Hispanic underrepresented), bone and soft tissue (Hispanic overrepresented), blood and bone marrow (Hispanic overrepresented) and genital cancers (AA underrepresented) in male and in skin (WNH underrepresented and Hispanic overrepresented), blood and bone marrow (WNH underrepresented and Hispanic overrepresented) and genital (AA overrepresented) cancers in female. The project also revealed a complexity of data analysis, different tumor types and prevalence of cancer by racial/ethnic groups and need for age stratification. We strongly believe that algorithmizing of when to perform tumor testing and to whom it should be offered is essential to reduce waste, to standardize care, and to prevent racial/ethnic disparities. Consequently, we developed two reflex testing algorithms for lung and pelvic cancers and one pilot testing of NGS approach for Lynch syndrome screening and molecular classification of endometrial cancers. Future analysis will assess the utility of such an approach.

PB5183 Unraveling the impact of variants of unknown significance in breast cancer risk modulation within the context of polygenic background

Authors:

y. jeong[1], J. Sung[1], J. Hopper[2], T. L. Nguyen[2], J. Lee[3], Y. Lee[3], T. Yoo[3], S. Lee[3]; [1]Genome & Hlth.Data Lab, Sch. of Publ. Hlth., Seoul Natl. Univ., Seoul, Korea, Republic of, [2]Ctr. of Epidemiology and Biostatistics, Melbourne Sch. of Population & Global Hlth., The Univ. of Melbourne, Melbourne, Australia, [3]Dept. of Surgery, Asan Med. Ctr., Univ. of Ulsan Coll. of Med., Seoul, Korea, Republic of

Background : Growing evidence suggests an interaction between high-penetrance genetic variants and individual's polygenic scores (PGS) in determining breast cancer (BC) risk. However, the effects of variants of unknown significance (VUS) in conjunction with PGS remain poorly understood. Goal : This study aims to investigate the modification of BC risk conferred by VUSs in five hereditary BC predisposing genes (*BRCA1/2, ATM, PALB2, CHEK2*) as identified by the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA), in the context of different PGS backgrounds. Methods & Results : We analyzed a dataset comprising 18,066 BC cases and 137,852 controls with no history of cancer from the UK Biobank's cohort of white females. The UK Biobank-enhanced version of BC-PGS was derived using 9,553,208 variants, revealing a significant distribution difference between cases and controls (AUROC 0.8033). VUSs were defined using ClinVar and ENIGMA for *BRCA1/2*, while missense and splice region variants were utilized for *ATM, PALB2*, and *CHEK2*. All genes exhibited higher proportions of VUSs
(*BRCA1* 4.26%, *BRCA2* 7.34%, *ATM* 15.12%, *PALB2* 2.23%, *CHEK2* 2.47%) compared to pathogenic or loss-of-function (frameshift, start lost, stop gain) variants
(*BRCA1* 0.1%, *BRCA2* 0.3%, *ATM* 1.83%, *PALB2* 0.17%, *CHEK2* 0.57%). To evaluate the increase in BC risk associated with VUSs based on BC-PGS, we calculated the BC proportion of VUS carriers in each BC-PGS quantile (Low: 0-5%, Intermediate: 5-95%, High: 95-100%), and compared it to the BC proportion of non-carriers. Individuals in the highest BC-PGS quantile (95-100%) showed significantly elevated BC risk increase due to VUSs (*BRCA1* 4.57%, *BRCA2* 4.29%, *ATM* 2.19%, *PALB2* 6.46%, *CHEK2* 6.51%) compared to the low (0-5%) and intermediate (5-95%) quantiles (*BRCA1* 0.25%, 1.7%; *BRCA2* 0.42%, 1.79%; *ATM* 0.36%, 1.50%; *PALB2* 3.63%, 3.01%; *CHEK2* 3.1%, 4.21%). Discussion : Our findings demonstrate that, similar to Tier1 variants, the risk of VUSs interact with the polygenic background. Given the higher frequency of VUSs and substantial increase in risk in highest PGS (95-100%) group, our findings suggest the importance of broadening the current list of pathogenic variants and incorporating polygenic background in prevention and genetic counselling of breast cancer.

PB5184 † Unveiling Hidden Associations: Leveraging Continuous Tumor Dynamics to Discover Novel Somatic Mutations Influencing Tumor Progression and Treatment Response in Precision Oncology

Authors:

E. Petter[1], J. LoPiccolo[2], S. Groha[2], K. L. Kehl[2], B. Pasaniuc[1], A. Gusev[2], N. Zaitlen[1]; [1]UCLA, Los Angeles, CA, [2]Dana-Farber Cancer Inst., Boston, MA

A central goal of personalized oncology is to identify specific tumor mutations affecting prognosis and treatment response. Studies to date have concentrated on single endpoints, such as overall survival and progression-free survival. Here, we present a novel method to model longitudinal tumor dynamics and identify associations between somatic mutations, treatments, and patient outcomes. We hypothesize that integrating continuous tumor progression and treatment response data, rather than solely relying on single endpoints, will enhance the power and resolution of personalized oncology research.

Our study focuses on ~9,000 pan-cancer patients at the Dana Farber Cancer Institute (DFCI) for which we obtained time-dependent outcomes capturing cancer progression and treatment response from radiology reports. Coupled with tumor sequencing, clinical phenotypes, and treatment history, this data provides an unprecedented opportunity to study the impact of somatic mutations on cancer progression and treatment response.

Rather than relying on only ~5,000 patient death dates, our method builds from the Andersen-Gill model for time-dependent outcomes, in order to additionally account for over 40,000 tumor progression and treatment response events in these same patients. We further put into use time-dependent treatment information collected from the Electronic Health Record (EHR), to identify interactions between somatic mutations and treatment. Specifically, we explored interactions with immunotherapy, targeted therapies, and common chemotherapy.

Our method detected 298 associations between somatic mutations and patient outcomes, across all cancer types and treatments, out of which 77 are only detectable when using the time-dependent outcomes for progression or response. This represents a 34% increase in discovered associations compared to single endpoint analysis. Furthermore, when examining time-dependent treatment interactions in lung cancer, we identified 35 significant interactions (5% FDR corrected) with HR ranging from 0.27-1.73 between somatic status and drug group. These interactions reflect somatic mutations that alter the rate of tumor progression or treatment response under a specific regime, and represent a potential route to sequencing guided treatment.

By leveraging longitudinal data and novel time-dependent modeling approaches, our research uncovers additional signals that are often overlooked in traditional approaches. We propose our method as a valuable tool in aiding the development of precision oncology and detecting candidate genes for the development of new companion diagnostic-guided therapies.

PB5185 Unveiling Inter- and Intra-Tumor Heterogeneity in Ductal Carcinoma *in Situ* (DCIS) and Invasive Ductal Carcinoma (IDC) through Integration of Unified Single-Cell Whole Genome Copy Number and RNA Expression Data

Authors:

T. Tate[1], I. Salas-Gonzalez[1], K. Kennedy[1], J. Remington[1], D. Arvapalli[1], S. Velivela[1], J. R. Marks[2], E. Hwang[2], V. Weigman[1], J. Zawistowski[1]; [1]BioSkryb Genomics, Durham, NC, [2]Dept. of Surgery, Duke Univ. Med. Ctr., Durham, NC

Introduction: Ductal Carcinoma in situ (DCIS) is a precursor to invasive ductal carcinoma (IDC) with complex heterogeneity influenced by genomic alterations and the tumor microenvironment. This study aims to uncover gene dysregulation mechanisms in breast cancer patients with a history of DCIS, using a unified single-cell copy number and RNA expression workflow. Methods: DCIS and IDC samples were collected from 11 patients post-mastectomy. Cells were isolated and either enriched for EpCAM using FACS or analyzed without enrichment. Unified whole genome and transcriptome amplification were performed on approximately 100 cells per sample (1225 cells in total) using ResolveOME™. DNA libraries were enriched for exomes and data was analyzed using the BaseJumper™ platform. Results: Our analysis of 11 patient biopsies provide evidence of potential characteristics underlying tumoral evolution in IDC. We observed vast heterogeneity among the tumor profiles, with some displaying a more quiescent nature. Across the 11 profiles, a range of 1.5-17% copy number events were identified, carrying potential genomic consequences. Importantly, these findings confirmed known DCIS copy number profiles, including 1q gains in 7 out of 11 cases and 16q loss in all cases. We identified additional copy signatures occurring in low proportions of patients. Notable alterations included 17p loss in 5 of 11 patients, chromosome 7 gain in 4 of 11 patients and 11q loss in 6 of 11 patients. These characteristic copy number alterations are associated with key genes, involved in cell cycle regulation and progression (CCND1, CKS1B), regulation of cell growth and proliferation (BRAF, NF1), migration (BRAF, PTK2), immune response (JAK1), and tumor invasion and metastasis (MMP7). Conclusions: Our findings emphasize the assorted copy number profiles associated with invasive breast cancer and highlight the potential involvement of key genes in tumoral evolution. By elucidating these mechanisms at the single-cell level, we gain valuable insights into the underlying processes driving tumoral evolution from DCIS to IDC, providing implications for personalized treatment strategies by identifying aggressive clonal cell populations and expanding treatment options.

PB5186 Unveiling Susceptible Transcription Factors and Novel Risk Genes in Colorectal Cancer: Integrating Large-Scale Genetic and Omics Data Analysis

Authors:

Z. Chen[1], W. Song[1], W. Wen[1], M. Devall[2], C. Dampier[2], F. Moratalla-Navarro[3], X-O. Shu[1], J. Long[1], J. Huyghe[4], S. Schmit[5], the Asia Colorectal Cancer Consortium (ACCC), L. Van Kaer[1], L. Wu[1], L. Hsu[4], Q. Cai[1], M. Dunlop[6], S. Gruber[7], R. Houlston[8], I. Tomlinson[9], U. Peters[4], V. Moreno[3], G. Casey[2], W. Zheng[1], X. Guo[1]; [1]Vanderbilt Univ. Med. Ctr., Nashville, TN, [2]Univ. of Virginia, Charlottesville, VA, [3]Catalan Inst. of Oncology (ICO), Barcelona, Spain, [4]Fred Hutchinson Cancer Ctr., Seattle, WA, [5]Cleveland Clinic, Cleveland, OH, [6]Univ. of Edinburgh, Edinburgh, United Kingdom, [7]City of Hope Natl. Med. Ctr., Duarte, CA, [8]Inst. of Cancer Res., London, United Kingdom, [9]Edinburgh Cancer Res. Ctr., Edinburgh, United Kingdom

Genome-wide association studies (GWAS) and subsequent functional experiments have provided strong evidence that risk regulatory variants can disrupt DNA binding affinities of transcription factors (TFs), and consequently leading to altered gene expression and an increased risk of cancer. Identifying these susceptible TFs is crucial for understanding the mechanisms of transcriptional dysregulation in cancer development. Moreover, our recent transcriptome-wide association studies (TWAS) approach, sTF-TWAS, by integrating genetic variants occupied by susceptible TFs, has demonstrated significant improvement in risk gene detection with increased statistical power and accuracy. However, the investigation of susceptible TFs and the integration of their occupancies with sTF-TWAS for risk gene discovery remains largely unexplored in colorectal cancer (CRC). In this study, we integrated TF ChIP-Seq datasets (n=219) generated from CRC-related cells, along with large GWAS data consisting of 100,204 CRC cases and 154,587 controls of European and East Asian ancestries. We used generalized mixed models (PMID: 34518541) to estimate the associations between the Chi-squared values (from GWAS summary statistics) and the binding status of TFs to genetic variants. At a Bonferroni-corrected $P < 0.05$, we identified 51 susceptible TFs, including CRC development-related TFs VDR, MYC, JUN, CDX2, NIPBL, MED12, and ETV5. Furthermore, we observed significant interactions among 151 pairs of TFs at $P < 3.9 \times 10^{-5}$ (0.05/1,275 possible TF pairs from 51 TFs), where genetic variants co-occupied by these TF-TF pairs exhibited a higher CRC risk compared to variants occupied by single TFs. Using our sTF-TWAS framework, we built prediction models for gene expression, alternative splicing (sp), and alternative polyadenylation (apa) by incorporating genetic variants occupied by the 51 identified susceptible TFs. These models were trained on transcriptomic data from normal colon tissues of European descendants (n=707) from the BarcUVa-Seq and GTEx projects, and East Asian descendants (n=364) from ACCC. At a Bonferroni threshold, we identified 153 CRC putative susceptibility genes, combining results from sTF-TWAS (n=116), sp-sTF-TWAS (n=43), and apa-sTF-TWAS (n=16). Notably, among these genes, 69 were not previously associated with CRC susceptibility, including 24 genes located at 21 loci that were at least 1Mb away from GWAS-identified risk variants. Our study identifies numerous susceptible TFs and their potentially regulated novel susceptibility genes in CRC and provides valuable insights into the molecular mechanisms driving this common cancer.

PB5187 Von Hippel-Lindau syndrome - a case report

Authors:

H. Singh, P. Kaur, I. Panigrahi, A. kaur, A. Arora; PGIMER, Chandigarh, India

INTRODUCTION: VHL syndrome is characterized by presence of CNS and retinal hemangioblastomas, renal cell carcinoma and renal cyst, pheochromocytoma, and tumors involving endolymphatic sac. The *VHL* gene is a tumor suppressor gene located on the short arm of chromosome 3 and has three exons encoding the VHL protein. **CASE DETAILS:** A 27 year-old male first born out of non consanguineous marriage, presented with hearing loss at the age of 17 years and was diagnosed to have Meniere disease for which grommet insertion was done. At the age of 22 years he had complaints of blurring of vision and was found to have bilateral retinal hemangioblastoma with retinal detachment right side for which pars plana vitrectomy was done. Magnetic resonance imaging of brain showed hyperintense lesion 20X20X30 mm in cortical and subcortical region of right lobe of cerebellum. Contrast enhanced computed tomography of abdomen showed few well defined hypodense non enhancing lesion seen in pancreas largest 30 mm in pancreatic tail and well defined 20X20 milimetres hypodense non enhancing non calcified lesion in mid pole of left kidney. Urine metanephrine screening test for pheochromocytoma showed normal excretion of metanephrines with value being 42microgram/24 hours (< 350). Ultrasonography of scrotum showed bilateral epididymal head cyst and bilateral mild varicoceles. With above constellation of findings suggestive of VHL syndrome clinical exome sequencing was done and a heterozygous missense variation in exon 1 of *VHL* gene on chromosome 3: *VHL*:c.C333G:p.(Ser111Arg) was observed and this has been previously reported as pathogenic for VHL syndrome. **CONCLUSION**: Identification of gene mutations enables appropriate prognostication, genetic counseling and further presymptomatic screening in at risk individuals in family.

Session Title: Cancer Poster Session I

PB5188 Whole exome sequencing of Moroccan prostate cancer samples identifies novel prostate cancer genes and several well-known signaling pathways.

Authors:

C. Samtal[1], M. Bendall[2], A. Wong[2], S. Ambs[3], N. H. Lee[4], **K. A. Crandall**[2], H. Bekkari[1]; [1]Lab. of Biotechnology, Environment, Agri-food and Hlth., Faculty of Sci. Dhar El Mahraz, Sidi Mohammed Ben Abdellah Univ., Fez, Morocco, [2]Computational Biology Inst., Milken Inst. Sch. of Publ. Hlth., George Washington Univ., Washington DC, DC, [3]Lab. of Human Carcinogenesis, Ctr. for Cancer Res., Natl. Cancer Inst., Bethesda, MD, [4]Dept. of Pharmacology and Physiology, George Washington Univ., Washington DC, DC

Prostate cancer (PCa) is the second cause of cancer death among Moroccan men. The data reported by Rabat registry indicate that the incidence rate for PCa similarly increases sharply with age after 50 years. After 75 years, the incidence reaches more than 274 new cases per 100.000 inhabitants per year. However, there are no genomic studies of this disease in the Moroccan population. Our study aims at identifying genomic features of prostate cancer in Moroccan men using Whole Exome Sequencing (WES). This study is the first in Morocco and one of the few attempts in the African continent using WES to analyze PCa. We analyzed the exomes of 12 Moroccan prostate cancer patients. Prostate cancer tumors and non-tumor adjacent tissue samples were collected from 2 sites in Central and Northeast Morocco. DNA was extracted from Formalin-Fixed Paraffin-Embedded (FFPE) and frozen tissue samples. After sequencing, samples were processed using Genome Analysis Toolkit (GATK) best practices. Somatic variant analysis of matched tumor and normal sequencing data lead to the identification of genes known to be associated with prostate cancer, and novel prostate cancer genes that were initially associated with other types of cancers. We identified novel variants that were not found in either of the following databases: COSMIC, dbSNP, and ClinVar. Our analysis identified several well-known signaling pathways that are involved in prostate cancer progression and tumorigenesis and are clinically targetable including *RTK-RAS*, *NOTCH*, *WNT*, *PI3K*, and *MYC* pathways. These findings represent the first and most comprehensive characterization of the Moroccan PCa exome to date. Because North African are underrepresented in genomic studies, our findings address a gap in the contribution of genetic variation to the incidence of prostate cancer and aggressiveness of the disease in the Moroccan and all North African populations.

Session Title: Cancer Poster Session II

PB5189 Yield of integrated DNA and RNA analysis of hereditary cancer associated genes based on cancer diagnosis.

Authors:

N. Kamps-Hughes[1], B. Heald[1], S. Nielsen[2], E. Borras[1], H. Kang[3], K. Nykamp[4], R. Nussbaum[1], E. D. Esplin[1], **B. Johnson**[5], D. Pineda-Alvarez[6], L. Fresard[1]; [1]Invitae, San Francisco, CA, [2]Invitae, Chicago, IL, [3]Invitae Corp., San Francisco, CA, [4]Invitae, Berkeley, CA, [5]Invitae, Fort Lauderdale, FL, [6]Invitae, Wellington, FL

Background RNA sequencing can help classify variants predicted to alter RNA splicing, as well as discover splice-altering variants in regions outside of the standard reportable range of targeted DNA panels. Prior research from our group showed that RNA sequencing impacted variant interpretation for 6.3% of 20,317 patients undergoing multi-cancer gene panel testing. The intronic variant discovery rate was 0.2%. Here we report the resolution of potential splicing variants and the discovery of intronic variants using RNA sequencing stratified by patients' reported cancer history.

Methods RNA sequencing was performed on cDNA from leukocyte mRNA for 63 transcripts from an 84 gene multi-cancer panel. RNA data were used as functional evidence in the Sherloc classification algorithm to reclassify potential splicing variants of uncertain significance to benign/likely benign (B/LB) or pathogenic/likely pathogenic (P/LP). Aberrant splicing was also used to discover variants outside of the reportable DNA range (all coding exons ±20bp of flanking intronic sequence). Cancer history was determined by clinician-reported data on the test requisition form. Data were stratified per no history of cancer, history of any cancer, and history of breast, prostate, colorectal, or pancreatic cancer. Descriptive statistics and Chi-square with Yates' correction were utilized, and significance was set at $p < 0.05$.

Results The cohort consisted of 61,388 patients. No cancer was reported in 43,285 (70.5%) patients, while 18,103 (29.5%) had any type of cancer (including 9,282 [15.1%] with breast, 1,405 [2.2%] with prostate, 2,393 [3.9%] with colorectal, and 1,054 [1.7%] with pancreatic cancer). Overall, RNA sequencing impacted variant interpretation for 1,448 (2.4%) of patients with 1,243 (2.0%) downgraded to B/LB and 213 (0.4%) upgraded to P/LP. There were no differences in the effect of RNA sequencing for variant interpretation based on no reported cancer history (2.4%), any cancer history (2.4%), breast (2.5%), prostate (2.4%), colorectal (2.5%), or pancreatic (2.6%) cancer. Additionally, no differences in variant discovery were observed based on no reported cancer history (0.1%), any cancer history (0.2%), breast (0.2%), prostate (0.1%), colorectal (0.1%), or pancreatic (0.3%) cancer.

Conclusion In this study, the impact of RNA sequencing on variant interpretation was 2.4%, with the majority of variants of uncertain significance being downgraded to B/LB. The effect of RNA sequencing did not differ based on the patient's reported cancer history.

Session Title: Cancer Poster Session III

PB5190 A multi omics classifier for prediction of androgen deprivation treatment response in prostate cancer patients

Authors:

I. Isewon, E. Alagbe; Covenant Univ., Ota, Ota, Nigeria

Clinical decision and treatment strategies have been based on the experience of a care giver as well as the pathophysiology of the disease. This evidence-based medicine strategy focuses on groups of people rather than individuals but is insufficient since treatment response differs between individuals. There has been a general move towards precision in oncology, notably due to the severe cytotoxic side effects of "one size fits all" cancer therapies, and identification of tumor-specific vulnerabilities. There is need to leverage on advances in high throughput sequencing and machine learning (ML) to improve treatment options for each patient. In this study, we developed a two-step classifier to predict the response of prostate cancer (PCa) patients to androgen treatment leveraging on high throughput multi-omics datasets provided by The Cancer Genome Atlas (TCGA). The TCGA PCa phenotype dataset contains records for 623 patients with 120 patients having missing values for primary treatment outcomes. Four PCa omics datasets were used: copy number variation, RNAseq, miRNAseq, and reverse phase protein array. Amongst the 120 patients with missing phenotypes, 68 had records for the four omics considered. Our investigation using ten ML algorithms reveals that tree-based algorithms such as decision tree, random forests, extreme gradient boosting, and gradient boosting machine had better predictive performance than probabilistic models such as naïve bayes and kernel-based methods such as support vector machines for the dataset. We also investigated the performance of all possible omics combinations. Our results show that there is an overall increase in performance when multiple omics datasets are used in contrast to single omics strategies. We have predicted for the first time, possible treatment response outcomes for 68 prostate cancer patients with missing treatment outcome phenotype values in TCGA with the following distribution: complete response (45), partial response (7), progressive disease (5) or stable disease (11).

Session Title: Cancer Poster Session I

PB5191 CRISPR/Cas9 Engineering of 3D Genome Structural Variants: Unveiling Predictive Models of Oncogene Activation in Cancer Genomes

Authors:

Z. Xu[1], D-S. Lee[2], S. Chandran[1], V. T. Le[1], R. Bump[1], J. Yasis[1], S. Dallarda[1], S. Marcotte[1], B. Clock[1], N. Haghani[1], C-Y. Cho[1], K. Akdemir[3], S. Tyndale[1], P. Futreal[3], G. McVicker[1], G. M. Wahl[1], J. R. Dixon[1]; [1]Salk Inst. for Biological Studies, La Jolla, CA, [2]Univ. of Seoul, Seoul, Korea, Republic of, [3]MD Anderson Cancer Ctr., Houston, TX

Higher order chromatin structure plays a critical role in the regulation of genes by distal regulatory sequences. Structural variants that alter 3D genome organization can lead to enhancer-promoter rewiring and human disease, particularly in the context of cancer. However, it remains unclear how widespread structural variants that alter 3D genome structure are in cancer genomes and what genes are affected by such events. Furthermore, recent studies have shown that only in a small minority of structural variants are associated with altered gene expression. Therefore, it is unclear whether or how an individual structural variant may contribute to oncogene activation. To address these questions, we have analyzed Hi-C data and structural variants from 92 cancer cell lines and patient samples representing diverse cancer types. We identified loci affected by recurrent alterations to 3D genome structure, including loci containing oncogenes such as *MYC*, *TERT*, and *CCND1*. We also find evidence that these loci are frequently affected by structural variants predicted to alter 3D genome structure from whole genome sequencing datasets. Using CRISPR/Cas9 genome engineering to generate *de novo* structural variants, we show that "Activity-by-Contact" models predict the likelihood of oncogene activation in the context of structural variants. However, such Activity-by-Contact models are only predictive of specific subsets of genes in the genome, suggesting that different classes of genes engage in distinct modes of regulation by distal regulatory elements. These results indicate that structural variants that alter 3D genome organization are widespread in cancer genomes and begin to illustrate predictive rules for the interpretation of the consequences of non-coding structural variants on oncogene activation.
